time for control room personnel to use protective breathing equipment; therefore, this does not represent a significant toxic or asphyxiation hazard to the control room personnel in the event of an accidental catastrophic failure of a storage tank.

For these calculations, the weather conditions assumed the highest ground and ambient air temperatures (corresponding to 42.2°C), with wind direction directly in line with the control room inlet and unchanging, and maximum cloud cover to maximise evaporation rate.

However, conditions such as weather patterns and local topography may vary from the assumptions made in the MCR habitability assessment (see Chapter 23), depending on where in the UK the station is built and where the PGS is located in relation to the MCR air inlet and to other buildings. Therefore, a site-specific safety case justification for the quantities and storage location for hydrogen, nitrogen, and carbon dioxide should be made at each site where a reactor will be constructed.

Claim IH-6.2: Class 1 SSC located within the NI will not be affected by releases of hazardous materials in locations outside of the NI

The site is graded such that the natural flow of liquid releases is away from the NI. Furthermore, the exterior walls of the NI represent significant reinforced concrete or metal structures. While degradation, due to chemical attack, of the NI exterior walls cannot be precluded, the extent would be minor based on the quantity of chemicals involved and the robustness of the walls.

Catastrophic failure of the gas storage tanks resulting in the loss of cryogenic liquids cannot threaten the NI. The PGS is approximately 250 m away from the NI; evaporation would therefore take place before significant quantities could reach the building. Note that this is dependent on the topography and the prevalent local weather conditions at the site, and therefore will need to be justified on a site-by-site basis if plant layout differs significantly.

Claim IH-6.3: A release of hazardous materials will not cause the loss of all divisions of Class 1 SSC delivering a Category A safety function

The layout of the plant and its Class 1 SSCs have been designed so that the complete loss of the equipment within any single room will not result in loss of the Category A safety functions.

The behaviour, in terms of movement, of hazardous liquids would be similar to that of any other liquid. The assessment of Internal Flooding (see Section 11.3) is therefore bounding in terms of the spread of hazardous liquids and their effects.

11.7.3 Toxic, Corrosive, or Flammable Material Safety Case Summary

11.7.3.1 Introduction and Overview

The safety design approach adopted for hazardous materials is based on:

- Minimising the quantities of hazardous materials stored on site;
- Storing hazardous materials at distances remote from the NI and therefore Class 1 SSCs delivering Category A safety functions;
- Maintaining a ‘habitable’ environment for operators in the MCR following the release of toxic gases on-site;

- Separation and segregation of redundant divisions of Class 1 SSCs.

The approaches stated above form levels of defence-in-depth which, together, reduce the risk associated with releases of hazardous materials to a level which is ALARP.

11.7.3.2 Applicable Codes and Standards

The tanks, vessels and pipework associated with the hazardous materials have been designed in accordance with the relevant sections of the ASME Boiler and Pressure Vessel Code (Reference 11.90). The codes and standards have been compared to equivalent UK codes and standards (Reference 11.25) to determine their suitability based on the safety significance of the SSC (Reference 11.26).

With regards to the assessment of the hazard presented by toxic, corrosive and flammable materials, no claim is made on the integrity of tanks, vessels or pipework to prevent their release under fault conditions.

The hazard presented by significant quantities of hazardous materials will be controlled in accordance with the COMAH regulations (Reference 11.117), while the onsite use of chemicals and the potential harm to operators will be managed through appropriate COSHH assessment.

11.7.3.3 Redundancy, Separation, and Segregation

The design of the AP1000 plant incorporates redundant divisions of Class 1 SSC, each of which is capable of delivering the Category A safety function. Where there is the potential for Class 1 SSCs to be compromised by a hazardous material, the redundant Class 1 SSC delivering the Category A safety function is unaffected. The provision of redundancy takes into account the following:

- IAEA-NS-G-1.11 “Protection against Internal Hazards other than Fires and Explosions in the Design of Nuclear Power Plants” (Reference 11.82).
- IAEA NS-R-1, “Safety of Nuclear Power Plants: Design” (Reference 11.21).
- APP-GW-J1R-008, “Safety Criteria for the AP1000 Instrumentation and Control Systems” (Reference 11.51).
- APP-GW-J1R-004, “AP1000 Instrumentation and Control Defence in Depth and Diversity Report” (Reference 11.52).
- ONR Nuclear Safety Technical Assessment Guide NS-TAST-GD-011, “The Single Failure Criterion” (Reference 11.83).

Within the Containment/Shield Building, redundant divisions of Class 1 SSC have been separated, so far as is reasonably practicable, by distance. While the Containment/Shield Building is a largely open space to maintain the free movement of gases, some compartments have been segregated by walls and floors providing some physical segregation.

Outside the Containment/Shield Building, the Auxiliary Building comprises both a RCA and non-RCA, which are physically segregated from one another by walls, floors and ceilings. Adjoining buildings are also physically segregated from the Auxiliary Building by walls, floors and ceilings. Access to either the RCA or non-RCA portions of the Auxiliary Building

is from the adjoining buildings, which are themselves sub-divided into RCA and non-RCA sections by walls, floors and ceilings.

The Containment structure provides a barrier to the intrusion of hazardous materials into the area where the main components of the Class 1 SSCs are sited. Outside the Containment structure, the plant and its Class 1 SSCs have been designed so that the complete loss of the equipment within any single room will not result in loss of the Category A safety functions. The fire barriers protecting redundant trains of the Class 1 SSCs from fire should also provide an adequate barrier to the spread of corrosive liquids, and therefore limit any damage to the equipment in one room.

Taking account of the potential loss of those SSCs affected by the toxic, corrosive, or flammable material concurrent with a credible, unrelated, single failure within the other SSCs, it is concluded that sufficient redundancy, diversity, and segregation is provided in the design and location of the SSCs to ensure that the Category A safety functions are maintained in the worst-case, normally permitted, plant lineup.

11.7.3.4 Toxic, Corrosive, or Flammable Material Assessment Approach

With the exception of releases of toxic materials, for which a habitability study of the MCR has been performed (see Chapter 23), the assessment of releases of hazardous materials has been qualitative. The potential for Class 1 SSCs to be exposed to hazardous materials along with the associated effects have been considered in determining whether or not all divisions of Class 1 SSC delivering a Category A safety function could be lost following a release.

11.7.3.5 Interface with Other Internal Hazards

The release of hazardous materials may be initiated by or the initiator for other internal hazards. For example, corrosive materials may induce pipework failure leading to an Internal Flood. Similarly, a missile may cause a rupture of a vessel containing hazardous materials. These combined hazardous effects are considered in Section 11.12.

Pressure Part Failure (see Section 11.4) and a release of hazardous material may arise simultaneously; the combined effects are also considered in Section 11.12.

Internal Fire (see Section 11.2) may ensue following the release of a flammable material. The analysis of Internal Fires bounds that of flammable materials on the basis that Internal Fires considers all sources of flammable material whether that material is normally contained or not.

11.7.3.6 Conclusions

With the exception of the habitability study of the MCR (see Chapter 23), the hazards presented by toxic, corrosive, or flammable materials have been qualitatively assessed. This assessment has shown that the risk to Class 1 SSCs delivering Category A safety functions, or to personnel required to undertake nuclear safety related actions is low. The reasons for this are:

- Hazardous materials are stored, and used, at concentrations which would have little bearing on the structural or mechanical properties of the SSC they may come in contact with.

- The bulk storage of hazardous materials is outside of the NI, at a distance at which any release would have limited capacity to directly affect either the exterior walls of the NI, or the Class 1 SSC located within.

- Under worst case weather conditions, a release of toxic material would not expose operators present in the MCR to concentrations above which toxic effects would prevail.

- The release of a hazardous material within the NI would either have no direct effect on Class 1 SSC (i.e., the SSC is insensitive to the make-up of the surrounding atmosphere) or would not affect all divisions of Class 1 SSCs delivering a Category A safety function.

11.7.4 Toxic, Corrosive, or Flammable Material Safety Analysis

11.7.4.1 Identification of Hazard Sources

Table 11.7-1 lists the principal hazardous materials present on an AP1000 plant site and where they are stored. The precise selection of chemicals and volumes may change based on site-specific requirements and operating experience; therefore, storage and use of chemicals not identified in this chapter or present in significantly greater concentrations or volumes will need to be justified on a site-by-site basis. Other intrinsically hazardous material is present onsite but in such small quantities that it poses a minimal threat.

11.7.4.2 Assessment of Toxic, Corrosive, or Flammable Materials

Bulk Gas Storage and the Plant Gas System – Hydrogen

The most significant threat from hydrogen is principally that of fire or explosion, should it leak and mix with air or oxygen; additionally, the pipework might explode by virtue of the high gas pressure. These issues are addressed in Section 11.2 on internal fires, Section 11.5 on internal explosions and Section 11.6 on internal missiles. However, hydrogen could potentially also asphyxiate personnel if its presence should exclude the normal air in a room or compartment containing personnel; however, this is unlikely given that the leakage amount and leak rate is limited, and any leaking hydrogen would very likely disperse by floating up and away before any significant mixing took place. Leakage of hydrogen, absent a resultant explosive or fire scenario, has limited potential to disable equipment involved in providing a nuclear safety function, or to prevent an action required for nuclear safety.

The possibility of leaking bulk hydrogen gas being drawn from outside into an HVAC intake for the MRC has been analysed (see Chapter 23), and the analysis shows that, providing the assumptions and criteria are met, the maximum concentration under worst case conditions after two minutes is 22600 ppm (cf. toxic limit of 70000 ppm) and therefore it does not represent a toxic hazard to control room personnel. Also the maximum concentration would not exceed the LFL for hydrogen posing no fire/explosion potential in the MCR. Therefore it is concluded that hydrogen presented as this scenario does not represent a significant toxic hazard or fire/explosion hazard.

Bulk Gas Storage and the Plant Gas System – Carbon Dioxide

The major threat from carbon dioxide is that of asphyxiation of personnel, should its concentration in the air rise above a few percent. There is also the hypothetical possibility of a cloud of carbon dioxide choking operation of various onsite diesel engines; however these SSCs are not Class 1 and their loss is not of immediate nuclear safety significance

Should the storage tank rupture catastrophically, the depressurising carbon dioxide would instantly solidify, thereby reducing the rate of evaporation and lessening the threat. As a result, there is minimal threat to any SSCs should the tank and/or its associated evaporator leak.

Once the carbon dioxide enters the turbine hall, any leak would be minimal in comparison with the volume of the building, given that the supply is through a small-bore pipe. The Turbine Building is also provided with carbon dioxide detection and alarms.

The possibility of leaking carbon dioxide gas being drawn into an HVAC intake (e.g., MCR) is summarised in Chapter 23 and the analysis shows that, subject to the assumptions made, the maximum concentration under worst-case conditions after 2 minutes is 6960 ppm (compared to the toxic limit of 40,000 ppm); therefore, it does not represent a toxic hazard to control room personnel. Therefore, it is concluded that carbon dioxide does not represent a significant toxic hazard.

Bulk Gas Storage and the Plant Gas System – Nitrogen

The threats from nitrogen are over-pressurisation events within the high-pressure subsystem pipework or a high-pressure portable cylinder and asphyxiation of personnel if any part of the system leaks, or should they inadvertently enter a compartment or tank in which the atmosphere is nitrogen rather than air (personnel breathing nitrogen are unaware that there might be little or no oxygen present, as nitrogen is odourless). There is also the hypothetical possibility of a cloud of nitrogen choking the operation of the various DGs onsite; however, these are not Class 1 SSCs, and delivery of Category A safety functions will not be prevented.

Portable nitrogen cylinders are used during plant outages for refilling the valve actuators of the MSIVs and the main feedwater isolation valves, and for the pressure testing of the Containment penetrations. Leakage of nitrogen from this source in contained environments would be an asphyxiation threat to nearby personnel and would be controlled on a site specific basis. There are no actions required to maintain the significant functions in the compartments containing the MSIVs, the main feedwater isolation valves, or the Containment penetrations because of a nitrogen leak.

Nitrogen is present within the RCDT and the WGS at all times other than when personnel access is required for maintenance during outages. Personnel would not need to enter these systems or be in their vicinity to perform any safety-significant required actions, so asphyxiation from leaking nitrogen would not be an issue for nuclear safety.

Nitrogen is present within the secondary side of the SGs and within the main steam lines during shutdown operations. Personnel would not need to be in the vicinity of the SGs or the main steam lines to perform any actions required to maintain Category A safety functions at these times, so asphyxiation from leaking nitrogen would not be an issue.

The scenario of leaking nitrogen gas being drawn into an HVAC intake is summarised in Chapter 23 and the analysis shows that, providing the assumptions and criteria are met, the maximum concentration under worst case conditions after two minutes is 27,700 ppm (compared to the toxic limit of 70,000 ppm). Therefore, this does not represent a toxic hazard to control room personnel. Consequently, it is concluded that nitrogen does not represent a significant toxic hazard.

Bulk Chemical Storage – Boric Acid

The only threat to nuclear safety from leaking boric acid is its potential to corrode the materials, principally the carbon steel of the RCS pressure boundary, especially if it were to be concentrated by evaporation. Leaking boric acid corrodes carbon steel at a high rate. It is postulated that an undetected, very minor leak of boronated coolant could result in corrosion at the leak site, which might then develop suddenly into a much larger leak, resulting in a LOCA (see Chapter 9); alternatively, corrosion-induced damage to valves in the makeup pipework could potentially result in difficulties injecting boron when required.

The RCS pressure boundary is built to the highest integrity because of the obvious challenge to nuclear safety from any loss of coolant. Reactor coolant pressure boundary components are designed, fabricated, inspected, and tested in conformance with the ASME Code, Section III. The part of the CVS that forms a portion of the RCS pressure boundary, the purification loop, is designed in accordance with ANSI/ANS-51.1-1983 (Reference 11.118). All surfaces of the RCS that come in contact with borated water are clad with austenitic stainless steel, or constructed of high nickel content or other non-corroding alloys.

All parts of the CVS in contact with reactor coolant or boronated makeup are constructed of austenitic stainless steel. The piping joints and connections are welded, except where flanged connections are required for equipment removal for maintenance and hydrostatic testing. The design of the CVS is based on the requirements specified in Nuclear Regulatory Commission technical report NUREG-0800 (Reference 11.119, Section 9.3.4).

Only extended duration leaks of boric acid are relevant to nuclear safety, as this is the only mechanism for the concentration and accumulation of the acid to build up to levels at which it might corrode the carbon steel surfaces of Class 1 or Class 2 SSCs. Even boron deposits from a small leak in the RCS or the CVS purification loop would be detected by the operators through regular periodic inspections of components. Surveillance of the CVS CIVs, the reactor coolant pressure boundary isolation valves, and the boron dilution mitigation valves, would detect any consequential accumulation of boric acid in the CVS room within the Containment. Leaks from equipment that contains borated water outside Containment (e.g., RNS, SFS, and CVS) would be quickly detected by regular visual inspection.

In general, boric acid is not especially hazardous to people, having both a low dermal and oral toxicity (Reference 11.51, Table 5.1), and it is considered highly unlikely that leaking boric acid solution could affect personnel engaged in supporting Category A safety functions.

Therefore, it is concluded that boric acid crystals or solution stored onsite do not represent a significant threat to nuclear safety or a toxic hazard.

Bulk Chemical Storage – Lithium Hydroxide

The only identified threat from leaking Lithium hydroxide is its potential to cause damage, by virtue of its caustic nature, to the RCS pressure boundary and to the makeup system pipework and valves, especially if it were to be concentrated by evaporation.

The potential for chemical attack from leaking reactor coolant is bounded by the boric acid, which is also present in the reactor coolant but at a much higher concentration; the maximum inventory of Lithium hydroxide stored in the CVS makeup pump room within the radiological Auxiliary Building is 5 kg (11 lbs) (Reference 11.120, Table 5.3).

There is a slight possibility of the Lithium hydroxide supplied to the site being contaminated with much higher levels of lithium-6 than specified. This would result in a challenge to the

Category A safety function to avoid the dispersion of radioactive material to the environment because of the consequent production and subsequent discharge of tritium. The site-specific operational quality assurance programme will minimise this possibility.

Therefore, it is concluded that Lithium hydroxide poses no significant threat to nuclear safety and does not represent a significant toxic hazard.

Bulk Chemical Storage – Hydrazine

Hydrazine solution is toxic to people if in contact with skin, inhaled, or ingested, and harmful to the environment if it is released.

Hydrazine is neither corrosive nor flammable (as a 35 percent w/v solution); however, it is toxic and would be a threat to the personnel and to the biological environment should it escape. It is not, however, a threat to nuclear safety because of its infrequent use and because personnel involved in actions required to maintain Category A safety functions have no need to go anywhere near where hydrazine could leak or escape (for example, the CVS makeup pump room within the radiological Auxiliary Building). Hydrazine will require a risk and a COSHH assessment for both storage and use.

Therefore, it is concluded that hydrazine does not represent a significant toxic hazard.

Bulk Chemical Storage – Sodium Hydroxide

This material is severely corrosive and toxic, but not flammable. It is not a threat to nuclear safety because of its storage and usage locations; there are no Class 1 or Class 2 SSCs and no actions required to maintain Category A safety functions are located anywhere close by. No nuclear safety claims need to be made. Caustic soda will require a risk and COSHH assessment for both storage and use.

Therefore, it is concluded that sodium hydroxide does not represent a significant threat to nuclear safety.

Bulk Chemical Storage – Diesel Oil

The most significant hazard from spilled diesel oil is fire; however, the combustion by-products from burning diesel may have an effect on the MCR. From the MCR habitability studies (Chapter 23), the maximum concentration under worst-case conditions after 2 minutes are as follows for these by-products: for CO_2, 2610 ppm (compared to the toxic limit of 40,000 ppm); for CO, 1.16 ppm (compared to the toxic limit of 1200 ppm); and for SO_2, 3.14 ppm (compared to the toxic limit of 100 ppm).

Therefore, toxic fumes from burning diesel do not represent a toxic hazard to control room personnel.

Bulk Chemical Storage – Trisodium Phosphate

Contact with TSP can cause chemical burns to the skin and eyes; therefore appropriate protective clothing and eye protection are used when loading or handling the storage baskets.

Bulk Chemical Storage – Hydrogen Peroxide

Contact with hydrogen peroxide can cause chemical burns to the skin and eyes; therefore appropriate protective clothing and eye protection are used when handling.

Bottled Gases

Certain gases (such as argon, acetylene, and oxygen) may be held in small quantities. These gasses are considered to be held in sufficiently small quantities and used for specific purposes (such as welding) that their use and risks will be assessed on an individual basis with appropriate local risk assessments.

Chemical Inhibitors

The specific chemicals used, other than the biocide, are determined by the local site water conditions. Some of these materials are corrosive and toxic, but none of them are flammable. Chemicals used on the site will require COSHH and risk assessments. They will be stored in relatively small quantities within the turbine hall and do not represent a significant threat to any Class 1 or 2 SSCs; no actions required to maintain Category A safety functions take place in that location.

However, it is postulated that biocides could threaten operator actions supporting Category A safety functions by producing noxious gases that are then drawn into HVAC intakes. In particular, the sodium hypochlorite can give off chlorine gas in some circumstances. An analysis (see Chapter 23) shows that these sources do not represent a toxic hazard to control room personnel. In any case, a supply of protective clothing, respirators, and self-contained breathing apparatuses adequate for 11 persons is stored within the MCR pressure boundary for other purposes.

Therefore, an accidental release of the types of chemical inhibitors used on the site does not represent a significant toxic hazard to control room personnel.

Refrigerant Gases

Typical refrigerant gases may be flammable and toxic, but not corrosive. Chemicals used onsite will require COSHH and risk assessments. They will be stored in relatively small quantities within the turbine hall and do not represent a significant threat to any Class 1 or Class 2 SSCs; no actions required to maintain Category A safety functions take place in that location.

It is postulated that the refrigerant could leak and then be drawn into HVAC intakes. An analysis (see Chapter 23) shows that these sources do not represent a toxic hazard to control room personnel. However, a supply of protective clothing, respirators, and self-contained breathing apparatuses adequate for 11 persons is stored within the MCR pressure boundary for other purposes.

Therefore, an accidental release of the types of refrigerant gases used onsite does not represent a toxic hazard to control room personnel.

11.7.4.3 Hazard Schedule

No hazard schedule is presented for toxic, corrosive, or flammable material hazards on the basis that the hazard has been assessed semi-qualitatively.

11.7.4.4 Discussion of Results

The analysis concludes that there are no toxic, corrosive or flammable material hazards which could result in the loss of all divisions of Class 1 SSC delivering a Category A safety

function. Further, the potential hazard to operators required to undertake actions in support of Category A safety functions is low.

The possible exceptions to this include a release of boric acid from the RCS and sodium hydroxide. However, both of these hazards would act slowly and be identified during routine plant maintenance. Should the hazard not be identified, it could be an initiator for a plant level fault, e.g., LOCA, however such a fault would be bounded by the assessment of faults (see Chapter 9).

11.7.5 Sensitivity and Cliff Edge Effects

The analysis of toxic, corrosive, or flammable material hazards has been undertaken semi-qualitatively.

For releases from the bulk gas storage locations, the hazard is realised by operators present in the MCR. The concentration of toxic chemicals in the MCR is dependent upon the source strength and subsequent dispersion. The analysis has assumed that the plant gas store is located at 250 m from the NI. Should it be located nearer, the concentration at the MCR would increase. However, the dispersion model has assumed worst case weather conditions which would not persist for significant periods of time. However, the actual siting of the PGS is subject to site-specific considerations and an analysis will be undertaken at that time to determine an appropriate safe distance from the MCR in the event that one of the bulk gas storage tanks were to leak.

The analyses of the effects of boric acid assume that the solution initially contains 2.5 wt% boric acid. At higher concentrations, the solution would be more acidic and therefore more effective at corroding the RCS pressure boundary. However, the increased boron concentration would have operational implications on reactor performance and as such is a closely monitored reactor chemistry parameter. It is therefore not considered credible that significantly higher concentrations of boric acid could exist in the RCS without being readily identified.

11.7.6 Combined Hazards Discussion

Releases of toxic, corrosive, or flammable materials has not identified a loss of Class 1 SSCs delivering Category A safety functions, or the incapacitation of operators required to undertake actions in support of Category A safety functions. In the event that the release of hazardous materials initiates or is initiated by another internal hazard, the effects would be transcended by the other internal hazard. The combined effects of hazardous materials with other internal hazards has therefore not been considered further, see Section 11.12 for further discussion.

11.7.7 ALARP Assessment and Discussion

The measures outlined above demonstrate that the risk of loss of a nuclear safety-significant system as a result of loss of corrosive, toxic, or flammable materials is low and has been addressed in the design of the plant (or will be addressed on a site-by-site basis), as well as by normal operational procedures and maintenance activities. The risks posed from corrosive, toxic, or flammable materials are at such a low level that no practical measures to reduce the risk further could be identified.

Specific measures taken to reduce risk include maximising the distances between the PGS, standby diesel fuel oil system, and NI so as to minimise the effects from a catastrophic loss of

a bulk container of liquefied gas, and the routing of pipework away from areas where Class 1 or Class 2 SSCs are present or where personnel are involved in safety-related operations.

11.8 Dropped Loads and Load Mishandling

11.8.1 Introduction

The AP1000 design is such that a dropped load event within the design basis will not compromise the ability of the AP1000 plant to safely shutdown. The Category A safety functions required for safe shutdown following a dropped load and the supporting post 72 hour Category B safety functions are shown to be maintained through a combination of claims including the segregation of SSCs.

Loads dropped by cranes and other types of lifting equipment have the potential for preventing delivery of Category A safety functions either directly through the load impacting an SSC, or indirectly because of the collapse of a floor or wall that causes failure of the SSC. The Class 1 SSC delivering Category A safety functions have been identified through fault studies, see Chapter 9. Additionally, potential damage to SSCs required to perform Category A safety functions may be caused by the mishandling of a load. Both load drops and the mishandling of a load are collectively referred to in this section as dropped loads.

The assessment concludes that Category A safety functions can continue to be delivered following a design basis dropped load through a combination of claims including equipment segregation (i.e., no claim has been made on the prevention or limitation of fault occurrence) (Reference 11.123).

11.8.2 Dropped Loads Claims, Arguments and Evidence

11.8.2.1 Claims Overview

This section presents the claims, arguments and underlying evidence made in relation to internal dropped load hazards with the potential to impact safe shutdown.

11.8.2.2 High Level Claim

Dropped loads could cause a transient from normal operation or shutdown conditions of the reactor power plant with the potential to result in a hazard on or off site being realised. In response to such a transient, it may be necessary to shut down the reactor and return it to a safe state. Depending on the exact nature of the transient, there are a number of courses of action to take to shut the reactor down and/or ensure sufficient cooling is provided. Availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be safely shutdown and cooled and that sufficient cooling can be maintained to irradiated fuel in the SFP. This is the basis of the following high level claim.

Claim IH-7.0: **Postulated dropped loads within the design basis will not prevent the delivery of the Category A safety functions and supporting post 72 hour Category B safety functions necessary to respond to the postulated event.**

This has been achieved by:

- Protecting delivery of Category A safety functions with passive safety features or structural barriers to prevent propagation of damage due to a dropped load;

- Ensuring that redundant SSCs delivering Category A safety functions are sufficiently separated and segregated so that a dropped load cannot prevent delivery of the safety function

- Mitigating the effects of a dropped load through appropriate qualification of SSCs to withstand the effects of vibration due to dropped load

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.8.2.3 Prevention Claims

A dropped load is deterministically assumed to occur as a result of a failure of a lifting device. There are therefore no specific claims made on the prevention of dropped load hazards.

Substantiation of the lifting devices is provided in the Sections 17.7 and 17.8, for light and heavy loads handling systems.

11.8.2.4 Protection Claims

Protective measures have been incorporated into the design to protect the delivery of Category A safety functions from the effects of a dropped load. The following specific protective claims are made in support of the overall high level claim:

Claim IH-7.1.1: **A dropped load on the reactor vessel will not prevent adequate cooling of the core**

Claim IH-7.1.2: **The floors of the SFP will not fail in the event of a dropped load onto the SFP**

Claim IH-7.1.3: **A dropped load from the Cask Handling Crane will not impact the SFP**

11.8.2.5 Mitigation Claims

The following mitigation claims are made in support of the overall high level claim:

Claim IH-7.2.1: **A single dropped load event cannot impact all divisions of SSCs delivering a single Category A safety function**

Claim IH-7.2.2: **Class 1 SSC, not directly impacted by a dropped load, will be capable of delivering their Category A safety function**

Claim IH-7.2.3: **There will be no dropped loads within Containment in Modes 1 to 4.**

11.8.2.6 Arguments and Evidence

Prevention Arguments and Evidence

There are no specific claims made on the prevention of dropped loads. Dropped loads are assumed to occur as a result of failures of lifting equipment. However, the cranes and lifting

devices have been designed to appropriate standards and are justified in Sections 17.7 and 17.8.

Protection Arguments and Evidence

Claim IH-7.1.1: A dropped load on the reactor vessel will not prevent adequate cooling of the core

A dropped load onto the RPV will not significantly distort the RPV, its connections or its internals sufficient to preclude cooling.

The reactor vessel and its associated supports and connections provide containment for the water cooling the fuel and support to the core structures that maintain flowpaths within the core.

A dropped load onto the reactor vessel can only happen in Plant Operation Modes 5 and 6, when Containment is open and the lifting equipment within it is used to support refuelling operations. The bounding load that could be dropped onto the reactor vessel is the IHP. Analysis has been conducted (Reference 11.121) that demonstrates that the reactor pressure vessel and associated supports and connections will withstand the impact from the dropped load.

Claim IH-7.1.2: The floors of the SFP will not fail in the event of a dropped load onto the SFP

The SFP liner can withstand the bounding drop, of a fuel assembly including control rod assembly and a handling tool attached, from the fuel handling machine.

The only lifting devices which operate above the SFP are the FHM and the new fuel elevator. Analysis has been conducted (Reference 11.122) that demonstrates that the SFP liner will not be penetrated by a dropped fuel assembly with a control rod assembly and a handling tool attached, which is identified as the bounding dropped load into the SFP. There is therefore no impact on the flood doors in the rooms below the SFP.

Claim IH-7.1.3: A dropped load from the Cask Handling Crane will not impact the SFP

The cask handling crane bridge beam is prevented from travelling sufficiently far in the westerly direction by end stops fitted to the cask handling crane rails.

The Cask Handling Crane rails incorporate passive end stops that prevent the bridge from running off the end of the rails. The end stops also prevent a fuel cask from overhanging the SFP or its supporting walls (Reference 11.123).

Mitigation Arguments and Evidence

Claim IH-7.2.1: A single dropped load event cannot impact all divisions of SSCs delivering a single Category A safety function

Class 1 SSC are spaced sufficiently far apart that a single dropped load cannot directly impact all divisions.

Analysis has been undertaken for a dropped load from each of the lifting devices within the Nuclear Island, which demonstrates that a single dropped load cannot directly impact all

divisions of Class 1 SSC required to deliver a Category A safety function. The hazard schedule (see Table 11.8-3) identifies the Class 1 SSC which may be directly impacted by a dropped load and the location of redundant Class 1 SSC capable of delivering the Category A safety function.

For a drop of the load with the largest footprint[17], anywhere within Containment, an analysis has been undertaken (Reference 11.123) which demonstrates that all divisions of Class 1 SSC delivering a Category A safety function cannot be directly impacted by a single dropped load.

Claim IH-7.2.2: Class 1 SSC, not directly impacted by a dropped load, will be capable of delivering their Category A safety function

Class 1 SSCs are qualified to deliver their Category A safety function following a design basis seismic event, which includes the effects of vibrations. With the duration of a design basis SSE being conservatively larger than impulse felt due to a dropped load, the effects of a design basis seismic event envelope those vibrations due to a dropped load (Reference 11.60).

Environmental qualification tests and methods (see Chapter 5) are based on the guidelines provided in IEEE 323-1974 (Reference 11.124) and IEEE 344-1987 (Reference 11.79), and include:

- Type testing: Testing of equipment in the environment, normal and abnormal, under which it will be required to perform its function;
- Analysis: Review of relevant data for similar components;
- On-going qualification: Maintenance and surveillance of in service equipment.

Equipment qualification program documentation consists principally of:

- Methodology for Qualifying Safety-Related Electrical and Mechanical Equipment (Reference 11.60): Over-arching document detailing the strategy for equipment qualification.
- Equipment Qualification Data Packages: Details the qualification program objectives, methods performance specification and qualification plan for each SSC subject to qualification.
- Equipment Qualification Test Reports: Details of the specific methods used during qualification and the results of the process.

The criterion for equipment qualification depends upon the environment, during normal and abnormal conditions, under which the SSC is required to operate. The Nuclear Island (including Turbine Building – North Bays) has been broken down into 11 environmental zones and a number of associated sub-zones. The normal and abnormal environmental

17. The load with the largest footprint handled within containment is the IHP. Although a load path has been established for the IHP which restricts movement of the IHP to certain areas within containment, the analysis conservatively assumes the IHP could be dropped anywhere within the coverage of the polar crane.

conditions for equipment qualification in each zone/sub-zone have been established (Reference 11.61).

Claim IH-7.2.3: There will be no dropped loads within Containment in Modes 1 to 4.

Lifting devices within Containment cannot be used or activated in Modes 1 to 4. There is no personnel access to Containment in Modes 1 to 4 except for infrequent inspections. Maintenance activities are not anticipated in the Containment during Modes 1-4. Spurious operation of the cranes is not possible during these modes as there is no access to controls.

11.8.3 Dropped Loads Safety Case Summary

11.8.3.1 Introduction and Overview

The safety design approach adopted for dropped load hazards consists of a range of complementary approaches. These are applied as appropriate to reduce the potential disruption to the passive safe shutdown Class 1 SSC. Dropped load events within the design basis do not prevent the delivery of the Category A safety functions necessary to respond to a postulated event. Preservation of required safety functions ensures alignment with fault studies and structural integrity analysis.

Dropped loads are assumed to occur as a result of Postulated Initiating Events (PIEs) leading to failure of lifting equipment to provide adequate support to loads lifted.

In summary, the safety case approaches adopted are as follows:

- Provision of redundant SSC, capable of delivering the Category A safety function, in segregated locations which cannot be affected by a single dropped load hazard;
- Protection of SSC, whose availability is required to deliver Category A safety functions, from the effects of dropped loads. This protection takes the form of a dropped load withstand capability which is demonstrated for certain key structures and the provision of passive safety features;
- Qualification of SSC to withstand the secondary effects of a dropped load (e.g., vibration).

The AP1000 design employs a mixture of the approaches stated above to form levels of defence-in-depth which, together, reduce the risk associated with dropped loads to a level which is As Low As Reasonably Practicable (ALARP).

11.8.3.2 Applicable Codes and Standards

The cranes and lifting equipment have been designed in accordance with relevant US codes and standards and are detailed within the Fuel Handling System Design Specification (Reference 11.125) and Mechanical Handling System Design Specification (Reference 11.126) as appropriate. With regards to the assessment of dropped loads as an internal hazard, no claim is made on the design of the cranes to prevent a dropped load with the exception of the end stop fitted to the Cask Handling Crane rail.

SSC claimed in support of this assessment are designed in accordance with the relevant US codes and standards. To evaluate the codes and standards against the UK expectations,

the codes and standards have been organised by the relative safety significance of the SSCs to which they have been applied (see Chapter 6).

The AP1000 Equivalence/Maturity Study of U.S. Codes and Standards (Reference 11.25), provides a clear and auditable demonstration that all codes and standards to support the design substantiation of UK safety related or safety significant SSCs have been identified and the suitability of the US standard assessed.

11.8.3.3 Redundancy and Segregation

The design of the AP1000 plant incorporates redundant divisions of Class 1 SSC, each of which is capable of delivering the Category A safety function. Where there is the potential for Class 1 SSCs to be compromised by a dropped load, the redundant Class 1 SSC delivering the Category A safety function has been identified. The provision of redundancy takes into account the following:

- IAEA-NS-G-1.11 "Protection against Internal Hazards other than Fires and Explosions in the Design of Nuclear Power Plants" (Reference 11.89).
- IAEA NS-R-1, "Safety of Nuclear Power Plants: Design" (Reference 11.21).
- APP-GW-J1R-008, April 2002, "Safety Criteria for the AP1000 Instrumentation and Control Systems" (Reference 11.51).
- APP-GW-J1R-004, April 2002, "AP1000 Instrumentation and Control Defence in Depth and Diversity Report" (Reference 11.52).
- ONR Nuclear Safety Technical Assessment Guide NS-TAST-GD-011, "The Single Failure Criterion" (Reference 11.127).

Within the Containment/Shield Building, redundant divisions of Class 1 SSC have been separated, so far as is reasonably practicable, by distance. While the Containment/Shield Building is a largely open space to maintain the free movement of gases, some compartments have been segregated by walls and floors providing some physical segregation.

Outside the Containment/Shield Building, the Auxiliary Building comprises both a RCA and non-RCA, which are physically segregated from one another by walls, floors and ceilings. Adjoining buildings are also physically segregated from the Auxiliary Building by walls, floors and ceilings. Access to either the RCA or non-RCA portions of the Auxiliary Building is from the adjoining buildings, which are themselves sub-divided into RCA and non-RCA sections by walls, floors and ceilings.

11.8.4 Dropped Loads Assessment Approach

A list of the cranes and lifting equipment is presented in Tables 11.8-1 and 11.8-2. This is compiled from the Mechanical Handling System Specification (Reference 11.126) and the Fuel Handling System Specification (Reference 11.125).

The cranes and lifting equipment considered are:

- Cranes and lifting platforms within the NI.
- Cranes and lifting platforms not in the NI.
- Monorail hoists.

- Elevators (lifts).
- Other lifting equipment.

Each item of lifting equipment is reviewed to determine the threat that a dropped load could pose and the possible impact on delivery of the Category A safety functions.

Assessment Criteria

The following criteria are used to identify which AP1000 lifting devices do not need to receive an in depth evaluation:

1. The hook coverage of the lifting device does not overlap any Class 1 SSC required to provide the principal means of delivering a Category A Safety Function.

2. The lifting device has passive devices controlling the load path in a safe manner[18].

3. The lifting device is unavailable during plant modes 1-4 and cannot lift a load over Class 1 SSC required to provide the principal means of delivering a Category A Safety Function during refuelling.

Dropped loads from lifting devices that meet all the above criteria cannot damage SSCs required to provide the principal means of safe shutdown and decay heat removal from the reactor and the SFP. These devices are identified and discussed in section 6 of Reference 11.123. Those lifting devices that do not meet all of the above criteria, i.e., have the potential to pose a threat of damaging SSCs required to provide the principal means of safe shutdown and decay heat removal from the reactor and the SFP, are evaluated on a case by case basis in Reference 11.121.

11.8.4.1 Equipment Qualification, Testing, and Maintenance

Systems and components claimed as part of the safety assessment of postulated DBAs, including dropped load/impact[19], are qualified to remain functional after exposure to environmental conditions, see Section 5.8. The plant equipment qualification methodology (Reference 11.60) presents information on the equipment qualification of mechanical and electrical SSCs which demonstrate that they are capable of performing their designated functions, while exposed to applicable normal, abnormal, test, design basis and post-accident environmental conditions. Information presented includes documentation of the qualification process and its applicability.

Active mechanical equipment is qualified for operability via an Operability Program which, combined with qualification of electrical attachments, demonstrates qualification under postulated environmental conditions. Class 1 equipment is qualified to maintain integrity and perform its safety function following a seismic event.

---

18. In practice, this criterion is only used, in conjunction with criteria 1 and 3, to exclude lifting devices, such as elevators, whose operating range is constrained by physical structures (such as lift shafts).
19. With the exception of the SFP liner and RPV, no claim is made within the assessment in Reference 11.123 on any SSC to remain functional following a dropped load/ impact, however SSC which are not directly impacted, but which may experience noise/ vibration are assumed to remain functional.

Procurement specifications include specific equipment qualification for all parts of the SSCs; where appropriate any SSCs that have an active functionality in the internal hazard environment are demonstrated through the appropriate accredited testing program. The qualification results are maintained as part of the equipment qualification file, which is maintained during the equipment selection and procurement process.

Qualification of equipment will be undertaken for those SSCs that are essential to maintaining nuclear safety by applying rigorous environmental qualification criteria.

Section 11.3.6 identifies the applicable environmental conditions conforming to General Design Criterion 4, as follows:

- Normal operating environmental conditions – Those conditions existing during routine plant operations for which the equipment is expected to be available on a continuous basis to perform required functions.

- Abnormal environmental conditions – Those plant conditions for which the equipment is designed to operate for a period of time without accelerating normal periodic tests, inspections, and maintenance schedules for that equipment. The maximum and minimum conditions identified as the abnormal condition are based on the design limits for the affected areas.

- DBA and post-DBA conditions – Those plant conditions resulting from various postulated equipment and piping failures during which the safety related equipment must operate without impairment of the function. The DBA and post-DBA conditions are discussed in the master equipment qualification environmental summary (Reference 11.61).

These environmental conditions are divided into mild and harsh environments, where a mild environment is that which can be expected to prevail during normal service conditions and the extremes of abnormal service. Electrical Equipment required to operate in a harsh environment will be qualified using a combination of type testing and testing and analysis. Mechanical equipment located in harsh environmental zones will be qualified to perform their required safety function. For active equipment, required to achieve a mechanical motion in delivering its safety function, qualification will comprise design, testing and analysis of critical sub-components supported by ongoing maintenance and surveillance programs. For non-active equipment whose safety function is delivered through structural integrity, qualification is achieved through design to appropriate codes and standards.

11.8.4.2 Combined Hazards Discussion

Dropped loads may initiate consequential internal hazards (e.g., pipework failure, missiles), their effect on Class 1 SSC are addressed separately in Section 11.12.

The consideration of credible combinations of dropped loads with other postulated internal hazards likely to occur independently of a dropped load is in Reference 11.75. This reference provides a coherent approach across all internal hazard types (e.g., fire, flooding, explosion, missiles, and pressure part failure).

Combinations of independent internal and external hazards (e.g., dropped load and extreme low ambient air temperatures) are considered to be Beyond Design Basis events and as such have not been explicitly considered in this section. However, compliance with relevant equipment and structural design codes as expressed in Chapter 5 ensure that combinations of

internal hazards discussed in Section 11.12 with the relevant abnormal operating occurrences (including environmental hazards as per References 11.60 and 11.61) are addressed.

11.8.5 Dropped Loads Analysis

11.8.5.1 Cranes and Lifting Equipment

The cranes and lifting equipment for the NI are Table 11.8-1. This table also indicates where in Reference 11.123 the dropped load assessment is summarised.

Cranes and lifting equipment located outside the NI are listed in Table 11.8-2. There are no Class 1 SSCs outside the NI and so dropped loads from these lifting devices are not included within the scope of this assessment as they pose no safety risk to operation of the plant (Reference 11.123).

11.8.5.2 Assessment of Dropped Loads

Within Containment, the bounding hazard is a drop of the IHP from the polar crane. The polar crane can only be used during plant modes 5 & 6. During these modes, the number of plant level faults (see Chapter 8), and therefore Category A safety functions, is greatly reduced. The analysis shows that of the required Category A safety functions, a drop of the IHP does not impact all Divisions of Class 1 SSC. In addition, analysis has shown (Reference 11.121 and 11.127) that, following a drop of the IHP onto the RPV, the RCS and DVI lines remain intact such that cooling of the reactor core can be maintained.

Outside of Containment in the RCA, the bounding hazard is a drop of the spent fuel cask from the cask handling crane. The cask handling crane is prevented from traversing over the SFP by end stops positioned to the west of the crane bridge beam. The analysis has conservatively assumed that a dropped fuel cask could penetrate the flooring of the levels below. Even still, there is sufficient redundancy in the unaffected Divisions of Class 1 SSC that the Category A safety functions can continue to be delivered. A dropped fuel cask could damage piping connections to the SFP resulting in a drain down of the SFP, however the design of the SFP precludes lower of the SFP level sufficient to uncover the spent fuel. The required make-up systems are unaffected by this fault.

A drop from the fuel handling machine operates has the potential to impact the SFP and potentially penetrate the floor leading to an uncontrolled drain down. Analysis has shown (Reference 11.122) that for the bounding drop, the SFP liner and civil structure remain intact. A drop from the fuel handling machine would therefore result in damage to spent fuel only, which is addressed separately as part of the fault analysis (see Chapter 8).

For drops from all other lifting devices installed throughout the plant, no more than one Division of Class 1 SSC could be impacted. As such, the ability to deliver Category A safety functions is unaffected.

11.8.5.3 Hazard Schedule

The dropped loads hazard schedule has been prepared based on the analysis of drops from lifting equipment (Reference 11.123). In accordance with relevant international guidance (Reference 11.82), the dropped loads hazard analysis has considered both primary and secondary effects in determining the bounding case. The dropped loads analysis has been prepared on the basis that:

- Class 1 SSC directly impacted by a dropped load will not be able to deliver the Category A safety function;
- A dropped load is assumed to penetrate all floors directly below the point of impact through to the ground floor;
- A dropped load may occur anywhere within the hook coverage of the lifting device;
- Within Containment, the maximum area of impact is equivalent to the footprint of the IHP;
- Outside of Containment, all Class 1 SSC present in a room are damaged where a dropped load impacts that room. Class 1 SSC in adjacent rooms are unaffected by the dropped load.

The dropped loads hazard schedule presents, for each lifting device, the:

- Divisions of each SSC affected;
- Category A safety function at risk;
- Unmitigated consequences should the plant be unable to effect safe shutdown;
- Redundant SSC available to deliver the Category A safety function, which have not been exposed to the same internal hazard.

The hazard schedule is presented in tabular form in Table 11.8-3, providing a concise and comprehensive summary of the postulated dropped loads, their significance and how the AP1000 plant is designed to cope with the hazard.

11.8.6 Sensitivity and Cliff Edge Effects

Based on the degree of conservatism applied to the drop calculations and the margin between the results and acceptance criteria, the value of sensitivity analyses or determination of cliff edge effects is considered minimal.

11.8.7 Combined Hazards Discussion

Dropped loads may initiate consequential internal hazards (e.g., pipework failure, missiles), their effect on Class 1 SSC are addressed separately in Section 11.12.

The consideration of credible combinations of dropped loads with other postulated internal hazards likely to occur independently of a dropped load is in Reference 11.75. This reference provides a coherent approach across all internal hazard types (e.g., fire, flooding, explosion, missiles, and pressure part failure).

Combinations of independent internal and external hazards (e.g., dropped load and extreme low ambient air temperatures) are considered to be Beyond Design Basis events and as such have not been explicitly considered in this section. However, compliance with relevant equipment and structural design codes as expressed in Chapter 5 ensure that combinations of internal hazards discussed in Section 11.12 with the relevant abnormal operating occurrences (including environmental hazards as per References 11.60 and 11.61) are addressed.

11.8.8 ALARP Assessment and Discussion

Deterministic analysis of postulated, design basis, dropped load events shows that the Category A safety functions will be available to provide a safe shutdown following the worst case dropped load.

The number of lifting operations required during normal operation has been minimised by design. Examples of where this has occurred include:

- Older PWR designs require multiple disassembly and lift operations to remove the reactor head. For the AP1000 design, only one lift is required to remove the integrated head package and place it on its storage stand.

- If a reactor coolant pump lift is required it can be carried out as a single lift as the pump and motor are removed and replaced as a single unit.

Although no account is taken within the assessment presented in this report of the frequency with which dropped loads occur, minimising the number of lifts will correspondingly lower the frequency with which loads are potentially dropped and therefore the overall risk.

Lifting plans have been established with a safe load path, which minimises the potential for a load to impact (either directly or following a dropped load) Class 1 SSC. Furthermore, the lift plans have been developed to minimise the height at which the load is carried and therefore the consequences following a drop.

A number of the cranes have been designed to codes and standards providing a high integrity design for nuclear lifting, or incorporate high integrity design features, such as redundant load paths and braking systems, and protective devices (e.g., limit switches) to reduce the likelihood of a dropped load. For these lifting devices, which lift the most sensitive loads or in the most sensitive areas, the likelihood of a dropped load is minimised.

Significant portions of the NI are seismically qualified for a design basis earthquake. With the exception of a fuel element drop onto the SFP, no credit has been taken for the ability of the civil structure to protect SSC present on lower levels from a direct impact. It is however reasonable to assume that, for a number of the loads, the floor would successfully terminate the fault progression although spalling of the ceiling into the room below could not be discounted.

On the basis of the above discussion, and given that Category A safety functions can be maintained in the event of a dropped load, it is judged that there would be minimal safety benefit from introducing additional measures to protect or mitigate a dropped load; the risk from dropped loads is therefore considered to be broadly acceptable and ALARP.

11.9 Biological Agents

11.9.1 Introduction

This section addresses the potential hazards arising from the ingress of biological agents and the lines of defence designed to prevent adverse influences to the safety of the generic AP1000 facility. It provides sufficient arguments and evidence to show that the delivery of Category A safety functions or supporting post 72 hour Category B safety functions will not be impaired by the influences attributable to biological agents. Claims required to meet this assertion are detailed throughout subsection 11.9.2, whilst a number of additional ALARP

measures are identified within subsection 11.9.7 to support the safety case made around these claims.

Biological agents discussed within this section are separated and addressed into the following categories:

- Microbiological (e.g., algae).
- Marine or freshwater life (e.g., fish, molluscs, and seaweed).
- Vermin (e.g., birds, insects, bats, and rodents).

Detrimental effects on the delivery of nuclear safety have been postulated for each of these biological agents, with the delivery mechanisms described in greater detail within subsection 11.9.4. As biological agent intrusion into AP1000 plant can emanate from outside the site boundary, it should be noted that these hazards are also identified within the external hazard analysis within Section 12.15.

Discussion of interfaces, applicable codes and the redundancy of systems is presented within subsection 11.9.3.

11.9.2 Biological Agents Claims, Arguments and Evidence

11.9.2.1 Claims Overview

To control intrusion by biological agents that may otherwise threaten the functionality of SSCs providing Category A safety functions or supporting post 72 hour Category B safety functions, the AP1000 takes the dual approach of preventing biological agent ingress coupled with early detection and remediation of any ingress. This approach is reflected in the prevention and mitigation claims defined within this section (claims 1 and 2, respectively). Additionally and although not formerly claimed, a number of ALARP measures are also defined to support the safety case made around these claims (see subsection 11.9.7).

11.9.2.2 High Level Claim

Although infrequent and of a low probability, biological agents may potentially cause a deviance from the normal operation of the reactor power plant with the potential to result in a hazard being realised. In response to such a deviance, it may be infrequently required to shut down the reactor and return it to a safe state or simply reduce power levels in maintaining a safe state of operation. Depending on the exact nature of the transient, there are a number of courses of action to take to shut the reactor down. Availability of the Class 1 SSCs required in delivering the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim.

Claim IH-8.0: **Postulated biological agent ingress within the design basis will not prevent the delivery of the Category A safety functions and supporting post 72 hour Category B safety functions necessary to respond to the postulated event.**

Within the design of the AP1000, this has been achieved by ingress prevention, detection and remediation of the intrusion. The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.9.2.3 Prevention Claims

Prevention against the risk from biological agents in support of the overall high level claim is provided by:

Claim IH-8.1: **Intrusion of biological agents is prevented by the incorporation of structural design features that bar entry into areas containing SSCs delivering Category A safety functions or supporting post 72 hour Category B safety functions.**

11.9.2.4 Protection Claims

As safety case claims are made against the prevention of biological agent ingress and by identifying and controlling biological agent ingress, no protective claims are made. Although not formerly claimed, however, a number of protective ALARP measures are identified (see subsection 11.9.7).

11.9.2.5 Mitigation Claims

Mitigation against the risk from biological agents in support of the overall high level claim is provided by:

Claim IH-8.2: **Detection and remediation of biological agents that may have entered the AP1000 plant will be undertaken before their ingress can result in the impaired performance of SSCs and prevent the delivery of a Category A safety functions or supporting post 72 hour Category B safety functions.**

11.9.2.6 Arguments and Evidence

Claim IH-8.1: **Intrusion of biological agents into the AP1000 plant is prevented by the incorporation of design features that bar their entry into areas containing SSCs delivering Category A safety functions or supporting post 72 hour Category B safety functions.**

The SSCs of the NI within the AP1000 design are designed to minimise the intrusion of biological agents into the NI through the incorporation of structural design features specified in appropriate building and design codes.

The primary functions of the buildings in the NI are to provide shielding and to maintain nuclear containment. The massive concrete and steel construction of the AP1000 NI and provision of secured access and egress routes for personnel ensure that buildings are adequately robust against the ingress of vermin.

Areas of potential vulnerability include penetrations into buildings and ventilation inlet and exhaust systems. Building codes and the design and construction of the NI will effectively prevent ingress via these routes, for example, by the incorporation of screens in the Shield Building air inlet and exhaust diffuser. To prevent ingress into the Shield Building via the PCS air inlets or discharge, No. 10 mesh screening (10 mesh per inch (25.4 mm) with 0.025 inch (0.635 mm) diameter wire) is typically placed behind the air inlet opening louvers and in the air discharge path leading to the elevated exhaust structure. To prevent vermin, such as insects, birds, and rats, from gaining access and fouling or damaging systems via other

ventilation systems, such as the DG inlet and exhaust systems, screens, meshes, and filters are installed.

The types of waterborne biological agents that could potentially affect nuclear safety are heavily dependent on the environment in which the station is operated, specifically on the source of the turbine condenser heat sink. This may be from a cooling tower, from a freshwater source, or most typically for the UK, from the marine environment. Therefore, the prevention methods for ingress by waterborne agents (e.g., algae blooms, sea weed, and molluscs) will be determined by the chosen heat sink for a particular site, and this will be addressed in the site-specific safety case. Similar prevention methods to those currently deployed at operating plants across the UK, such as the use of drum screens, will be available to control the potential intrusion of marine life.

The potential hazards microbiological agents create are difficult to exclude purely by design, but may be effectively mitigated by monitoring, detection, and routine treatment with appropriate biocides (see Claim 2 below).

Claim IH-8.2: **Detection and remediation of biological agents that may have entered the AP1000 plant will be undertaken before such ingress can result in prevention of the delivery of a Category A safety functions or supporting post 72 hour Category B safety functions.**

In addition to the protection to the Class 1 SSCs provided by the NI buildings, additional measures will be in place to control an infestation by biological agents from disrupting the provision of the Category A safety functions. See, for example, the biological fouling safety design approach identified in Chapter 12, Section 12.15. These measures follow the best practice approaches from existing NPPs of using chemical control to minimise the risk of microorganisms fouling tanks, HXs, and pipework and, a regime of regular inspection and surveillance of the safety significant SSCs within the NI and across the remaining AP1000 plant structures for the early detection of infiltration of any biological agents (macro or microscopic).

A regime of routine monitoring, sampling, and analyses of all systems containing water will ensure that the presence of microbiological growths are detected in the early stages, well before they could present any challenge to nuclear safety, and can then be treated and controlled with the appropriate biocide or algaecide. As part of the auxiliary systems, there are various water systems with piping, tanks, HXs, and other components. These systems are routinely treated or dosed with biocides and/or algaecides to control the growth of microorganisms that cause fouling and to limit the formation of biological films that may reduce heat transfer in condensers and HXs.

For open cooling water systems like the CWS or the SWS that cool the CCS HXs, the addition of biocide is performed by local feed injection, monitored, and adjusted as necessary. Biocides, such as sodium hypochlorite, are recommended in preference to toxic gases, such as chlorine, which may increase the toxic gas risk.

In the PCS, the PCCWST and PCCAWST are periodically monitored and dosed with hydrogen peroxide to control biological growth.

Other water systems like the DTS do not typically require treatment, since this water is constantly being used and replenished. This water is treated to maintain a very low oxygen content, which minimises the potential for algae or other biological growth.

The ingress of freshwater or marine life into systems like the CWS when direct cooling is employed is already prevented by the use of drum screens and treatment systems suitable for the local conditions. Additionally, biological growth as a consequence of marine or freshwater life would either be detected directly by routine monitoring and maintenance, or noticed as a gradual loss of system performance. Any growth would be rectified during routine testing and maintenance outages.

Similarly, a regime of routine monitoring and maintenance throughout the life of the station will detect the entry of any animals or birds into the NI, whereupon remedial actions can be undertaken to remove the creatures and the repair of entry routes.

11.9.3 Biological Agents Safety Case Summary

11.9.3.1 Introduction and Overview

The biological agent hazard challenging the AP1000 is categorised as microbiological (e.g., algae), marine or freshwater life, such as fish, molluscs, and seaweed, and vermin, such as birds, insects, bats, and rodents. Detrimental effects on the delivery of nuclear safety have been postulated for each of these biological agents (see subsection 11.9.4), with the potential to prevent the delivery of Category A safety functions or supporting post 72 hour Category B safety functions. The safety case for control of biological agents is based principally on the demonstration of the following:

- Ingress prevention
- Detection and remediation of intrusion

Specific claims are detailed in subsection 11.9.2, whilst a number of additional ALARP measures are identified within subsection 11.9.7 supporting the safety case made around those claims. The inherently robust structural design of the plant, normal operating procedures and maintenance activities form the basis of the measures to prevent, detect and control the ingress of biological agents. The redundancy, separation, and segregation of the plant involved in the postulated biological agent ingress is discussed below along with identification of any applicable codes and standards, and any interfaces with the assessment of other internal hazards.

11.9.3.2 Applicable Codes and Standards

The appropriate building and design codes used throughout the AP1000 plant (see Chapter 16) mean it is inherently designed to minimise the intrusion of biological agents, e.g., the incorporation of screens in the Shield Building air inlet and exhaust diffusers.

11.9.3.3 Redundancy, Separation, and Segregation

Sufficient redundancy, separation, and segregation in the design and location of the Class 1 SSCs ensure that the Category A safety functions can be maintained in the worst-case, normally permitted, plant line-up, despite loss of those SSCs affected by biological agent ingress and the presence of a credible, unrelated, single failure within the other SSCs.

The Containment structure provides a robust barrier to the intrusion of biological agents into the area where Class 1 SSCs are sited. Outside the Containment structure, the Class 1 SSCs in the Auxiliary Building have been designed so that the complete loss of the equipment within any single room will not result in loss of Category A safety functions. The concrete fire barriers protecting redundant trains of the Class 1 SSCs from fire should also provide an

adequate barrier to spread of biological agents, and therefore limit any damage to the equipment in only the affected room. Materials used in the construction of the Class 1 SSCs are generally not susceptible to attack by biological agents.

Large quantities or swarms of insects that could cause blockage of the large, multiple PCS air inlets or large PCS outlet are highly unlikely. Additionally, the PCS inlets and outlets are subject to periodic inspection to ensure that no such blockage exists. Furthermore, the heat removal capability of the PCS is still maintained by the application of water onto the outside surface of the Containment shell. A decrease in air flow would impact the ability of the PCS to attain low Containment pressure following a DBA, since water evaporation at low temperature would be decreased, but boiling would still be effective in removing heat.

Large quantities or swarms of insects could conceivably cause the blockage of the intakes for HVAC, DGs, or other systems that rely on an air supply to maintain their function. Typically for DGs, protection is afforded by having separation by distance between DG intakes and exhaust, and by the standard practice of having screens and air filters on intakes. Additionally, the DGs are a defense in depth function, not depended upon to provide power to any Class 1 SSC for the AP1000 plant, so a loss of one or all DGs does not affect safe shutdown of the plant. The batteries providing power to the Class 1 SSCs would clearly not be susceptible to this hazard.

Adequate redundancy is provided within each Class 1 safety system such that even in the loss of a single SSC, for example, as a result of a fire (which is assumed to disable the whole train), the Category A safety function can still be provided by a redundant train located in a different fire compartment (or fire zone within the Containment). This compartmentalisation of safety systems also provides protection from system damage resulting from animal ingress, as any significant damage in one area would be confined, detected, and mitigated before it could spread to other areas.

In addition, penetrations between compartments are minimised mainly to reduce the potential routes for the spread of fire and hot gases, but this would also limit access and egress routes for vermin. Class 1 cables are routed in separate raceways in galvanised steel solid-bottomed and lidded trays, which again would reduce the opportunity for vermin to cause damage.

11.9.3.4 Biological Agents Assessment Approach

Principally, the AP1000 design takes the dual approach of ingress prevention and, detection and remediation of any intrusion to control the risks associated with biological agents. Detailed analysis of the hazard presented by biological agents is not appropriate for a generic assessment as the environmental conditions of each site will vary as will the specific challenges to each site necessitating finely tailored control measures, particularly those in relation to the site-specific heat sink. As such this will be addressed during the detailed design phase and in the site-specific safety case.

11.9.3.5 Interface with Other Internal Hazards

Control of biological agent impact on the AP1000 has an indirect reliance on the inherent compartmentalisation and redundancy within the design (see Chapter 16), e.g., fire barriers protecting redundant trains of the Class 1 SSCs from fire (discussed within Section 11.2) limits the spread of biological agents by also acting as a barrier to their propagation.

Discussion of the use of biocides to control biological ingress, e.g., sodium hypochlorite is presented within the Chemical Inhibitors discussion of subsection 11.7.4.2. There is also a

less significant interface with internal flooding, as nesting material is identified as an initiator of block drains and therefore flooding (see Section 11.3).

Where biological hazards originate outside the AP1000 plant site boundary they are also addressed within the external hazard analysis. Section 12.15 covers the external threat from biological agents.

11.9.3.6 Conclusions

Sufficient evidence has been shown throughout this section that the risk of loss of a nuclear safety-significant system as a result of biological agents is low and controlled. Biological agents have been shown to not prevent the delivery of the Category A safety functions and the post 72-hour Category B safety functions. This is due to the combination of inherent design features, routine and non-routine early detection regimes, and the application of routine and non-routine remediation actions, respectively preventing, detecting and controlling the risk to the AP1000 from biological agents.

11.9.4 Biological Agents Safety Analysis

11.9.4.1 Identification of Hazard Sources

Microbiological growth has the potential to form a biological film that can reduce the effectiveness of heat transfer in condensers and HXs and to contaminate potable water supplies. In the extreme, algae growths (blooms) could restrict the flow of water and block filters.

Similarly, marine (or freshwater) life such as fish could be drawn into water inlets and restrict water flow to condensers or HXs.

Bird, animal and insect infestations are a threat to nuclear safety through the following potential mechanisms:

- Nest material could block drains, resulting in flooding.
- Fouling and waste products could cause corrosion.
- Electrical cables could be gnawed, causing broken circuits and short circuits.
- Mechanical damage to delicate systems could result from creatures getting into them.
- Seals between compartments could be damaged by creatures physically forcing passage through, subsequently allowing smoke and noxious gas to pass.
- Radioactive material could be spread from radiologically controlled areas to clean areas or even the external environment by the movement of creatures.
- The bodies of dead creatures could be drawn into pump suction pipework, clogging them or damaging the pump mechanism.

11.9.4.2 Assessment of Biological Agent Impact and Control

The potential for biological agent ingress is constantly present within the plant environment. As such it is not possible to eliminate the hazard presented by biological agent ingress and

therefore the AP1000 design takes the dual approach of ingress prevention and, detection and remediation of any ingress to control the risks associated with biological agents. The inherently robust design of the plant, normal operating procedures and maintenance activities form the basis of the measures to prevent, detect and control the ingress of biological agents.

Analysis of the hazard presented by biological agents is not appropriate for a generic assessment as the specific environmental conditions of each particular site will mean the specific hazard challenging each site may vary, necessitating finely tailored control measures, particularly those preventing in relation to the site-specific heat sink. As such this will be addressed during the detailed design phase and in the site-specific safety case.

11.9.4.3 Hazard Schedule

Whilst subsection 11.9.4.1 postulates generic detrimental effects of the expected categories of biological agents, no specific hazard schedule is presented for biological agents as the hazard presented by each agent in its constituent environment remains to be finalised during the detailed design phase. These hazards will be captured and recorded within the site-specific safety case.

11.9.4.4 Discussion of Results

Analysis of the threat posed by biological agents is fundamentally site-specific; as such this level of detailed assessment will be undertaken during the detailed design phase and captured within the site-specific safety case. Therefore no results are presented here.

11.9.5 Sensitivity and Cliff Edge Results

Analysis of the threat posed by biological agents is fundamentally site-specific; as such this level of detailed assessment will be undertaken during the detailed design phase and captured within the site-specific safety case. Therefore no discussion of cliff edge transition effects is presented here.

11.9.6 Combination of Hazards and Consequential Hazards

Biological Agents as a hazard initiating consequential internal hazards and, their effect on Class 1 SSC are addressed separately in Section 11.12.

Consideration of credible combinations of Biological Agents with other postulated internal hazards likely to occur as the result of a biological event is considered unlikely the basis that this internal hazard does not result in the loss or damage of Class 1 SSCs and, as such, its contribution to combinations of internal hazards is of no consequence (Reference 11.75).

Combinations of independent internal and external hazards (e.g., dropped load and extreme low ambient air temperatures) are considered to be Beyond Design Basis events and as such have not been explicitly considered. However, compliance with relevant equipment and structural design codes as expressed in Chapter 5 ensure that combinations of internal hazards discussed in Section 11.12 with the relevant abnormal operating occurrences (including environmental hazards as per References 11.60 and 11.61) are addressed.

11.9.7 ALARP Assessment and Discussion

The biological agent safety case is based principally on the preventative and mitigative claims of, precluding ingress where possible, and, detecting and remediating it where not. To further

support this case and although not formerly claimed, a number of controls are also identified as ALARP measures. These include:

- All Class 1 SSCs are separated into zones for the prevention of loss by any single event, such as fire. This has the additional benefit that animal ingress is extremely unlikely to penetrate multiple barriers and cause any significant damage without operators becoming aware and initiating corrective actions. This is also pertinent in relation to the unlikely possibility of animal ingress leading to the spread of contamination across zones.

- Class 1 cables are routed in separate raceways in galvanised steel solid-bottomed and lidded trays to reduce the opportunity for vermin to cause broken circuits and short circuits from gnawing.

- Materials used in the construction of the Class 1 SSCs are generally not susceptible to attack by biological agents.

In concert with the safety case claims, the measures outlined above provide sufficient evidence that the risk of loss of a nuclear safety-significant system as a result of biological agents is low and has been addressed in the design of the plant (or will be addressed on a site-by-site basis) and by normal operational procedures and maintenance activities. Thus, the risks posed from biological agents are at such a low level that further measures to reduce the risk further are not considered to be practical.

11.10 Onsite Transport

11.10.1 Introduction

This section covers the potential threats to nuclear safety from onsite transport accidents, including collisions between transports and with AP1000 plant civil structures, as well purely vehicular accidents and their effects on the loads transported.

The onsite transport hazard sources are described in subsection 11.10.4.1, with the impact of the hazard and its means of control addressed in subsection 11.10.4.2, the claims, argument and evidence of control being provided in subsections 11.10.2.

11.10.2 Onsite Transport Claims, Arguments and Evidence

11.10.2.1 Claims Overview

Whilst most of the claims to control the risk of an onsite transport accidents are by definition dependent on site specifics and local procedures, the primary claim placed at this stage is the physical protection provided by the buildings to the material and systems within them, i.e., the structure of AP1000 plant NI buildings fully protect the SSCs delivering the Category A safety functions within them. This is complemented by the siting of NI buildings and defined areas of onsite travel, as shown within Chapter 6, which establish protection against onsite vehicular impact.

11.10.2.2 High Level Claim

Incidents involving onsite transport have the potential to cause the failure of AP1000 SSCs due to vehicular impacts. This in turn may either initiate a transient from normal operation of the reactor power plant with the potential to result in a hazard on or off-site being realised, or

detrimentally affect the response to a transient. The availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim.

Claim IH-9.0: **Postulated onsite transport within the design basis will not prevent the delivery of the Category A safety functions and supporting post 72 hour Category B safety functions necessary to respond to the postulated event.**

This high level claim is delivered by a set of three claims for the protection provided to systems from onsite transport events. These being:

- Protection to Class 1 SSCs provided by the NI structure
- Protection to the NI provided by adjacent structures
- Protection provided by the transport container

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.10.2.3 Prevention Claims

No prevention claims against the risk of onsite transport accidents are made as it is not practicable to prevent vehicle access to the AP1000 plant site (primarily the auxiliary and Turbine Buildings) for the various removals or deliveries required to safely operate the station.

11.10.2.4 Protection Claims

It is not possible to eliminate onsite transport as it is required for the normal operation of AP1000 plant; therefore Class 1 SSCs have to be protected from a transport incident and its effects. The following protective claims are made in support of the overall high level claim:

Claim IH-9.1: **The NI will protect the Class 1 SSCs from the effects of an onsite transport event.**

Claim IH-9.2: **The Radwaste Building, Annex Building and turbine hall protect the NI from an onsite transport collision.**

Claim IH-9.3: **Radioactive material transported onsite is protected by its transport package.**

11.10.2.5 Mitigation Claims

No mitigation claims against the risk of onsite transport accidents are made.

11.10.2.6 Arguments and Evidence

The risks associated with onsite transport accidents do not prevent the delivery of the Category A safety functions and the post 72-hour Category B safety functions, due primarily to the inherently robust civil structural design of the building, which is justified to protect against external hazards, see Chapter 12. This in concert with the siting of plant buildings, providing the maximum impact protection to the safety significant systems sited within the

NI buildings. Where radioactive material is transported onsite, the integrity of transport containers provides protection to the loads in accordance with nuclear industry standards.

Thus, the risks from an onsite transport accident leading to the loss of Class 1 and 2 SSCs as a result of an onsite transport incident is low and is suitably controlled by these measures. The following sections expand on these arguments.

Claim IH-9.1: The NI will protect the Class 1 SSCs from the effects of an onsite transport event.

Controlled vehicular access is required to the AP1000 plant site to deliver and pick up equipment, supplies, and nuclear materials required for the operation of the plant. Additionally, maintenance and repair work onsite will also require vehicles to access the site to support these activities. Such access is reasonably expected to fall within the site security plan in limiting and controlling vehicles inside the protected zone.

Appropriate AP1000 plant buildings have receipt and loading bays designed to be accessed by vehicles. The radiological portion of the Auxiliary Building has a loading bay suitable for trucks or a railroad car. This bay is used for the delivery and collection of new nuclear fuel, for the removal of spent nuclear fuel in transfer casks, and for the removal of used filter cartridges and spent resin. The Radwaste Building has a loading bay for the removal of other solid radiological waste material and for use by temporary equipment that may be employed for waste treatment. The Turbine Building has a bay for the delivery of equipment and supplies and removal of spent condensate treatment resin. Additionally, bulk supplies will be delivered to other AP1000 plant facilities, including those outside the plant security zone, to ensure the ongoing operation of the AP1000 reactor. Examples of these supplies include diesel fuel, bulk liquefied gases, compressed gas, and chemicals. Thus, it is not practicable to prevent vehicle access to the AP1000 plant site.

Additional measures are in place to minimise the frequency and consequences of an incident involving a collision of a vehicle with either another vehicle onsite or an SSC of the AP1000 plant. These are discussed in subsection 11.10.6 and cover procedural controls on vehicle movements and best practice in road layout and facility siting.

The AP1000 plant Class 1 SSCs are located in the buildings of the NI (Containment/Shield Building and Auxiliary Building). These are C-I buildings that are designed to protect the SSCs within them from seismic events and external hazards (for example, tornado-induced missiles). See Chapter 12 for a discussion of the design External Hazards and Chapter 16 for seismic analysis and qualification. No Class 1 SSCs are located in the Turbine Building, Annex Building, Radwaste Building, or other AP1000 plant facilities outside the NI. Class 2 SSCs are located both within the Shield and Auxiliary Buildings and in other structures of the AP1000 plant.

The Containment, Shield Building, and the Auxiliary Building provide a high level of protection to the SSCs within them. As C-I structures, they are designed to withstand the effects of earthquake while maintaining their integrity. Their seismic category, analysis methods, and results are discussed within Chapter 16. Additionally, the NI structures provide protection to the SSCs within them from externally-generated impacting objects. In Chapter 12, it is shown that a tornado-created missile (car of mass 1.81 tonnes travelling at 46.9 meters per second (105 mph)) that impacts the buildings of the NI will not cause a breach of a NI structure. The structures of the NI (Containment Vessel/Shield Building and Auxiliary Building) are, therefore, demonstrated to be robust when impacted by a significant mass travelling at speed.

Vehicle movement onsite will cover a wide range of loads from small loads to significant loads such as nuclear fuel casks, which may weigh up to 110 tonnes. While specific calculations for a worst-case vehicle collision with an AP1000 plant building have not been carried out, the analyses for seismic response and tornado missiles provide a high degree of confidence that the buildings will prevent a vehicle impact from disrupting SSCs located within the NI.

Claim IH-9.2: The Radwaste Building, Annex Building and turbine hall protect the NI from an onsite transport collision.

In addition, the Containment, Shield Building, and Auxiliary Building are protected on three sides by other AP1000 plant structures; including the Turbine Building, Radwaste Building, Annex Building. Chapter 6 provides a site layout drawing showing the positions of the main buildings and facilities.

The Turbine Building, Radwaste Building, Annex Building, and DG building do not contain Class 1 SSCs but will contain Class 2 SSCs. The portions of the Turbine Building, Radwaste Building, and Annex Building closest to the NI are designed to survive a C-II event. These C-II portions of the buildings consist of reinforced concrete and steel-framed structures with reinforced concrete walls and floor slabs. Roof slabs will be of reinforced concrete or metal decking.

The remaining portions of these buildings, while not designed to survive a C-II event, are of high-quality commercial construction, consisting of reinforced concrete and steel-framed structures with either reinforced concrete walls or insulated metal sidings. Floor and roof slabs will be of reinforced concrete or metal decking. General statements of intent regarding the construction of the buildings are provided within Chapter 16. These buildings are judged to provide some protection to the SSCs contained within them. A vehicle impact with these buildings could breach the building perimeter, but this impact would not affect the Class 1 or Class 2 SSCs in the C-I buildings, nor the Class 2 SSCs in the C-II portion of these buildings. If Class 2 SSCs are lost, the plant may experience a DB transient or entry into a Technical Specification (Tech Spec) condition. In either case, the Class 1 SSCs are available to ensure the delivery of the Category A safety functions.

Where access is required to receipt and loading bay areas within the AP1000 plant building, there is a possibility of a low-speed vehicle impact with the building structure. An impact with the building structure at the low speeds applicable during entry and exit from loading bays (5 mph or less) is judged not to cause failure of a C-I or C-II structure.

Any consequential hazards arising as a result of vehicle impact, such as fire, explosion, or missile generation, is bounded by the consideration of these hazards within Section 11.2, 11.5, and 11.6, and the consideration of consequential hazards presented in Section 11.12.

Claim IH-9.3: Radioactive material transported onsite is protected by its transport package.

Movement of radioactive materials such as LLW or ILW or spent fuel to onsite stores, or dispatch to offsite disposal facilities, is not fully defined at this stage. However, movements of nuclear materials that are to be dispatched offsite will be carried out in IAEA-approved packages in accordance with the requirements specified in TS-R-1 (Reference 11.129). These will provide a suitable level of protection to their contents from transport accidents. Transport of radioactive material in these approved packages will prevent uncontrolled dispersion of radioactivity or uncontrolled exposure of plant personnel or the public to radiation from a transport package.

Transport of radioactive material in transport packages will be subject to site administrative controls. These will be developed by the site licensee, and are expected to be in accordance with applicable radioactive material transportation regulations.

Radioactive material will also be moved onsite from the facilities where it is generated (the radiological Auxiliary Building and Containment structure) to the storage and packaging facilities within the Radwaste Building. The packaging arrangements for this material, its waste route, and means of transport will be defined by the site licensee prior to the operational phase.

Hence, accidents involving onsite transport of radioactive material will not result in the failure to deliver Category A safety functions.

11.10.3 Onsite Transport Safety Case Summary

11.10.3.1 Introduction and Overview

The onsite transport safety case is built on the demonstration of three claims, these being:

- Protection to Class 1 SSCs from the NI structure
- Protection to the NI provided by adjacent structures
- Protection provided by the transport container

These claims are argued (subsection 11.10.2.6), to be true based on the layout of the AP1000 structures and the protection provided by the NI to the SSCs that are located within it. Additional control and mitigation measures are presented in subsection 11.10.6 that apply to future onsite controls that a Licensee would be expected to apply. The safety case also addresses the transport of radioactive material onsite. Protection is provided by the transport containers for these movements.

11.10.3.2 Applicable Codes and Standards

Adherence to appropriate building and design codes (Chapter 16) mean the buildings of the AP1000 are designed to protect their contents from bounding external events (such as seismic or tornado-induced missiles) and therefore are protected against the effects of onsite transport accidents.

Transport of radioactive material within transport package loads will be in accordance with applicable radioactive material transportation regulations. Where packages are dispatched offsite, they will meet the requirements of TS-R-1 (Reference 11.129).

11.10.3.3 Redundancy, Separation, and Segregation

The distribution of Class 1 and 2 SSCs on an AP1000 plant is such that complete loss of operability of the SSCs within a room or compartment because of disruption resulting from an onsite transport accident would not result in loss of the Category A function.

Adequate redundancy is provided within each Class 1 safety system such that, even if the loss of a single SSC were to occur (for example, as a result of a resultant secondary fire), the Category A safety function can still be provided by a redundant train located in a different compartment or area of the Containment. This compartmentalisation of safety systems provides some protection from system disruption resulting from an impact with an AP1000

plant building, if the impacting object were to penetrate the building perimeter or cause a localised failure of systems within a building.

11.10.3.4 Onsite Transport Assessment Approach

The assessment approach taken to control the risks associated with onsite transport accidents presented throughout this section is principally based on the qualitative arguments of a robust inherent civil structural design and the siting of buildings with respect to protecting the NI. Discussion of the integrity of radioactive material loads carried by onsite transports is also presented below. These measures are supplemented by various site-specific protections and local transport procedures that will be implemented by the Licensee (see subsection 11.10.6).

11.10.3.5 Interface with Other Internal Hazards

The primary claim that the structure of the NI buildings of the AP1000 plant fully protects the SSCs delivering the Category A safety functions within them from structural collapse and shock-induced vibration damage caused by onsite transport accidents relies upon its inherently robust civil structural design (Chapter 16). This is justified elsewhere for bounding external hazards such as tornado or seismic events (see Chapter 12).

Indirectly fire, flooding, internal missile and other explosion effects are identified as possible additional outcomes of an onsite transport accident. Previous sections of this chapter (e.g., Section 11.2 for internal fire, Section 11.3 for flooding, Section 11.6 for internal missiles and Section 11.5 for explosions) have shown that any consequential hazards arising as a result of vehicle impact, are bounded by the consideration the effects of those hazards (also see Section 11.2 for consideration of consequential hazards).

11.10.3.6 Conclusions

Sufficient evidence that the risk of loss of a nuclear safety-significant system as a result of onsite transport accidents is low and well controlled has been shown throughout this section. The integrity of the plant's civil structural design, the siting of plant buildings and the integrity of the radioactive loads transported onsite provide the primary protection against the risk of an accident. It is anticipated that these will be supported by site-specific measures and local procedures as defined by the Licensee specifically for the site.

11.10.4 Onsite Transport Safety Analysis

11.10.4.1 Identification of Hazard Sources

Onsite transports accidents could directly damage the civil structures of the AP1000 plant buildings leading to structural collapse onto Class 1 or 2 SSCs, or cause shock-induced vibration damage to such SSCs inside; indirectly, there is the possibility of fire, flooding, and explosion effects. Additionally, the movement of radioactive material around the site could potentially be affected by a transport accident, releasing the radioactivity.

The principal buildings of concern are the NI and the Radwaste Building. The NI is where the Class 1 SSCs are located and most Class 2 SSCs are located. The Radwaste Building includes storage facilities for holding and processing the various categories of waste generated onsite prior to packaging and shipping offsite in approved containers. No Class 1 SSCs are located in the Radwaste Building.

The following buildings and structures of the AP1000 plant do not contain Class 1 SSCs but will contain Class 2 SSCs, and have been shown in previous sections of this chapter not to pose a secondary hazard (e.g., Section 11.6 for internal missiles, Section 11.5 for explosions, or Section 11.3 for flooding) to the safety-significant SSCs elsewhere onsite:

- Turbine hall
- Annex building
- DG building
- Service water cooling towers
- Onsite storage tanks (water, diesel fuel, boric acid)

Damage to any of these from an onsite transport accident would have one of two effects: it could initiate a DB operational transient, such as loss of grid; alternatively, it could force entry into a Tech Spec action condition, because of loss of availability of required systems, such as reactor coolant makeup through the CVS. Design Basis operational transients are addressed in Chapter 9. Entry into a Tech Spec condition would, in the worst case, lead to a controlled shutdown of the reactor. These two conditions are not considered further in this chapter.

11.10.4.2 Assessment of Onsite Transport Impact and Control

The safety justification for the onsite transport is based on the location of Class 1 SSCs and the protection of these SSCs from transport hazards by the NI structures. Detailed analysis of the onsite transport hazard has not been carried out as the site layout and requirements for vehicular deliveries will only be defined during the licensing phase. Assessments have been carried out of the capability of the NI to withstand a range of external hazards (Chapter 12), which are argued to provide confidence that the NI will provide protection from a vehicular impact. Detailed analysis of the onsite transport of radioactive material has not been carried out as it is argued that transport containers will be specified to comply with transport regulations and so no release of radioactive material will occur in the event of an onsite transport incident.

11.10.4.3 Hazard Schedule

No hazard schedule is presented for onsite transport as the hazard is dependent on site layout which is anticipate to be defined at the Licensing stage.

11.10.4.4 Discussion of Results

The safety justification for the onsite transport is based on the location of Class 1 SSCs and the protection of these SSCs from transport hazards by the NI structures. Additionally protection to the NI is provided by the other AP1000 buildings grouped around the NI. This approach is discussed in subsection 11.10.2.6. Detailed analysis of the onsite transport hazard has not been carried out as the site layout and requirements for vehicular deliveries will only be defined during the licensing phase.

11.10.4.5 Sensitivity and Cliff Edge Results

The argument and evidence in support of the onsite transport claims is not dependent on the assessment of onsite transport, rather it is dependent on AP1000 location of Class 1 SSCs, protection provided to the SSCs from the NI and the protection of the NI by adjacent

buildings. With all Class 1 SSCs located in the Containment and Auxiliary Building, protection from on-site transport hazards is provided by both the robust design of these structures (see External Hazards, Chapter 12, and sections 11.5, Internal Missiles, and 11.6, Internal Explosions) and the plant layout (Chapter 6) which places the Annex Building, Turbine Building, and Radwaste Building between normal transport routes and the Class 1 SSC locations. This cumulative passive protection, as well as anticipated active site security restrictions, does not lend itself to the consideration for cliff edge effects for onsite transport hazards.

11.10.5 Combination of Hazards and Consequential Hazards

Discussion of combined and consequential hazards is presented within the Combination of Hazards section (see Section 11.12).

11.10.6 ALARP Assessment and Discussion

The measures outlined in subsection 11.10.2.6 demonstrate that the likelihood of loss of Class 1 and 2 SSCs as a result of an onsite transport incident is low and has been addressed in the design of the plant or will be addressed on a site-by-site basis. In addition to the physical protection that the buildings provide to material and systems within them, additional external protection measures will be specified as required during the detailed site design phase. These measures are reasonably expected to include the following:

- Control of vehicular access to the site, including speed limitations, and escorting of significant loads
- Layout of access roads to minimise the potential for vehicles to reach high impact speeds.
- Definition of site access routes to minimise the potential for vehicle to vehicle collisions.
- Provision of armoured barriers to protect buildings from vehicle impacts
- Design of landscaping features to provide protection to buildings from vehicle impacts.

The risks posed from onsite transport are at such a low level that measures to reduce the risk further are not considered to be practicable.

11.11 Electromagnetic Interference

11.11.1 Introduction

This section covers the potential threats to nuclear safety from EMI originating onsite. Within this section, EMI includes radio frequency interference (RFI) and electrostatic discharge (ESD). Offsite-originated EMI (including lightning) is addressed within Section 12.16.

The EMI hazards sources are described in subsection 11.11.4.1, with the impact of the hazard and its means of control addressed in subsection 11.11.4.2, the claims, argument and evidence of control being provided in subsections 11.11.2.

11.11.2 Electromagnetic Interference Claims, Arguments and Evidence

11.11.2.1 Claims Overview

Two claims are made for the control of the hazard from EMI; prevention of EMI at source (i.e., emissions) and protection of systems from EMI (i.e., susceptibility).

11.11.2.2 High Level Claim

Internal electromagnetic interference has the potential to disable sensitive electronic equipment in the AP1000 plant, or may cause it to activate spuriously. This in turn may either initiate a transient from normal operation of the reactor power plant with the potential to result in a hazard on or off site being realised, or detrimentally affect the response to a transient. The availability of the Class 1 SSCs required in delivering the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim.

Claim IH-10.0: **Postulated internally generated electromagnetic interference within the design basis will not prevent the delivery of the Category A safety functions and supporting post 72 hour Category B safety functions necessary to respond to the postulated event.**

This claim is delivered by a claim on the prevention of EMI and a claim for the protection provided to systems from EMI. The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.11.2.3 Prevention Claims

The generation of levels of onsite EMI that could potentially disable sensitive electronic equipment in the AP1000 plant, or cause it to activate spuriously are prevented by the design and selection of electrical and electronic systems deployed on the AP1000 site.

The following preventative claim is therefore made in support of the overall high level claim:

Claim IH-10.1: **Electrical and electronic equipment, and communication systems, are designed, tested, and located so as not to generate levels of EMI emissions that will interfere with delivery of Category A safety functions.**

11.11.2.4 Protection Claims

It is not possible to eliminate all sources of EMI and so systems and components that could be adversely affected by EMI have to be protected. The following protective claims are made in support of the overall high level claim:

Claim IH-10.2: **Where appropriate, electrical and electronic equipment, and communication systems, will be protected from the effects of EMI through established system design measures.**

11.11.2.5 Mitigation Claims

No claim is made for the mitigation of EMI.

11.11.2.6 Arguments and Evidence

The risks associated with electromagnetic interference do not prevent the delivery of the Category A safety functions and the post 72-hour Category B safety functions, due principally to the complementary twofold approach of minimising EMI emissions (Claim 1) at source and protecting susceptible systems from EMI (Claim 2).

Claim IH-10.1: **Electrical and electronic equipment, and communication systems, are designed, tested, and located so as not to generate levels of EMI emissions that will interfere with delivery of Category A safety functions.**

All likely generators of EMI within the AP1000 plant have been identified. Electrical equipment can generate EMI by conduction through cables, radiated magnetic fields, radiated electric fields, or ESD. Likely generators of EMI have been specified to minimise the risk of them spuriously generating levels of EMI that could cause a hazard to AP1000 plant equipment, including Class 1 equipment. EMI generated from sources outside the AP1000 plant are addressed within external hazard analysis (Section 12.16).

The philosophy for the management of EMI for the AP1000 design is set out in the EMC management philosophy (Reference 11.130). It defines the standards that the AP1000 design will meet in the UK and how the requirements of SI 3418 (Reference 11.131) will be applied by Westinghouse.

While compliance with SI 3418 does not directly regulate safety-related matters, poor control of EMC can have a significant and detrimental effect on the reliable operation of electrical, electronic, and programmable electronic systems. This is recognised in Reference 11.132, regarding C&I safety, which sets out general requirements for systems. Measures in place to ensure that the electrical and electronic systems of the AP1000 plant are not susceptible to EMI are addressed below. The correct operation of the systems is also dependent on ensuring that the electromagnetic environment within which electrical and electronic systems operate is known and controlled to remain within acceptable limits. SI 3418 (Reference 11.131) requires that equipment shall be designed and manufactured having regard to the state of the art so as to ensure the EMI it generates does not exceed a level above which radio and telecommunication equipment or other equipment cannot operate as intended.

The electrical and electronic equipment of the AP1000 plant will comply with SI 3418 (Reference 11.131) and so will maintain an electromagnetic environment that allows the correct operation of other electrical and electronic equipment. This will be ensured by application of the EMC management philosophy (Reference 11.130) and the Westinghouse procurement system.

A small number of exclusions to SI 3418 (Reference 11.131) is set out in the EMC management philosophy (Reference 11.130). These cover the following:

- Equipment that is considered inherently benign in terms of EMC
- Electrical equipment having no active electronic parts

Electrical equipment that is not intended for a fixed installation and is not otherwise commercially available will follow a different acceptance route. The EMC management philosophy (Reference 11.130) mandates the following process:

- Characterisation of the electromagnetic environment (Reference 11.130, Section 6.0) to understand the potential operating conditions of the various plant areas and the impact on equipment.

- EMC management plan (Reference 11.130, Section 7.1), defining the strategy for the project to achieve EMC between equipment.

- EMC risk log (Reference 11.130, Section 7.2), covering potential hazards and mitigations.

- EMC control plan (Reference 11.130, Section 7.3), detailing how the requirements of the EMC management plan and statutory obligations will be met.

- EMC installation code of practice (Reference 11.130, Section 7.4), detailing installation requirements that comply with best practice in EMI design, installation, and the EN61000-5 series of standards. The EN61000-5 series provides guidance on installation and EMI mitigation. System and component selection, design, installation, and testing of electrical equipment will be in accordance with the EMC emission requirements of the C&I general design criteria. Detailed management will be exercised over selection, testing, and operational use of communication systems that are inherently EMI emitters, including frequency allocations and power levels/antenna gains.

- EMC test specification (Reference 11.130, Section 7.5), detailing EMC tests on individual apparatus, systems, and sites to demonstrate that EMC requirements are met. This will capture the IEC 61000-4 series of standards that address requirements for testing against EMI. AP1000 plant electrical equipment (safety related and non-safety related) will be EMC-qualified for emissions primarily by type-testing, rather than by analysis. This testing will include conducted emissions through cables (30 to 2 MHz), radiated magnetic fields (30 to 100 kHz) and radiated electric fields (2 MHz to 10 GHz).

Claim IH-10.2: **Where appropriate, electrical and electronic equipment, and communication systems, will be protected from the effects of EMI through established system design measures.**

EMI is a potential threat to the correct operation of electronic equipment. It has the potential to cause malfunction, damage, or spurious operation of C&I equipment. In the AP1000 plant, electronic equipment supports the delivery of all categories of safety function through its roles in monitoring the plant and providing a means of plant control. In particular, Category A safety functions that require C&I to deliver them are supported by the systems discussed below.

The categorisation document and Classification of C&I systems is provided in Appendix A of Chapter 15. This classification includes the following systems and functions:

- PMS
- PLS
- DAS
- Operation and control centre system (OCS)

- DDS
- In-core instrumentation system (IIS)
- Special monitoring system (SMS)

Any of these C&I systems could be susceptible to onsite EMI. EMI has the potential to cause the system to behave in an unpredictable manner, by doing the following:

- Causing the system to provide incorrect indications
- Initiating actions when not required
- Preventing the initiation of actions when required

To ensure that the C&I systems operate correctly in the presence of EMI, the AP1000 design adheres to standards and follows best practice in the characterisation of the electromagnetic environment, the design of the systems, the selection of system components, the placing of the systems equipment, and the testing of the systems when installed. This philosophy for the management of EMC for the AP1000 design is set out in Reference 11.130 in defining the standards that the AP1000 design will meet in the UK and how the requirements of Statutory Instrument (SI) 3418 regarding EMC (Reference 11.131), will be applied. The principal means by which the effects of EMI on the C&I systems of the AP1000 plant will be minimised are the following:

- The architectural design of the C&I systems takes into account the presence of EMI and incorporates features to minimise the potential impact of EMI on the correct operation of the C&I. This is in compliance with BS IEC 61513:2001 (Reference 11.132), which sets out general requirements for design response to EMI. Features incorporated into the design are discussed within subsection 11.11.3.3.

- An EMC installation code of practice is an element of the EMC management philosophy (Reference 11.130). This will capture best practice in the EMI design, procurement, and installation of systems to minimise their EMI susceptibility. System/component selection, design, installation, and testing of electrical equipment will be carried out in accordance with the EMC susceptibility requirements of C&I general design criteria.

- An EMC test specification is another significant element of the EMC management philosophy (Reference 11.130). This will capture the IEC 61000-4 series of standards that address requirements for testing against EMI. AP1000 electrical plant equipment will be EMC-qualified for susceptibility primarily by type-testing, rather than by analysis. This testing will include conducted susceptibility through cables (16 to 30 MHz), radiated susceptibility magnetic fields (30 to 100 kHz), and radiated susceptibility electric fields (30 MHz to 10 GHz), assuming the equipment is Conformité Européene (CE) marked. If the equipment is not CE marked, then more stringent tests will be applied.

While much of the activity to control EMI and to deliver systems that are compatible with each other will occur at the build stage, there are design features within the AP1000 plant C&I systems that reduce the susceptibility of C&I to EMI. These provide confidence that the C&I design will not be susceptible to EMI, as follows:

- Category A and 72 hour supporting Category B equipment is placed in areas of low EMI fields.

- Fibre optic communications are used in areas with potentially high EMI fields.
- C&I electronics and sensors are grounded with regard to EMI protection.
- Class 1 cables that carry electrical signals that are assessed as potentially susceptible to EMI are routed in separate raceways in galvanised steel solid-bottomed and lidded trays, which provide some shielding to EMI. These cables will also be routed away from MV/LV electrical cables.
- Cabinets containing C&I equipment provide some shielding to their contents.

The structure of the AP1000 plant buildings provides a degree of protection to the propagation of EMI by ensuring that internal metal structures are earthed in accordance with best practice (Reference 11.133).

Input and output signal conditioning units, are used within systems that are required to withstand the EMI and ESD conditions that exist in specific areas of the plant.

The AP1000 plant Class 1 equipment has electrical surge withstand capability and can withstand EMI, RFI, and ESD conditions that would exist before, during, and after a DBA without loss of safety function for the time required to perform the safety function.

11.11.3 Electromagnetic Interference Safety Case Summary

11.11.3.1 Introduction and Overview

The electromagnetic interference safety case is built on the demonstration of two claims, these being:

- Prevention of level of plant generated EMI that could cause failure of Class 1 SSCs (Emissions)
- Protection of Class 1 SSCs from EMI that could cause its failure or spurious operation (Susceptibility)

These claims are argued (subsection 11.11.2), to be true based on the application of relevant codes and standards for the control of the EMI environment (subsection 11.11.3.2) and the control of system susceptibility to EMI. Additionally design features of the Class 1 control and instrumentation systems have been highlighted (subsection 11.11.3.3) which either reduce or eliminate the potential for an EMI induced failure. Sources of onsite EMI are identified (see subsection 11.11.4.1), to provide additional confidence that the measures set out in the arguments for emissions and susceptibility can be applied to those EMI sources. Although not the core of the case, supplementary operational measures, e.g., limiting static, access control and training also provide additional EMI controls on a site-specific basis. Thus, the risks from electromagnetic interference leading to the loss of Class 1 and 2 SSCs are low and suitably controlled.

11.11.3.2 Applicable Codes and Standards

Management of EMI and the standards that the AP1000 design will meet in the UK is set out in the EMC management philosophy (Reference 11.130). This document outlines how the requirements of how the UK statuary instrument on electromagnetic compatibility (SI 3418 [Reference 11.131]) will be applied.

SI 3418 does not directly regulate safety-related matters, but adherence to it does provide reliable operation of electrical, electronic, and programmable electronic systems that minimises the emission of potentially detrimental EMI. EMI generated should therefore not exceed a level above which radio and telecommunication equipment or other equipment cannot operate as intended. Equipment that is considered inherently benign in terms of EMC and electrical equipment having no active electronic parts are noted exclusions from requirements of SI 3418 (Reference 11.131) (see EMC management philosophy [Reference 11.130]).

To address the safety case claims of minimising EMI at source and protecting against EMI, adherence to two series of International Electrotechnical Commission (IEC) standards is stipulated. The IEC61000-4 series outlines testing and measurement techniques, whilst the IEC61000-5 series outlines installation and mitigation guidelines.

This section also cites the more generic 'Nuclear Power Plants, Instrumentation and Control for Systems Important to Safety, General Requirements for Systems' (BS IEC 61513-2001 [Reference 11.132]) and 'IEEE Standard Criteria for Safety Systems for Nuclear Power Generating Stations' (IEEE 603-1991 [Reference 11.133]) as supplementing the more directly applicable EMI codes and standards discussed above.

11.11.3.3 Redundancy, Separation, and Segregation

The distribution of safety-significant SSCs in an AP1000 plant is such that complete loss of operability of the safety-significant SSCs within a room or compartment because of EMI would not result in the loss of a safety function.

Adequate redundancy is provided within each Class 1 safety system such that even if the loss of a single SSC were to occur (for example as a result of a fire), the Category A safety function can still be provided by a redundant train located in a different compartment or area of the Containment. This compartmentalisation of safety systems provides protection from system disruption resulting from EMI. It is recognised that the form of the physical barriers and the separation, while adequate for physical hazards such as fire are flood, may not be completely adequate for EMI, which can propagate widely. However, the physical barriers and the redundancy, separation, and segregation of systems do provide some protection to AP1000 plant systems.

Each of the four divisions of the protection and safety monitoring is completely segregated from the others, so any onsite EMI would have to affect more than one division before any nuclear safety consequences could occur. The complete loss of operability of electronic equipment within a cabinet would not result in a challenge to a safety function.

11.11.3.4 Electromagnetic Interference Assessment Approach

The AP1000 design takes two complementary approaches to the control of the hazard from EMI. These are the minimisation of EMI at source (i.e., emissions) and the protection of systems from EMI (i.e., susceptibility). These two approaches are summarised in subsection 11.11.2.6, respectively. Analysis of the EMI hazard for the AP1000 reactor plant is directly dependent on the selection and placement of electrical and electronic equipment with the AP1000 site. This level of detail will be completed during detailed design and supplier selection.

11.11.3.5 Interface with Other Internal Hazards

No interfaces with other internal hazards are identified, though the external hazard analysis assesses offsite-originated EMI (including lightning) within Section 12.16.

11.11.3.6 Conclusions

Sufficient evidence has been shown throughout this section that the risk of loss of a nuclear safety-significant system as a result of EMI is low and well controlled. The combination of minimising emissions and protecting susceptible systems form the principle basis of the case. Additional site-specific measures that will be finalised by the operator during the Licensing phase to support the case.

11.11.4 Electromagnetic Interference Safety Analysis

11.11.4.1 Identification of Hazard Sources

Onsite EMI can arise from either the intentional generation of electromagnetic radiation from communication systems, or the unplanned, unintentional, or unwanted generation of EMI from the normal or abnormal operation of an electrical plant and equipment. Any EMI is potentially capable of disabling sensitive electronic equipment in the AP1000 plant, or may cause it to activate spuriously. Either way, it could initiate fault sequences or prevent the safety measures in place from performing their required functions, thereby resulting in the loss of safety functions.

The principal area of EMI concern is the NI, as this is where the safety-significant elements of the C&I systems are located. The possible sources of EMI are identified below, and the threats to specific safety-significant equipment are reviewed within subsection 11.11.4.1. None of the other buildings and structures of the AP1000 plant contain safety-significant C&I systems. They are, therefore, not considered further as far as EMI is concerned.

There are many potential sources of onsite EMI within the AP1000 plant. These come from the deliberate generation of electromagnetic radiation for communication purposes (e.g., using radio frequencies) and the unplanned, unintentional, or unwanted generation of EMI from the normal or abnormal operation of electrical plant and equipment, as discussed below.

Intentional Sources of EMI within the AP1000 Plant

The AP1000 plant will have both fixed and mobile communication systems onsite and a separate normal business network for communications:

- Communications networks
  - There are multiple redundant and diverse communication networks distributed widely throughout the plant, including voice over internet protocol, digital enhanced cordless telecommunications, pagers, land mobile radio, and a sound powered telephone system. The mobile communication system relies on distributed relay transmitters throughout the NI, resulting in the intentional presence of electromagnetic radiation in all rooms and compartments. None of the communication system components are Class 1SSCs.
- Business network

– The extensive network for normal administration will use a fibre ring with switches to copper/wireless connected peripherals. This is distributed widely throughout the plant, and will include the following peripheral equipment: telephones, workstations, television/video, cameras, laptops, handheld computers. This network is not used for nuclear safety, and does not contain Class 1 SSCs. Failure of the business network will not prevent a safe plant shutdown.

Unintentional Sources of EMI within the AP1000 Plant

EMI will also be created by the normal or abnormal operation of electrical plant and equipment onsite. The principal sources of unintentional EMI that have been identified are:

- Reactor trip switchgear and RCP switchgear; these are within the clean Auxiliary Building and are potential sources of arcing.
- Relays used in the instrument and motor control rooms.
- The MOVs used throughout the NI.
- The battery charger rectifiers within the clean Auxiliary Building; these are potential sources of high-frequency interference.
- Equipment containing thyristors, relays, and circuit breakers.
- Wireless crane controllers.

11.11.4.2 Assessment of Electromagnetic Interference Impact and Control

The potential for EMI from either intention or unintentional generation is constantly present on the site. It is not possible to eliminate EMI and so a layered approach to its control is adopted. This consists of the minimisation of EMI at source through the design and specification of possible EMI generators and then the minimisation of its impact through the protection provided to sensitive components and systems. Thus the careful choice of components and compliance with codes and standards are argued to address the claims made for prevention and protection. This is supported by measurement of the delivered EMI environment and testing of systems and components within that environment. This approach therefore does not depend on the prior analysis of EMI for the AP1000 plant.

11.11.4.3 Hazard Schedule

No hazard schedule is presented for EMI as the EMI hazard does not create distinct and localised failure of SSCs in a predictable manner. The EMI hazard has to be controlled through minimisation of harmful EMI generation and suitable and sufficient protection of susceptible SSCs.

11.11.4.4 Discussion of Results

The safety justification for the EMI internal hazard is based on two complementary approaches to the control of the hazard from EMI. These are the minimisation of EMI at source (i.e., emissions) and the protection of systems from EMI (i.e., susceptibility). These two approaches are summarised in subsection 11.11.2.6, respectively. Analysis of the EMI hazard for the AP1000 reactor plant will be directly dependent on the selection and

placement of electrical and electronic equipment with the AP1000 site. This level of detail will be completed during detailed design and supplier selection.

11.11.4.5 Sensitivity and Cliff Edge Results

The argument and evidence in support of the EMI claims is not dependent on the assessment of EMI, rather it is dependent on system and component selection, design, installation, and testing of electrical equipment in accordance with the EMC emission requirements of the C&I general design criteria. These approaches are applied to ensure that levels of EMI on the AP1000 plant do not reach levels at which a cliff edge transition occurs.

11.11.5 Combination of Hazards and Consequential Hazards

Discussion of combined and consequential hazards is presented within the Combination of Hazards section (see Section 11.12).

11.11.6 ALARP Assessment and Discussion

The arguments presented in subsection 11.11.2.6 demonstrate that the risk of loss of a nuclear safety significant system as a result of EMI is low and has been addressed in the design of the plant (or will be addressed on a site-by-site basis), and by normal operational procedures and maintenance activities. Specific measures taken to reduce risk include the application of relevant good practice as contained in standards and referred to from the EMC regulations (Reference 11.131), application of a management system to the control of EMI (Reference 11.130), and incorporation of features into the design of the Class 1 C&I systems to provide redundancy, separation, and segregation. In addition the following operational measures are reasonably expected to be implemented:

- A “responsible person” will be appointed to ensure EMI is managed through life (design, construction, commissioning, operation, and decommissioning). During the early stages (design up to handover), the responsible person will be a Westinghouse appointment. After handover, the responsible person will be appointed by the Operator. Significant and detailed files will be maintained of EMI design and operating features, which will be subject to formal configuration control throughout the plant life.

- Plant personnel will be trained in the effects of ESD and its potential damage to equipment.

- Plant personnel have knowledge of any plant equipment that is ESD-sensitive, including being clearly highlighted by warning signs.

- Access to electronic cabinets will be under strict administrative control.

- Antistatic floor tiles, mats, and wrist straps will be used when necessary as defined in the equipment operation and maintenance manuals.

- Use of two-way radios and cell-phones will be restricted in the vicinity of sensitive equipment, and an exclusion zone will be established for the use of such communications equipment.

Thus, the risks posed from EMI have been argued to be at such a low level that additional measures to reduce the risk further are not considered to be practicable.

11.12 Combinations of Hazards

A Combined Hazard Analysis has been performed in order to identify and assess the effects to SSCs as resulting from the combined effects of internal hazards as well as consideration of hazards with the potential to initiate plant level faults. The AP1000 plant has been designed such that internal hazards and any combination of hazards within the design basis will not compromise the ability of the plant to safely shutdown and maintain it in a safe condition. The Category A safety functions required for safe shutdown following a combined hazard event, and the supporting post 72 hour Category B safety functions, are shown to be maintained through a combination of claims made on:

- Minimising the inventory of hazardous material;
- Equipment design;
- Segregation of hazards and SSCs delivering Category A safety functions;
- Structural barriers and partitions.

Consequences from combined hazards, which have the potential to directly damage SSCs required to deliver Category A or supporting post-72 hour Category B safety functions have been systematically identified on a conservative deterministic basis. The results of this assessment are provided in more detail within the Combined Hazards Topic Report (Reference 11.75). The barriers that protect these safety functions are also identified and evaluated to confirm that they will provide protection against the identified combination of hazards.

The assessment of combined hazards has been undertaken using the same conservative assumptions as the individual internal hazard assessments (References 11.73, 11.76, 11.77, 11.93, 11.110 and 11.123). Where a causal link is identified between correlated[20] internal hazards, the combined impact on Category A safety functions is assessed. Where the conservative assumptions underpinning the assessment of individual hazards are no longer valid, revised assumptions are presented and the assessment updated to reflect this accordingly.

This assessment concludes that the Category A safety functions of Class 1 SSCs are protected from the effects of all credible combinations of internal hazards and can therefore continue to be delivered. Further, post 72-hour supporting Category B functions necessary to respond to the postulated event, and their Class 1 connections, are preserved.

11.12.1 Scope of Combined Hazards and Process

The AP1000 design has been evaluated for the impact of internal hazards in confirmation that SSCs required to deliver Category A or supporting Post-72 hours Category B safety functions will perform as required following an internal hazard (Sections 11.2 through 11.11).

[20] Internal hazards are considered to be correlated where the effects of the primary internal hazard are experienced by the source of the subsequently initiated internal hazard.

When the results of engineering judgement, deterministic safety assessments and probabilistic safety assessments indicate that combinations of events could lead to anticipated operational occurrences or to accident conditions, then such combinations of event are considered to be design basis events depending on the likelihood of occurrence (Reference 11.134). To this end, combinations of internal hazards within the design basis will be evaluated where:

- An internal hazard induces sequential internal hazard(s); or
- A common initiator results in simultaneous internal hazards;
- Independent internal hazards with a combined event frequency > 1E-05 / reactor year.

The AP1000 NI was systematically assessed for hazard combinations followed by areas outside the NI, but within the plant envelope. More severe[21] hazard combinations were also assessed for effects on Category A and supporting post-72 hour Category B safety functions.

All credible combinations of hazards, either consequential, correlated or independent, are captured in the hazard schedule which clearly identifies all divisions of Class 1 SSC affected, as well as links to the fault schedule where relevant.

This assessment concluded that Category A safety functions will continue to be delivered following various design basis combined hazards through a combination of claims made on structural barriers, equipment qualification, passive flood relief systems and, where necessary, minimal operator actions to isolate inexhaustible sources of flooding following identification by a level sensor (i.e. no claim has been made on the prevention or limitation of fault occurrence). These claims are consistent with the claims made through each individual hazard assessments summarized in Sections 11.2 through 11.6 and Section 11.8.

11.12.2 Claims, Arguments and Evidence

This section presents the key claims, arguments and underlying evidence made in relation to combinations of internal hazards with the potential to impair safe shutdown.

11.12.2.1 High Level Claims

SSCs important for nuclear safety must be protected from dynamic and environmental effects within the plant, including those of internal hazards. An internal hazard could cause a Postulated Initiating Event (PIE) and potentially lead to an accident condition. In response to a PIE, Class 1 SSC may be required to return the reactor to a safe shutdown state. Depending on the nature of the transient, there are a number of actions required to shut the reactor down. Availability of the Class 1 SSCs required delivering the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim:

Claim IH-11.0: **Postulated combinations of internal hazards within the design basis will not prevent the delivery of the Category A safety functions and the supporting post-72 hour Category B safety functions necessary to respond to the postulated event.**

[21] A more severe hazard combination is one which results in more severe consequences than those previously assessed, for example where the primary internal hazard initiates multiple flood sources leading to a higher flood elevation than that previously assessed.

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

The assessment of combined internal hazards has, as a basis, used the output from each of the individually assessed internal hazards. The assessment has therefore also taken cognisance of the SSC claimed to prevent, protect or mitigate the individual internal hazard progression, for each individual internal hazard (for example the Class 1 fire barriers which are claimed to protect redundant Divisions of Class 1 SSC from the spread of fire). These individual claims have not been repeated here. This assessment has shown that combinations of internal hazards:

- Do not invalidate the claims made for individual internal hazards;
- Do not result in damage to all Divisions of Class 1 SSC delivering Category A safety functions such that the ability to safely shutdown the reactor is maintained.

There are therefore no claims, arguments or evidence made specifically in regard to combinations of internal hazards.

11.12.3 Safety Case Summary

11.12.3.1 Introduction and Overview

The safety design approach adopted for internal hazards is based on hazards not preventing delivery of the Category A safety functions as necessary to respond to a postulated initiating event. Preservation of the required safety functions has ensured alignment with the fault studies and structural integrity analysis. It is however conceivable that the combined effects of one (or more) internal hazards may be present simultaneously or sequentially. In order to maintain alignment with the fault studies and structural analysis, credible combinations of internal hazards have been assessed to evaluate their cumulative effects on the plant.

Throughout the AP1000 plant, a combination of measures designed to prevent, protect and mitigate the consequences of internal hazards ensures that the Category A safety functions can continue to be delivered and, as such, reduces risk to a level which is ALARP.

11.12.3.2 Applicable Codes and Standards

There are no design codes or standards specific to the assessment of combined hazards. The design codes and standards as applicable to each of the individual internal hazards remain applicable to the assessment of combined hazards.

11.12.3.3 Redundancy, Separation and Segregation

There are no new redundancy, separation or segregation design features specific to the assessment of combined hazards. The design features of redundancy, separation and segregation to each of the individual internal hazards remain applicable to the assessment of combined hazards.

11.12.3.4 Assessment Approach

11.12.3.4.1 Identification of Credible Combinations

The approach adopted for assessing the combined effects of internal hazards is broadly similar whether the combination is consequential, correlated or independent.

The following sub-sections discuss the methodology used to determine whether or not combinations of internal hazards are credible and as such require consideration as part of this assessment.

Consequential Internal Hazards

In order to determine whether an internal hazard could initiate another internal hazard, a review was undertaken using technical experts and key contributors to the assessment of individual internal hazards to establish the root causes and contributing factors leading to initiation of the internal hazards (Reference 11.135). The expert panel review considered the following:

- The unacceptable performance of plant or equipment which could give rise to an internal hazard (e.g. mechanical failure of hoist ropes leading to a dropped load);
- The conditions which must exist for the unacceptable performance to be realised (e.g. stress or fatigue of hoist ropes);
- Whether the existence of an internal hazard could give rise to the conditions necessary to cause unacceptable performance of plant or equipment.

The output from the review identified root causes of internal hazards and, where applicable, those internal hazards which provide the necessary conditions for the root cause.

Although a secondary internal hazard could credibly be initiated as a consequence of a primary internal hazard, not all primary internal hazards will prevail in those rooms or areas where plant/ equipment giving rise to the secondary internal hazard are present. rooms or areas in which either the plant or equipment, whose unacceptable performance could give rise to an internal hazard, or conditions necessary for the primary internal hazard to trigger the unacceptable performance do not exist, are screened as potential locations for consequential internal hazards.

Correlated Internal Hazards

Correlated internal hazards are assumed to arise where the root cause is a common initiator to the unacceptable performance of multiple items of plant and equipment. In contrast to consequential internal hazards, for which the initiator is local, correlated internal hazards may arise where the root cause is experienced globally. In such situations, the result may be that the same internal hazard is initiated in more than one area of the plant.

Independent Internal Hazards

Independent internal hazards are assessed where two (or more) completely independent internal hazards (i.e. where there is no common cause or mode for hazard initiation) occur (or for which the effects persist) at the same time.

Independent internal hazards have been assessed as within the design basis where the best estimate initiating event frequency for the two (or more) hazards is greater than 1.0 E-5/reactor year. Combinations of internal hazards with an initiating event frequency less than 1.0 E-5/reactor year are either considered for cliff edge effects or screened from further consideration where the combined initiating event frequency is less than the BSO benchmark. The effects of the internal hazards are assumed to exist until such time as the post event recovery period is complete[22].

Assessment of Credible Combinations

Where a mechanism has been identified to link two (or more) internal hazards, a room-by-room analysis has been undertaken (Reference 11.75) identify locations where the two internal hazards and associated mechanism exist. Where this is the case, the combination of internal hazards has been subject to detailed assessment.

The consequences of combinations of internal hazards are based on the combined effects of the individual hazards. The effects of the individual internal hazards are taken from the respective hazard schedules. Unless one of the internal hazards causes the loss of SSC provided to prevent, protect or mitigate the internal hazard progression, the effect of each individual internal hazard is taken as the fully mitigated consequences.

11.12.3.4.2 Assessment and Screening for Consequential Internal Hazards

Deterministic links have been identified between internal hazards as follows:

- An internal fire may be initiated by internal flooding, missiles or dropped loads;
- An internal flood may be initiated by internal missiles, dropped loads or pressure part failure[23];
- An internal missile may be initiated by internal fire, flooding or dropped loads;
- A dropped load may be initiated by internal missiles or pressure part failure;
- An internal explosion may be initiated by internal fire, flooding, missiles, dropped loads or pressure part failure;
- A pressure part failure may be initiated by internal missiles or a dropped load.

Mechanisms as possible causes for initiating internal hazards associated with onsite transport, biological fouling, toxic, corrosive or flammable chemicals and electromagnetic interference have not been identified on the basis that these internal hazards do not result in loss or damage of Class 1 SSC and as such their contribution to combinations of internal hazards is of no consequence.

A summary of the credible consequential internal hazards is presented in

Table 11.12-1.

---

[22] The post event recovery period is the duration from hazard initiation until the plant is returned to its normal state either by repairing or replacing the affected SSC.

[23] Pressure part failure is also a source of flooding in its own right.

11.12.3.4.3 Assessment and Screening for Correlated Internal Hazards

External hazards, as described in Chapter 12, have been considered as potential causes of correlated internal hazards. Each of the external hazards has been evaluated for the potential to initiate internal hazards; with the exception of earthquake, the plant or equipment giving rise to the internal hazard is located within the NI and, as such, is protected from the effects of the external hazards by the exterior walls of the NI. Therefore, earthquake is the only common cause of correlated internal hazards as summarised in Table 11.12-2. It is conservatively assumed that all non-seismic components may fail due to the earthquake.

11.12.3.4.4 Assessment for Independent Internal Hazards

Although not explicitly derived, the majority of internal hazards are considered to be infrequent faults with an initiating frequency of 1.0 E-4/reactor year or less. As a result, having two of these events occur as independent events at the same time would be less than 1.0 E-8/reactor year, which is below the cut-off frequency for explicit assessment within the design.

The one hazard that is more frequent is internal fires; the initiating event frequency for internal fires is informed from operating plant experience to be about 2.0 E-1/reactor year (summation of mean values in Table 4-4 from NUREG-2169 [Reference 11.13611.136]). The effect of internal fires has been considered within the PSA (see chapter 10) in terms of core damage frequency. The assessment shows that, under such conditions, the core damage frequency is below the BSL.

On this basis, it has not been considered credible that two independent internal hazards could occur together. The consequences of combinations of independent internal hazards have therefore not been explicitly assessed.

11.12.3.5 Conclusions

The purpose of assessing combinations of internal hazards has been to determine the response of the plant to combinations of internal hazards and in doing so validate the ability to safely shut down, in response to design basis plant level faults. The assessment has been undertaken in a conservative manner, assessing combinations of hazards in a deterministic fashion and as such, explores the sensitivity of the plant to withstand the individual internal hazards.

The individual internal hazard assessments have been performed on a deterministic basis. These assessments conclude that the Category A safety functions will be available to provide a safe shutdown following the worst case postulated internal hazard initiating event. In the unlikely event that the Class 1 SSCs fail for some unrelated reason, the Category A safety function would, for the less severe events, be maintained by other, additional and redundant, Class 2 SSCs.

The individual internal hazard assessments consider the plant response to discrete hazards, whereas this report analyses the possible combination of internal hazards (consequential and concurrent) that could occur. The analysis of combinations of internal hazards has used the same deterministic basis to demonstrate that the conclusions of the discrete analyses (that the Category A safety functions will be available to provide a safe shutdown following the worst case postulated internal hazard initiating event) remain valid and that there is a significant design margin of the AP1000 against design basis internal hazards.

On the basis that the AP1000 design has been shown to be ALARP for each of the individual internal hazards, and given that there are no combinations of internal hazards which the plant cannot tolerate, it is judged that the AP1000 design is also ALARP from a combined hazards perspective.

11.12.4 Combined Hazards Analysis and Assessment

11.12.4.1 Assessment of Consequential Internal Hazards

Consequential Hazards Initiated by Internal Fire

A postulated internal fire scenario could consequentially initiate an internal missile due to shorting of electrical equipment. Such a missile would arise from rotating equipment, such as pumps, and the source is assumed to generate multiple missiles. While the effects of a missile are bounded by those of an internal fire, both of which place a claim on internal walls to protect redundant divisions of Class 1 SSC, a missile could consequentially initiate internal flooding which would progress beyond the physical boundary of a room or area.

The combined consequences of internal fires, missiles and flooding do not result in the loss of all divisions of Class 1 SSCs delivering Category A safety functions such that there remains sufficient Class 1 SSCs to safely shut down the plant in response to a plant fault. The only exception to this is a fire in 1250 AF 01 which could consequentially result in the DWS, FPS and VWS source terms being released in room 12501. During all modes, the flooding is no more onerous than that described by flooding scenario FL16.

Internal fire could also initiate an internal explosion; however, should the internal fire result in the direct release of flammable material it would be expected to burn in the presence of a direct heat source rather than generate an explosive atmosphere. The exception to this is an internal fire which damages or disables the HVAC servicing the battery rooms. In such a scenario, the loss of HVAC would be detected by the low exhaust flow sensors while the presence of hydrogen in the battery rooms would be detected by the hydrogen detectors. Both measures are claimed in the assessment of Internal Explosions (see Section 11.5) as preventative measures and as such the possibility of an internal explosion is precluded.

Consequential Hazards Initiated by Internal Flooding

Internal flooding is a potential initiator for fire, missiles and explosions.

A postulated internal flooding scenario could consequentially initiate an internal fire where the flooding affects high voltage electrical equipment. The only high voltage systems are associated with the RCP and CVS pumps; however the cables and junction boxes are qualified for a submerged environment and would therefore not initiate an arc flash.

Internal missiles could potentially arise where the maximum flood height comes into contact with rotating equipment leading to an over speed of the motor. It is noted that shorting out such rotating equipment due to flooding would more likely simply shutdown such equipment. However, given that redundant divisions of Class 1 SSC are protected from the consequences of missiles by internal walls and floors, the combined effects of internal flooding and missiles would only be more onerous than the flooding itself where the missile is initiated in a room containing Class 1 SSC. Of all the type II rooms containing rotating equipment, only rooms 12162, 12163 and 12306 have a flood height sufficient to submerge rotating equipment, the combined effects of which are as follows:

- Flooding scenario FL21 would completely submerge rooms 12162, 12163. The additional hazard presented by an internal missile is therefore bounded by the flooding event and there are no combined consequences.

- Flooding scenario FL11 could generate a missile in room 12306. A missile in room 12306 would be more onerous than the assessed bounding internal flood; however, it would still be bounded by an Internal Fire (scenario Fire 26; Reference 11.73) which results in total burnout of the room. Therefore, based on evaluation, the combined consequences are tolerable.

An internal explosion could occur where flooding affects the HVAC system serving the battery rooms. However, the formation of a flammable atmosphere is prevented by SSC which would remain unaffected by the flooding (Section 11.3).

Consequential Hazards Initiated by Pressure Part Failure

An internal Pressure Part Failure could consequentially initiate Internal Flooding. However, it is reasoned that Pressure Part Failure and Internal Flooding are mutually-inclusive events rather than consequential. The essential SSCs within the room which are required to function following a Pressure Part Failure are either protected from the dynamic effects, and/ or qualified for the environmental effects, of Pressure Part Failure (see Section 11.4). Similarly, the essential SSCs in the room which may be exposed to Internal Flooding are either above the maximum flood height or qualified for submergence (see Section 11.3). On this basis, detailed analysis of the combined effects of Pressure Part Failure and Internal Flooding is not warranted.

A pressure part failure is also a potential initiator for dropped loads and internal explosions. However, there are no pressure part failures with the potential to impact lifting equipment and therefore a subsequent dropped load is not credible. Similarly, a pressure part failure could result in the release of flammable material; however, the assessment of internal explosions (see Section 11.5) concludes that it is not possible to generate an explosive atmosphere due to the preventative measures identified.

Internal Hazards Initiated by Internal Explosions

Internal explosions are prevented within the NI (see Section 11.5). On this basis it is not possible for an explosion to be the initiator for combined consequential internal hazards.

Internal Hazards Initiated by Internal Missiles

An internal missile could initiate internal flooding and/or a pressure part failure. Missiles originating from high energy systems or rotating equipment may generate multiple missile sources which in turn could initiate a number of flooding sources. Whereas, low or moderate energy systems will only initiate a single missile source which can initiate at most a single other flooding source[24]. Where the missile source originates in a Type III room, the consequential effects will be those associated with flooding, while a missile in a Type II room will have the combined consequential effects of a missile and the associated flooding source(s). The consequential flooding is bounded by that which is assessed in the Internal Flooding Topic Report (Reference 11.76), with the following exceptions:

[24] The missile source could be, for example, a valve stem, which will itself constitute a source of flooding.

- A failure of the SFS pump in room 12272 could impact the FPS, CCS, SFS, WLS, WSS and CVS lines. The total source volume for this fault exceeds that described by flooding scenario FL21. This scenario places a claim on operator action to isolate sources of flooding in response to alarms in the MCR triggered by redundant flood level sensors located in room 12154. The additional source inventory associated with this fault would not significantly reduce the response time and as such the claim made with regards to FL21 is considered to remain valid for this fault.

- A missile generated within room 12501 could result in additional sources of flooding being initiated to that which is described by flooding scenario FL16. However, when the FPS is serviced by the PCCWST, the maximum flood height on level 1 does not exceed 17.8 cm (7 in), which is below the critical flood height on this level.

- A missile generated within rooms 12306, 12405 or 12505 could result in a larger source volume than that described by flooding scenarios FL11, FL14 or FL17, respectively. However, these rooms communicate directly with the Turbine Building 1st bay and flooding would therefore be restricted to the room of inception which is bounded by the effects of the initiating missile (i.e. total loss of all SSC in the room).

In all other rooms, the missile initiated flooding is bounded by the assessment undertaken for internal flooding (see Section 11.3).

In all cases, redundant Class 1 SSC is either located in a room that is not affected by the consequential flooding hazard or (in the case of some in-Containment SSCs) are qualified to continue to perform their safety function when submerged. It is demonstrated, therefore, that the consequential flooding hazards do not compromise the claimed redundancy against missile damage for Category A safety functions.

Furthermore a missile could initiate a dropped load. However the effects of a dropped load, which could damage SSC in multiple rooms, will bound those of a missile hazard, which is assumed to only damage SSC within a single room. The assessment of consequential hazards initiated by a dropped load (see Section 11.8) is therefore bounding.

A missile could also initiate, or be the precursor to, pressure part failure. The effects of both missiles and pressure part failure are restricted to the room identified as the source location based on claims made on the civil structure (see Sections 11.4 and 11.6). The effects of a missile will bound those of pressure part failure on the basis that the missile hazard will result in the damage/ loss of all SSCs present in the room and the combined effects of missiles and pressure part failure are no more onerous than those of missiles alone (see Section 11.6).

Consequential Hazards Initiated by a Dropped Load

A dropped load is assumed to consequentially initiate an internal flood and/or pressure part failure where the dropped load damages pipework. However, the effects of pressure part failure are confined to the room in which the hazard initiates and are therefore bounded by a dropped load which assumes complete loss of all SSC in the affected room(s), regardless of the dropped load footprint.

Within Containment, all Class 1 SSC required for safe shutdown are qualified for the effects of flooding (see Section 11.3). A dropped load within Containment cannot result in the loss of all divisions of Class 1 SSC (see Section 11.8), therefore the combined effects of a dropped load and flooding within Containment are bounded by the effects of a dropped load.

Within the RCA of the Auxiliary Building, a dropped load could initiate a flooding event which is more onerous than that described by flooding scenario FL21. However, the additional sources are not significant and, as such, the claims made for internal flooding (see Section 11.3) remain valid. The combined effects of a dropped load from the cask handling crane and flooding, as described by FL21, do not result in the loss of all divisions of Class 1 SSC delivering a Category A safety function.

In the non-RCA side of the Auxiliary Building, the only lifting equipment are the MSIV monorail hoists. A dropped load in the MSIV compartments may potentially impact the pipework in this area and the rooms below. The MSIV monorail hoists are only operated during an outage (i.e. during plant modes 5 & 6) when the fluid systems located within the MSIV compartments are isolated and the bounding flood event for the MSIV rooms, as described by flooding scenario FL13 (see Section 11.3), would not be realised. However, a drop from the MSIV hoist in room 12404 during mode 5 or 6 operations may potentially impact the FPS piping in room 12300 before impacting Division B of the IDS batteries in 12104. The potential flood source term associated with the FPS during all modes is no more onerous than that already defined in FL09. While a dropped load in room 12404 could therefore result in the loss of Division B of the IDS batteries, there would remain Divisions A, C & D of the IDS batteries to deliver the Category A safety functions.

11.12.4.2 Assessment of Correlated Internal Hazards

The only reasonable means by which correlated internal hazards could be initiated is through a significant seismic event. All non-seismically qualified SSC are assumed to potentially fail and where these SSC are the sources of internal hazards (e.g. flooding from pipework rupture), the internal hazard is assumed to arise. Furthermore, the correlated internal hazards may initiate consequential internal hazards.

In the detailed analysis, each of the internal hazards has been evaluated in turn to derive the consequences of correlated hazard initiation; this detailed analysis concludes:

- Within Containment, non-seismically qualified pipework may fail but the subsequent flooding would be bounded by the analysis undertaken as part of the flooding assessment (see Section 11.3). All other sources of internal hazards or consequential internal hazards are qualified for both seismic and flooding and as such the correlated internal hazard is no more onerous than that already assessed.

- Within the Auxiliary Building RCA, a number of flooding sources are non-seismically qualified and could potentially result in flooding. In addition, there are three non-seismically qualified lifting devices which may result in a dropped load. However, given the infrequent use of these devices, and the low probability of a seismic event, this contribution to a combined dropped load / flooding scenario would logically be characterized as very small. The dropped load could potentially result in consequential flooding due to impact with additional flooding source terms, while flooding has the potential to initiate internal missiles.

- Within the Auxiliary Building non-RCA, the only significant source of flooding is potentially from the non-seismically qualified PWS; however, the MSIV monorail hoists are also non-seismically qualified and could lead to a dropped load. During use of the MSIV hoists (plant modes 5&6 only), the potential flooding source terms which may be impacted are isolated with the exception of the FPS. All four divisions of the IDS batteries could potentially be affected by the subsequent flooding, however the flood-up level sensor (see Section 11.3), which is seismically qualified, would alert operators to the flooding and prompt isolation.

Although a seismic event has the potential to initiate a number of internal hazards at a number of locations, their combined effect does not result in the loss of all divisions of Class 1 SSC delivering a Category A safety function (i.e. there remain redundant divisions which are unaffected by the totality of the hazard).

11.12.4.3 Hazards Schedule

The Combined Hazards Schedule (Table 11.12-3) has been prepared based on the results of the Combined Consequence Analysis. The hazard schedule is presented in tabular form and combines the bounding primary hazard and bounding consequential hazards into each schedule entry. The schedule presents, for each combination of internal hazards, the:

- SSCs affected by the combination of internal hazards;
- Category A safety function at risk;
- Unmitigated consequences should the plant equipment be unable to support safe shutdown;
- Redundant SSC available to deliver the Category A safety function, which has not been exposed to the same internal hazard combination.

The schedule is presented in two main sections:

- The first presents the primary and consequential internal hazards resulting from internal fire, internal flooding, internal dropped loads and internal missiles.
- The second presents the correlated internal hazards (i.e. hazards that can occur concurrently) during or immediately following a seismic event.

To simplify the presentation of correlated internal hazards, dropped load hazards are not tabulated where the dropped load cannot directly impact a Class 1 SSC. Secondary flooding hazards as a consequence of impacts on piping and vessels are, however, included in the schedule.

The combined hazards schedule does not present any consequential internal hazards associated with Pressure Part Failure (PPF). The PPF safety case is made on the basis that the SSC lost/damaged are either not essential or if they are then they are protected from the dynamic effects of PPF and qualified for the subsequent environmental effects in the room.

Depending on the failure mode for the pressure part it may be a source of internal flooding only, or a source of both internal flooding and internal missiles. The assessment of internal missiles (Section 11.6) has assessed the effects of internal missiles resulting from PPF and conservatively assumes that SSCs in the room will be lost or damaged. The internal flooding assessment (Section 11.3) has included PPF as a source of internal flood hazards. Internal flooding within the room in which the PPF occurs will have no additional consequences compared to the assumption that all SSCs in the room are lost.

The consequential flooding will however migrate to other areas of the plant. The combined effects of PPF and flooding in other areas of the NPP are therefore bounded by the internal flooding analysis, which shows acceptability, in terms of Class 1 SSC redundancy, to either lose SSCs located below the maximum flood height or credit SSCs as qualified for the flooded environment.

11.12.5 Conclusions and Discussion

The purpose of the combined hazards assessment has been to assess the response of the AP1000 plant to combinations of internal hazards and, in doing so, validate the ability to safely shut down in response to design basis plant level faults. This assessment has been undertaken in a conservative manner, assessing combinations of hazards in a deterministic fashion and as such, exploring the sensitivity of the plant to withstand combinations of individual internal hazards.

Deterministic analyses of postulated, design basis, internal hazards have been performed (Sections 11.2 to 11.6 and 11.8). These analyses show that the Category A safety functions will be available to provide a safe shutdown following the worst case postulated internal hazard initiating event.

The analysis of combined hazards demonstrates that the conclusions of the discrete analyses of individual internal hazards are substantiated in that the Category A safety functions are available to provide a safe shutdown following the worst case combined internal hazard initiating event. The individual internal hazard analyses have been shown to remain valid and that there exists a significant design margin against design basis internal hazards.

On the basis that the AP1000 design has been shown to be ALARP for each of the individual internal hazards, and given that there are no combinations of internal hazards which the plant cannot tolerate, it is judged that the AP1000 design is also ALARP from a combined hazards perspective.

11.13 Conclusions

The following internal hazards that have the potential to affect the safety of the AP1000 plant have been identified:

- Internal Fire;
- Internal Flooding;
- Internal Missiles;
- Internal Explosion;
- Pressure Part Failure;
- Dropped Loads;

- Toxic, corrosive and flammable materials;
- On-site transport;
- Biological Material;
- Electromagnetic Interference.

Additionally, credible combinations of internal hazards have been identified and their effects analysed.

Each hazard, or credible combination of, has been assessed for its potential to challenge the high level claim and, where necessary, further Sub-Claims, supported by arguments and evidence, have been made to ensure that the high level claim is not compromised.

The assessment has shown that the Class 1 SSCs delivering the Category A safety functions are adequately protected from internal hazards such that if one division is lost, the safety function can still be delivered. Protection from internal hazards of Class 2 SSCs delivering Category A safety functions and providing defence in depth and Class 2 SSCs delivering supporting Category B safety functions have also been assessed, where appropriate.

Where an internal hazard also has the potential to initiate an internal fault, this has been identified with an appropriate link to the fault schedule in each of the relevant hazard schedule(s). Analysis and assessments have established to high degree of reliability that there are no internal hazards which can both initiate a plant level fault (including impacts on the spent fuel storage) and result in the loss of all divisions of Class 1 SSC (or Class 2 SSC as appropriate) delivering Category A safety functions claimed in response to the PIE.

The assessment has considered the potential for there to be a single failure in active components and shown that there remains sufficient division of redundancy to deliver the Category A safety function.

Sensitivity analysis has been undertaken for each of the internal hazards, confirming that there are no cliff edge effects. The assumptions used throughout the assessment are conservative; a small change in these assumptions does not lead to a significant increase in the hazard.

The assessments covering each of the systematically-identified internal hazards in this chapter conclude that the high level, prevention, protection, and mitigation claims and arguments have been validated, and therefore that the AP1000 design is robust, being tolerant to faults arising from internal hazards, and that the designed safety measures are effective.

Table 11.5-1 Flammable Substances

Tank Tag	Flammable Substance	Volume (m^3)(4)
CFS-MT-01	Hydrazine	3
CFS-MT-02	Hydrazine	3
CFS-MT-03(1)	3-Methoxypropylamine	3
CFS-MT-04(1)	3-Methoxypropylamine	2
CFS-MT-13(2)	3-Methoxypropylamine	3
DOS-MT-01A	Number 2 Diesel Oil	356
DOS-MT-01B	Number 2 Diesel Oil	356
DOS-MT-02A	Number 2 Diesel Oil	8
DOS-MT-02B	Number 2 Diesel Oil	8
DOS-MT-03	Number 2 Diesel Oil	3
FPS-MT-02	Number 2 Diesel Oil	2
LOS-MT-01(3)	Turbine Lubricating Oil	79
LOS-MT-2A(3)	Turbine Lubricating Oil	50
LOS-MT-2B(3)	Turbine Lubricating Oil	50
WWS-MV-01	Waste Oil	1
ASS-EP-006	Number 2 Diesel Oil	4
PGS-MT-05	Liquified Hydrogen	4470
PGS-MT-07A	Gaseous Hydrogen	15
PGS-MT-07B	Gaseous Hydrogen	15
PGS-MT-08A	Gaseous Hydrogen	15
PGS-MT-08B	Gaseous Hydrogen	15

Notes:

1. Ammonium Hydroxide, Ethanolamine, and Morphaline in CFS-MT-03 and CFS-MT-04 are excluded as flammable liquids because they are bounded by other chemicals in the same tanks, in this case 3-Methoxypropylamine.
2. Ethanolamine, and Morphaline in CFS-MT-13 are excluded as flammable liquids because they are bounded by other chemicals in the same tank, in this case 3-Methoxypropylamine.
3. The volume of gases are reported as at STP.
4. The volume of flammable substances are reported as whole numbers; the exact quantity may vary slightly.

Table 11.12-1: Combined Consequential Hazards Credibility Matrix

		Consequential Hazard					
		Fire	**Flood**	**Missile**	**Drop Loads**	**Explosion**	**PPF**
Initiating Hazard	**Fire**		N	Y – when fire causes over speed of rotating equipment or over heating of valves	N	Y – Only if fire damages motors leading to loss of HVAC	N
	Flood	Y - Only where flooding contact high voltage power cables/Equipment		Y - when flooding causes a failure of over speed control	N	Y - Only if flood water damages motors leading to loss of HVAC	N
	Missile	Y - where there exists the potential to damage high voltage	Y – Where the missile is low energy a single flood else for high energy all sources.		Y – consequences of missile are bounded by dropped loads	Y	Y
	Drop Loads	Y - Only where dropped load contacts high voltage power cables/Equipment	Y - Where flooding sources are impacted by dropped	Y – consequences of missile are bounded by dropped load		Y – Only if piping containing H_2 can be damaged by drop	Y - Where piping is impacted by dropped load
	Explosion	N	N	N	N		N
	PPF	N	Y - high energy / pipe whip create cascading flooding events	N	Y	Y – only when pipe whip can cause leak of H_2	

"Y" indicates a positive response; "N" indicates a negative response

Table 11.12-2: Combined Correlated Hazards Credibility Matrix

		Correlated Hazards					
		Fire	Flood	Missile	Drop	Explosion	PPF
Initiating Hazard	Earthquakes	Y – Only if high voltage cable is routed using non-seismic raceway or conduit.	Y – Where non-seismic qualified piping exists with a significant volume.	N – Non-seismic qualified equipment is comprised of moderate or low pressure systems – not capable of producing missiles.	Y- Where non-seismic lifting equipment could drop a load.	Y – Only where hydrogen sources are generated or routed around non-seismic qualified equipment.	N – Non-seismic qualified equipment is not located near high energy piping or SSCs.
	External Flooding	N	N	N	N	N	N
	Accidental Aircraft Crash	N	N	N	N	N	N
	External Explosion	N	N	N	N	N	N
	Extreme Ambient Temperatures	N	N	N	N	N	N
	Meteorology	N	N	N	N	N	N
	Extreme Wind	N	N	N	N	N	N
	Offsite Fire and Smoke	N	N	N	N	N	N
	Offsite Missiles	N	N	N	N	N	N
	Biological Phenomena	N	N	N	N	N	N
	Electromagnetic Interference	N	N	N	N	N	N

"Y" indicates a positive response; "N" indicates a negative response

12 EXTERNAL HAZARDS

12.1 INTRODUCTION

This chapter contains specific supporting information on the nuclear safety withstand of the AP1000 design in response to design basis external hazards. The definition of an external hazard as applied in this chapter is a natural or man-made hazard that is initiated from outside the AP1000 plant site boundary. Figure 6-8 shows the standard AP1000 plant site layout. The site boundary will lie beyond this but will only be defined as part of the licensing process for a specific United Kingdom (UK) site.

The Office for Nuclear Regulation (ONR) Safety Assessment Principles (SAPs) (Reference 12.2) specifies that the effect of external hazards on nuclear facilities be identified and considered in the safety assessments. The safety assessment should demonstrate that risks from the external hazards are removed, minimised, or are tolerable. This can be done by showing that necessary plant and equipment are designed to meet appropriate performance criteria against the postulated hazard.

The ONR SAPs external and internal hazards (EHA) EHA.1 to EHA.17 relate to external hazards that could have a detrimental effect on nuclear safety. These SAPs include the following three engineering principles applicable to both external and internal hazards:

- **EHA.4** – For natural external hazards, characterised by frequency of exceedance hazard curves and internal hazards, the design basis event for an internal or external hazard should be derived to have a predicted frequency of exceedance that accords with Fault Analysis Principle FA.5.

  The thresholds set in Principle FA.5 for design basis events are 1 in 10,000 years for external hazards and 1 in 100,000 years for man-made external hazards.

- **EHA.7** – A small change in design basis fault or event assumptions should not lead to a disproportionate increase in radiological consequences.

- **EHA.11** – Facilities should be shown to withstand weather conditions that meet design basis event criteria. Weather conditions beyond the design basis that have the potential to lead to a severe accident should also be analysed.

More detailed background information regarding the implementation of the SAPs is provided in the ONR Technical Assessment Guide (TAG) NS-TAST-GD-013 (Reference 12.3).

For natural hazards, SAP EHA.4 (see also SAP FA.5) defines the frequency of exceedance for a UK design basis event that should conservatively have a predicted frequency of not greater than 1.0E-04/yr; i.e., equivalent to a 1 in 10,000 year event (Reference 12.3, Section 5.5). The 1.0E-05/yr design basis criterion should be applicable to man-made external hazards (Reference 12.3, Section 5.6).

A UK design basis assessment requires a deterministic analysis of an internally initiated event that is expected to occur more frequently than 1.0E-05 per year (Reference 12.3 and 12.60). Any event that occurs less frequently than this is regarded either as beyond design basis (BDB) or, if its frequency is less than 1.0E-07 per year, as incredible. Specifically, SAP EHA.1 Paragraph 235 states that any non-discrete hazards with a frequency on their hazard curve which is below once in ten million years; i.e., less than 1.0E-07 per year may be excluded (Reference 12.2).

The hazard grouping and screening process is described in Section 12.5; Table 12-1 and Table 12-2 provide the detailed analysis. Some UK external hazards such as volcanic action, meteorite and asteroid activity have been screened out because of their low frequency. Hazards such as fog and mist have been excluded because their effect will have no direct impact on the safety of the facility.

12.1.1 Design Basis Event Values

So that a comparison can be made with the AP1000 design values, the loading associated with a 1 in 10,000 year event are derived for:

- Rain
- Ambient temperature
- Wind speed
- Snow loading

Additionally, the Principia Mechanica seismic response spectra (RS) for the UK (Reference 12.5) cited in this report is defined for a 1 in 10,000 year event. Other natural hazards that have been considered generically in this report, such as coastal flooding, are considered to be site-specific and will be addressed further in the site-specific Pre-Construction Safety Report (PCSR).

12.1.2 Climate Change

Where appropriate, climate change in the form of increased ambient temperatures has been considered based on United Kingdom Climate Projections 2009 (UKCP09) (Reference 12.6). The climate change projections considered here are the maximum published projections to the year 2080 and therefore encompass the 60-year design operating life of the AP1000 Plant (Refer to Section 1.4.1). The effect of climate change post-operation, when the plant is being decommissioned, should be considered when appropriate climate change data becomes available.

12.2 CATEGORISATION AND CLASSIFICATION OF SYSTEMS, STRUCTURES AND COMPONENTS

The AP1000 design categorisation and classifications scheme for the UK is described in detail in Chapter 5.

12.3 NUCLEAR SAFETY CLAIMS

The systems, structures, and components (SSCs) and their ability to provide their defined Category A safety functions are the principal means of maintaining nuclear safety in response to each of the identified external events.

Since the Class 1 SSCs are capable of mitigating design basis accidents (DBAs), the external hazards safety is substantiated by demonstrating protection of Class 1 SSCs from design basis external hazards. Specific external hazard protection is also provided within the design basis to protect the Class 2 SSCs that are provided to support Class 1 SSC operations after 72 hours following a design basis accident. Note that these Class 2 SSCs are backed up by use of offsite SSCs connected to class 1 connections in the plant and as a result are only intended to reduce the probability that the offsite SSCs will need to be used. The protection provided is based on risk informed insights (PCSR Section 5.9.1.1).

The high level claim is made that postulated external hazards within the design basis do not prevent the delivery of the Category A safety functions. This will be demonstrated with supporting sub-claims, arguments, and evidence in the following sections for each external hazard in turn in Sections 12.6 to 12.16.

12.4 AP1000 NUCLEAR SITE

In the AP1000 plant coordinate system, the plant grade elevation is defined at an elevation of 100 m (100 ft), with grade being defined as the ground level within a half-mile radius of the nuclear island (NI).

The principal building structures of the AP1000 plant site are the following:

- NI
- Turbine building
- Annex building
- Radwaste building
- Diesel generator building

The NI of the AP1000 plant consists of the following:

- Shield building
- Containment vessel
- Auxiliary building

The foundation for the NI is an integral basemat that supports these buildings. Only these structures of the NI are classified as UK Class 1 structures. The external hazards in this chapter are assessed against the Class 1 SSCs and those SSCs with the potential to adversely interact with the Class 1 SSCs of the NI.

12.5 SCOPE OF EXTERNAL HAZARDS

12.5.1 External Hazards Grouping

Tables 12-1 and 12-2 identify the external hazards grouping for man-made and naturally occurring hazards respectively. For each hazard category, the potential source(s) of the hazards are identified. For identified hazard source(s), postulated initiating events that could result from the source(s) are cited. The initiating events in Tables 12-1 and 12-2 have been compiled primarily from the ONR guidance (Reference 12.3) and International Atomic Energy Agency (IAEA) sources (References 12.8, 12.9, and 12.10). Table 12-2 provides definitions of some of the cited hazards.

Table 12-1 and Table 12-2 identify the potential consequences of initiating events and the safety features in place to mitigate the consequences. For each initiating event, one of the following six outcomes is stated:

1. The initiating event is addressed in this chapter.

2. The initiating event can be screened out because of a low probability of occurrence or negligible consequences.

3. It can be bounded by another initiating event.

4. The initiating event can be considered under another hazard grouping.

5. The initiating event is specific to a site and consequently requires site-specific information and will be considered in a site-specific PCSR.

6. The initiating event (e.g., fire) is addressed as part of Internal Hazards as described in Chapter 11.

The identified groups of hazards in Tables 12-1 and 12-2, after the screening process cited in these tables, were reduced to 11 generic external hazards categories that are discussed in Sections 12.6 to 12.16.

12.5.2 Hazards Selected for Detailed Review

The eleven generic external hazards categories in this chapter are assessed against the Class 1 SSCs of the AP1000 plant NI to ensure that they do not prevent the delivery of Category A safety functions.

The following hazards are identified in Tables 12-1 and 12-2 as requiring detailed consideration in this chapter:

- Earthquakes
- External flooding
- Accidental aircraft crash
- External explosion
- Extreme ambient temperatures
- Meteorology
- Extreme wind
- Offsite fire and smoke
- Offsite missiles
- Biological fouling
- Electromagnetic interference (EMI) and lightning

Licence applicants referencing the standard AP1000 design will provide site-specific information related to site location and description, exclusion area authority and control, and population distribution as follows:

- **Site information** – Site-specific information on the site and its location will include political subdivisions, natural and man-made features, population, highways, railways, waterways, and other significant features of the area.

- **Exclusion area** – Site-specific information on the exclusion area will include the size of the area and the exclusion area authority and control. Activity that may be permitted within the exclusion area will be included in the discussion.

- **Population distribution** – Site-specific information will be included on population distribution.

The plant has the inherent capability to withstand certain types of external accidents as a result of the specified design conditions associated with earthquakes, wind loading, and radiation shielding. Acceptability for external accidents associated with a given site will be covered in the licence application.

Each licence applicant referencing the AP1000 design will provide analyses of accidents external to the nuclear plant relative to a specific site. The determination of the probability of occurrence of potential accidents that could have severe consequences will be based on analyses of available statistical data on the occurrence of the accident together with analyses of the effects of the accident on the plant's required supporting structures and components.

12.6 EARTHQUAKES

12.6.1 Safety Design Approach

The safe shutdown earthquake (SSE) is used as a design basis for AP1000 plant Class 1 SSCs. The operating basis earthquake has been eliminated as a design requirement following the recommendations of SECY-93-087 (Reference 12.59). In specifying design criteria for the SSE, consideration is given to lower magnitude earthquakes having a greater probability of occurrence, as well as to larger magnitude earthquakes having a lower probability (see section 12.6.3.4).

The AP1000 plant has been designed so that any seismic event within the design basis will not prevent the delivery of Category A safety functions.

12.6.2 Seismic Categorisation of Safety-Related Systems

A method for categorisation of safety functions and classification of SSCs has been developed specific to the UK, which is presented in detail in Chapter 5. Structures are assigned a seismic category depending on their required performance during and following a seismic event. Civil engineering structures are categorised according to their safety function and are classified according to their significance in delivering this function according to UK practice. A seismic category is assigned accordingly.

The seismic category definitions are presented below.

- **Seismic Category I (C-I)** – Applies to safety-significant SSCs. C-I SSCs are designed to maintain both functionality and integrity under seismic loading within the design basis.

- **Seismic Category II (C-II)** – Seismic C-II SSCs are designed so that an SSE does not cause unacceptable structural failure of, or interaction with, C-I items that could degrade the functioning of a safety significant SSC to an unacceptable level, or could result in incapacitating injury to occupants of the main control room (MCR).

- **Non-nuclear seismic category** – Non-nuclear seismic (NNS) SSCs are those that are not classified as C-I or C-II. Even though a structure has been assigned as NNS, some form of seismic justification is undertaken. Normal industrial practice is to provide some form of seismic protection to all new nuclear structures.

Tables 15A-1 through 15A-4 present the seismic categories that have been assigned to the AP1000 plant safety significant equipment and buildings.

Non-seismic structures are evaluated to determine that their seismic response does not preclude the safety functions of C-I SSCs. This is satisfied by compliance with one of three options:

- The collapse of the non-seismic structure will not cause the non-seismic structure to strike a C-I SSC.
- The collapse of the non-seismic structure will not impair the integrity of C-I SSCs.
- The structure is reclassified as C-II and is analysed and designed to prevent its collapse under the SSE.

12.6.3 Ground Motions

12.6.3.1 UK Ground Response for Nuclear Facilities

UK seismic RS have typically been based on the Principia Mechanica Ltd (PML) derived spectra and have generally been accepted in the UK as a reasonable surrogate to the ground motion of the hazard (Reference 12.3, Annex 3). These are appropriate for typical forms of building construction. The PML spectra address three generic types of site ground conditions: hard (frequency of soil column > 5Hz), intermediate (frequency of soil column in the range 2 to 5 Hz) and soft (frequency of soil column < 2 Hz). A number of UK nuclear-licensed sites have undertaken a site-specific seismic hazard to determine appropriate free field horizontal peak ground acceleration (PGA) at their location. The maximum value this can achieve in the UK is 0.25g for a 1 in 10,000 year earthquake (Reference 12.13). The vertical spectrum is usually taken as two-thirds of the horizontal value (Reference 12.3). Where the building mass is significant in comparison to the mass of the soil volume (such as for heavy shielding associated with reactor buildings), the PML spectra may not be appropriate and soil-structure interaction on a site-specific, case-by-case basis is normally undertaken to evaluate the response of the system.

12.6.3.2 AP1000 Design Spectra

Chapter 16 and Reference 12.61 describe the derivation of RS for the AP1000 design for C-I and C-II SSCs. A bounding series of ground motion and floor response spectra (FRS) for a range of critical damping ratios has been generated using an extensive range of synthetic time-history ground accelerations for six different soil profiles, together with FRS at key levels within the NI structures based on soil-structure models and industry-accepted software including ANSYS and SASSI. The spectra comply with industry guidance with respect to power density requirements and minimum amplitude content across the frequency range. The design basis event (DBE) ground motion is stated as 0.3g both horizontally and vertically.

The AP1000 plant is designed for an earthquake defined by a PGA of 0.3g horizontally and vertically and can be compared to the UK PGA values provided in Section 12.6.3.1. The AP1000 Design earthquake is referred to as the certified seismic design response spectra (CSDRS). Figures within Reference 12.52 depict the horizontal and vertical design RS for the AP1000 plant, scaled to the SSE at 0.3g.

Chapter 16 and Reference 12.52 discuss the FRS at a number of levels within the NI structures for the six soil profiles considered (i.e., hard rock, firm rock, soft rock, upper-bound soft-to-medium soil, soft-to-medium soil, and soft soil) derived from the SASSI soil-structure interaction analyses for the NI buildings. The frequencies for rock and medium and soft soil columns have been determined from the shear wave velocities cited in Reference 12.52:

- The frequencies for the AP1000 design rock profiles range from 5.4 to 16.7 Hz and thus bound the PML rock values.

- The AP1000 plant upper-bound soft-medium and soft to medium frequencies range from 2.8 to 3.98 Hz and would reasonably represent the PML intermediate soil spectra.

- The AP1000 plant soft soil profile has a frequency of approximately 2.2 Hz and would fall within the PML intermediate soil profile, rather than the PML soft-site spectra.

The UK design basis RS horizontal acceleration with a PGA of 0.25g marginally exceeds the AP1000 design SSE RS in the range of 8 to 12Hz. However, the probabilistic seismic margin analysis utilising a 0.5g review level earthquake provides confidence in the deterministic 0.3g PGA assessment undertaken for the AP1000 design and that the loading demand of the UK design basis RS will be met. Accordingly, it should be confirmed on a site-specific basis there will be no loss of Category A safety functions resulting from a UK design basis earthquake. The design RS are applied at foundation level in the free field at hard rock sites and at finished grade (100 m/100'-0") in the free field at firm rock. A comparison of spectra associated with sites other than hard rock requires the use of soil structure interaction analysis (such as SASSI analysis). Therefore, comparison to PML spectra and the AP1000 spectra is made. This comparison between the UK PML spectra and AP1000 spectra is discussed in Section 12.6.3.3.

The geological conditions that apply to the AP1000 design are summarised in Chapter 4. The specific ground conditions at sites in the UK would need to be confirmed by site-specific ground investigation to confirm the adequacy of the soil for compliance with the AP1000 design parameters. Where these fall outside the given specifications, justification on a site-specific basis would be undertaken by the licence applicant.

The AP1000 plant will be demonstrated to satisfy all seismic design acceptance criteria using the site specific input. This demonstration may include a combination of comparisons on ground motion and soil conditions, and site specific analyses. The nuclear island has been designed to the CSDRS for a wide variety of soil conditions. It is therefore expected tha the site specific demand will be lower than the standard plant design basis. It is not expected that there will be significant changes for the AP1000 plant in the UK. The basic design will retain the existing design and hence retain the margins inherent in the enveloping parameters of the standard plant seismic design. Where design changes are required for other reasons, the revised design will be demonstrated to satisfy site specific requirements.

Non-seismic AP1000 plant buildings are designed to Uniform Building Code (UBC) requirements for various ground motions, depending on the safety requirement. Note however that the Turbine building and Annex 4 office building are built to the International Building Code (IBC).

12.6.3.3 Comparison of UK PML and AP1000 Design Spectra

Figure 12C-1 in Appendix 12C shows a comparison of the PML RS accelerations for the hard, intermediate, and soft sites for 5 percent damping with a peak horizontal ground

acceleration of 0.25g against the AP1000 design spectra for 5 percent damping and a peak ground acceleration of 0.3g. The graph shows that for each PML site type, there is a limited frequency range over which the AP1000 design RS is less onerous than PML. The maximum differential response is approximately 15 percent for the soft site at 8 Hz, 15 percent for the intermediate site at 10 Hz, and 11 percent for the hard site at 12 Hz. This implies that over a tight frequency band the design requirement of the AP1000 design may be less conservative than PML. However, the severity of this apparent deficiency can be moderated to a considerable extent, as the design demand (i.e., seismic forces generated) is also dependent on the participating mass within that frequency range and the method used to combine the modal responses.

The FRS presented (Reference 12.61) suggests that for a number of the FRS levels, the peak response over the 8 to 12 Hz range is governed by the hard site input motion.

12.6.3.4 Seismic Margin Analysis

A Seismic Margin Assessment (SMA) is a study employed to identify those SSCs important to seismic risk to assess the capacity of components required to bring the plant to a safe, stable condition and to identify potential vulnerabilities.

The purpose of the SMA is to identify the magnitude of seismic event that an SSC is able to withstand, or perform its required duties.

With regard to SMA, a seismic margin earthquake (SME) is specified such that, for safety-significant systems required for safe shutdown, the seismic adequacy is verified to the level of the SME. When an SMA has been performed for the safety-relevant components of that plant, the consequences of an increased seismic hazard above the SME for the SSE can be understood, thereby demonstrating the absence of any cliff-edge effects. To this extent, the SME can be considered as the beyond-design-basis earthquake.

An SMA based on a probabilistic safety assessment (PSA) considers sequence-level high-confidence, low-probability failures (HCLPF) and fragilities for all sequences leading to core damage or containment failures, up to approximately one-and-two-thirds of the ground motion acceleration of the design basis SSE. It is conservatively assumed for the risk-based SMA that no credit is taken for the mitigation functions of the non-safety-significant components and systems.

The SMA for the AP1000 design has been performed based on established criteria, design specifications, existing qualification test reports, established basic design characteristics and configurations and public domain generic data in AP1000 plant PSA.

For the AP1000 design, the SMA has established a review level earthquake (RLE) equal to 0.5g. It is demonstrated in Section 10.18 that for the Class 1 SSCs, the magnitudes of high-confidence, low-probability failure events are equal to or greater than 0.5g which provides confidence in the deterministic 0.3g PGA assessment undertaken for the AP1000 design and that the loading demand of the UK design basis PML RS will be met. A 0.5g RLE withstand capability is beyond that required by UK seismic conditions, which generally would require a design basis earthquake of 0.25g (Reference 12.15) with seismic margins being considered at 0.35g.

For the AP1000 design, SMA provides assurance that the design satisfies EHA.7 (i.e. small change in design basis fault or event assumptions should not lead to a disproportionate increase in radiological consequences) as well as assuring margin for BDB earthquakes.

SMA provides reasonable assurance that the AP1000 design can withstand earthquakes with a return period of 1.0E-7 /yr (EHA.1 implies consideration of events with this return period).

Design to SSE with near-elastic response is conservative and provides margin for BDB Basis earthquakes.

12.6.3.5 Ground Rupture, Liquefaction, and Bearing Capacity

The ONR advises that it is generally impractical to design nuclear plants to resist ground rupture (Reference 12.3). The potential for liquefaction occurs for certain types of soil (typically saturated loose sands or hydraulically deposited sands with uniform grading), but techniques exist for assessing the potential for liquefaction and improving ground conditions to negate its effects. The AP1000 plant has not been specifically designed to account for either ground rupture or liquefaction effects. The licence applicants will be required to address the following regional and site-specific geological, seismological and geophysical information, as well as conditions caused by human activities:

- Structural geology of the site
- Seismicity of the site
- Correlation of earthquake activity with seismic sources
- Seismic wave transmission characteristics of the site
- Geological history
- Evidence of paleoseismicity
- Site stratigraphy and lithology
- Engineering significance of geological features
- Site groundwater conditions
- Dynamic behaviour during prior earthquakes
- Zones of alteration, irregular weathering, or structural weakness
- Unrelieved residual stresses in bedrock
- Materials that could be unstable because of mineralogy or unstable physical properties
- Effect of human activities in the area

Seiches and tsunami are addressed generically in Section 12.7.5.

The licence applicant will also address the following site-specific information related to the stability and uniformity of subsurface materials and foundations:

- Excavation
- Bearing capacity
- Settlement
- Liquefaction

The licence applicant may identify site-specific features and parameters that are not clearly within the site envelope. These features and parameters may be demonstrated to be acceptable by performing site-specific seismic analyses. A site-specific evaluation can be performed if the site-specific spectra are outside the range evaluated for the standard AP1000 design.

12.6.4 Long Period Ground Motion

The ONR external hazards TAG (Reference 12.3, Table 1) cites long period ground motion as a seismic hazard that should be considered. Water contained in tanks is susceptible to long period motion i.e., low frequency response.

The hydrodynamic mass effect of the water within the passive containment cooling water storage tank (PCCWST) on the shield building roof, the in-containment refuelling water storage tank (IRWST) within the containment internal structures, and the spent fuel pool (SFP) in the auxiliary building is evaluated. Since the water in the PCCWST responds at a very low frequency (sloshing) and does not affect building response, the horizontal mass is reduced to exclude the low frequency water sloshing mass. The total mass of the water in the IRWST and the SFP in the auxiliary building is included in the NI seismic model (Reference 12.61):

- **PCCWST** –The seismic analysis indicates that significant sloshing may take place in the PCCWST. The tank is lidded and will not lose water during a seismic event.

- **IRWST** – The seismic analysis indicates that sloshing is unlikely to take place in the IRWST and therefore it is not expected to lose water during a seismic event.

- **SFP** – For the fuel handling area, Appendix C of Reference 12.16, considers the effect of an SSE during normal operation with water in the SFP and associated pools with the seismic hydrodynamic load acting on the pool walls. The SSE may result in sloshing of the free water surface with loss of water from the pools.

12.6.5 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, seismic-induced damage to SSCs outside the NI will not prevent the delivery of Category A safety functions.

The radwaste building is designated as non-seismic and analysed to the UBC. A separation gap is provided between adjacent structural components of the two buildings above grade, the greater of either two times the absolute sum of the maximum displacement of each building under the most unfavourable load combination or 10.16 cm (4 in), whichever is more. In addition, an impact analysis based on the kinetic energy associated with the maximum velocities of the two buildings has been undertaken to show that the collapse of the radwaste building does not undermine the safety function of the NI structures. The radwaste building form comprises a steel frame which is comparatively light in relation to the robust, heavy concrete components used for the NI structures. Accordingly, it would be expected that the radwaste building impact effects would not compromise the integrity or function of the NI structures.

The portion of the annex building adjacent to the NI is designated as C-II and analysed according to the SSE.

The turbine building is divided into two sections: The first bay adjacent to the NI is designated as C-II and designed to address the SSE ground motion. The remaining bays are classified as non-seismic and analysed according to the UBC or IBC (see Section 12.6.3.2).

The interfacing of the adjoining annex building and the turbine building with the NI is discussed in Chapter 16.

12.7 EXTERNAL FLOODING

12.7.1 Safety Design Approach

External flooding of the nuclear power plant from natural causes can be attributed to probable maximum flood, site and adjacent area probable maximum precipitation run-off, seiches or tsunamis, and ground water.

Contributors to generic site flooding considered here are:

- Extreme rainfall or precipitation
- Groundwater flow
- Extreme river and sea levels
- Seiches and tsunamis

However, site-specific issues such as surface runoff and upstream dam failure, which are not considered here, may provide local flooding.

The AP1000 plant has been designed so that an extreme flooding event within the design basis will not prevent the delivery of Category A safety functions.

12.7.2 Extreme Rainfall

12.7.2.1 Diversion of Rainwater from the Nuclear Island

The NI structures are designed to resist the incursion of a design basis rainfall.

The roofs of the shield and auxiliary buildings do not have internal roof drains thus minimising water ingress. The roofs are sloped such that rainfall is directed towards gutters located along the edges of the roofs or over the roof edge; therefore, ponding on the roofs is precluded. Water from roof drains and scuppers, as well as run-off from the plant site, is conveyed to catch basins, underground pipes, or directly to open ditches.

Dynamic forces associated with the probable maximum precipitation are not factors in the analysis or design of the AP1000 plant, since the finished grade is adequately sloped to prevent water accumulating on the NI.

12.7.2.2 Change in UK Rainfall Resulting from Climate Change

The Department for Environment, Food and Rural Affairs (DEFRA) UKCP09 (Reference 12.17) discusses precipitation changes. In winter, UKCP09 shows projected increases by 54 percent for the 2080 medium emissions scenario at the 90 percent probability level in areas of southern England. In the summer, there are corresponding increases of 7 percent over parts of southern England.

12.7.2.3 Extreme Recorded UK Rainfall

The Meteorological Office recorded data on extreme rainfall in England and Wales (Reference 12.18) provides the following time-related rainfall maxima figures: 92 mm/hr (3.6 in/hr) and 32 mm/5 min (1.26 in/5 min). These extreme UK rainfall intensity values are bounded by the AP1000 design envelope of 525.8 mm/hr (20.7 in/hr) and 160.0 mm/5 min (6.3 in/5 min) respectively (see Table 12-4), resulting in AP1000 design rainfall intensity values that are a factor of five greater than predicted UK maxima. Such a factor bounds the predicted precipitation increase of 54 percent for the UK previously discussed.

12.7.2.4 Predicted UK Rainfall for Design Basis Event

The ONR TAG for External Hazards NS-TAST-GD-013 (Reference 12.3) refers to British Standard (BS) European Standards (EN) 12056-3: 2000 for drainage systems to buildings. This standard defines rainfall intensity in litres per second, but the rainfall values are equivalent to that given in BS 6367:1983 (Reference 12.19) which provides rainfall intensity values in millimetres per minute for the UK for various storm durations and a range of return periods up to 1 in 35,000 years.

From Appendix A of BS 6367: 1983 (Reference 12.19), the return period associated with the AP1000 design storm rain intensity value of 160 mm/5 min (6.3 in/5 min) duration exceeds the 1 in 35,000 year event for the heaviest intensity of rainfall within mainland UK (i.e., excluding Northern Ireland). The intensity for a 1 in 10,000 year return period for the 5-minute storm duration storm is 42 mm (1.7 in). Hence, there is a factor of 3.8 in the design capacity of the NI to remove rain water compared to the 1 in 10,000 year return period design basis rain intensity value.

Consequently, the AP1000 design is conservative compared to the UK design basis rainfall, even allowing for climate change over the life of the facility that could result in a predicted increase of 54 percent precipitation increase for the UK, discussed in Section 12.7.2.2.

12.7.3 Groundwater

The NI structures are designed to resist the infiltration of normal ground water up to a plant elevation of 99.39 m (98 ft). A waterproof system for the Class 1 structures below grade (below ground level) will be installed to limit the infiltration of subsurface water as described in Section 16.9.1.

The actual site soil properties of the various layers under possible groundwater conditions during the life of the plant, as part of a site-specific assessment, will be compared to the range of values assumed in the standard design.

12.7.4 Extreme River and Sea Levels

The NI structures have been designed to withstand and prevent ingress of water from land or sea-based external flooding events.

The highest possible sea-water level would be caused by a combination of a high spring tide, a coincidental surge and coincidental maximum wave height conditions.

Adequate coastal defences as well as site elevation prevent flooding from seawater, which can include extreme high tides, tsunamis, seiches and storm surges. Flood defences and their levels will vary from site to site; however, most UK sites are likely to be coastal or estuarine and subject to the risk of flooding from the sea directly or through interactions between excess river flow and tidal conditions. Accordingly, the maximum seawater level, including the level of storm surge, is site-specific and should be assessed on a case-by-case basis.

Sea level change predictions from DEFRA UKCP09 (Reference 12.20) in the period from 1990 to 2080 for the average sea-level rise for the medium emissions scenario at the 50-percent probability level is projected to be between 244 and 363 mm (9.6 and 14.29 in). This range does not allow for contribution from land movements so this should be covered in the site-specific assessment. However, it should be noted that the maximum vertical land movement is predicted to occur in South Western England by a lowering of the region of 2.5 mm/yr (0.09 in/yr) (Reference 12.21).

12.7.4.1 High Tides and Storm Surges

High spring tide levels are gravitationally induced and depend locally on topographical influences.

Storm surges are short-lived local increases in water level above that of the tide and are driven by wind and atmospheric pressure gradients. The effects of climate change also need to be taken into consideration. Combined changes in storm surges and relative sea level rise can be estimated by adding together the two components (Reference 12.22). When they occur at the same time as a high tide, storm surges can cause overtopping of sea defences and flooding. The projected long-term trends in storm surge around the UK are relatively small and even the 1 in 50 year return surge is not projected to increase by more than 90 mm (3.5 in) anywhere around the UK coast (Reference 12.22) by 2080. A site-specific assessment will be required to identify current storm surge levels, and therefore, the risk from an increase in storm-surge heights.

12.7.5 Tsunamis & Seiches

Seiches are bounded by tsunamis in magnitude (Reference 12.23, Section 3.2(11)), and therefore, have been screened out of this assessment.

The most likely scenario (Reference 12.24) for a significantly damaging tsunami in the UK is an anomalously large, relatively close earthquake producing a tsunami that would only be severe locally. Such earthquakes are themselves rare, and are unlikely to produce a tsunami. For most scenarios, the heights of tsunami waves arriving close to the shore will be comparable to those of typical storm surges (Reference 12.24). All major UK centres of population have flood defence infrastructure designed to cope with the expected range of storm surges.

However, certain characteristics of tsunami events (e.g., the number of waves and the range of wavelengths) are likely to create sea conditions different from those during a storm surge. Also, tsunami events may occur at any time; they are not associated with adverse meteorological conditions. Therefore, it cannot be assumed that the impact of a tsunami would be comparable to that of a storm surge simply on the basis of a similar wave height.

The largest tsunami to impact the shores of the British Isles was that caused by the great Lisbon earthquake of 1st November 1755 (Reference 12.25). For such a Lisbon-type tsunami, travel times are approximately 4-1/2 hours to the Cornish coast, which provides in most scenarios adequate time to mitigate the impact of the tsunami; e.g., by shutting the reactor down.

Coastal sea defences and site elevation are the primary defence against a tsunami in the UK. The actual defences and site elevation will vary significantly around the coastline of the UK and the risk from a tsunami and seiches should, in conjunction with the local coastal defences, be evaluated on a site-specific basis.

12.7.6 Flood Design of the Nuclear Island

12.7.6.1 Siting of the Nuclear Island Platform Level

The AP1000 reactor is designed for a normal groundwater elevation up to plant elevation 99.39 m (98 ft) and for a flood level up to a plant elevation of 100.0 m (100 ft). For structural analysis purposes, grade elevation is established as a plant elevation of 100.0 m (100 ft) with grade being defined as the ground level within a 0.8-km (0.5 mi) radius of the NI (PCSR Table 4-9). Actual grade will be a few centimetres lower to prevent surface water from entering doorways. Site-specific considerations will be required to determine if the maximum probable flood height is bounded by the maximum designed probable flood height. At the time of site licensing, the applicant will need to demonstrate that the probable maximum 1 in 10,000 year flood is below this elevation.

At the time of site licensing, the applicant will need to demonstrate that the probable maximum flood from sources such as streams and rivers, potential dam failures, probable maximum surge, and tsunami flooding is below the actual sites grade elevation.

Flooding of water intake structures, cooling canals, reservoirs or channel diversions would not prevent safe operation of the plant.

There is minimal dynamic water force associated with the probable maximum flood or high groundwater level because these water levels are below the finished grade.

12.7.6.2 Nuclear Island Flood Withstand – Penetrations

Because the probable maximum flood for the generic AP1000 design is less than grade elevation the exterior doors are not required to be watertight for protection from external flooding. Also, there are no access openings or tunnels penetrating the exterior walls of the NI below grade.

The shield building penetrations are designed to maintain containment integrity under DBA conditions. Process piping penetrations through the exterior walls of the NI below grade are embedded in the wall or are welded to a steel sleeve embedded in the wall.

The effect of high tides will be dependent on the location of the plant relative to the sea which will require a site-specific assessment. Climate change will need to be taken into consideration for high tides. Sea-level rises will vary from region to region.

12.7.6.3 Nuclear Island Flood Withstand – Basemat

The NI basemat is designed to withstand the upwards hydrostatic pressure of groundwater up to an elevation of 610 mm (24 in.) below grade, and therefore will resist overturning and sliding effects following a design basis flood.

12.7.7 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, flood-induced damage outside the NI will not prevent the delivery of Category A safety functions.

Flood-induced damage to SSCs outside the NI is not a safety concern and will not compromise Class 1 SSCs in the NI. The annex, radwaste, and diesel generator buildings have parapets with large weir openings to drain water to scuppers and drains to preclude the accumulation of water on the roofs.

12.7.8 Combined Hazards

The most credible combination of hazards involving external flooding is judged to be extreme wind and flooding (sea water or precipitation). However, the biggest risk to the site would be from an extreme rainfall event and an extremely high sea level with a storm surge. High winds could potentially lead to greater wave heights, leading to overtopping of the sea or river defences. Accordingly in conjunction with local coastal defences, such a scenario should be assessed on a site-specific basis.

Buoyancy effects on the NI basemat are considered in turn with wind, earthquake, and tornado loading.

Flooding of the AP1000 plant site resulting in physical isolation of the site by the inaccessibility of access roads would not be an issue for at least 7 days following a design basis flood.

12.8 ACCIDENTAL AIRCRAFT CRASH

This section considers the threat to the AP1000 plant from accidental aircraft impact. The deterministic study of aircraft impact, including the effects of shock-induced vibration and fire effects, on the plant is addressed under external hazards malicious acts – which are not presented in the PCSR due to their sensitive nature. Separate documentation is provided to address malicious aircraft impact. Design features which provide protection against malevolent aircraft impact are as follows:

- Shield Building design such that aircraft impact would not inhibit core cooling capability or not impact containment integrity.
- Auxiliary Building and spent fuel pool design such that SFP integrity is not compromised.
- Diverse key systems and separation of key systems.

UK air navigation regulations (Reference 12.26) restrict flying in the vicinity of UK nuclear sites. All of the designated UK nuclear new build sites with either an existing or a decommissioned nuclear power plant (NPP) have over-flying restricted to a height above 610 m (2000 ft) and a radius greater than 3.7 km (2 nautical mi).

The first stage in calculating the frequency of an aircraft striking an installation is to establish a background crash rate. The background crash rates cited in Reference 12.27 are applicable to all UK sites and only need to be modified when a site lies close to an airfield or a flight path. These crash rates have been derived by Atkinson and Thompson as an update to the report by Byrne (Reference 12.28).

Assuming the facility is not located within 8 km (5 mi) of an airfield (Reference 12.27, Paragraph 151) or close to a flight path (which is not allowed by legislation as previously described), the combined crash rate for light, small and large transport, helicopters and Military Combat Aircraft (MCA) is 4.8E-07 and 51.3E-07 crashes per year for the NI and the AP1000 generic site, respectively (see Table 12A-1 in Appendix 12A). Thus, considering the NI only, compared to the generic AP1000 site, this reduces by an order of magnitude the effective target area (ETA) and the corresponding crash frequency per annum.

Aircraft impact has been screened-out because it requires a site-specific location to fully substantiate. It should be confirmed on a site-specific basis that the generic background crash rate and the UK legislation that restricts flying in the vicinity of UK nuclear sites are applicable to the designated AP1000 plant site.

12.9 EXTERNAL EXPLOSIONS

According to the combustion mode, an explosion can take the form of a deflagration, which generates moderate pressures, heat, or fire, or a detonation which generates very high near-field pressures and usually thermal effects. These types of explosions can occur only in the case of special fuel-air mixtures; whether the ignition of a particular chemical vapour or gas behaves as a deflagration or as a detonation depends primarily on the concentration of the chemical vapour or gas present (Reference 12.10, Section 6.5).

12.9.1 Safety Design Approach

The AP1000 plant has been designed so that external explosions will not prevent the delivery of Category A safety functions.

12.9.2 Nuclear Island Explosion Withstand

The NI structures can resist an off-site explosion. IAEA Safety Guide NS-G-1.5 (Reference 12.10, Paragraph 6.27) notes that structures will often have been designed to accommodate extreme loadings such as those resulting from aircraft impacts, tornado-generated pressure and missile loads, or earthquakes. The reinforced concrete walls are a minimum of about 0.6 m (2 ft) thick compared with the shield building, which has a nominal wall thickness of 0.914 m (3 ft). It is often unnecessary, therefore, to apply additional design measures to mitigate the effects of design basis external explosions, unless their effects are found to be more severe than those corresponding to the other extreme loadings already considered.

The screening distance value for an initiating explosive event based on conservative approaches (Reference 12.29) can be determined by calculating the scaled distance corresponding to safe values of overpressures based on a trinitrotoluene (TNT) equivalent initiating explosion.

In determining the load from solid detonation explosions (e.g., by a TNT equivalent) in the context of NPP, design and operating experience has shown that explosive hazards have

effects close to and often enveloped by other hazard sources such as impacts and wind (Reference 12.10, Paragraph 6.20).

An explosion involving the detonation of high explosives, munitions, chemicals or liquid and gaseous fuel from facilities and activities in the vicinity of the plant will be considered on a site-specific basis as the AP1000 plant design has an inherent capability to withstand external explosions.

12.9.3 Operator Intervention

Various detectors and alarms (e.g., seismic alarms) are available that have the potential to alert the operators that an external explosion event has occurred and if necessary to shut the reactor down. For situations where the possibility of external explosion has been identified, a site-specific emergency-plan must be adopted.

12.9.4 Regulations

The risk of an external explosion at UK sites has been reduced by the introduction of Control of Major Accident Hazards (COMAH) regulations.

COMAH regulations identify hazards from surrounding sites, which will help to reduce the risk posed by the surrounding sites. The implementation of COMAH regulations (Reference 12.30) provides significant controls on hazardous activities that may lead to an explosion. The COMAH is enforced by the Competent Authority (CA) which comprises the ONR, Environment Agency (EA), Health and Safety Executive (HSE), Scottish Environmental Protection Agency, and Natural Resources Wales working in partnership. The CA is overseen and coordinated by the Competent Authority Strategic Management Group. Planning legislation may be used to restrict the development of installations and facilities that could adversely affect the safety of an NPP.

12.9.5 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, explosion-induced damage outside the NI will not prevent the delivery of Category A safety functions.

Extreme explosion damage to SSCs outside the NI is judged to be bounded by the consideration of earthquake loading which has been shown will not compromise Class 1 SSCs on the NI.

12.9.6 Combined or Sequential Hazards

There will be no loss of Class 1 SSCs as a result of combined hazards arising from a design basis explosion event.

During periods of extremely high temperatures, there is a possible risk of bush fires and fuel tank explosions. The combined effects of these hazards, however, are judged to be no more severe than the individual consequences. The risk to nuclear safety would be during periods of drought and high ambient temperature when a demand is put on the fire water supplies. This issue is covered in Section 12.10.5.

12.10 EXTREME AMBIENT TEMPERATURES

12.10.1 Safety Design Approach

The plant has been designed so that an extreme ambient temperature within the design basis will not prevent the delivery of Category A safety functions.

12.10.2 Minimum Ambient Temperature

12.10.2.1 AP1000 Design is Bounding of UK Minimum Air Temperature

The minimum daily air temperature recorded in England, Wales and Scotland was -27.2°C (-16.9°F) (Reference 12.31 and Table 12-4). However, the UK minimum ambient air temperature for a 1 in 10,000 year event is lower than the minimum recorded temperature as discussed below.

BS EN 1991-1-5:2003 (Reference 12.32) and its UK national annex document (Reference 12.34) defines minimum shade air temperature actions for the 1 in 50 year and methodology to calculate 1 in 10,000 year events. For the 1 in 50 year return period, Figure NA.1 of Reference 12.32 gives the minimum ambient shade air temperature based on hourly recorded values (Reference 12.32, Section 1.5.3) as -21°C (-5.8 °F) (at Inverness). Converting this temperature using the 1.0E-04/yr correction factor of 1.830 (Annex A.2 of Reference 12.32) gives the minimum UK ambient by 1 in 10,000 year air temperature as -38.4°C (-37.1°F).

These figures need to be adjusted for altitude relative to mean sea level (MSL) and for climate change. BS EN 1991-1-5:2003 (Reference 12.32) suggests reducing the minimum shade air temperature by 0.5°C (0.9 °F) for every 100 m (328 ft) increase in altitude. Hence, for a site at 140 m (459.3 ft) above MSL, the minimum temperature would be -39.1°C (-38.4 °F).

Annex 5 of NS-TAST-GD-013 (Reference 12.3) notes that ambient temperature is likely to be affected by climate change. Climate change predictions from DEFRA UKCP09 (Reference 12.33) show that the average UK winter temperature rise is predicted to be +4.2°C (7.6 °F) for the 2080 medium emissions scenario at the 90 percent probability level. Hence, the minimum ambient air temperature in the UK would increase from -38.4°C (-37.1°F) to -34.2°C (-29.6 °F) at MSL in 2080 which is bounded by the plant design temperature of -40.0°C (-40°F) (see Table 12-4).

Consequently, not allowing for climate change that is predicted to raise the minimum ambient air temperature, the minimum recorded UK mainland temperature (-27.2°C (-16.96°F)) and the 1 in 10,000 year return period minimum ambient temperature based on minimum hourly recorded values (-38.4°C (37.1°F)) are bounded by the plant minimum design temperature of -40.0°C (-40°F) (see Table 12-4).

Additionally, BS EN 1991-1-5:2003 (Reference 12.32) suggests that local features such as sheltered low-lying areas may need to be considered on a site-specific basis using local meteorological data.

12.10.2.2 Minimum Sea-Water Temperature

The minimum achievable sea temperature is -2°C (28.4°F) as this is the temperature at which sea water with an average salinity freezes.

The service water system (SWS) supplies cooling water to remove heat from the heat exchangers cooling water in the turbine building. The AP1000 UK design specifies that the SWS will be served via cooling towers to act as a heat sink and is therefore not based on sea or estuary water cooling. Consequently, the SWS is dependent on ambient air temperature rather than sea temperature.

12.10.2.3 Shield Building

The shield building houses the PCCWST. This tank contains water that is used to augment cooling of the external containment surface in the event of an accident. There is an engineered heating system to keep the water temperature in the PCCWST above the technical specification (Tech Spec) limit of 4.4°C (40°F).

During plant outages in cold weather, the hot water heating system supplies hot water to the plant chilled-water piping that serves the containment building recirculation fan coil units to maintain acceptable ambient air temperatures inside the containment. During a loss of normal alternating current (ac) power, provisions are made to power the hot water heating system from the onsite standby diesel generators.

The containment shell is a path for the removal of decay heat from the containment atmosphere to the environment. However, this process is effective at the minimum ambient temperature.

12.10.3 Maximum Ambient Temperature

12.10.3.1 AP1000 Design is Bounding of UK Maximum Air Temperature

The maximum daily air temperature recorded in England, Wales, and Scotland was 38.5°C (101.3°F) on 10 August 2003 in Faversham, Kent (Reference 12.31). However, for a 1 in 10,000 year event, this peak recorded temperature is exceeded as discussed below.

Annex A.1 of BS EN 1991-1-5 (Reference 12.32) (and its UK national application document (Reference 12.34)) define maximum shade air temperature for the 1 in 50 year and methodology to calculate 1 in 10,000 year events based on maximum hourly recorded values (Reference 12.32, Section 1.5.3). For the 1 in 50 year return period, Figure NA.2 of Reference 12.34, the UK National Annex of Reference 12.32, gives the maximum UK ambient coastal shade air temperature as +31°C (87.8°F) (on the east and south coasts of England). Converting this figure using the 1.0E-04/year correction factor of 1.30 (Annex A.2 of the standard Reference 12.32) gives the maximum UK temperature as +40.3°C (104.5°F).

These figures should be adjusted for altitude relative to MSL and for climate change. BS EN 1991-1-5:2003 (Reference 12.32) suggests applying +1.0°C (1.8°F) to the maximum shade air temperature for every 100 m (328 ft) above MSL. Hence, for a site at 140 m (459.3 ft) above MSL, the maximum temperature would increase to +41.3°C (106.3°F).

ONR TAG NS-TAST-GD-013 (Reference 12.3) notes that temperature is likely to be affected by climate change. Climate change predictions from DEFRA UKCP09 (Reference 12.33) show that the average UK summer temperature rise is projected to be +5.7°C (10.26°F) for the 2080 medium emissions scenario at the 90 percent probability level. Hence, the maximum coastal shade air temperature in the UK may equal +45°C (113°F) at MSL which is less than the AP1000 plant maximum design temperature of +46.11°C (115°F) (see Table 12-4).

The approximate maximum shade air temperatures for coastal locations around the mainland UK for a 1.0E-04/year return period at MSL and incorporating climate change values of +5.7°C (10.26°F) at 2080 are:

- East and South coasts of England: +45°C (113°F).
- Welsh coast: +46°C (114.8°F).
- Scottish coast: +42°C to +45°C (107.6°F to 113°F)

Consequently, the maximum recorded UK mainland temperature (38.5°C (101.3°F)) and the predicted 1 in 10,000 year return period (including climate change at 2080) UK mainland maximum coastal ambient temperature based on hourly recorded air temperatures (+46°C) (114.8°F) are bounded by the AP1000 plant maximum design temperature of +46.11°C (115°F) on the external walls and roof of the NI (see Table 12-4). The site-specific survey in conjunction with DEFRA UKCP09 will determine what is the appropriate climate change temperature increase to apply to the site.

Annex 5.4 of NS-TAST-GD-013 (Reference 12.3) refers to BS 5400 to assess solar gain in safety-related structures, but does not identify a standard or code of practice to evaluate air temperatures. However, solar gain is to some extent site-specific even within the UK and should be considered on a site-specific basis. Additionally, BS EN 1991-1-5:2003 (Reference 12.32) suggests that local features such as sheltered low-lying areas may need to be considered on a site-specific basis using local meteorological data.

12.10.3.2 Maximum Sea-Water Temperature

The UK climate projections predict the UK shelf sea temperatures to rise by between 1.5°C and 4°C (2.7°F to 7.2°F) by the end of the 21st century. This will give rise to maximum sea temperatures in UK waters of approximately 24°C (75.2°F) by the end of the 21st century (Reference 12.35).

As discussed in Section 12.10.2.2, the SWS is dependent on ambient air temperature rather than sea temperature.

The licence applicant will address water supply sources to provide makeup water to the SWS cooling towers.

12.10.3.3 Containment and Shield Buildings

The containment and shield building structures are not affected by the maximum expected ambient temperatures cited above.

The qualification of equipment for expected accident conditions inside the containment bounds any effects of maximum ambient temperature. Engineered cooling functions are capable of maintaining containment temperatures below the Tech Spec limit of 49°C (120°F) if required.

The steel containment vessel provides the path for the removal of decay heat from the containment atmosphere to the environment following an accident and its performance is affected by the ambient temperature. The passive containment cooling system (PCS) meets the AP1000 design ambient temperature of 46.11°C (115°F).

The shield building houses the PCCWST. This tank contains water that is used to augment cooling of the external containment surface in the event of an accident. The PCCWST

maximum water temperature has a Tech Spec limit of 49°C (120°F). It is unlikely that the contents of the PCCWST will ever reach a maximum water temperature of 49°C (120°F) considering that the AP1000 plant maximum air design temperature is 46.11°C (115°F).

12.10.3.4 Spent Fuel Pond

The spent fuel storage facility is located within the auxiliary building fuel handling area and contains post-irradiated fuel which requires active cooling. The spent fuel pond can have the cooling water supply interrupted for a period of up to 7 days without fuel uncovering. The cooling pond has a sufficient heat sink and local make-up water volume to maintain cooling for this period. Although extreme ambient temperature will be a factor in the rate of evaporation, there are appropriate alarms and indications in place to detect when the water level drops below a specific point.

12.10.4 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI; extreme ambient temperature-induced damage outside the NI will not prevent the delivery of Category A safety functions.

12.10.5 Combined Hazards

There will be no loss of Class 1 SSCs as a result of combined hazards arising from a design basis extreme temperature event.

No credible combination of hazards has been identified that could result in greater impact on nuclear safety than would be achieved by each hazard occurring independently.

It is feasible, during periods of extremely high temperature that there will be an increased risk of bush and forest fire. However, the combined effects of these hazards are judged to be no more severe than the individual consequences. The greatest risk to nuclear safety would be during periods of drought and high ambient temperature when a demand is put on the fire water supplies.

Extreme ambient temperatures themselves are not considered to lead to any consequential hazard. There is, however, the potential for pipe work failures in systems containing liquids that are not subject to trace heating or other protection during periods of extreme cold. The consequences of the flooding would be no worse than the internal flooding considered in Chapter 11.

Extreme ambient temperatures of –40.0°C (–40.0°F) and 46.11°C (115°F) are considered for the Class 1 structures in combination with the SSE.

12.11 METEOROLOGY

12.11.1 Safety Design Approach

The AP1000 plant has been designed so that an extreme meteorological event within the design basis will not prevent the delivery of Category A safety functions.

12.11.2 Snow Loading

The load on roofs caused by extreme snowfall, uniform and drifted, is discussed in Section 16.4.1.3.

The AP1000 Plant Civil Structural Design Criteria (Reference 12.16) specifies the imposed ground snow loading as 3.6 kN/m^2 (75 lbs/ft^2) as a uniform blanket determined in accordance with American Society of Civil Engineers (ASCE) 7-98 (Reference 12.55). The potential of snow sliding from a higher sloping roof and being deposited onto a lower roof, is bounded by missiles discussed in Section 12.11.2.2. The ASCE 7-98 snow load corresponds to the 1 in 50 year return period for the AP1000 design. Such a snow loading is applicable to the NI as all the structures of the NI have a concrete roof (see Section 12.4) methodology for the application of snow loading on structures is delineated in Section 16.4.1.3 and Reference 12.16.

The ONR TAG for External Hazards (NS-TAST-GD-013, Annex 5.2, Reference 12.3), states that snow loading should be at least as onerous as given in BS 6399-3 1988 (Reference 12.56), taking account of drifting effects where this can occur.

Uniform Snow Loading

Figure 1 of BS 6399-3: 1988 (Reference 12.56) gives a maximum 1 in 50 year return period snow-on-ground loading value of 1.0kN/m^2 (0.145 lbs/ft^2) (associated with a region of the Scottish Highlands). More typical regional values are 0.8kN/m^2 (0.116 lbs/ft^2) (North-east coastline) and 0.5kN/m^2 (0.073 lbs/ft^2) (elsewhere). Applying an altitude factor of 1.076, equivalent to 140 m (459.3 ft) above MSL, provides 1.076kN/m^2 (0.156 lbs/ft^2), 0.86 kN/m^2 (0.124 lbs/ft^2) and 0.54kN/m^2 (0.078 lbs/ft^2) respectively for the snow on ground loading. The roofs of the shield building and auxiliary building (i.e., the Class 1 structures) attract a maximum snow-on-roof coefficient of 0.8 (Reference 12.56, Figure 2) for a uniform blanket loading, thus giving 0.86 kN/m^2 (0.124 lbs/ft^2), 0.69 kN/m^2 (0.1 lbs/ft^2) and 0.43 kN/m^2 (0.062 lbs/ft^2) for the three regions considered.

For a 1 in 10,000 year snow loading, a return period probability factor of 2.28 is applied to the 1 in 50 year return period event magnitude. This return period probability factor is the same factor adopted for United Kingdom Atomic Energy Authority (UKAEA) sites (Reference 12.57), as provided in the first issue of BS6399-3: 1988. Consequently, the AP1000 design ground snow loading of 3.6 kN/m^2 (0.052 lbs/ft^2) roofs still bounds the maximum UK uniform snow loading for a 1 in 10,000 year event of 2.28 kN/m^2 (0.33 lbs/ft^2).

The methodology for the application of snow loading on structures is delineated in Section 16.4.1.3 and Reference 12.16.

Drift Snow

Drifted snow is considered to be an exceptional event in BS 6399-3: 1988 (Reference 12.56, Section 7.4.1) Drifted snow is characterised by a triangular snow (rather than a uniform) distribution in locations where it can possibly occur (e.g., where the Class 1 auxiliary building roof abuts the upper shield building wall). The methodology for the application of snow loading on structures is delineated in Section 16.4.1.3 and Reference 12.16.

UK practice also highlights the possibility for snow dropping off sloping high level roofs onto low level roofs below. As the adjacent shield building is warm and uses the ventilation as a cooling system to the reactor, it is conceivable that snow could avalanche down the inclined roof of the shield building onto a drift onto the auxiliary building roof creating a ‘double loading’ effect in conjunction with possible dynamic amplification from the cascaded snow.

However, the dynamic amplification of avalanching snow from the shield building onto the low level roofs of the surrounding structures will be bounded by the external missiles considered in Section 12.14.

It is concluded that the AP1000 design parameters exceed the UK requirements for ground snow loading for a 1 in 10,000 year event. Additionally, the UK design basis snow event for both uniform and drifting snow is unlikely to exceed the AP1000 design snow loading on the concrete roof members in the auxiliary building. Additionally, allowing for snow avalanched off the adjacent shield building onto the low level roofs of the surrounding structures will be bounded by the design basis external missiles. This should be confirmed on a site-specific basis.

12.11.2.1 AP1000 Design is Bounding of UK Maximum Snow Loading

The shield and auxiliary buildings roofs of the NI are designed for a ground snow load of 3.6 kN/m^2 (0.052 lbs/ft^2), which bounds the UK 1 in 10,000 year ground snow loading of 2.28 kN/m^2 (0.33 lbs/ft^2).

No allowance for change in snow loading resulting from climate change has been considered as the DEFRA United Kingdom Climate Projections 2009 (UKCP09) projections (Reference 12.6) for snowfall do not yield consistent or robust estimates.

12.11.2.2 Avalanche

Snow dropping off sloping high-level roofs onto low-level roofs below is discussed within the snow drift section of Section 12.11.2.

12.11.2.3 Air Ducts

Other than those on the shield building, no Class 1 air ducts have been identified in the safe shutdown components table.

The air inlets on the shield building are equipped with screens. The screens are designed to help prevent foreign objects or debris from entering the air flow path. In the event of a snow or ice storm, some fraction of these air inlets could temporarily become blocked with snow or ice. The air inlets are designed such that a portion of the inlet area can be blocked without a significant effect on the peak containment pressure for DBE.

The PCS radiant heaters ensure the PCS air flow path is free from blockage of snow and ice prior to an accident. Radiant heaters are provided at the shield building inlet to prevent inlet blockage due to a build-up of snow or ice. The system provides for heating the inlet structures to ensure they are clear of ice and snow to provide for assumed air flow through the system. The system also provides for heating the chimney base plate (shield plate) to keep that region clear of ice and snow and prevent any air-flow blockage.

12.11.2.4 Combined Hazards

There will be no loss of Class 1 SSCs as a result of combined hazards in conjunction with snow loading.

Seismic loads are combined with the specified live loads as delineated in Reference 12.16.

12.11.3 Drought

12.11.3.1 Lead Time

Substantial lead time will ensure that preventative measures can be put into place so that drought will not affect the safety functions. Because of the nature of this hazard, there will be a substantial lead-time before drought impacts upon the plant. Ultimately, the supply of water for plant systems and fire protection will be governed by monitoring procedures such that any shortfalls will stimulate protective actions by operators.

12.11.3.2 Safe Shutdown

Water storage systems that are required for safe shutdown include the passive core cooling system (PXS) and the PCS. Both systems use water storage tanks, which are filled during normal operating conditions and will, therefore, be full before an extreme drought scenario. After 7 days, additional water will be required for PCS and SFP makeup. This water can be transported from the nearby river / sea.

12.11.3.3 Ground Water

There is a potential effect of drought on the building foundations resulting from changes in the groundwater level. This will need to be considered on a site-by-site basis because of differences in geology and groundwater tables. On a site-specific basis, the soil properties of the various layers under possible groundwater conditions during the life of the plant will be compared to the range of values assumed in the standard design.

12.11.3.4 Combined or Consequential Hazards

There will be no loss of Class 1 SSCs resulting from combined hazards arising from drought.

No credible combination of hazards has been identified that could result in greater impact on nuclear safety than would be achieved by each occurring independently. The potential for combined hazards associated with drought is discussed in the section on extreme ambient temperatures (Section 12.10).

12.11.4 System, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, snow and drought-induced damage outside the NI will not prevent the delivery of Category A safety functions.

Snow-loading damage to SSCs outside the NI is judged to be bounded by consideration of missile loading which has been shown not to prevent the delivery of Category A safety functions of the NI. Ice effects do not have to be considered outside the NI.

It is judged that drought-induced damage to SSCs outside the NI will not prevent the delivery of Category A safety functions of the NI.

12.12 EXTREME WIND

This section considers the threat to the nuclear safety-significant features from extreme winds. Wind comes in many forms and is influenced by many factors, including location, altitude, direction, and topography.

Sources of extreme wind include:

- Hurricanes
- Cyclones
- Tornadoes or water spouts
- Tropical typhoons
- Sustained wind
- Gusting wind
- Sand storm

Wind-induced missiles are discussed in the section on missile hazards (see Section 12.14).

12.12.1 Safety Design Approach

Extreme winds can affect plant structures in the following ways:

- If wind forces exceed the load capacity of a building or other external facility, the building fabric or framing might collapse.

- Damage caused by wind may result in loss of off-site power (LOOP). This is a DBE covered in the design basis fault analysis presented in the AP1000 Fault Schedule located in Appendix 8A. In the event of LOOP, the Class 1 safety systems will maintain the plant in a safe state for an indefinite time with support from post 72 hour SSCs including either onsite or offsite ancillary equipment.

The AP1000 design wind is specified as a basic wind speed of 64.82 m/s (145 mph) with an annual probability of occurrence of 0.02. Wind loads are calculated for exposure Category C, which is applicable to shorelines in hurricane-prone areas with an Importance Factor of 1.15. The site parameters for the design wind may be demonstrated to be acceptable for other exposures or topographic factors by comparison of the wind loads on the structures. For example, for a site at a location with exposure Category D, the wind speed should be equal to or less than 58 m/s (129.7 mph).

The plant has been designed so that an extreme wind loading within the design basis will not prevent the delivery of Category A safety functions.

12.12.2 Tornadoes

A tornado is a violent rotating column of air and is the most intense of all atmospheric phenomena occurring typically in the form of a visible condensation funnel, whose narrow end touches the earth and is often encircled by a cloud of debris and dust. Most tornadoes have wind speeds between 32 m/s to 50 m/s (71.6 mph to 111.8 mph), are approximately 20 to 100 m (65 ft to 328 ft) across and travel a few kilometres before dissipating (Reference 12.37). If the tornado reaches a water body (such as the sea, a lake or a reservoir) it is termed a waterspout. A tornado may become a waterspout as the rotation moves from land to sea (and vice-versa).

12.12.2.1 Nuclear Island Tornado Withstand

The procedures described in Section 16.7.6 are used to determine the tornado wind loading in conjunction with the differential atmospheric pressure cited in Table 12-4 as effective loads on NI structures at a wind velocity of 134 m/s (300 mph). Additionally, the NI is checked for

resistance against sliding and overturning resulting from the safe shutdown winds and tornadoes as described in Section 16.13.6.2.

The containment air baffle is located within the upper annulus of the shield building, providing an air flow path for the PCS. The air baffle separates the downward air flow entering at the air inlets from the upward air flow that cools the containment vessel and flows out of the discharge stack. The air baffle is a Class 1 structure designed to withstand the wind and tornado loads defined in Table 12-4.

The NI nonradioactive ventilation system includes tornado-protection dampers designed to close automatically and protect against the effect of 134 m/s (300mph) wind.

12.12.2.2 AP1000 Design is Bounding of UK Historical Tornado Data

The UK has the highest frequency of reported tornadoes per unit area in the world. About 30 to 50 tornadoes are reported each year in the UK. Many tornado reports are from the western Midlands, eastern Midlands, central-southern England, south-eastern England, and East Anglia (Reference 12.42).

Two tornadoes in Britain are known to have reached T8 on the International Tornado Intensity Scale (Reference 12.39) based on their wind speed. However, because these two tornadoes occurred many years ago (in 1091 and 1810), their actual intensities are not known; and it is possible that they may have been even stronger.

A tornado with an intensity of T8 has a maximum wind speed of 107 m/s (239.4 mph) (Reference 12.40). This compares to the design parameters for a Class 1 structure for a design basis tornado (see Table 12-4) velocity of 134 m/s (300 mph) which is the sum of the maximum rotational speed (107.3 m/s (240 mph)) and the maximum translational speed (26.8 m/s (60 mph)) of the tornado. A velocity of 134 m/s (300 mph) is equivalent to T10 on the International Tornado Intensity Scale (Reference 12.39). As Class 1 structures are designed to resist tornado wind loads corresponding to wind speeds of 134 m/s (300 mph) without exceeding the allowable structural design stresses, the design basis tornado velocity for a Class 1 structure bounds the maximum recorded tornado velocity. Climate change may affect worldwide weather patterns but the UK DEFRA climate change projections do not make any predictions of the frequency and intensity of future UK tornadoes. It is considered to be extremely unlikely that a UK tornado will exceed the design basis tornado velocity of the plant design over the plant lifetime.

The following are the design parameters applicable to the AP1000 design basis tornado:

- Maximum wind speed – 134 m/s (300 mph)
- Maximum rotational speed – 107 m/s (240 mph)
- Maximum translational speed – 26.8 m/s (60 mph)
- Radius of maximum rotational wind from centre of tornado – 45.7m (150 ft)
- Atmospheric pressure drop – 13.8 kPa (2.0 psi)
- Rate of pressure change – 8 kPa/s (1.2 psi/s)

It is also noted that tornado wind speeds greater than the plant design basis have a return frequency of between 1.0E-06 and 1.0E-07 per year for a plant sited anywhere in the contiguous United States (US).

12.12.2.3 AP1000 Design is Bounding of UK Design Basis Tornado Loading

ONR NS-TAST-GD-013 (Reference 12.3) refers to the Meaden Report (Reference 12.41) for UK tornado risk assessment which states that the Sussex coast has the highest recorded annual tornado-density in Britain with a 1 in 10,000 year horizontal tornado wind speed of 65.3 m/s (146 mph) (Reference 12.41, pg. 107). This tornado wind speed is bounded by the design of Class 1 structures which are designed to withstand tornado wind speeds of 134 m/s.

For the UK, Table 5.19 of Reference 12.41 gives the pressure drop and rate of pressure change for a range of tornado wind speeds (55 m/s, 60 m/s, 65 m/s and 70 m/s (123 mph, 134 mph, 145 mph, 157 mph)) for four different combinations of translational and rotational components. The maximum pressure drop for a 65 m/s (145 mph) tornado (translation velocity 5 m/s and rotational velocity 60 m/s (134 mph)) is 3.7 kPa (0.53 psi) and a reported maximum of 7 kPa (1.0 psi). The maximum rate of pressure drop for the 65 m/s (145 mph) tornado is given as 1.140 kPa/s (0.165 psi/s). These values are significantly lower than the AP1000 plant tornado design values which allow for a maximum atmospheric pressure drop of 13.8 kPa (2.0 psi) and rate of pressure change of 8 kPa/s (1.2 psi/s) (Table 12-4).

12.12.3 Hurricanes or Tropical Cyclones

Hurricanes are tropical features and generally require sea temperatures much higher than those around the UK, even in the summer. Hence, hurricanes are extremely unlikely to form at UK latitudes. However, the UK does sometimes experience the remnants of old hurricanes coming out of the tropics; as they get entrained into the Atlantic westerly flow at higher latitudes, they can reach the UK and Western Europe (Reference 12.42), where they become conventional storms in the UK and are reflected in UK extreme wind conditions.

The class 2 SSCs that provide the installed post 72-hour plant support of the Class 1 SSCs that are outside the NI are designed for hurricane wind loading. The hurricane wind speed is defined as a 3 second gust at 89.4 m/s (200 mph) (Reference 12.16, Section 5.2).

12.12.4 Wind Loading

The shield and auxiliary buildings are designed to resist an exterior wall wind load corresponding to a 1 in 50 years return period wind speed for a 3 second gust of 64.8 m/s (145 mph) (see Table 12-4). The wind loads are developed using an Importance Factor of 1.15, thus increasing the effective return period to 1 in 100 years.

12.12.4.1 AP1000 Design is Bounding of UK Design Basis Wind Loading

Using conservative assumptions for wind direction and site location, Table 12-5 compares UK 1 in 50 year and 1 in 10,000 year wind pressures, derived from the corresponding wind speeds, to the AP1000 1 in 50 year design wind pressures over the height of the AP1000 plant buildings cited in Table 4 of the Wind Evaluation and Code Requirements (Reference 12.43).

No allowance for change in wind speed resulting from climate change has been considered as the DEFRA UKCP09 climate change projections for wind do not yield consistent or robust estimates of wind speed (Reference 12.44).

From Table 12-5, the AP1000 plant 1 in 50 year design wind pressures significantly exceed the conservatively derived British Standard 1 in 10,000 year wind pressure loading values. It is, therefore, concluded that the AP1000 design wind loading bound the UK wind loading for a 1 in 10,000 year event.

1 in 50 year wind

The ONR Technical Assessment Guide for External Hazards (NS-TAST-GD-013, Annex 5.1, Reference 12.3), states the hazard should be at least as onerous as given in BS 6399-2:1997 (Reference 12.54) for the derivation of extreme wind loading.

The 1 in 50 year 3 second gust design wind speed for the AP1000 plant is 64.82 m/s (145 mph). Figure 6 in BS6399-2: 1997 (Reference 12.54), provides a maximum average hourly wind speed of 27 m/s (60.4 mph) for the 1 in 50 year return period event that occurs at the north Scottish coast. Allowing for an enhancement for altitude and topography (140 m (459.3 ft) above MSL), provides a mean hourly wind speed of 30.78 m/s (68.9 mph). This 1 in 50 year hourly wind speed is converted to a 3 second gust speed the (the effective wind speed used in structural design) using the terrain and building factor S_b factor of (Reference 12.54) (see Table 12-5), which is dependent on the site location relative to the sea, height above ground, and building component dimension.

From Table 12-5, the AP1000 design pressures for the 1 in 50 year wind significantly exceed the British Standard 1 in 10,000 year wind pressure loading values. Further conservatism is present in the AP1000 design of the nuclear island by use of an Importance factor of 1.15 in calculation of the wind pressures. Application of this Importance Factor is equivalent to designing the nuclear island for a 1 in 100 year wind.

1 in 10,000 year wind

The 1 in 50 year effective wind speed is converted to a 1 in 10,000 year effective wind speed by multiplying by a probability factor, S_p derived from Annex D.1 of Reference 12.54. Using conservative assumptions for wind direction and site location, Table 12-5 compares BS 6399-2:1997 (Reference 12.54) design wind pressures, derived from the corresponding wind speeds in (Reference 12.54, Section 2.1.2.1) to the 1 in 50 year AP1000 design wind pressures over the height of the buildings cited in Reference 12.43, Table 4.

The AP1000 plant is not designed for a 1 in 10,000 year wind because this condition is enveloped by the tornado with a maximum wind speed of 134.2 m/sec (300 mph). This wind speed exceeds the 1in 10,000 year wind. From Table 12-5, the AP1000 design pressures for the 1 in 50 year wind exceed the conservatively derived British Standard 1 in 10,000 year wind pressure loading values. Further conservatism is included because the US design includes the Importance Factor of 1.15 discussed above and also applies a load factor for concrete structures, which constitutes the exterior fabric of the entire NI, of 1.7) to the values cited in Table 12-5, whilst the UK would normally apply a load factor of 1.0 to the 1 in 10,000 year design pressures. This margin would be expected to account for any discrepancies in local pressure differences, arising from e.g., vortices, determined using ASCE 7-98 (Reference 12.55) and BS 6399-2 (Reference 12.54).

It is, therefore, concluded that the AP1000 design parameters significantly exceed the UK requirements for a 1 in 10,000 year wind loading.

12.12.5 Sand Storms

This hazard is most relevant to sites in desert areas, and therefore, does not strictly apply in the UK, except conceivably in very dry and windy conditions from soil and dust, and at coastal sites from beach sand. The hazard would be readily apparent and operational measures would be available to control the effects. Also, important building ventilation systems where dust ingress might be undesirable generally have installed plenum inlet filtration to exclude airborne solids.

12.12.6 Sea Spray

Sea spray caused by high winds coming in from the sea could cause possible corrosion of the open power lines to the site with the potential to cause a LOOP. This DBE is covered in the design basis fault analysis presented in the AP1000 Fault Schedule. In the event of LOOP, the Class 1 safety systems will maintain the plant in a safe state for an indefinite time with support from post 72 hour SSCs including either onsite or offsite ancillary equipment. Consequently, sea spray is not considered to be a threat to nuclear safety. Details of appropriate inspections will be described on a site-specific basis and will be carried out by the site licence applicants.

12.12.7 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, extreme wind induced damage outside the NI will not prevent the delivery of Category A safety functions.

The failure of structures not designed for tornado loadings, and hence, by inference wind gusting, will not affect the capability of Class 1 SSCs. The structures adjacent to the NI are the annex building, the radwaste building, and the turbine building.

- The portion of the annex building adjacent to the NI is classified as seismic Category II and is designed to Seismic Category I structure tornado loading.

- The radwaste building is a small steel-frame building. If it were to collapse in the tornado, it would not impair the integrity of the NI.

- The turbine building First Bay, which is adjacent to the NI, is classified as Seismic Category II and is designed to the same tornado loading as seismic Category I structures. The other portions of the turbine building are classified as NNS and designed per the IBC. The main structure is designed for tornado loading. The impact of tornado-driven sheet metal siding from the turbine building on the NI is evaluated.

More detail on the tornado withstand of the buildings outside of the NI are given in Sections 16.4.2.1 and 16.4.3.

The passive containment cooling ancillary water storage tank is a cylindrical steel tank located at ground level near the auxiliary building. It is analysed, designed, and constructed using the method and criteria for seismic Category II building structures and is also designed and analysed for hurricanes including the effects of sustained winds, maximum gusts and associated wind-borne missiles. Also as noted in Section 12.12.3, Class 2 SSCs intended to support Class 1 SSCs after 72-hours following a design basis fault are designed so they are designed to survive hurricane wind loading.

12.13 OFFSITE FIRE AND SMOKE

Sources of fires considered in this section are:

- Marine-based
- Land-based (including bush and forest fires)

Marine fires, such as fires aboard a ship, and land-based fires (for example, bush or forest fires) pose a threat to nuclear safety through the possibility of smoke and toxic or hot fumes entering the building and affecting personnel and equipment, restricting access to the site or

affecting off-site power. Man-made external fire hazards may arise from fixed hazardous facilities or from transport of combustible material. These hazards should be assessed on a site-specific basis.

The effects of fires external to the site boundary are considered to be bounded by internal fires onsite originating outside plant buildings, and are addressed in Chapter 11. Accordingly, smoke infiltrating the site boundary, rather than fire, is the consideration of this section.

12.13.1 Safety Design Approach

The plant has been designed so that external fire and smoke will not prevent the delivery of Category A safety functions.

12.13.2 Nuclear Island Ventilation System

The NI heating and ventilation air intakes will detect smoke, and their intakes will be isolated, thus, preventing ingress of smoke.

The heating, ventilation, and air conditioning (HVAC) system of the AP1000 design NI comprises three separate ventilation systems:

- NI non-radioactive ventilation system (VBS)
- Radiologically controlled area ventilation system (VAS)
- Containment air filtration system (VFS)

In addition, the radwaste, annex, turbine and diesel generator buildings are designed with independent ventilation systems and are not discussed as part of this chapter.

12.13.2.1 Nonradioactive Ventilation System

The VBS intakes are designed such that upon detection of external smoke, fire dampers are closed so that smoke does not reach safety-significant systems.

The outside air of the MCR and the control support area (CSA) is continuously monitored by smoke detectors located at the outside air intake plenum and the return air is monitored for smoke upstream of the supply air handling units.

The VBS isolates the MCR and or the CSA area from the normal outdoor air intake and provides 100 percent recirculation air to the MCR and CSA areas when a high concentration of smoke is detected in the outside air intake.

The portion of the VBS servicing the auxiliary building is designed so that smoke, hot gases and fire suppressant will not migrate from one fire area to another. Fire or combination smoke and fire dampers are provided to isolate each fire area from adjacent fire areas. These combination smoke and fire dampers close in response to smoke detector signals or in response to the heat from a fire.

12.13.2.2 Radiologically Controlled Area Ventilation Subsystem

The VAS serves radiologically controlled equipment. The ventilation air of the VAS system is continuously monitored by smoke detectors located in the common ductwork downstream of the supply-air handling units and upstream of the exhaust fans.

12.13.2.3 Containment Air Filtration System

VFS is located on the NI and the seismic C-II part of the annex building.

Fire dampers are provided where the ductwork penetrates a fire barrier to maintain the fire resistance rating of the fire barriers. The supply of outside air is continuously monitored by a smoke detector located in the ductwork downstream of the supply-air handling units.

12.13.3 Smoke Barriers

The design of the AP1000 plant is such that routes of entry of external smoke (other than air intake systems) are blocked by fire doors, and smoke entry is unlikely because of long transition spaces.

External fires could affect SSCs or operations if smoke were to enter the MCR or the remote shutdown room. There are no likely smoke paths into the MCR from surrounding areas, with the exception of the HVAC ductwork which is previously addressed. For smoke to leak into the MCR through corridors and doors, smoke would have to pass from within the annex building through a set of fire doors and through the two MCR vestibule doors (one vestibule door will always be closed). The MCR and CSA are positively pressurised, thus, eliminating the potential for smoke to migrate from a low-pressure area to a high-pressure area through the doors and corridors.

12.13.4 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, smoke-induced damage outside the NI will not prevent the delivery of Category A safety functions.

12.13.5 Combined or Consequential Hazards

No credible combination of hazards has been identified that could result in more impact on nuclear safety than would be achieved by each occurring independently.

There will be no loss of Class 1 SSCs from consequential hazards arising from an external fire, as no credible consequential hazards have been identified as a result of an external fire.

12.14 OFF-SITE MISSILES

The term “missile” is used to describe a moving object that is capable of striking any component of the plant. Malicious missiles, whether explosive or not (for example, improvised explosive devices and rockets), are specifically excluded from consideration. Missiles covered in this chapter include:

- Wind-induced missiles
- From adjacent sites

12.14.1 Safety Design Approach

The plant has been designed so that an external missile within the design basis will not prevent the delivery of Category A safety functions.

12.14.2 Wind Borne Missiles

12.14.2.1 Nuclear Island Tornado Missile Withstand

Class 1 SSCs are enclosed in structures that are designed to withstand the design basis missiles. Impacting missiles into the NI protective barriers are defined in the Reference 12.16 Section 5.2.3.3. Three such design basis missiles are considered to be tornado borne:

- A (deformable) 1814.4-kg (4000 lb) automobile with an impact velocity of 47 m/s (105 mph) horizontally or 33 m/s (74 mph) vertically considered to be able to impact at all plant elevations up to 9.1m (30 ft) above grade. The assessment for this missile and impact velocities were subsequently extended up to 59 m (193 ft) above grade in Reference 12.7 to address higher wall elevations and roof impacts.

- A rigid missile with a mass of 125 kg (275 lb) and 203 mm (8 in) in diameter impacting with a horizontal velocity of 47 m/s (105 mph) or 33 m/s (74 mph) vertically.

- A rigid, solid sphere with a mass of 0.065 kg (0.14 lb)and sufficiently small size (25 mm (1 in) diameter) to pass through any openings in the protective barriers with an impact velocity of 47 m/s (105 mph).

The methodology for justifying missile and protective structures for postulated missiles is discussed in Section 16.5.1.3. One formula for estimating the penetration of steel plate is from the Ballistic Research Laboratory cited in the R3 Impact Procedure (Reference 12.45) which is the recognised impact procedure manual within the UK nuclear industry. The Ballistic Research Laboratory formula employs a rigid missile, which is a conservative assumption as all the energy is assumed to be dissipated into the target rather than being partially absorbed by the missile itself.

Class 1 structures are permitted to sustain local missile damage such as partial penetration and local cracking or permanent deformation or both, provided that structural integrity is maintained and Class 1 SSCs required to function during or after passage of a tornado are not subject to damage by secondary missiles, such as from concrete spalling.

12.14.2.2 AP1000 Design is Bounding of UK Design Basis Missile Loading

Reference 12.3 refers to the Meaden Report (Reference 12.41, Section 5.14) for UK tornado risk assessment which cites several missile configurations:

- 63-kg (138.9 lbs) timber plank (0.1 m x 0.3 m x 3.65 m (3.9 in x 11.8 in x 143.7 in)) at a speed of 32.2 m/s (72 mph) horizontally or 21.5 m/s (48 mph) vertically at a height up to 60 m (196 ft).

- 34.5-kg (76 lbs) steel pipe (75 mm (2.95 in) diameter x 3 m (118.1 in) long) at a horizontal speed of 22.3 m/s (49.88 mph) or 14.8 m/s (33.1 mph) vertically, at a height of up to 30 m (98.4 ft).

In consideration of the AP1000 design basis for missiles, as previously discussed, it can be concluded that the AP1000 design parameters exceed the likely UK extremes for tornado effects.

12.14.3 Missiles from Adjacent Sites

Deflagrations and detonations on adjacent facilities have the potential to result in missiles that could impact the site structures. Such events will be assessed on a site-specific basis, although it is unlikely that such missiles would be outside the design basis missiles defined in Section 12.14.2.

12.14.4 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, design basis missile-induced damage outside the NI will not prevent the delivery of Category A safety functions.

Class 2 SSCs intended to support Class 1 SSCs after 72-hours that are located outside the NI are designed for impact from hurricane borne missiles defined in Reference 12.16 (Section 5.2.3.2). Offsite SSCs provide a backup to the installed SSCs.

12.15 BIOLOGICAL FOULING

12.15.1 Safety Design Approach

The ONR technical assessment guide on external hazards (Reference 12.3, Annex 7) states that such hazards should be considered as part of SAP EHA.1 addressing the general need to cover all credible hazards.

The plant has been designed such that biological fouling will not prevent the delivery of Category A safety functions. This is achieved in the design and operation by:

- Plant cleanliness
- Screens on air and water inlets
- Inspection of screens

There have been instances on UK nuclear power stations where micro-organisms, birds, animals, and fish have entered into safety-significant areas and have compromised nuclear safety. The principal mechanisms that have been observed are blocking of cooling water systems, gnawing through electrical cables, and blocking of drains with nest material; there are potentially other mechanisms that should also be considered. The hazards are managed by the licensee or operator control programmes and good housekeeping. However, damage to electrical and control cabling (caused by rodents) may affect Class 1 and Class 2 systems; this is addressed in Chapter 11.

A related issue, outside the scope of assessment of external hazards and plant safety, is the possibility of radioactive contamination being spread beyond controlled areas by animal life. This is generally managed on site by measures aimed at limiting the population of animals and birds, and even low-level activity will not be readily accessible to them as the radioactivity is contained within structures and not open to the environment.

Examples of land or air-based biological hazards are:

- Rodents and birds
- Insects (airborne swarms, infestation)
- Tree roots (site-specific)

Examples of water-based biological hazards are:

- Seaweed (marine growth)
- Fish or jellyfish
- Microbes (organic materials)

12.15.2 Land and Air Inlet Systems

Potential hazards from animal entry include blockage to the safety-significant air inlets to the NI buildings.

The use of the appropriate building design and construction codes, which ensure reasonable precautions are taken, supplemented with routine inspections and surveillance by the licensee or operator throughout the life of the plant, will preclude the entry of animals to the AP1000 plant buildings. Grounds maintenance, to include the maintenance of trees on and near the site, will be site-specific.

Large quantities or swarms of insects could conceivably cause the blockage of intakes such as the HVAC or other systems that rely on an air supply to maintain their function. Although there are no AP1000 design features to explicitly protect against ingress of an infestation, measures to preclude bird and animal entry are applicable such as:

- Intake filters for instrument air, service air and high-pressure air compressors.
- Shield building air inlets are fitted with screens.
- The MCR and CSA have features to isolate these areas from the normal outdoor air intake and also provide filtered outdoor air.

12.15.3 Water Inlet Systems

The NI structures are designed to resist biological fouling through the protective features used in the design of the water inlet systems. The AP1000 design does not require external water sources to achieve Category A and post 72-hour Category B safety functions and these systems are classified accordingly.

12.15.4 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, biologically induced damage outside the NI will not prevent the delivery of Category A safety functions.

Design features to protect against biological entry of Class 2 and 3 water systems include:

- The SWS supplies cooling water to remove heat from cooling water system heat exchangers in the turbine building. Chemical treatment processes are designed to limit biological film formation in the SWS.
- The potable water system is designed to furnish water for domestic use and human consumption. Tests for microbiological and bacteria presence in potable water are conducted periodically.

There are no safety-significant water systems outside the NI that could adversely affect safe shutdown by the entry of biological agents. The effects of damage to SSCs within non-NI buildings and the structures of these buildings or on safety significant plant located on the NI are bounded by the consideration of seismic hazards.

12.15.5 Combined or Consequential Hazards

There will be no loss of Class 1 SSCs from combined hazards arising from a biological fouling event as no credible combination of hazards has been identified that could result in greater degradation of nuclear safety than would be achieved by each occurring independently.

There will be no loss of Class 1 SSCs from consequential hazards arising from a biological fouling event as no credible consequential hazards have been identified as a result of such an event.

It is possible that flooding or high sea levels could increase the amount of biological fouling. This will be a site-specific issue dependent upon the location of the service water supply connection; adequate inspections will be needed to maintain connection pathways.

12.16 ELECTROMAGNETIC INTERFERENCE AND LIGHTNING

12.16.1 Safety Design Approach

The plant has been designed so that EMI and lightning will not prevent the delivery of Category A safety functions.

12.16.2 Electromagnetic Interference

The following have been considered as external sources emitting EMI:

- **Natural EMI sources** – Sources that are associated with natural phenomena. They include atmospheric charge or discharge phenomena such as lightning and precipitation static; extraterrestrial sources including radiation from the sun; and galactic sources such as radio stars, galaxies, and other cosmic sources.

- **Man-made EMI sources** – Sources associated with man-made devices such as power lines.

- **Conducted EMI** – Noise signals transmitted via electrical conduction paths (such as wires and ground planes).

- **Radiated EMI** – Electric and magnetic fields transmitted through space from source to receptor.

- **Intentional radiating emitters** – Emitters whose primary function depends on radiated emitters. Examples include electronic licensed communication systems such as communication, navigation, and radar systems.

- **Unintentional (incidental) radiating devices** – Devices that radiate radio frequencies, but that is not considered their primary function.

- **Restricted radiating devices** – Devices that intentionally use electromagnetic radiation for purposes other than communication or data transfer (such as operating systems and wireless microphones).

Although the man-made EMI sources previously listed are defined as external EMI sources to the plant site, they can be considered in conjunction with internal EMI sources within the site boundary and consequently are addressed in Chapter 11. Natural EMI sources are considered to be bounded by lightning and are addressed in Section 12.16.3.

All Class 1 electrical power is provided from the Class 1 direct current (dc) power system: No AC power system is required to operate the Class 1 safety systems. The Class 1 system provides 250 V DC power for Class 1 SSCs and vital control instrumentation loads including monitoring and control room emergency lighting. It is required for safe shutdown of the plant during a loss of AC power and during a DBA with or without concurrent LOOP.

The protection and safety monitoring system (PMS) has electrical surge withstand capability and can withstand EMI, radio frequency interference and electrostatic discharge conditions that would exist before, during and after a DBA without loss of safety function.

12.16.3 Lightning Protection

The AP1000 design lightning protection system, consisting of air terminals and ground conductors provides protection of exposed structures and buildings housing safety-related and fire protection equipment in accordance with National Fire Protection Association (NFPA) 780 (Reference 12.50). Also, lightning arresters are provided for the transmission lines and at the high-voltage terminals of the outdoor transformers. The isophase bus circuit, which carries a large current, connecting the main generator and the main transformer and the medium-voltage switchgear is provided with lightning arresters. In addition, surge suppressors are provided to protect the plant instrumentation and monitoring system from lightning-induced surges in the signal and power cables that are connected to external devices.

Direct-strike lightning protection for facilities is accomplished by providing a low-impedance path by which the lightning strike discharge can enter the earth directly. The direct-strike lightning protection system, consisting of air terminals, interconnecting cables, and down conductors to ground, are provided external to the facility in accordance with NFPA 780 (Reference 12.50). The system is connected directly to the ground to facilitate dissipation of the large current of a direct lightning strike. The lightning arresters and the surge suppressors connected directly to the ground provide a low-impedance path to the ground for the surges caused or induced by lightning. Thus, fire or damage to facilities and equipment resulting from a lightning strike is avoided.

The design of direct-strike lightning protection and the associated grounding depends on the lightning activity at the plant site and the soil resistivity of the ground. These are site-specific issues and need to be considered on a site-by-site basis.

Lightning is not considered to have a significant impact on the operation of the plant (Reference 12.8, Table I.2).

12.16.4 Systems, Structures, and Components Outside the Nuclear Island

As there are no Class 1 SSCs outside the NI, EMI and lightning-induced damage outside the NI will not prevent the delivery of Category A safety functions.

12.16.5 Combined or Consequential Hazards

Provision of lightning protection to the relevant standard will eliminate the potential for fire in protected buildings and structures. Lightning strikes to surrounding areas, buildings or structures may initiate a fire within the site boundary. The consequences of on-site fire are covered in Section 11.2 and demonstrated to not prevent the delivery of Category A and post-72-hour Category B safety functions.

No other credible combined hazards have been identified involving EMI or lightning.

12.17 CONCLUSIONS

This chapter provides specific supporting information on the nuclear safety withstand of the AP1000 plant against design basis external hazards.

Tables 12-1 and 12-2 identify the external hazards grouping for man-made and naturally occurring hazards respectively. For each hazard category, potential source(s) of the hazards are identified. Postulated initiating events that could result from the identified sources are cited.

The identified groups of hazards in Tables 12-1 and 12-2, after the screening process have been reduced to 11 generic external hazards categories. These have been assessed in this chapter against the Class 1 SSCs of the AP1000 design to ensure that the ability to deliver Category A safety functions is not compromised.

Where relevant, the effect of combined and consequential hazards has been reviewed. The majority of the external hazards assessed in this document fall within the bounds of the generic site parameters (see Table 12-4) and may thus be regarded as within the design basis of the plant. This is mainly due to the inherent robustness of the AP1000 design.

The following paragraphs summarise the safety design approach for each of the hazards considered in detail in Sections 12.6 to 12.16.

12.17.1 Seismic Hazards

The AP1000 plant has been designed so that an earthquake with a 0.3g PGA, defined as the SSE, will not prevent the delivery of Category A safety functions.

The UK design basis RS horizontal acceleration with a PGA of 0.25g marginally exceeds the AP1000 design SSE RS in the range of 8 to 12Hz. However, the probabilistic seismic margin analysis utilising a 0.5g review level earthquake provides confidence in the deterministic 0.3g PGA assessment undertaken for the AP1000 design and that the loading demand of the UK design basis RS will be met. Accordingly, it should be confirmed on a site-specific basis there will be no loss of Category A safety functions resulting from a UK design basis earthquake. SMA provides reasonable assurance that the AP1000 design can with withstand BDB earthquakes

12.17.2 External Flooding

The plant is designed for a floodwater level up to site grade elevation at 100 m (reference elevation 100.0 ft). At the time of site licensing, the applicant will need to demonstrate that the maximum flood from sources such as streams and rivers, potential dam failures, probable maximum surge, and tsunami flooding is below the actual site grade elevation.

The design can conservatively manage UK design basis rainfall, even allowing for climate change over the life of the facility.

12.17.3 Accidental Aircraft Impact

Aircraft impact has been screened-out because it requires a site-specific location to fully substantiate. It should be confirmed on a site-specific basis that accidental aircraft crash frequencies and UK legislation that restricts flying in the vicinity of UK nuclear sites are applicable to the specific site under consideration.

12.17.4 Explosion

In the context of design for an NPP, design and operating experience has shown that explosive hazard has effects close to and often surpassed by other hazards sources such as impacts, earthquakes and tornado loading.

The risk of an external explosion at UK sites has been reduced by the introduction of COMAH regulations.

Various detector and alarms (for example, seismic detectors) are available to alert the operators that an external explosion event has occurred and if necessary take appropriate action; e.g., to shut the reactor down.

An explosion involving detonation of high explosives, munitions, chemicals or liquid and gaseous fuel from facilities and activities in the vicinity of the plant will be considered on a site-specific basis as the design of the AP1000 plant design has an inherent capability to withstand external explosions.

12.17.5 Extreme Ambient Temperature

The minimum recorded UK temperature and the 1 in 10,000 year return period minimum ambient temperature are bounded by AP1000 design minimum ambient design temperature. Taking into account climate change, which is predicted to increase the minimum ambient air temperature, will not impact this assessment.

The maximum recorded UK ambient temperature and the UK maximum temperature for a 1 in 10,000 year return period, including climate change, are bounded by the AP1000 plant maximum design temperature.

The AP1000 UK design specifies that the service water will be cooled via cooling towers (which act as the heat sink) and therefore sea water cooling is not required.

12.17.6 Extreme Wind

The AP1000 design basis tornado wind velocity for a Class 1 structure bounds the maximum recorded and 1 in 10,000 year event tornado velocity. Climate change may affect the

frequency and intensity of future UK tornadoes; but over the lifetime of the plant it is unlikely to exceed the design basis tornado velocity of the AP1000 design.

The AP1000 design wind loading bounds the UK 3 second gust wind loading for a 1 in 10,000 year event.

12.17.7 Other Extreme Meteorological Effects

The shield and auxiliary buildings roofs of the NI are designed for a uniform snow load that bounds the maximum UK snow for uniform loading for a 1 in 10,000 year event.

It is considered that the design basis external missiles discussed in Section 12.14 bound snow avalanching from the roof of the shield building onto the low level roofs below, and therefore, will not threaten any Class 1 SSCs and will bound the potential for avalanche from any other NI buildings.

Substantial lead time will ensure that preventative measures can be put into place so that drought will not affect the safety functions. Due to the nature of this hazard, there will be a substantial lead-time before drought impacts upon the plant. Ultimately, the supply of water for plant systems and fire protection will be governed by monitoring procedures such that any shortfalls will stimulate protective actions by operators.

12.17.8 Offsite Smoke and Fire

Any fires that penetrate the site boundary are considered to be internal fires and are addressed in Chapter 11. Accordingly, smoke infiltrating the site boundary, rather than fire is the consideration of this chapter.

The NI heating and ventilation system air intakes will detect smoke, and the intakes will be isolated, thus preventing ingress of smoke.

12.17.9 Offsite Missiles

AP1000 design Class 1 SSCs are enclosed in structures that are designed to withstand the three design basis missiles. These design basis missiles bound the identified UK design basis external missile loading.

12.17.10 Biological Fouling

Potential hazards from animal entry include blockage to the safety-significant air and water inlet systems of the NI.

The use of the appropriate building design and construction codes, which ensure reasonable precautions are taken, supplemented with routine inspections and surveillance throughout life will preclude the entry of animals to the AP1000 site buildings. Ground maintenance, to include the maintenance of trees on and near the site, will be site-specific.

Ingress of birds and insects is prevented by screens, filters and isolation from normal outdoor air on air intakes.

A common hazard for NPPs is biological fouling entering through open water systems. The AP1000 design has taken this into account by including features to prevent and protect against such occurrences.

12.17.11 Electromagnetic Interference and Lightning

The PMS has electrical surge withstand capability and can withstand EMI, radio frequency interference, and electrostatic discharge conditions that would exist before, during, and after a DBA without loss of safety function for the time required to perform its function.

The lightning arresters and the surge suppressors connected directly to ground provide a low-impedance path to ground for the surges caused or induced by lightning. Thus, fire or damage to facilities and equipment resulting from a lightning strike is avoided.

12.17.12 Summary of Key Conclusions

This chapter has considered the threat to nuclear safety from identified UK external hazards on the AP1000 plant at a generic site. The PCSR and supporting references demonstrate that the AP1000 plant has an adequate design to ensure that the identified external hazards will not prevent the delivery of Category A safety functions.

A number of site-specific assessment requirements have been identified in this report for specific external hazards. In addition to these hazard-specific assessments, there are a number of overall site requirements including accident or incident management and emergency preparedness that will need further consideration at the appropriate stage.

Tables 12-1 and 12-2

The following list of external hazard initiating events is compiled from a variety of sources (References 12.3, 12.8, 12.9, 12.10). The list is divided into two tables: man-made events and natural events.

For the postulated initiating events, the potential consequences are identified and the safety features that are in place to mitigate the consequences are identified. For each initiating event, one of the following six outcomes is stated:

1. The initiating event is addressed in this chapter.

2. The initiating event can be screened out because of a low probability of occurrence or negligible consequences.

3. It can be bounded by another initiating event.

4. The initiating event can be considered under another hazard grouping.

5. The initiating event is specific to a site and consequently requires site-specific information and will be considered in a site-specific PCSR.

6. The initiating event (e.g., fire) is addressed in Chapter 11.

Table 12-1: External Hazards Man-Made Initiating Events

Hazard Grouping		Hazard Source	Initiating Event	Consequence	Mitigating or Safety Feature	Comment
1.	Explosions	Oil refinery Chemical plant Nuclear plant Pipelines Mining Quarrying Marine	Site-specific but given generic consideration in Section 12.9. AP1000 plant requires design review if frequency > 1.0E-05/yr.			
			Deflagrations Detonations	Over-pressure: Collapse of parts of the plant or disruption of systems and components (Reference 12.9)	-	Pending site-specific information regarding explosion risks, the concrete construction of the AP1000 NI should be capable of withstanding substantial overpressures (see Section 12.9.1).
				Fire	-	Considered in Section 12.13 to be addressed as an internal hazard fire (Reference PCSR Chapter 11).
				Ground vibrations	AP1000 plant designed for a design basis earthquake.	Screened-out; pending site-specific information, considered to be bounded by the SSE seismic ground motion.
				Missiles	If the plant had been designed to accommodate the effects of externally generated missiles resulting from other events such as a hurricane, typhoon, tornado, or aircraft crash, the effects of missiles generated by an explosion may already have been taken into account (Reference 12.10, Paragraph 6.10).	Pending site-specific information, addressed by design basis external missiles in Section 12.14.
				Temperature	-	Considered in Item 2 below.
				Release of toxic gases	-	Screened-out as site specific. AP1000 plant requires design review if frequency >1.0E-05/yr (Section 12.1).
				Release of radioactive substances	-	Addressed Chapter 11.

Table 12-1: External Hazards Man-Made Initiating Events (cont.)

Hazard Grouping		Hazard Source	Initiating Event	Consequence	Mitigating or Safety Feature	Comment
2.	Fire	Oil refinery Chemical plant Nuclear plant Pipelines Mining Quarrying Marine Bush/forest Seismic	Conflagration	Fire	-	Fire is addressed in Chapter 11 as to the affect on the NPP an external fire has to transverse the site boundary – where by definition it becomes an internal hazard.
				Temperature: Impaired habitability of main control room, disruption of systems and components, ignition of combustibles	The NI comprises wholly of concrete clad structures that house the Class 1 SSCs and therefore affords protection from external heat sources.	Screened-out: externally initiated fire is an initiator to fire within the NI. Survivability of Class 1 SSCs in a design basis fire is demonstrated in Section 11.2.
				Sparks	The NI structures and equipment will protect against smoke and debris entering the buildings.	Screened-out: ingress into the NI is addressed the same as smoke.
				Smoke, dust: Blockage of intake filters, impaired habitability of control and other important rooms		Considered in Section 12.13.
3.	Missiles	Turbine disintegration Wind borne Deflagrations Detonation	Impact	Penetration, perforation or spalling of systems and components that would impair Class 1 safety functions.	Designed to withstand design basis wind borne missiles.	Turbine disintegration from AP1000 turbine building is considered in Section 11.6. Adjacent plant will be considered in site-specific assessment. Missile impact considered in Section 12.14.
			Loss of grid	-	Off-site power is assumed to be unavailable if missile trips a turbine-generator or reactor protection system.	Screened-out: the passive reactor protection systems can maintain safe shutdown conditions after DBE, following a LOOP for an indefinite time with support from post 72 hour SSCs including either onsite or offsite ancillary equipment.

Table 12-1: External Hazards Man-Made Initiating Events (cont.)

Hazard Grouping		Hazard Source	Initiating Event	Consequence	Mitigating or Safety Feature	Comment
4.	Air traffic Corridor	Light aircraft		Impact onto the NI	UK legislation restricts flying in the vicinity of UK sites (considered in Section 12.8).	Screened-out Requires a site-specific location to fully substantiate (e.g., in terms of target area).
		Helicopters			UK legislation restricts flying in the vicinity of UK sites (considered in Section 12.8).	
		Large or small Transport Aircraft			Has a probability of occurrence of < 1.0E-07 per year (see Appendix 12A).	
5.	Aircraft crash: military			Impact onto the NI	Has a generic probability of occurrence of < 1.0E-07 per year (see Appendix 12A).	Screened-outRequires a site-specific location to fully substantiate.
6.	Windfarms		Missile generation	Impact onto the NI	-	Considered in Item 3 above.
			Electromagnetic Interference	-	-	Considered in Item 22 below.
7.	General infrastructure	Electrical sub stations, Phone masts	Electromagnetic Interference	-	-	Considered in Item 22 below.
		Dam failure	Flooding	-	-	Site-specific considered generically in Item 13 below.

Table 12-1: External Hazards Man-Made Initiating Events (cont.)

Hazard Grouping		Hazard Source	Initiating Event	Consequence	Mitigating or Safety Feature	Comment
8.	External Transport	Liquified natural gas (LNG) vessel	Fire	Loss of Category A safety functions	-	Considered in Item 2 above.
			Missile generation	Impact onto the NI	-	Considered as a DBE in Item 3 above.
			LNG explosion	Over-pressure: Collapse of parts of the plant or disruption of systems and components (Reference 12.9)	-	Considered in Item 1 above.
		Ship collision	Impact	-	-	Screened-out as site specific.
			Oil contamination	Blockage or damage of plant water intakes	-	Addressed in Item 9 below: Non-biological fouling.
		Railway	-	Damage to the infrastructure of the AP1000 site	-	Screened-out as site specific.
		Road vehicles	-	Impact into the NI	AP1000 design basis missile considers an automobile impacting at 47 m/s.	Considered in Section 12.14.2.1 as a tornado borne missile.
		Barges	-	Damage to the infrastructure of the AP1000 site.	-	Screened-out as site specific.
9.	Non-biological fouling	-	Oil contamination	Blockage or damage of plant water intakes	AP1000 has protective features to prevent ingress through its open water systems.	Addressed by Item 20 below as the same precautions apply for the water inlet systems.
		-	Rubbish or domestic waste		-	Addressed by Item 20 below: biological phenomena.

Table 12-1: External Hazards Man-Made Initiating Events (cont.)

Hazard Grouping		Hazard Source	Initiating Event	Consequence	Mitigating or Safety Feature	Comment
10.	Eddy currents into ground (Reference 12.9)	-	Electric potential into ground	-	-	Bounded by lightning and earthing considerations.
11.	Toxic chemical	Containment leak from adjacent plant	-	Release to the environment	-	Screened-out as site specific. Requires design review if frequency >1.0E-5/yr. (Section 12.1)

Table 12-2: External Hazards Naturally Induced Initiating Events

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
12.	Seismicity	Earthquake ground motion	Internal and external structural and infrastructure damage.	AP1000 has been designed to a 0.3g PGA earthquake loading.	Considered in Section 12.6 as a 1 in 10,000 UK DBE.
		Tsunamis	"	"	Addressed in Item 13 below: flooding.
		Seiches	"	"	Addressed in Item 13 below: flooding.
		Long period ground motion (Reference 12.3, Table 1)	"	"	Considered in Section 12.6.
		Liquefaction	"	"	Addressed in Item 26 below: surrounding influences.
		Subsidence	"	"	
		Settlement	"	"	
		Fire	"	"	Seismically initiated events are considered as generic internal fires addressed in Chapter 11.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
13.	Flooding	Tides		The AP1000 design; e.g., orifices in the NI, are sited above the level of the maximum probable flood so as not to allow water ingress. Basemat and exterior wall of the NI are designed to resist upward and lateral pressures caused by the probable maximum flood	Pending site-specific information addressed by design basis external floods in Section 12.7.
		Sea- and river-based flood	Overturning or sliding of the NI as described in Section 12.7.6.		
		Rain	Flooding of NI internal structures	Ponding of water on the sloping roofs of the NI cannot occur. The design capacity of the NI to remove rain water bounds the 1 in 10,000 year return period design basis rain intensity value.	Considered in Section 12.7.2 as a 1 in 10,000 UK DBE.
		Barometric effects	Increased water levels	-	Included as a contribution to storm surges in Section 12.7.4.
		Tsunamis	Overtopping of sea defences	The heights of tsunami waves arriving close to the shore are comparable to those in typical storm surges. All major UK centres of population have flood defence infrastructure designed to cope with the expected range of surges (Reference 12.24).	Pending site-specific information, considered generically in Section 12.7.5.
		Seiches	"	-	Bounded by tsunamis in magnitude (Reference 12.23, Section 3.2(11)).
		Storm surges	Overtopping of sea defences	-	Site specific: Predicted trends in storm surges due to climate change considered in Section 12.7.4.1.
		Ground water levels	Flotation, uplift of the NI.	The AP1000 plant is designed for a normal groundwater elevation up to plant elevation 99.39 m (98 ft) above.	Site specific. Licence applicant will address site–specific information on ground water Pending site-specific information, considered generically in Section 12.7.3.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
13. (cont.)	Flooding (cont.)	Snow/Ice melt	Flooding of NI internal structures	"	Screened-out considered as contributing to external flooding.
		Wind induced waves	Overtopping of sea defences	"	Screened-out pending site-specific information considered generically as a contribution to storm surges in Section 12.7.4.
		Natural obstruction (Dam forming) in water courses	Flooding of site/ disruption to plant infrastructure	"	Pending site-specific information is considered to be addressed under external flooding.
		Channel changes	Flooding of site/ disruption to plant infrastructure	"	Screened-out as site-specific issue.
		Surface run-off	Flooding of site/ disruption to plant infrastructure	"	Screened-out as site-specific issue.
		Landslides or avalanche into bodies of water	Disruption to plant/ plant infrastructure	"	Screened-out as a site-specific issue. Site-specific analysis should be carried out to ensure that there is no risk from surrounding land formations.
		Failure of water retaining structures (Dam Failure)	Flooding of site/ disruption to plant infrastructure	"	Site specific issue.
		Climate Change	Increased flood water depth	"	Considered in Sections 12.7.2 and 12.7.4.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
14.	Extreme Ambient Temperature	Low ambient air temperature	Embrittlement/ equipment malfunction	UK minimum ambient temperature for a 1 in 10,000 year event bounded by AP1000 design basis.	Considered in Section 12.10.2.1 as a 1 in 10,000 UK DBE.
		High ambient air temperature	Equipment malfunction.	UK maximum ambient temperature for a 1 in 10,000 year predicted bounded by AP1000 design basis.	Considered in Section 12.10.3.1 as a 1 in 10,000 UK DBE.
		Extremes of ambient ground temperature	-	-	Screened-out as a site-specific issue dependent on site characteristics.
		Extremes of ambient sea/river temperature	Blockage of plant water outflows or coolant water.	-	The AP1000 design is not dependent on sea and river temperatures as the service water removing heat from the heat exchangers cooling water of the UK AP1000 design envisages the service water will be served via cooling towers to act as a heat sink and therefore does require sea water cooling (see Sections 12.10.2.2 and 12.10.3.2).
		Solar effects	Enhances ambient temperature on external surfaces	-	Pending site-specific information, considered generically in Section 12.10.3.1.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
15.	Meteorological	Snow	Roof damage	UK maximum snow loading for a 1 in 10,000 year event is bounded by AP1000 design basis.	Considered in Section 12.11.2 as a 1 in 10,000 UK DBE.
		Snow/Ice air inlet Blockage	Blockage to PCS	-	Considered in Section 12.11.2.
		Hail		-	Considered as a missile – other missiles bound (Reference 12.8, Table I.2). Bounded by design basis missiles considered in Item 3 above.
		Roof Avalanche	Roof Damage	-	For the AP1000 design, sliding snow avalanching from the shield building which is the biggest/highest building on the NI would not be expected to threaten adjacent structures on the NI as this scenario would be bounded by the design basis missiles considered in Item 3 above (see Section 12.11.2.2).
		Frost	Water freezing	-	Screened-out: Bounded by snow and ice considerations (Reference 12.8, Table I.2.).
		Humidity	Condensation of water vapour on cool surfaces	-	Screened-out: Conventional engineering design provisions such as electrical systems situated outdoors will provide adequate protection and humidity does not represent a significant hazards and will not be considered further.
		Frazil (see Table 12-3 for definition)	-	-	Bounded by sea ice.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
15. (cont.)	Meteorological (cont.)	Sea Ice	Blockage of plant water outflows or coolant water.	-	Screened-out as a site-specific issue: Water supply sources will be addressed by the licence applicant.
		Rime Ice (see Table 12-3 for definition)	Roof damage. Downing of grid. cables	-	Screened-out: Considered bounded by snow loading. The passive reactor systems can maintain safe shutdown conditions following a LOOP for an indefinite time post 72 hours with support from post 72 hour ancillary equipment and onsite and offsite water sources..
		Ice Storm	Damage to fabric of building	-	Screened-out: Considered bounded by snow and design basis external missile loading.
		Drought	Effect on building Foundations	Substantial lead time will ensure that preventive measures can be put in place to ensure that drought will not affect safety functions.	Considered in Section 12.11.3.
16.	Extreme Wind	Hurricane (see Table 12-3 for definition)	Structural damage	AP1000 design tornado wind velocity bounds the hurricane wind velocity (see Table 12-4).	Screened out: by the location of the UK. Remnant of North Atlantic hurricanes are reflected in UK meteorological data (see Section 12.12.3).
		Cyclones			
		Tropical Typhoons (see Table 12-3 for definition)			
		Tornadoes/Water Spouts (see Table 12-3 for definition)	Structural damage	AP1000 tornado design for Class 1 structures is bounding of UK historical tornado data.	Tornado governs water spouts (Reference 12.8, Table I.2). Considered in Section 12.12.2.
		Wind: Sustained Wind: Gusts	Structural damage	Extreme UK Wind Loading for a 1 in 10,000 year event, is bounded by the AP1000 design basis of the plant.	Considered in Section 12.12.4 as a 1 in 10,000 UK design basis.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
17.	Airborne Activity	Abrasive dust	Blocking of penetrations/vents and disruption to the grid supply	-	Judged equivalent. Sand storms considered in Section 12.12.5.
		Sand storms		-	
		Sea spray	-	-	Considered in Section 12.12.6.
		Fog/Mist	Could increase the probability of human made hazard involving surface vehicles or air.	-	Screened-out: A phenomenon which by itself has no significant impact on the operation of a nuclear power plant and its design basis (Reference 12.8, Table I.2).
18.	Volcanic Activity	Volcanic Activity	Structural collapse	-	Screened-out: For a UK site there is no indigenous volcanic activity. Therefore assumed to have a probability of occurrence of less than 1.0E-07/yr (Reference 12.8, Table I.2). There are currently no design criteria to counter volcanic activity.
		Volcanic Ash	Blocking of penetrations/vents.	-	Screened out: The distance from the UK to any active volcanoes is such that ash particulate will be small and well dispersed.
19.	Geotechnic Faults/Fissures	-	-	-	Screened-out: There are no known surface faults in the UK.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
20.	Biological Phenomena	Rodents Birds Fish Jellyfish Insects Marine growth Tree roots Microbes Leaves	Blockage of inlets, vents and penetrations. Damage by rodents and corrosion resulting from bird residue.	-	Considered in Section 12.15.
21.	Natural Collisions	Tree Logs	Blockage of water inlets	-	Screened-out: Bounded by ice blockage in Item 15 above.
22.	Electromagnetic Interference	Solar flares Static electricity Electromagnetic pulse External EMI Variation in the grid Frequency	Fire Electric & electronic malfunction. Electrocution.	-	Considered in Section 12.16.
23.	Lightning	-	Fire Electric & electronic malfunction. Electrocution	-	Considered in Section 12.16.
24.	Glaciations	-	-	-	Screened-out as a site-specific issue.

Table 12-2: External Hazards Naturally Induced Initiating Events (cont.)

Hazard Grouping		Initiating Events	Consequence	Mitigating or Safety Feature	Comment
25.	Meteorite/ Asteroid	Meteorite	Impacting of Plant	-	Screened-out: Probability of occurrence. Less than 1.0E-07/yr depending on latitude (Reference 12.8, Table I.2). Therefore can be screen-out owing to their low frequency of occurrence).
		Asteroid		-	Screened-out: Probability of occurrence less than 1.0E-07/yr (Reference 12.47) for an asteroid > 1 km (0.62 mi) in diameter. Therefore is BDB and can be screened out owing to their low frequency of occurrence
26.	Surrounding Influences	Settlement/Subsidence Ground heave Mining Caverns Leaching Contaminated land Radon Geysers Coastal erosion Slope instability Soil stability	-	-	Screened-out as site-specific issues (Reference 12.8, Table I.2).
		Liquefaction	-	-	Screened-out: Site specific. The Licence applicant will demonstrate for soil sites that the potential for liquefaction is negligible for both the soil underneath the NI foundation and the soil adjacent to the NI.

Table 12-3: Hazard Definitions

Deflagration	Is a technical term describing subsonic combustion that usually propagates through thermal conductivity. Deflagrations (Reference 12.10, Paragraph 6.15) are usually associated with relatively dilute gas or vapour for which most of the chemical energy is dissipated in the form of heat.
Detonation	Is a supersonic combustion and propagates through shock compression.
Boiling Liquid Expanding Vapour Explosion	This is a type of explosion that can occur when a vessel containing a pressurised liquid is ruptured.
Precipitation	Is any product of the condensation of atmospheric water vapour that is pulled down by gravity and deposited on the earth's surface.
Frazil Ice	Is a collection of loose, randomly oriented needle-shaped ice crystals in water and resembles slush. It sporadically forms in rivers, lakes and oceans, on clear nights when the weather is colder, and air temperature reaches minus 6°C (42.8°F) or lower. Frazil ice is the first stage in the formation of sea ice.
Rime Ice	A coating of ice; e.g., on grass and trees, formed when extremely cold water droplets freeze almost instantly on a cold surface.
Hurricane	Hurricanes form in the north Atlantic Ocean and the northeast Pacific Ocean, east of the dateline. A hurricane only forms in the tropics where the sea-surface temperature is at least 27°C (80.6°F) in the north Atlantic Ocean and the northeast Pacific Ocean. It is characterised by a large low-pressure centre and numerous thunderstorms that produce strong winds and heavy rain. Collectively, hurricanes, typhoons and cyclones are known as tropical cyclones.
Tornadoes	A major whirlwind is termed a *tornado*, if it reaches a water body (such as a sea, lake or reservoir) it is termed a *waterspout*. A tornado may become a waterspout as the rotation moves from land to sea (and *vice-versa*). A tornado is a violent rotating column of air and is the most intense of all atmospheric phenomena occurring typically in the form of a visible condensation funnel, whose narrow end touches the earth and is often encircled by a cloud of debris and dust. Most tornadoes have wind speeds between 32 m/s and 50 m/s (71.6 mph to 111.8 mph), are approximately 20 to 100 m (65 ft to 328 ft) across, and travel a few kilometres before dissipating. However, the most extreme can attain wind speeds of more than 134 m/s (300 mph), are more than 1.6 km (1 mi) across and can travel for more than 100 km (62 mi).
Typhoons	In the western Pacific hurricanes are called typhoons, and in the Indian Ocean they are called cyclones. Collectively, hurricanes, typhoons, and cyclones are known as tropical cyclones.

Note:

1. The AP1000 wind pressures have been calculated from Reference 12.43 (Table 4), disallowing for gust factor (G) and external pressure coefficient (Cp) which are similar to BS 6399-2 factors.

APPENDIX 12A
AIRCRAFT CRASH FREQUENCY

12A.1 Derivation of Target Area

The ETA of the AP1000 Facility and the NI is estimated from the following relationships:

For light aircraft, small and large transport aircraft and MCA accidents initiated over 2000 feet:

$$ETAA = l.w + 0.8.h(w + l)$$ (Reference 12A.1, Equation 13)

For helicopters:

$$ETAH = l.w + 0.62.h(w + l)$$ (Reference 12A.1, Equation 15)

where,

l is the 'envelope' length equal to the length of the facility;
w is the 'envelope' width;
h is the 'envelope' height.

The values assigned for l, w and h for both the entire AP1000 site and the NI are specified in Table 12A-1.

12A.2 Summary of Aircraft Crash Frequencies for AP1000

Table 12A-2 provides an overall crash rate of 4.8E-07 and 5.13E-06 crashes per year for the NI only and the AP1000 site, respectively. Thus, considering the NI only reduces by an order-of-magnitude the ETA for the entire AP1000 generic site and the corresponding crash frequency per annum.

For the NI, the combined crash rate includes all aircraft types. However, the aircraft that form the greatest risk to the NI by virtue of their mass and velocity are small and large transport aircraft and MCA. However, these classes of aircraft can be screened out as they have crash rates of less than 1.0E-07/yr and are, thus, BDB (Reference 12A.2, Annex 2.2).

The background crash rates quoted for MCA assumes that the site in question is not within an area of high crash concentration, which tends to correspond to areas where low-level flying occurs. There are two such areas in the UK; one in Northern England and the other around Lincolnshire. If the site falls within these zones then a value of 5.81E-05 km-yr^{-1} is applied. If the site falls within a transition zone (i.e., within 50 km of the boundary of a high MCA crash concentration zone), then a reduced crash rate per year is applied as outlined in Reference 12A.3, Paragraph 149. Such a transition zone would apply to areas such as Sellafield and Hartlepool.

APPENDIX 12B
POST-FUKUSHIMA ASSESSMENT

12B.1 Introduction

On March 11, 2011, a magnitude 9 earthquake (on the Richter scale) struck the east coast of Japan. The earthquake, together with the resulting series of large tsunami waves affected several nuclear power facilities, either directly by damaging onsite equipment, or indirectly by impairing the supporting infrastructure, such as the electrical power grid.

Tokyo Electric Power Company Fukushima Dai-ichi Nuclear Power Station faced a particularly challenging situation including a loss of all ac electrical power for four of their six units and a loss of ultimate heat sink (UHS) makeup. Consequently, severe damage to the fuel and a series of hydrogen explosions occurred.

Considering the accident at the Fukushima Dai-ichi nuclear power station in Japan, several initiatives were launched worldwide to assess the lessons learned. These include but are not limited to the European stress tests, the ONR Interim and Final Report (References 12B.1 and 12B.2), and the IAEA Expert Mission Report (Reference 12B.3).

The AP1000 plant design and its passive safety concepts have been developed considering catastrophic events, which may lead to a complete and extended loss of power and infrastructure damage limiting site accessibility. As a result, the AP1000 plant design is very robust against these types of events. However, reviewing lessons learned is a hallmark of the nuclear industry and inherent to the Westinghouse safety culture. Therefore, Westinghouse established an internal expert team to perform a comprehensive review of the AP1000 plant design in light of the events at the Fukushima Dai-ichi nuclear power plant.

The intent of the initial Westinghouse review was to challenge the plant's design and further evaluate the performance of the AP1000 plant design when subjected to extreme hazards, such as those experienced at the Fukushima Dai-ichi site. The initial review was conducted with the best preliminary information available to Westinghouse at the time. The review team challenged the plant's design for combinations of scenarios involving extreme external hazards and loss of station power sources. Information from the initial reviews was utilised to generate summary assessments of AP1000 plant design's ability to cope with station black out (SBO) events, arrangements for spent fuel pool cooling, and protection against external hazards. The review team also identified tasks, as described below, which required further assessment.

As more formalised information and recommendations have become available, the results of the initial internal evaluations have been reviewed, refined, and formalised to be able to respond to government and regulatory requests such as the recommendations presented in HM Chief Inspector final report and the requests from the European Commission.

Following the events at Fukushima, the European Commission declared that "the safety of EU nuclear power plants should be reviewed on the basis of a comprehensive and transparent risk assessment" in the form of a "stress test." Driven by this recommendation, the European Nuclear Safety Regulators Group developed the European Union "Stress Test" specifications (Reference 12B.1). While the stress test is mainly designed for applications to an operating plant, it does provide a framework under which a new plant design such as the AP1000 plant can be 'stressed' to evaluate the robustness of the design. The stress test is defined as a targeted reassessment of the safety margins of nuclear power plants in light of the events which occurred at Fukushima: extreme natural events that challenge the plant safety functions and could lead to a severe accident.

The European Stress test provides an appropriate tool by which to present the results of the AP1000 evaluation and inform the response to Chief Inspector Weightman's recommendations.

This assessment consisted of the following:

- An evaluation of the response of the AP1000 nuclear power plant when facing a set of extreme situations, as defined below in the description of work section.
- Verification of the preventative and mitigating measures chosen following a defence in depth logic – initiating events, consequential loss of safety functions, and severe accident management.

For the assessment of these extreme situations, sequential loss of the lines of defence was assumed using a deterministic approach, irrespective of the probability of this loss. This approach allows for the evaluation of the levels of defence available following different external hazards, both within and BDB. The assessment reports on the response of the plant and on the effectiveness of the preventative measures. The assessment identifies if there are any potential vulnerabilities for the considered extreme events in order to verify the robustness of the plant's defence in depth design, and identify if there are any reasonably practical enhancements that could provide potential margin improvements.

The assessment focused on the impact of such extreme events relative to maintaining the key plant safety functions of core cooling, containment integrity, and spent fuel pool cooling. The focus of the technical scope of the AP1000 plant stress test assessment will be placed on the following issues:

- Initiating events
    - Earthquake
    - Flooding (not limited to a tsunami)
    - Combination of both
    - Other potential limiting external hazards
- Consequences of loss of safety functions from initiating events considered in the standard plant design
    - Loss of electrical power, including SBO
    - Loss of UHS
    - Combination of both
- Severe accident management issues
    - Means to protect from and to manage loss of core cooling functions
    - Means to protect from and to manage loss of cooling functions in the spent fuel pool
    - Means to protect containment integrity

Unlike an operating nuclear facility, site and operator-specific design aspects cannot be completely addressed in the stress test evaluation for the AP1000 design, but generic considerations are provided. These aspects include such items as site location, geography and topology; return period considered in the design basis for extreme events; site-specific emergency responses facilities; and site-specific flooding protection measures.

The UK AP1000 Plant Post-Fukushima Assessment is summarised in Section 12B.3

12B.2 Assessment of Fukushima Lessons Learned

Reviewing lessons learned is a hallmark of the nuclear industry and inherent to the Westinghouse safety culture. As part of Generic Design Assessment, Westinghouse evaluated the lessons learned coming from the various international reviews. The assessment of lessons learned is documented in Reference 12B.4.

12B.3 UK AP1000 Plant Post-Fukushima Assessment

The UK AP1000 Plant Post-Fukushima Assessment is documented in Reference 12B.5. The assessment has 9 sections which are summarised below.

Section 2 provides a description of the AP1000 plant standard site characteristics and a description of the AP1000 standard plant, including AP1000 plant main parameters; the scope and main results of the PSA.

Section 3 discusses the AP1000 seismic design and the margin against BDB seismic events. The AP1000 plant is designed for an earthquake defined by a PGA of 0.30g and the CSDRS specified in the assessment. The magnitude of the AP1000 SSE envelopes the PGA defined in the EUR. The EUR defines the horizontal PGA as 0.25g. Therefore, the AP1000 SSE, in terms of PGA, provides 20 percent margin relative to general European seismic requirements as specified in the EUR. Section 3.2 describes the seismic margin assessment (PCSR Section 12.6.3.4) which as discussed was performed to demonstrate margin over the SSE of 0.3g. The goal of the SMA was to demonstrate that the plant HCLPF is at least 0.5g PGA. The results of the SMA actually show even a greater margin for most of the safety functions.

Section 4 discusses the plant protection and robustness against flooding events. The AP1000 plant is designed for a normal groundwater elevation up to plant elevation 99.4 m (98 ft) and for a probable maximum flood level up to plant elevation 100 m (reference elevation 100.0 ft), which is also the plant reference grade level. The robustness evaluation performed in Section 4.2 has shown that:

- The AP1000 design provides margin beyond the flooding design basis to maintain a safe shutdown condition with no fuel damage or radiological releases to the general public for extreme BDB flood levels.
- The combination of a BDB seismic event with a BDB flood event will not result in more severe consequences than those described for the individual events.

Sections 3 and 4 therefore show that the AP1000 design provides a unique capability to respond to design basis and BDB events due to three fundamental safety advancements:

- The AP1000 Design Self Actuates. For SBOs, critical SSCs will automatically achieve a fail-safe configuration without the need for operator action or ac/dc power.

- The AP1000 Design is Self-Sustained. The AP1000 design's passive approach to safety de-emphasises the importance of ac power and cooling supply.

- The AP1000 Design is Self Contained. SSCs critical to placing the reactor in a safe shutdown condition are protected within the steel containment vessel and further surrounded by a substantial "steel concrete" composite shield building.

Section 5 provides the results of the assessment of the AP1000 design in case of LOOP, SBO, and loss of UHS as a consequence of a BDB seismic event coincident with a BDB flood event to confirm the robustness of the AP1000 design in mitigating extreme natural hazards. The various lines of defence of the plant against LOOP/SBO types of event are described and their robustness against severe BDB external events was assessed.

One of the major differences of the AP1000 design when compared to the currently operating pressurised water reactors, is the extreme robustness of the design to loss of water makeup capability. On the reactor side, heat is removed first from the reactor core by the PXS, which has sufficient water inventory protected inside containment to operate for very long period of times, then heat is removed from the containment by the PCS. The spent fuel decay heat is removed by heating up and boiling off SFP water with steam released to the atmosphere through a vented path. Safety systems (in-containment water inventory, SFP water inventory, PCS water inventory) have sufficient capacity to support the safety functions for at least 72 hours. As discussed in Sections 3.2 and 4.2, those passive safety systems are very robust against extreme BDB events. Even credible BDB events will not result in a challenge to the passive systems to fulfil their functions during the first 72 hours. After 72 hours, makeup will need to be provided to the PCCWST and the SFP, as described above. Note that a MAAP analysis has shown that:

- In the highly unlikely case of an operator not being able to supply water to the top of the containment after 3 days of cooling, air cooling alone will be sufficient to provide an HCLPF after 3 days. The equilibrium containment pressure, while above the ASME Service Level C pressure limit, still corresponds to a low probability of failure.

- In the highly unlikely case of an operator not being able to supply water to the top of the containment after 7 days of cooling, pressure within the containment vessel would slowly increase but would not be expected to reach the normal design pressure for over 2 days. Even in the case of this very unlikely event, considering that the steel containment vessel has a very large margin above the normal design pressure, the peak containment pressure will not exceed the ASME Service Level C pressure limit.

Section 6 describes the severe accident mitigation features of the AP1000 passive plant that are designed to minimise any radiological impact from hypothetical accidents resulting in extensive damage to the nuclear fuel in the reactor core. Severe accident management capabilities have been integrated into the AP1000 plant design from the beginning of the design process. PSA and the associated analyses and testing were used to identify scenarios, boundary conditions and postulated severe accident phenomena that must be mitigated to ensure containment integrity in the event of core damage.

Section 7 provides a brief overview of the human factors considerations important to BDB situations and a discussion of the assumptions made of the site-specific emergency plan. It also includes the human factors assessments conducted on a sample of two limiting operator

actions that would be required after a postulated BDB extreme external event to ensure successful long-term (post-72 hour) cooling of the plant. This BDB extreme external event is postulated to be a BDB seismic event with subsequent BDB tsunami that occurs either at power or during a refuelling outage with full core offload. Both actions are assessed to be feasible and likely to succeed, given the assumptions of the site-specific emergency plan.

Section 8 provides the ALARP arguments to determine if there any enhancements that could be incorporated into the design of the AP1000 plant for the UK to further enhance the plant's design margin against BDB extreme events. As mentioned previously, the AP1000 is robust; no additional changes are required to maintain the key safety functions. However, the proposed design changes enhance the coping capabilities of the AP1000 during BDB extreme external events and improve the margin against external hazards. The proposed design changes have been included in the Design Reference Point (Reference 12B.6) and have been incorporated as appropriate into this PCSR. The design changes are summarised below:

- BDB flood protection for Class 1 batteries – This design enhancement protects the Class 1 electrical supply system batteries from BDB flooding by adding water proof doors, sealing penetrations, adding HVAC snorkels and adding a latched and gasket seal over ancillary diesel generator exhaust.
- Enhanced power supply for communication system – This design enhancement extends the power supply for the communication systems during a SBO.
- Improved post-72 hour cable connections – This design enhancement improves the connection of the offsite diesel generators by significantly reducing the length of temporary cable as well as the cable diameter required to connect the offsite diesel generators to its loads .
- Addition of PCCAWST connection – This enhancement improves the accessibility to the PCCAWST during BDB extreme external events to use the PCCAWST as a source of makeup water for the SFP and Containment cooling. The proposed design enhancement is comprised of adding a new connection line to the PCCAWST, a new isolation valve and a flanged connection.

Section 9 provides a summary of results of the Fukushima assessment performed for the UK AP1000 design and the conclusions. This is summarised in Section 12B.4.

12B.4 Conclusions

It can be concluded that for a Fukushima-like event, the AP1000 design demonstrates robustness with respect to BDB external hazards. The passive safety systems ensure that the core remains cool, the containment remains intact, and SFP cooling is maintained for the first 72 hours. After 72 hours, the AP1000 design has permanently installed ancillary equipment as well as connection points for portable equipment to extend the operation of the passive safety systems indefinitely.

The AP1000 nuclear power plant passive design represents a significant improvement over conventional pressurised water reactors, and is developed around the fundamental design principles of safety, simplification and standardization. The development of the AP1000 plant safety concept based on passive systems allows full realization of the benefits of these fundamental design principles. The adoption of passive systems as the primary means to deliver safety functions, combined with reliable defence in depth active systems, allows achievement of both an unparalleled level of safety and optimised support for investment

protection. These benefits are especially evident when evaluating the AP1000 design's ability to meet the lessons learned and recommendations coming from the international nuclear industry. Westinghouse as a nuclear industry leader, has incorporated lessons learned and will continue to evaluate the plant for design enhancements that may enhance the performance of the AP1000 design in response to BDB extreme events.

For the UK AP1000 generic design, Westinghouse has identified design enhancements that provide additional margin against BDB extreme external events. These enhancements are not required to meet safety goals; however, they provide enhanced coping capabilities and support plant operations following such extreme events.

APPENDIX 12C
COMPARISON OF UK PML AND AP1000 EARTHQUAKE SPECTRA

12C.1 Comparison of UK PML and AP1000 Earthquake Spectra

Figure 12C-1 compares the UK PML hard, intermediate and soft site spectra for 5 percent critical damping for PGA of 0.25g with the AP1000 hard site spectra at 5 percent critical damping for a PGA of 0.3g given in Reference 12C.1.

Class 3, non-seismic structures will be designed in accordance with the Eurocode or IBC as defined within Chapter 16.

The vertical spectrum is usually taken as two-thirds of the horizontal value per NS-TAST-GD-013 (Reference 12C.2).

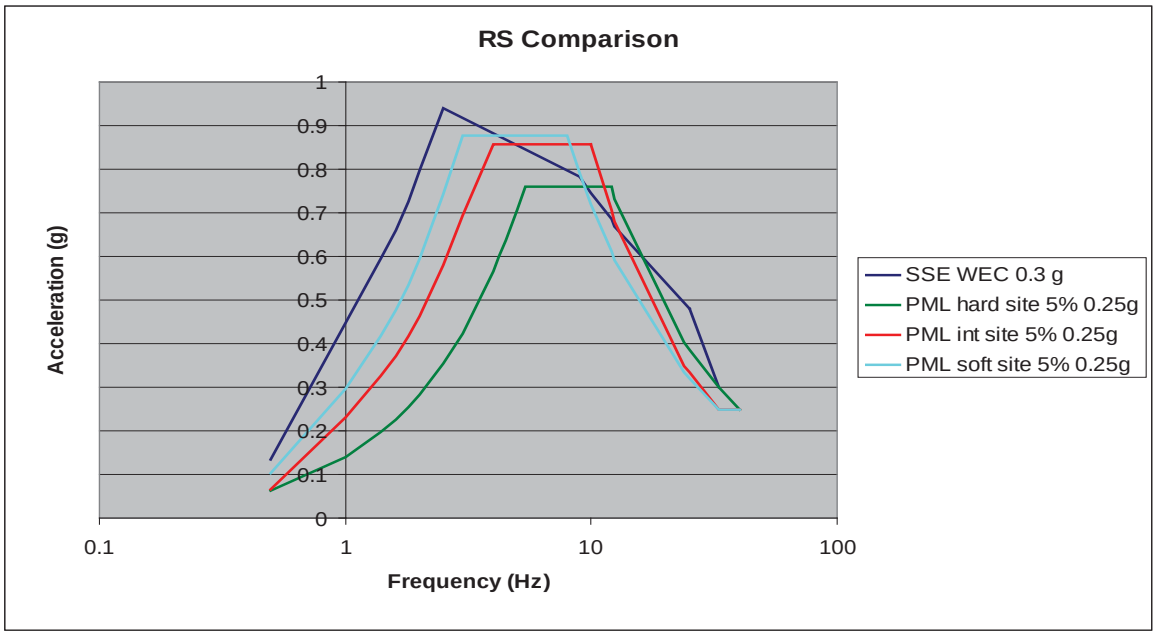

Figure 12C-1: Comparison of PML and AP1000 Earthquake Spectra

Notes: PML values are taken from the digitised tables, interpolating linearly between frequency values when necessary. AP1000 values are taken from Table 2 and Figure 1 of APP-GW-G1-003 (Reference 12C.3).

13 HUMAN FACTORS

13.1 Introduction

This chapter describes how an integrated and managed Human Factors (HF) Engineering programme has been rigorously and systematically applied throughout the concept analysis and design phases of the Standard AP1000 Plant design. The measured and proportional application of HF processes and methodologies has ensured that the design considers at all times the role of the human operator in the safe and efficient operation of AP1000. It further demonstrates, for a sample of scenarios where operators are required to take action in order to maintain or restore nuclear safety, a methodology for conducting Human Error Analysis (HEA) of nuclear-safety related tasks. The HEA methodology results provide input to the substantiation of an argument that risk of failure in those actions has been reduced, as low as reasonably practicable (ALARP), for the Standard AP1000 Plant design.

13.2 Regulatory Expectations, Safety Principles and Standards

This Pre-Construction Safety Report (PCSR) chapter has been constructed within a United Kingdom (UK) regulatory framework as informed by:

- Office for Nuclear Regulation (ONR) Safety Assessment Principles (SAPs) (Reference 13.1);
- Legal requirement for a duty holder to reduce risks, '*as low as reasonably practicable*' (ALARP) (Reference 13.2), which is the concept that drives ONR's 'goal-setting' regulatory regime for nuclear safety (Reference 13.3);
- International and national modern safety standards and industry guidance recognised by ONR as providing the relevant good practice (RGP) underpinning the SAPs and Technical Assessment Guides (TAGs).

13.2.1 Safety Assessment Principles (SAPs)

The SAPs provide the ONR with a framework for consistent regulatory judgements on nuclear safety, radiation protection and radioactive waste management activities of new (proposed) and existing nuclear facilities. The SAPs may also provide guidance to designers and duty-holders on the appropriate content of safety cases in clarifying ONR's expectations in this regard.

The key SAPs in providing guidance on the appropriate content of the HF safety case for AP1000 during the UK generic design assessment (GDA) are the specific HF principles EHF.1 to EHF.11. These cover the HF topics, processes and methodologies that will ensure:

- There has been a systematic, through-life, approach to human factors integration (HFI) within the design, assessment and management of systems and processes
- The allocation of safety actions between humans and engineered structures, systems or components (SSCs) has been substantiated.
- A systematic approach has been taken to identify human actions that can impact safety for all permitted operating modes and all fault and accident conditions identified, in the safety case, including severe accidents.

- Administrative controls needed to keep the facility within its operating rules for normal operation or return the facility back to normal operations have been systematically identified.

- Proportionate analyses have been carried out for all tasks important to safety and used to justify the effective delivery of the safety functions, to which they contribute.

- Workspaces in which operations (including maintenance activities) are conducted have been designed to support reliable task performance. The design should take account of the physical and psychological characteristics of the intended users and the impact of environmental factors.

- Suitable and sufficient user interfaces have been provided at appropriate locations to provide effective monitoring and control of the facility in all normal operating modes, fault and accident conditions.

- A systematic approach to the identification and delivery of personnel competence has been applied.

- Procedures have been produced that support reliable human performance during activities that could impact on safety.

- The number of competent personnel needed to operate the facility safely, in all its operational states, has been assessed and is understood.

- Proportionate analyses of human actions and administrative controls that are necessary for safety as part of the design basis analysis (DBA), probabilistic safety analysis (PSA) and severe accident analysis (SAA) aspects of the safety case.

Because modern nuclear power plants (NPPs) are relatively complex, socio-technical systems with an inter-related reliance on both engineered and human components to maintain nuclear safety, HF becomes a transverse topic spanning numerous other technical areas and safety disciplines. For this reason, a number of the ONR's other SAPs contain guidance that is pertinent to the content of the HF safety case. Key amongst these are:

- Leadership and management for safety - The organisation focuses on achieving and sustaining high standards of safety and establishing and sustaining a positive safety culture (MS.1). Learns from internal and external sources to continually improve safety decision making and safety performance (MS.4).

- Engineering principles - The design concept, of defence in depth (DiD), providing multiple independent barriers to fault progression, should be applied (EKP.3). Safety functions are identified based on an analysis of normal operation and of fault sequences determined through fault analysis (EKP.4) and appropriate safety measures provided to deliver the safety functions (EKP.5). SSCs should be classified on the basis of the safety functions they deliver and their significance to safety (ECS.1). Where safety functions are delivered or supported by human action, those human actions should be identified and classified on the basis of those functions and their significance to safety (ECS.2). Where reliable and rapid protective action is required, automatically initiated, engineered safety measures should be provided (ERL.3). For requirements that are less demanding, or on a longer timescale, administrative safety measures, i.e., those involving operator actions based on procedures, may be acceptable (ERL.3). The design and layout should facilitate access for necessary activities and minimise adverse

interactions while not compromising security aspects (ELO.1).

- Safety systems - For all fast acting faults (typically less than 30 minutes), safety systems should be initiated automatically and no human intervention should then be necessary to deliver the safety function(s) (ESS.8). The design should be such that the operators or other facility personnel cannot negate a correct safety system action, but can initiate safety system functions and perform the necessary actions to deal with circumstances that might prejudice safety (ESS.8). Where human intervention is needed to support a safety system following the start of a requirement for protective action, then the timescales, over which the safety system will need to operate unaided, before intervention, should be demonstrated to be sufficient (ESS.9). In keeping with internationally accepted relevant good practice for power reactors, no human intervention should be necessary for approximately 30 minutes from the start of the safety system initiation (ESS.9). There should be direct means of confirming to operating personnel: (a) that a demand for safety system action has arisen; (b) that the safety systems have operated (actuated) fully and correctly; and (c) whether any limiting condition (operating rule) has been exceeded that takes the safety system beyond its substantiated capability (ESS.13). Suitable and sufficient safety-related system control and instrumentation should be available to the facility operator in a central control room, and as necessary at appropriate secondary control or monitoring locations (ESR.1).

- Fault analysis - Fault analysis should be carried out comprising suitable and sufficient DBA, PSA and SAA to demonstrate that risks are ALARP. Where the fault analysis is in support of a design under development, the analysis should be against a well-defined reference point in the design process. Where facility-specific or site-specific details have yet to be finalised, all the assumptions made in lieu of these should be stated explicitly and then used to support the later design and construction activities. The DBA provides an input into safety classification and the engineering requirements for systems, structures and components performing a safety function; the limits and conditions for safe operation; and the identification of requirements for operator actions (FA.9). The PSA model provides an adequate representation of the facility (FA.13) accounting for contributions to the risk including, but not necessarily restricted to: (d) unavailability due to testing and maintenance; (e) pre-fault human errors (e.g., misalignments and miscalibrations); (f) human errors that lead to initiating faults; (g) human errors during the course of fault sequences, including those required for repair or recovery actions; and (h) potential dependencies between separate human activities (either by the same or by different operators) (FA.13). The PSA is used to inform the design process and help ensure the safe operation of the site and its facilities (FA.14), supporting modifications to design or operation (FA.14) and supporting the demonstration that risks are tolerable and ALARP (FA.14).

13.2.2 As Low As Reasonably Practicable (ALARP)

The term ‘as low as reasonably practicable’ (ALARP) is used to express the Requesting Party’s legal duty to reduce risks so far as is reasonably practicable (SFAIRP), and is a concept that must be applied at all levels of risk, extending below the level that may be deemed broadly acceptable. In simple terms, it is a requirement to take all measures to reduce risk where doing so is reasonable.

To inform and guide its employees engaged in developing ALARP justifications and to enable a standard approach to be taken across the different topic areas of GDA, Westinghouse has provided the basis for determination of appropriate ALARP assessments

(Reference 13.6) and guidance on developing justifications for risks that are ALARP in supporting the safety case.

This guidance, as consistent with Reference 13.4, explains that the substantiation of risk being reduced ALARP requires a balanced argument containing elements of:

- Compliance with RGP, including adequate standards and codes, industry best practice and lessons learned;
- Demonstration of 'optioneering' as outlining the different options and assessing the pros and cons of each before making a decision, on which presents risks ALARP;
- Inclusion of quantitative and qualitative risk assessment, including (where appropriate) numerical assessments of the associated risk levels as derived from the PSA.
- Use of cost benefit analysis as an augmentation to the overall ALARP justification to determine whether the expected costs of implementing the option are grossly disproportionate to the benefits and thus aid in determining which option is ALARP.

13.2.2.1 Relevant Good Practice (RGP)

One of the basic tenets of ALARP is the recognition and use of RGP. Although not the sole criterion, RGP may be referred to as the use of modern standards and practices. In order to demonstrate RGP, it may be necessary to construct an appropriate qualitative argument, consisting of technical quantitative bases as well as recognition of expert-level knowledge.

Demonstration of RGP generally considers one or more of the following:

- Use of Industry Accepted Codes, Standards and Practices
- Use of Proven Technology
- Use of Applicable Testing

Use of Industry Accepted Codes, Standards and Practices

Reference to UK-specific codes and standards is preferable, but not absolutely necessary to define RGP. Demonstration of RGP does not require conformance to UK codes and standards if an equivalency to existing codes or standards has been established.

The HF standards used as RGP in the design and assessment of the AP1000 design (Table 13-1 have undergone an equivalence and maturity study (Reference 13.7 – Section 5.4) to determine whether they have been utilised as RGP in the UK or are recognised in UK and Europe as RGP (i.e., equivalence) and (b) were current good practice or equivalent at the time that design decisions were taken and are not significantly different now (i.e., maturity). The results of this RGP equivalence and maturity study found them to be broadly compatible with UK and International practices.

Use of Proven Technology

The recognition by nuclear industry workers, maintainers and operators of familiar, proven designs of SSCs used in nuclear new build applications contributes substantially to an operations and HF RGP argument. However, ALARP optioneering (Section 13.2.2.2) has

also revealed newer/innovative technologies, such as visual display unit (VDU) based, point and click, soft control human system interface (HSI) in the main control room (MCR) that are able to offer additional advantages over existing technology, but for which there is not extensive operational experience.

Use of Applicable Testing

RGP may be confirmed through the utilisation of applicable test results, in demonstrating suitability of the design, or operational practice. For example, use of the integrated systems validation (ISV) test results (Section 13.7.3 and Reference 13.54) provides evidence in demonstrating RGP, as related to MCR HF design implementation. Such test results verify assumptions on human action times, through direct simulation and analysis of operator practices. This validation then establishes RGP for the assumptions.

13.2.2.2 Optioneering

Inherent within the ALARP decision-making process is appropriate consideration of different options. A formal option assessment process was used in the rationale for the evolution of the AP1000 design (Section 13.6.1) and expert panel optioneering in the selection and development of existing design features through, for example, HF, operations, and HSI design participation in the design change proposal (DCP) process (Reference 13.15).

13.2.2.3 Risk Assessment

Risk is defined as a combination of probability and consequences and may be of a quantitative or qualitative nature. All of these factors are considered in an ALARP evaluation. The results from risk assessments, e.g., DBA, PSA, and SAA are used to support ALARP justifications. HF has taken the output from these, risk-based fault analysis methods, to identify operator actions important to nuclear safety (Section 13.8.1) and screened them for further qualitative HEA (Section 13.8.3) proportionate to the consequence of their failure exceeding certain threshold criteria (Section 13.8.2). The task analysis output from this qualitative HEA will then be used in human reliability analysis (HRA) to substantiate or derive estimations of human error probability (HEP) for human-based safety claims (HBSCs) modelled in the PSA event trees (Reference 13.8).

13.3 Limitations to the HF Safety Substantiation during GDA

The level of safety demonstration that can be reliably performed is dependent upon the design development progress at the time of the assessment. Assessment of a generic design for the UK, pre-construction and prior to there being fully trained and licenced operators, will mean that the development of the HF safety case has been conducted at a generic, non-site specific level, rather than that of a detailed, operating design.

13.3.1 Standard AP1000 Plant Design Development Phase

As illustrated by Figure 13.1, there has been an extensive and comprehensive HF Engineering programme applied to the AP600/AP1000 design over a period of some 20 years preceding GDA. This has resulted in a Standard AP1000 plant design where all necessary systems, displays and controls are provided to maintain or return plant to safe operation in normal, emergency and accident conditions.

13.3.2 Plant Design Configuration

The Standard AP1000 plant design configuration, against which this HF safety case for GDA has been conducted, is defined by the latest revision of the Design Reference Point (DRP) (Reference 13.9) and the high level design documentation pertinent to the issue of a Design Acceptance Certificate and a Statement of Design Acceptance referenced therein. The DRP also includes design changes approved by the designer for implementation in the AP1000 design configuration for GDA.

Whilst HF Engineering, or HFI activities, in earlier AP1000 design development have been focused predominantly on plant operation from the main control centres, the HF guidance that has been provided in the design of local control panels and manually activated local equipment will be significantly enhanced by feedback from AP1000 construction projects currently underway.

13.3.3 Operating Condition Scope

The HF Engineering programme, preparatory analyses, design input, and verification and validation has addressed credible plant operations, comprising all modes of normal operation as well as emergency and accident conditions, and selected abnormal/infrequent operations, test, inspection, surveillance, and maintenance activities.

HF task support verification, HF design verification and an HF ISV tests have been completed for the standard AP1000 plant design. These HF verification and validation (V&V) activities are further described in section 13.7. Completion of the HF V&V activities have resulted in a significant number of 'issues' and operator performance concerns that have been captured, recorded and grouped into human engineering discrepancies (HEDs). The resolution plans for each of the HEDs and HED issues fall into one or more of the following categories: Corrected through design change; Procedure change; Training program change; or justified as-is.

The resolution plan of each HED issue has been assessed and agreed with the requisite Westinghouse engineering disciplines. Re-verification and re-validation of the implemented resolution plans are intended to be conducted during the UK site licencing phase, where the results become substantiation in support of a claim for risk from human error being reduced ALARP.

13.3.4 Operating Location Scope

The AP1000 HF engineering programme adopts a tailored approach to HF analysis. A framework was adopted to establish the level of HF involvement in the different areas or systems in which HF are influential. The level of involvement is dependent on the potential safety or operational consequences of an operator error, degree of human involvement in the task, nature of the task, task complexity, required speed of operator response, or a combination.

The HSI design element of the HF Engineering Programme Plan (Reference 13.10) addresses the HSI resources that are located in the Operation and Control Centre System (OCS). However, the risk-proportionate, tailored approach to the application of HF Engineering resources means that rigorous attention has been paid to the design of the MCR and HSI to monitor and control plant functions important to the maintenance of nuclear safety. Other core areas, in which there is a significant reliance on successful operator performance in order to prevent a risk to safety, or where operator performance is essential to maintain operational integrity, have been given equal importance.

This concentration of HFI effort on the OCS during early AP1000 design activity, in combination with the passive nature of many SSCs to provide their safety function, has meant that direct HF involvement with the design of SSCs for maintenance and maintainability has been limited to the provision of good practice HF guidance principles for designers (Reference 13.57), as informed by the Electric Power Research Institute (EPRI) Utility Requirements Document (Vol. III, Chapter 1, Section 8 of Reference 13.20). More thoroughly assessed from an HF perspective has been the maintenance, test, inspection and surveillance (MTIS) activity associated with the use of Squib valves in the AP1000 design. This has included a demonstration in the use of three dimensional modelling to enhance the HF assessment of squib valve MTIS activity conducted for the analysis of GDA sample actions OPR-011 and OPR-106 (Reference 13.54 and 13.96). In addition, feedback available from AP1000 build projects in China and the United States (US) is designed to inform the ongoing HF assessment of MTIS on SSCs that will be conducted during the UK site licencing phase.

Site licensing is anticipated to include HF maintenance and maintainability assessments of appropriate risk significant maintenance activities as per the HF error screening and analysis process.

13.3.5 Safety Categorisation and Classification Scope

The identification of operator and maintenance actions and the subsequent risk-proportionate, tailored approach to HF assessment has been guided by the classification of a system's importance to safety and the categorisation of the safety function that the system delivers (Reference 13.11).

The operator and maintenance actions that are associated with safety systems and the safety-related DiD systems have been used in the identification of operator actions that are important to safety. These actions have been screened for detailed HEA dependent upon the consequence of the unavailability of these systems on demand.

13.3.6 HF Interfaces with other parts of the PCSR

This chapter provides the main discussion on the HF element of the UK AP1000 safety case. It includes the overall basis for safety, the process for integrating HF into the design, and the safety arguments and evidence that relate to both the holistic HF safety case and to specific HBSCs. Because of this holistic approach to the formulation of an HF basis for safety and of the transverse, cross-cutting nature of the HF topic, there are numerous interfaces with these other technical areas and safety disciplines. Examples of these HF interfaces with other chapters include:

Chapter 7	Lifecycle Engineering and Safety (Design Change Control; MTIS)
Chapter 8	Fault and Accident Analysis (HF; Fault Schedule and Fault Groups)
Chapter 10	Probabilistic Safety Analysis
Chapter 11	Internal Hazards (Fire; Flood)
Chapter 14	Fault Analysis Results and Conclusions (SSCs Identified in the Safety Case; Emergency Instructions Identified in the Safety Case; Assessment that Risks are ALARP)
Chapter 19	Control and Instrumentation (C&I) (Plant Protection)
Chapter 25	Accident Management (Onsite Emergency Response Facilities)

HF has also been integrated across other technical areas of the UK AP1000 programme through support to the resolution of their GDA Issues. When it has been identified that HF has a part to play in the resolution of a GDA Issue or that the safety case for the technical area makes claims on the actions of a human operator, then HF team support is provided as required. The technical disciplines where HF currently provides support and has an interface are more fully reported in Reference 13.95 and by the examples listed below:

- Cross Cutting Issues as relating to lessons learned from the Fukushima event
- Civil Engineering with regards to the Fuel Handling Area
- C&I issues related to the use and safety substantiation of various operator interface panels.
- Electrical Engineering regarding HF input to maintenance philosophy.
- Fuel Design and the use of BEACON™ Core Monitoring System
- Fuel System and the HF contribution to the Safety Case and design input to implementation of diverse flux protection
- Mechanical Engineering procedures for MTIS activity and isolation of systems including squib valves. The operation and maintenance of hybrid metric and imperial systems.
- PSA and the use of detailed HF task analysis and cognitive-level HEA to inform HEPs for inclusion in the Level 1 and 2 PSA models, including Fire PSA.
- Radiation Control and Protection, including HF review of relevant safety case for e.g., primary sampling and spent fuel pool (SFP) criticality, etc.

13.3.7 Considerations for Site Licensing

In the design of AP1000 systems and operational tasks, Westinghouse designers have been guided by HF requirements and constraints influenced by national regulatory and legislative expectations, a US-based population target audience description (TAD), or anticipation that systems will be used in the context of US operating practices and culture. When these situations are identified during HFI assessment and task analysis for HEA, and have been used in the HF safety substantiation for GDA, then they are recorded as ‘assumptions’. A list of assumptions is being maintained in a separate, living document that is intended to be shared with a UK Site Licensee to inform the scope of a site-specific safety substantiation of their Conduct of Operations, operating procedures, organisational culture, training programme, staffing, emergency plans, and maintenance programme, among others.

Assumptions made in the HF analysis and safety substantiation of operator actions for the GDA sample have been recorded under the following generic headings in the Qualitative Error Analysis report (Reference 13.54):

- Conduct of Operations
- Procedure Use and Adherence
- Staffing

- Training
- Human Performance
- Safety Culture
- Human System Interface
- Other/Miscellaneous, e.g., MTIS process

Each of these topic areas are ultimately the responsibility of a future operating utility organisation. The final design of systems and processes adopted by a future UK licensee will be influenced by national legislation, local working practices and industry expectations. This will require that safety substantiation of operator actions are reassessed in light of the implemented site-specific design. Significant deviation from the 'solutions' and assumptions envisaged by Westinghouse designers in the US will require that the licensee substantiate the design given the absence of or alternates to Westinghouse solutions or assumptions.

In addition to assumptions, there remain open 'issues' that are the result of HF Engineering process related to the site-specific HF V&V activity. These HED issues are captured in a formal tracking system (Section 13.5.4 and 13.7.4), for resolution and any required re-verification or re-validation during site licencing, governed by the AP1000 Human Factors Engineering Discrepancy Process (Reference 13.60).

The HED issues currently residing in the formal tracking system tend to be Operations and Control Centre centric, emanating from scenarios enacted using the MCR and RSR simulator. Other areas where the HF Engineering process and risk-proportionate HF analysis require site-specific inputs are in the areas of local control stations and maintenance and maintainability of systems providing safety and safety-related functions.

Many of the local control stations will be supplied as part of separate vendor contracts for systems procured during the site-specific design and construction. The procurement contracts will include appropriate specifications and requirements to ensure that the HSI of a vendor supplied control station is compliant with modern standards and the adopted set of HSI guidelines (Reference 13.46). When locally let contracts are for the procurement of systems providing a safety function, it is expected that a requirement for the vendor organisation to engage the assistance of an 'in-house' HF capability to integrate HF into the design and to interpret HSI requirements will be required.

HFI in the design for maintenance of systems providing safety and safety-related functions has been predominantly informed by HF guidance documents (Reference 13.46 and 13.47). However, a methodology for the HF analysis of MTIS activity on installed systems has been demonstrated for the ADS, IRWST, and containment recirculation squib valves as part of the GDA operator action sample analysis (Reference 13.54 – OPR-011 and OPR-106). This methodology has made use of three dimensional CAD models, in conjunction with relevant maintenance procedures and experienced engineers, to conduct detailed task analysis of selected MTIS operations. This work has resulted in a number of design enhancement HF recommendations. Site licensing activities are expected to include HF maintenance and maintainability assessments of appropriate risk-important maintenance activities per the HF error screening and analysis process.

Issues arising from the HF analysis of MTIS activity on local systems and components that are conducted during the site licensing phase, along with feedback that will emanate from existing AP1000 build projects, would also reside in a formal tracking system, where issue

resolution may result in raising appropriate design change proposals (DCPs).

13.4 Overall Basis for Safety

This Section presents a claims, arguments and evidence 'road map' for the remainder of this chapter and 'signposts' other documents comprising the HF safety case for the standard AP1000 plant design in GDA.

An over-arching HF safety claim is made about the reduction of opportunity for, and risk from, human error, along with under-pinning sub-claims about the part that HFI in design, operating conduct, and human reliability play in the reduction of that risk. Each claim is followed by a bulleted list of arguments to elaborate the claim. Below each argument is an indented list of references to the sections of this HF chapter, and to other PCSR chapters and to documents that comprise the HF safety case for GDA, where evidence may be found to substantiate the claims.

Claims made below about the risk from human error being reduced ALARP are not fully substantiated. There is work yet to be finished with respect to ALARP substantiation. Detailed human error analysis, including ALARP substantiation, was completed for a sample of safety significant human actions (Reference 13.54). This demonstrated methodology needs to be completed for other safety significant human actions as identified and screened from the human action database

13.4.1 Overall HF Safety Claim

The overall HF safety claim is:

> **The role of the operator in ensuring nuclear safety is understood, and the risk to nuclear safety arising from human failure has been identified and reduced ALARP for the Standard AP1000 plant design.**

The role of the operator is to operate equipment controlled from the main control area (MCA) during all modes of normal operation, plant transients and emergencies. This includes manipulating actual controls; monitoring equipment and system parameters; documenting evolutions and significant events; performing operator actions required by Alarm Response Procedures (ARPs), addressing prioritised alarms and interpreting alarm significance and diagnosing and recognising trends (Reference 13.37).

The term "operator," as used in this overall HF claim, also includes the human operator as 'equipment operator' and 'maintenance engineer.' The equipment operator performs operations duties and responsibilities outside the MCR, as directed by the MCR, including locally performed unit evolutions and system operations under the direction and command of the MCA Supervisor; supporting identification, diagnosis, and resolution of abnormal conditions (Reference 13.37). The maintenance engineer maintains equipment and systems important to nuclear safety, conducting scheduled MTIS activities.

The arguments and evidence presented below to support the sub-claims will, in their entirety, substantiate this overall HF safety claim and demonstrate that risk from human failure has been reduced ALARP for GDA.

13.4.2 Human Factors Integration (HFI) into the Standard AP1000 plant design

Claim 1 - The implementation of a comprehensive, integrated and managed HF Engineering Program promotes high levels of confidence in the ability of the Standard

AP1000 plant design to support successful completion of the operational tasks and maintenance activities important to safety and assigned to the human operator.

- The HF Engineering program activities have been delivered and executed by suitably qualified and experienced persons (SQEPs) HF practitioners to support and inform the developing design. A tailored, risk-proportionate approach to the HF Engineering methodologies and analyses has been effectively managed throughout the design development lifecycle phases.

Selected Design Change Proposals included in the 2015 Design Reference Point for GDA," October 2015.

Claim 2 - The design of the MCR and of the HSI supports safe and reliable operations during normal modes of operation, abnormal and emergency conditions, and recovery operation during severe accident (i.e., core-damage).

Claim 2.1 - The design of the Remote Shutdown Room (RSR) and of the HSI supports the means to safely achieve and maintain Safe Shutdown following evacuation of the MCR.

- HF preparatory analyses have been completed and the results used to inform the HSI design, procedure development, and training program development. The output of these completed analyses included a list of controls, indications, and alarms that must be present in the HSI to safely monitor and control the plant under normal, abnormal and emergency conditions. Early HF analyses also included the assignment of processes to automation or manual (i.e., the human) or to a combination; determination of MCR and plant staffing levels; along with identification of any critical, risk-important or safety-significant human actions.

  Section 13.6.2 Operating Experience Review

  Section 13.6.3 Functional Requirements Analysis and Allocation of Function

  Section 13.6.5 Task Analysis

  Section 13.6.5.2 Operational Sequence Analysis 1

  Section 13.6.5.2.1 Criteria for Critical and Risk-Important Human Actions

  Section 13.6.15 Staffing

  Reference 13.65 Not Used.

- A Concept of Operations was first developed early during the conceptual design phases of the HSI. It presents the HSI resources to be used by operators with a vision of their functionality to support their decision making. The vision of the HSI functionality was based upon past modernisation projects, operating experience reviews, and conceptual integration into a compact, primarily "soft" control environment. The concept of operations describes the operational philosophy of each MCR position and the operational use of the HSI resources at those positions. It is extended to the RSR, local distributed control and information system (DCIS) workstations, and local panels. As such, the concept of operation provides high-level operational concepts and design bases to be used by the HSI resource designers to inform the development of their respective functional requirements and design specifications. As the HSI and control centre design evolved and matured, the concept of operations was revised accordingly to reflect the actual design.

  Section 13.6.4 Concept of Operations

Kingdom AP1000 RSR Control Strategy for Class 1 Displays and Controls – ALARP Justification," December 2016.

Section 13.6.10 Local Control Stations

- The use of modern standards, good practice guidance in the design of HSIs in nuclear power plant control rooms has informed and shaped the design and assessment of the control rooms, other operation and control centres, and their HSI resources.

  Section 13.2.2.1 Relevant Good Practice

  Section 13.6.6.1 HSI Design Guidelines

  Reference 13.46 Westinghouse Report APP-OCS-J1-002, Rev 6, "AP1000 Human System Interface Design Guidelines," July 2016.

  Reference 13.47 Westinghouse Report APP-GW-GRP-001, Rev 2, "AP1000 Local Panels and Maintainability Human Factors Design Guidelines," February 2014.

- HF verification and validation activities are used to verify and validate that the MCR and HSI designs support safe and reliable operation during normal operation, abnormal and emergency conditions. These activities are also used to verify and validate that the RSR and its HSI can be used to safely achieve and maintain safe shutdown.

- The HF task support verification (TSV) verifies that the HSI and control centres include the information and controls required to enable execution of operator tasks.

  Section 13.7.1 HF Task-Support Verification

- The HF design verification (DV) verifies that the HSI and the operation and control centre designs (i.e., MCR, RSR, local control stations, etc.) have been completed per industry accepted guidelines.

  Section 13.7.2 HF Design Verification

- The HF ISV utilises an AP1000 simulator to validate the MCR and RSR designs, the HSI designs, and the plant operating procedures, including the HSIs and procedures for evacuation to the RSR in the event of the MCR becoming uninhabitable due to smoke or fire.

  Section 13.7.3 HF Integrated System Validation

- Any deficiencies resulting from the completion of these V&V activities are documented as HEDs. Resolutions for the HEDs are agreed upon, implemented and then re-verified/re-validated.

  Section 13.7.4 Human Engineering Discrepancy Resolution Verification

- The impact of approved and implemented design changes that occur following the completion of the TSV, DV, and ISV is determined and appropriate regression with respect to the completed HF verification and validation is completed as part of the plant start-up HF engineering verification activity.

  Section 13.7.5 Plant Start-up HF Engineering Design Verification

13.4.3 Design Philosophy Claims

Claim 3 - The design and operating philosophy for the Standard AP1000 plant design reduces reliance on operator action to ensure nuclear safety and reduces the sensitivity of the plant to human error.

- The design of AP1000 is inherently safe, provides DiD, backup systems, is simple in design in having fewer systems, equipment and components to maintain, having less complicated plant evolutions and reliance on the human operator for safety.

  Section 13.6.1 AP1000 Design Philosophy

  Section 13.6.2 Operating Experience Review

  Section 13.6.2.2 Utility Customer Requirements

- Functions have been appropriately allocated between humans and engineered systems and the reliance upon the human operator to maintain safety reduced.

  Section 13.6.2.4 Target Audience Description

  Section 13.6.3 Functional Requirements Analysis and Allocation of Function

- Per the AP1000 HF program, probabilistic and deterministic criteria have been defined to identify both critical human actions and risk important human actions associated with the AP1000 plant. The criteria have been applied and the results documented. No critical human actions are identified from the application of the respective criteria. However, risk important human actions are identified and serve as input to other elements of the HF program (i.e., task analysis, HSI design, and HF verification and validation).

  Section 13.6.5.2.1 Criteria for Critical and Risk-Important Human Actions

  Section 13.6.5.3 Operational Sequence Analysis 2

  Section 13.7.1 HF Task-Support Verification

  Section 13.7.3 HF Integrated System Validation

Claim 4 - The plant procedures, including the Conduct of Operations, applied to the Standard AP1000 plant design support safe and reliable operation during normal operation, abnormal operation, and emergency conditions.

- A full and comprehensive set of plant procedures have been developed to address normal operations, plant system operations, abnormal operations, alarm response, emergency operations, and maintenance, test, inspection, and surveillance operations. Procedure development includes consideration of operating experience, utility input and review, and industry good practice.

  Section 13.6.13 Development of Procedures

  Section 13.6.13.1 Procedures

- Operators are required and trained to use procedures at all times.

  Section 13.6.13.3 Importance of Operating Procedures

  Section 13.6.14 Development of Training Programs

Section 13.6.16 Conduct of Operations

Section 13.7.3 HF Integrated System Validation

- A comprehensive and challenging set of scenarios has been exercised for ISV tests on the AP1000 simulator to assess the effectiveness of plant procedures (general operating, alarm response, abnormal operating and emergency operating procedures), and the effectiveness of the HSI design.

  Section 13.7.3 HF Integrated System Validation

- The workload and work share between operators during normal operation and in emergency and fault conditions has been assessed in operational sequence analysis (OSA) and ISV tests.

  Section 13.6.5.3 Operational Sequence Analysis 2

  Section 13.7.3 HF Integrated System Validation

- The staffing levels assigned to the MCR of the Standard AP1000 plant supports safe and reliable operation of the plant.

  Section 13.6.15 Staffing

Claim 4.1 – The Control Room Severe Accident Management Guidelines (SAMGs), entered from Emergency Operating Procedures (EOPs), guide the Control Room operators in the management of severe accidents (i.e., core damage) in the first 24 hours after core damage.

- The AP1000 SAMGs were developed to focus on managing the accident in the first day (24 hours) after core damage. The guidelines consist of the following three major parts:

  Section 13.6.13.2 Severe Accident Management Guidelines

  1. Control Room Severe Accident Management Guidelines
  2. TSC Severe Accident Management Guidelines
  3. TSC Severe Challenge Response Guidelines

  Reference 13.84 Westinghouse Report UKP-GW-GGR-201, Rev. 1, "UK AP1000 Plant Post-Fukushima Assessment," July 2016.

- The Control Room SAMGs consist of two separate guidelines; the appropriate guideline is determined by the status of the Technical Support Centre (TSC) at the time the SAMGs are implemented. Severe Accident Control Room Guideline Initial Response (SACRG-1) is used by Control Room staff until the TSC is functional. SACRG-1 guides Control Room staff actions in a well-defined and prioritised manner to respond to inadequate core cooling and protection of the fission product barriers. SACRG-2 is used by the Control Room staff after the TSC is established and it is ready to use the TSC SAMG. This guideline is intended to foster communications between the Control Room staff and the TSC technical staff with the goal of enhancing the Control Room acceptance of the recommendations made by the TSC.

- The Control Room personnel are ultimately responsible for all actions taken during

normal operation and the accident until a senior management person assumes this responsibility as will be described in the site specific Emergency Plan (to be developed during Site Licensing). A declaration is made that passes the ultimate decision making responsibility for the senior plant operator in the MCR to the senior plant management official designated in the plant Emergency Plan (typically the TSC Director). In severe accident management, the TSC is expected to make decisions and pass recommendations to the Control Room for implementation.

Reference 13.98 Westinghouse Report APP-GW-GJP-500, Rev 0, "Executive Volume for AP1000 Severe Accident Management Guidelines," March 2015.

13.4.4 Substantiation of Human-Based Safety Claims (HBSCs)

Claim 5 - The HBSCs, identified as part of the DBA, PSA and SAA, have been substantiated ALARP.

- The process of identification and risk-proportionate substantiation of operator actions important to safety has been broad and comprehensive, accounting for areas of the fault analysis (DBA, PSA, and SAA) and the normal plant operating modes, abnormal operations, and emergency operations and beyond design basis condition through application of recognised HF analysis methods.

  Section 13.8.1 Identification of Operator Actions Important to Safety

  Section 13.8.2 Risk Proportionate Screening

  PCSR Chapter 25 Accident Management

- Type A, pre-fault, maintenance latent errors have been identified through a systematic consideration of the MTIS activities conducted on the passive safety and DiD safety-related systems claimed in the PSA event trees, and of other Class 1 and 2 SSCs.

  Section 13.8.1.1.1 Probabilistic Safety Analysis (PSA)

  Section 13.8.1.1.2 Design Basis Analysis (DBA)

- Type B, operator and maintainer induced initiating events have been identified through a systematic consideration of the internally initiated faults, faults initiated by internal and external hazards, faults presented in the Fault Schedule and composite fault list.

  Section 13.8.1.1.2 Design Basis Analysis (DBA)

- Type C, post-fault operator errors have been identified through a systematic consideration of the PSA systems and accident sequence analyses.

  Section 13.8.1.1.1 Probabilistic Safety Analysis (PSA)

- The HFEs and operator action errors identified in the Human Action Database (HAD) have undergone risk-based screening based on criteria relating to core damage frequency (CDF) and large release frequency (LRF) increase thresholds and on the safety classification and safety function category level of error affected SSCs.

  Section 13.8.2 Risk Proportionate Screening

- A methodology for the analysis of human errors has been conducted at a cognitive level

on a sample of Type A, B and C errors in GDA. Completion of this analysis in site licencing of the remaining operator actions important to safety will serve as input to the PSA activity and substantiate the risk to nuclear safety from human error reduced ALARP.

Section 13.9 Substantiation of Human-Based Safety Claims

Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

Claim 6 – A sample of Type A, B and C errors have undergone cognitive-level HEA to identify credible error modes and mechanisms (root cause) and performance shaping factors so that error reduction mechanisms can target the risk of failure ALARP for the Standard AP1000 plant design.

- A credible approach, based on empirical studies of current psychological research, has been devised to conduct HEA on the operator action sample during GDA that has identified context specific cognitive failure modes for the key action steps in the task analysis.

  Section 13.8.3.2 Cognitive-Level

  Reference 13.94 US NRC, NUREG-2114, Rev 1, "Cognitive Basis for Human Reliability Analysis," January 2016.

  Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

- The underlying internal error mechanism and performance shaping factors have targeted proposed error reduction mechanisms and ALARP design recommendations.

  Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

  Reference 13.93 Westinghouse Report UKP-GW-GL-072, Rev 0, "Supplemental Information for the Human Factors Safety Case – Potential Improvements as Proposed in the ALARP Analysis," November 2010.

Claim 7 – The symptom-based approach of the emergency operating procedures (EOPs) and of the incontrovertibly different entry conditions to each EOP has reduced the potential for diagnostic error such that it is considered to be reduced ALARP for the Standard AP1000 plant design.

- A credible approach to the identification of diagnostic error potential has been devised and HEA of the sampled operator errors did not identify increased potential for misdiagnosis and entry to incorrect procedure.

  Section 13.8.3.3 Misdiagnosis

  Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

- The symptom-based nature of the abnormal operating procedures (AOPs) and EOPs means that operators are not required to operate in "knowledge space" and so are not required to try and immediately diagnose the fault or the cause of the fault.

Section 13.6.13.1.2 Abnormal, Emergency Operating and Alarm Response Procedures

Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

- The entry conditions to each of the EOPs are clear and easily discernible and checked from readily available HSI displays.

  Section 13.6.13.1.2 Abnormal, Emergency Operating and Alarm Response Procedures

  Section 13.6.7.1 Distributed Control and Information System

  Section 13.6.7.6 Computerised Procedures System

- The EOP network is always entered through the reactor trip procedure (E-0). The procedure instructs the operator to manually trip the reactor as an "immediate action" (IA), even if automatic reactor trip has occurred, and prompts the operator to verify that reactor trip has occurred and that all the safety systems have operated as required. Following verification of proper safety system operation, the procedure then steps the operator through several diagnostic steps and based upon plant symptoms or state the operator is directed to the appropriate optimal recovery procedure within the EOP network. Therefore, the entry conditions for each EOP are incontrovertibly different and so the potential for entry to and execution of the wrong EOP is considered to be highly unlikely.

  Section 13.6.13.1.2 Abnormal, Emergency Operating and Alarm Response Procedures

- As a result of monitoring the key safety parameters and set-points associated with the critical safety functions, as directed by the EOPs and presented by the computerised procedures system, the operators are directed to the correct function response procedure in a timely manner.

  Section 13.6.13.1.2 Abnormal, Emergency Operating and Alarm Response Procedures

  Section 13.6.7.1 Distributed Control and Information System

  Section 13.6.7.6 Computerised Procedures System

- An HF ISV test was executed to validate, among other objectives, the HSI design and the plant operating procedures (including EOPs). The completion of this test, the identification of any HEDs, and the resolution and re-verification/revalidation of the HEDs ensures the risk of misdiagnosis is ALARP.

  Section 13.7.3 HF Integrated System Validation

  Section 13.7.4 Human Engineering Discrepancy Resolution Verification

  Section 13.7.5 Plant Start-up HF Engineering Design Verification

- The AP1000 Conduct of Operations provides the standards and guidance, governing the behaviour of operations personnel, to achieve a high-level of performance that contributes to safe, reliable plant operations.

Section 13.6.16 Conduct of Operations

Reference 13.66 Administrative Procedure APP-GW-GJP-115, Rev 1, "Conduct of Operations," June 2014.

Claim 8 – The equipment design, task or operating context conditions that may cause behaviour in violation of procedures have been identified through HEA or observed during the HF ISV test. Respective ISV HEDs have been identified. Resolution of these HEDs shall be agreed upon, implemented, and re-verified/re-validated such that the risk for violation is ALARP.

- A credible approach to the identification of violation potential has been devised and the HEA of the Type C post-fault operator errors in the sample did not identify potential high-workload, stress and task goal conflict situations where violation potential may become more likely.

  Section 13.8.3.4 Design Induced Violation

  Reference 13.54 Westinghouse Report UKP-GW-GL-126, Rev 0, "United Kingdom AP1000 Human Factors Qualitative Error Analysis," June 2016.

- The allocation of functions has resulted in a plant design and consequential operator tasks and job design that reduce the likelihood of situations that present conflicting task goals to the operator, high-workload or time-induced stress that might increase the potential for operator behaviours in violation of procedures.

  Section 13.6.3 Functional Requirements Analysis and Allocation of Function

- The HF ISV test, utilising the high-fidelity AP1000 simulator facility, has been completed. HEDs and any contributing HED issues related to violation have been identified and documented. The process for resolution of HEDs, the implementation of the resolutions, and the re-verification and re-validation of the resolutions is defined. Efforts to reach agreement between HF and the respective engineering disciplines on the HED resolutions are in progress. Implementation of the agreed upon resolutions occurs throughout 2017 and the re-verification/re-validation is scheduled for early 2018.

  Section 13.7.3 HF Integrated System Validation

  Section 13.7.4 Human Engineering Discrepancy Resolution Verification

  Section 13.7.5 Plant Start-up HF Engineering Design Verification

13.5 HF Engineering Programme

International Safety Standards and RGP require that the design of a new NPP take a systematic consideration of HF at an early stage in the design process and that it shall continue throughout the entire process (Reference 13.13).

HF Engineering, or the UK analogous HFI, is a good practice approach to the application of HF to system's development. HF Engineering is a methodology that provides both an organising framework to help ensure that all relevant HF technical issues are identified, tracked and addressed, and a management strategy that provides for a timely and appropriate integration of HF activities throughout the design development project.

The HF Engineering programme elements that have been used throughout the design development of AP1000 have been based on the NUREG-0711 HF Engineering Program

Review Model (Reference 13.14). The HF Engineering Program starts in the early planning and concept phase with the high-level safety and operational goals for the plant being identified through examination of:

- Design evolution from predecessor systems (Section 13.6.1
- Operating experience review (Section 13.6.2)
- Utility/Customer design requirements (13.6.2.2)
- A Concept of Operation (Section 13.6.4)

In the 'analysis' phase the functions necessary to achieve the plant's high-level operational and safety goals were defined and refined in to increasing levels of system detail. System and sub-system level functions were then allocated to human and system resources. Decomposition of the human-assigned functions into tasks and of the engineered-assigned functions into delivery SSCs then informs the specification for the necessary alarms, information, controls, and task support that is needed to complete the functional assignments using:

- Function requirements analysis and allocation of function (Section 13.6.3)
- Task analysis (Section 13.6.5)
- Identification and treatment of human actions important to safety (Section 13.6.5.2 and 13.6.5.3)

In the 'design' phase, personnel tasks are analysed to identify the alarms, displays, procedures and controls that will be required for task performance. The detailed design of the HSI, procedures, and training requirements are best designed to support operator assigned tasks:

- Human System Interface Design (Section 13.6.6)
- Procedure Design and Development (Section 13.6.13)
- Job and Role Design, Staffing and Qualifications (Section 13.6.15)
- Conduct of Operation (Section 13.6.16)

During the HF V&V phases, which are currently being conducted for AP1000 build programs in other countries, V&V activities comprehensively determine that the control centre and HSI design conforms to HF Engineering design principles:

- Design Verification (Section 13.7.2)
- Task-Support Verification (Section 13.7.1)
- Integrated Systems Validation (Section 13.7.3)

The HF elements of the HF Engineering programme have been systematically applied in the conceptual and planning phases of the AP600 since the 1980s and early 1990s and remain and continue to be a significant focus for the design development of the AP1000 in 2016 and for GDA (Figure 13.1).

This period of time also encapsulates the ongoing HF Engineering program for AP1000 projects currently in advanced stages of construction, system installation and commissioning. Where appropriate, the HF analysis and output data from the HF

verification and validation activities conducted for the standard AP1000 plant design has been used as supporting evidence in the substantiation of HBSCs for a UK AP1000 in GDA.

The rest of this Section 13.5 provides an abbreviated account of the HF Engineering programme management, methodologies and assessments that has been used to construct a human factors safety case that provides the substantive evidence to support the overall HF claim and reduce the risk from human error ALARP for GDA.

Key to the effectiveness of applying successive HF Engineering technical programme elements throughout the design lifecycle has been the management strategy to ensure that they are integrated in an effective and timely manner with other project design and safety disciplines and executed by suitably qualified and experienced HF practitioners.

The information on how the HF technical and management programme has been conducted for AP1000 is captured in the Westinghouse HF Engineering Program Plan (Reference 13.10), analogous to the HFI Plan in the UK. The stated aims of the HF Engineering Program Plan are, as well as delivering the technical program, to:

- Describe the scope of the HF Engineering program, outline the technical approaches, identify the HF Engineering team, describe the organisational structure, and define roles and responsibilities.

- Assist in avoiding costly re-design via the incorporation of human factors into the design process in a timely manner.

- Detail the documentation required to illustrate that the design was developed in accordance with applicable human factors design, operation, and maintenance principles.

13.5.1 HF Engineering Program Management

The AP1000 project is sizeable and complex, encompassing a large number of technical, safety and management disciplines, such as mechanical, electrical, process, civil, structural, control systems, instrumentation, radiological systems, nuclear safety, and conventional safety. Each discipline or group has clearly defined responsibilities and authorities.

In the early design stages, the primary focus of the HF Engineering Program Plan has been the MCR and the supporting control and monitoring facilities and systems. Therefore, the HF Engineering function has traditionally been placed within the AP1000 C&I project organisation in order to integrate HF Engineering into the C&I design activities.

The AP1000 Project organisation is based on a matrix-type structure, with a relatively flat management hierarchy. The individual engineering, technical, and support groups typically comprise a relatively small number of people. Personnel can be a part of more than one group. This aids flexibility in the use of resources, facilitates communication, and maximises the use and application of the available engineering expertise and experience.

13.5.2 HF Engineering Management Function

The Westinghouse HF Engineering team function resides within the C&I group organisational structure, along with other human performance influencing functions, such as procedures, training and operations. However, there is an appreciation within the group's management structure that HF team coverage extends beyond control centre HSI

and operations and is given sufficient autonomy to reach out and interact with other project technical and safety disciplines as required. An example of this is the ongoing support that the Westinghouse HF team is providing to other project technical areas in order to identify claims that they may be making on operators in compiling the safety case for their systems and in resolving their GDA Issues (Reference 13.95).

By reporting to a single C&I Project Manager, the HF Engineering function is effectively integrated within the larger C&I team, ensuring that all team members are clearly aware of each other's roles and responsibilities. A schematic of the HF Engineering Group is provided in Figure 13.2.

13.5.3 HF Engineering Qualifications and Expertise

The HF Engineering specialists have a background in human factors, psychology, systems engineering, or a combination of these areas. They are qualified and experienced in applying knowledge about human characteristics, skills and limitations to the design, operation, and maintenance of systems or facilities. The HF Engineering specialists are well-versed in the application of human factors knowledge, techniques, and standards to systems or facilities that are potentially hazardous and/or complex, such as nuclear reactors, non-reactor nuclear facilities, and other process industries.

13.5.4 HF Engineering Technical Process Management

The HF Engineering program is managed through an iterative process of detailed task analyses, multi-discipline design review and V&V assessments of the OCS and local C&I HSIs. The design is placed under formal configuration control and proposed design changes are fully assessed by HF and other design disciplines to identify operations or maintenance impacts before formal design change approval (Reference 13.15).

A formal HF Engineering tracking system (Reference 13.10 Section 4.2.5) is used by the HF Engineering Lead to manage the resolution of HF issues or items that result from task analysis, design review, and HF V&V activities and ensure that these items are recorded, dealt with, and resolved in a timely, efficient manner.

The items entered in the HF tracking system constitute one or more of the following:

- An undocumented assessment or analysis required to support a design decision
- An undocumented assessment that is required at a later stage in the design lifecycle when the required level of design or operations detail becomes available
- An issue identified from task analysis results, including the human error analyses of section 13.8.3
- An issue identified from a non AP1000 project that is known or anticipated to be an unresolved issue for AP1000
- A HF action item identified during the course of a design review meeting that cannot be closed as part of the design review process
- An issue identified during human factors V&V activity

Formal design reviews are undertaken at key points in the HF design development process. The objective of these reviews is to provide a systematic evaluation of the AP1000 by a multi-disciplinary team, which includes utility representatives.

Formal engineering tests have been conducted to provide timely feedback during the HSI design process (References 13.16, 13.17, 13.18). A relatively limited scope simulation was utilised to execute these tests to address and evaluate specific design issues (e.g., the use of large screen display units for overview displays, soft controls, alarm presentation, supervisory repeater functionality, etc.). The results of the engineering tests were used to refine the design, as required. The simulator-based tests used a sample of actual reactor control room operators and supervisors in order to obtain realistic results and to benefit from the subjects' operations experience.

These HF engineering tests are considered to be of high importance due to the application of modern standards C&I HSI technology and new passive safety systems used in the design of AP1000. The AP1000 MCR includes operator interfaces comprising of VDU and soft control-based systems. Operator performance data are collected using video and audio recordings of the scenario, verbal communication and feedback from operators and observers during scenarios and by post-scenario questionnaires and debriefing.

The effective management of these integrated, cross-discipline, elements of the human factors programme, as summarised in subsections 13.5.1 through 13.5.4, give confidence and some level of assurance that the operator interfaces of the OCS and local panels are designed to be intuitive to use and will promote effective and safe operational practices. Ultimately, this will be assessed through the HF ISV test carried out on the high fidelity AP1000 simulator (Section 13.7.3).

13.6 Integration of HF in the AP1000 Design

13.6.1 AP1000 Design Philosophy

The current design of AP1000 has evolved from natural circulation cooled reactors that were designed for military applications in the US in the 1970s and 1980s, and based on similar technology and proven components, and which could perform their safety functions without the need for ac power.

The evolution of the AP1000 design from earlier generations of pressurized water reactors (PWRs) is described in Reference 13.19. This reference details some 44 evolutionary changes from previous designs, key of which from a human factors perspective have been:

- Use of digital C&I, giving the opportunities to implement advanced control and monitoring concepts such as soft control, integrated alarm systems, and advanced human interface resources.

- Use of an advanced Control Room, with the main operator-systems interface via computer based monitors, mice and keyboards. The VDU based workstation allows a number of systems to be integrated in to one flexible interface technology, including large screen displays that enable plant overview and alarm status information to be visible from all operator locations, thus facilitating crew situational awareness and decision-making.

The evolutionary improvement to safety is consistent with the ONR's expectations for the demonstration of ALARP with respect to new commercial reactor designs (Reference 13.4). That is:

- New reactor designs should demonstrate a level of safety that is no less than a comparable facility already working or being constructed in the UK or somewhere else in the world.

- Evolutionary designs, which have been designed taking account of experience of earlier designs, must show how the evolution has maintained or improved the design from a safety perspective.

The AP1000 design philosophy has also been one that is consistent with ensuring an inherently safe design, avoiding hazards rather than controlling them. Throughout there has been DiD against potentially significant faults or failures, providing a series of independent barriers (inherent features, equipment and procedures) that prevent faults from occurring in the first instance, and to help ensure that there is appropriate protection or mitigation of accidents in the event that prevention fails. The AP1000 specifically focuses on securing safety through design characteristics at the top of the safety measures hierarchy, with many passive safety features that do not rely on control systems, active safety systems, alternating current (ac) power, or human intervention (Reference 13.19).

13.6.2 Operating Experience Review

The incorporation of operating experience reviews (OERs) into the design and operation of nuclear facilities is good human factors practice (Reference 13.22) and is one of the criteria used by the UK ONR to assess leadership and management for safety.

Nuclear industry guidance on the incorporation of operator experience into design and operations is largely focused on gathering information internally during operations, as well as gathering external data from international organisations, including the World Association of Nuclear Operators (WANO), Institute of Nuclear Power Operations (INPO), and International Atomic Energy Agency (IAEA). Westinghouse has been proactive in gathering operating experience from a large range of sources, including the utilities operating their plants and more recently from AP1000 new build programmes at advanced stages of build, system installation and commissioning in both China and the US.

13.6.2.1 Operating Experience Collected to Support the AP1000 Design

Operating experience has been explicitly addressed by the HF Engineering process that developed the requirements for the AP1000 design and its predecessors. In particular the ALWR Program was organised to make extensive use of the extraordinary database of information and lessons learned from over 40 years of experience in operating over 100 Light Water Reactor (LWR) plants in the US and many more overseas. This operating experience comprises over 1,700 reactor years in the US and over 5,000 reactor years world-wide.

In order to meet these requirements and incorporate appropriate features in the AP1000 plant's design, operations and maintenance, Westinghouse reviewed existing databases of LWR operating experience to identify both positive experiences as well as causes of significant events and unplanned outages. During the design phase of the AP600 and AP1000, extensive reviews of industry operating experience were performed and assessed with respect to their applicability to the AP1000 design.

The results of these OERs are described in References 13.24, 13.25, 13.26 and 13.27, the latter, of which focuses on operating experience documented in US Nuclear Regulatory Commission (NRC) IE Bulletins, Circulars, and Information Notices as well as NRC Generic Letters and regulatory Information Summaries. In particular, a HF Engineering Operating Experience Review (Reference 13.27), assessed pressurised water reactors (PWRs) at both Westinghouse and non-Westinghouse plants; issues for boiling water reactors and a pressurised heavy water reactor designs which were applicable to the AP1000 design; and HSI experience from other industries, where limited experience exists

in the nuclear industry.

Revision 3 of the OER document for AP1000 (Reference 13.27) incorporates operating experience data gathered from 1996 to 2006 and includes issues associated with more advanced system interface design, such as large display screen networks (a "bank" of large displays showing general plant status information), implementation of soft controls, and group situational awareness. Many of the issues identified during this time relate to operator training, teamwork, and the use of procedures and have been addressed by Westinghouse accordingly. In addition, since 2006, Westinghouse continues to collect relevant operating experience from a range of available sources and databases to ensure that new lessons learned are also incorporated into the AP1000. Items that cannot be immediately incorporated are entered into the human factors engineering tracking system for future resolution (Section 4.2.5 of Reference 13.10).

More recently, there is emanating from AP1000 new build projects important construction, equipment installation and commissioning operational experience. The design, safety and operation of the UK AP1000 will ultimately benefit from the experience gained from these, predecessor, AP1000 builds.

13.6.2.2 Utility Customer Requirements

In the mid-1980s, the US utilities, nuclear plant vendors, nuclear architect/engineers and industry consultants such as the EPRI worked together to generate a detailed specification and set of requirements for the next generation of nuclear reactor designs. This resulted in the ALWR Utilities Requirements Document (URD) (Reference 13.20), which set a minimum acceptable standard for plant design.

For Westinghouse, and the design of the AP600/AP1000, the URD set the same basis for comparison of nuclear reactor designs in the US, so that technology selection would be based upon the delivery of the best value whilst meeting the minimum acceptable standard in the URD. A few years later, the European utilities also formed a steering group for new nuclear in Europe under the banner European Passive Plant and developed a derivative URD called the European Utility Requirement (EUR) (Reference 13.21). Both the URD and the EUR have ensured that utility involvement became a part of the development of AP600 and then AP1000, incorporating best practices from around the world and reinforcing worldwide standardisation.

13.6.2.3 Ongoing Consultation with Utilities

The utilities continue to be involved throughout the design development of the AP1000 plant. This involvement has included:

- Attending formal design reviews to review the completeness and technical content of the functional design and the system specification for the control system and operator interfaces (e.g., References 13.29 and 13.30).

- Providing currently licensed and qualified control room operators from existing plants to participate in the HF tests on the early prototype designs and detailed designs of the operator interfaces (References 13.16, 13.17, and 13.18).

- Attendance at workshops to review the detailed designs of the operator interface and, to address outstanding issues from completed HF tests, and to review disposition of actions taken from previous workshops (e.g., Reference 13.31).

- The provision of licensed operator candidates, having completed AP1000 training, to participate in the human HF ISV simulator tests (Reference 13.59)

- Representation (review member) on the plant configuration change control board, where decisions are made on implementation of design changes (Reference 13.15).

- Providing reviews of operating procedures developed for AP1000 that help integrate industry operating experience into the procedures and help ensure the quality and practicality of the procedures.

13.6.2.4 Target Audience Description (TAD)

A part of any decision to allocate safety functions to human elements of the system (Section 13.6.3) will be determined by an understanding that the operator selected to fulfil that safety function will have sufficient mental and physical aptitude to be trained and to reliably perform the actions necessary for the task (see Section 13.6.14). A TAD is the collection of the physiological and psychological attributes possessed by the population, from which operators may be recruited, and, for which system designers, should accommodate in their design.

The AP1000 plant has been designed to physically accommodate the 5th percentile female to the 95th percentile male dimensions based on data initially selected for the U.S. population.

It is good engineering design practice to design workstations so that they shall accommodate from the 5th to the 95th percentiles of dimensions of the intended user population. This is a General Requirement stipulated in BS EN ISO 11064-4 2013 (see Table 13-1), an internationally adopted standard for the effective design of workplaces/spaces. BS EN ISO 11064 is also recognised by the UK ONR as a source of relevant good practice that has informed the advice provided to their inspectors in the TAG on Workplaces and Work Environment (NS-TAST-GD-062, Revision 2, February 2014).

The impact of a UK anthropometric data set and of potential UK nuclear worker stereotypical behaviours on the design of AP1000 is discussed at Section 13.6.17. Invariably however the design of structures and the installation of systems important to safety, when they must also accommodate and interface with human operators and maintainers, will require there to be made design compromise between conflicting operational and structural engineering requirements, e.g., the size of MTIS-access ports that can be made in normally pressurised vessels and still comply with structural integrity codes. Section 13.6.12 describes the maintenance and maintainability activities that have been completed and the scope of HF maintenance assessments to be completed during site licensing.

There is no specific selection criteria developed for the AP1000 plant operators. However it is usual practice within the US nuclear industry to use the Edison Electric Institute Plant Operator Selection System (POSS) test battery to aid in the selection of candidates for electric utility industry operators in fossil, nuclear, or hydro power plants. POSS consists of a group of 5 short aptitude tests – reading comprehension, mechanical concepts, mathematical usage, spatial ability, tables and graphs – that have been found to be related to success in plant operations work.

13.6.3 Functional Requirements Analysis and Allocation of Function

A key HFI process activity in the early design planning and analysis stages is the analysis

of functional requirements to identify those functions that must be performed to satisfy plant safety objectives (functional requirements analysis), and the analysis of the requirements for plant control and the assignment of control functions to (1) personnel (e.g., manual control), (2) system elements (e.g., automatic control and passive, self-controlling phenomena), and (3) combinations of personnel and system elements (e.g., shared control and automatic systems with manual backup).

The Westinghouse design process for functional requirements analysis and allocation of function for AP600/AP1000 (Reference 13.32) has followed the good practice guidance and methodology within NUREG-0711 (Reference 13.14), and was further informed by IAEA TECDOC 668 (Reference 13.33) and so can be deemed comparable to the process outlined in the ONR's TAG (Reference 13.34) on this subject. Reference 13.32 provides both a description of the methodologies used for functional requirement analysis and function allocation and presents the results of applying these processes.

The functional requirements analysis and function allocation process follows a four stage process whereby (1) the functions that need to be allocated are identified; (2) functions are allocated using a set of guidelines and heuristics; (3) the reasons for allocation are justified and documented; and (4) the function allocation is tested and identified problems resolved through an iterative design and test process.

(1) Functional requirements analysis begins with identification of safety functions required to prevent or mitigate the consequences of postulated accidents that could cause undue risk to the health and safety of the public. For each critical safety function (CSF), the set of plant processes (plant system configurations and SSCs for the critical function success paths) that are responsible for or capable of carrying out the function are clearly defined. Key inputs to the functional requirements identification process at that time were the Emergency Response Guidelines and system specification documents for each of the plant systems.

(2) Each system process or component on a CSF success path was then allocated to automatic actuation or manual control on the following heuristic decision basis:

Automatic

- The operator is NOT able to perform the required task due to human limitations.
- Automation is necessary due to regulatory design requirements.
- Automation is necessary due to utility design requirements.
- Automation provides a safety benefit as identified in the PSA.
- Automation is preferred based on operating experience.
- Automation is preferred due to concerns for operator overload.
- Automation is inherent in the passive design.
- Tasks are not well suited to human performance and are better suited to automation.

Manual

- Human performance is required because automation is not technically feasible.

- Human performance is required by design recommendations or requirements.
- Human performance is preferred because of consideration of safety requirements, task complexity, cost/benefit considerations to implement automation, and the value of human judgment.
- As a backup to the automatic functionality

(3) The following HF considerations were incorporated into the early planning and analysis stages of the AP1000 project and function allocation:

- Tasks were not assigned to operators when it was known that they would be unable to accomplish critical safety actions in a timely manner. [There are no critical human actions identified by either deterministic or PSA criteria as defined by Reference 13.35, Section 2.1].
- Tasks are not assigned to operators when they are complex or not routinely performed and when there is a likelihood of error or a high workload may occur due to the initiation of a transient.
- Tasks are not assigned to operators when operating experience indicates that human capabilities may be inadequate to execute tasks with sufficient reliability.
- Tasks are not assigned to operators when the PSA/HRA indicates that HEPs are too high to maintain plant safety.
- Tasks are not assigned to operators when activities are not well-suited to human strengths (for example, the activities require sustained vigilance).

The allocation of functions has resulted in a plant design and consequential operator tasks that reduce the likelihood of situations that present conflicting task goals to the operator and potential violation of procedures. For example, the requirement in current plants for operators to throttle safety systems to prevent the reactor coolant system (RCS) overfill in some post-accident conditions is not required in the AP1000 plant. Also, in current plants the operators are typically required to make a number of actions to cool the RCS and depressurise it to the shutdown cooling system cut in conditions, to align and start-up the shutdown cooling system and to re-align the water cooling systems servicing the shutdown cooling system. None of these operator actions are required for the AP1000.

(4) The basis of the function allocation focuses primarily on the responsibilities of operators with respect to an individual function, system, or process. However, it is recognised that in an operational setting, the operators will have responsibilities across multiple systems. Further HF Engineering process activities define and evaluate the role of the operator to monitor and control multiple plant and safety functions.

The function allocation process (Reference 13.32) concluded by defining a number of principles that have helped to shape a concept for operation (Section 13.6.4) and inform HSI requirements (Section 13.6.6) for AP1000.

- Automatic actuation and control functions are needed for a variety of design reasons (e.g., when an operator may not respond quickly enough or the

workload may be too high to reliably perform control actuation functions).

- For system and component actuation, the human operator serves as a backup to the automated system.

- For system and component control, the human operator serves as a back-up when automation fails, but for certain operating conditions, the use of manual control is preferred.

- The human operator always determines when execution of an EOP is complete and the plant has reached a safe and stable state following a fault condition.

- The operator has limited control over passively actuated and passively controlled functions.

In the design and evaluation of the AP1000 plant, particular attention has been paid to the operators' role as supervisory controller and system monitor of automated systems. This includes the following human factors considerations:

- Situation awareness of the status and operation of the automated systems (that is, the ability to detect and understand changes in automated system performance)

- Ability to detect degradation in automated system performance and establish manual control

- Ability to make a smooth transition from the use of Class 3 SSCs to Class 1 SSCs

- Monitoring and supervisory control of passive systems (including decisions and actions to mitigate events before necessitating a transition to actuation of Class 1, passive SSCs)

- Optimising operator workload and workload transitions

- Operator vigilance and the need to keep the operator involved and knowledgeable of the plant status

Where functions were allocated to human operators, the following principles are applied:

- Develop displays that aid the operator in understanding about the process from both physical system and functional perspectives.

- Use plant systems to monitor for set point violations and other significant changes to aid the operator in identifying important changes.

- Use plant systems for monitoring parameter values that are needed in completing procedures and then informing the operator about the status of those parameters in the context of the procedure step.

- Aid the operator in locating and accessing important plant and system status information that may become relevant to operations.

Supported by this functional analysis, the role of the operators in the AP1000 plant, at a high level, remains the same as in many current nuclear power plants. Operators function as supervisory controllers of the automated systems. The operators monitor the state of the plant, systems, and equipment; they verify that automatic systems have actuated and are responding as required; and they take manual actions when necessary. Also, as in current plants, the operators respond to emergency events guided by EOPs, where the role of the operator includes monitoring the plant state, verifying plant parameters, and monitoring the automatic operation of Class 1 and 2 systems.

13.6.4 Concept of Operations

The difference between the role of the operator in the AP1000 plant and in current plants is one of degree, and not a fundamental change in character. At a detailed level, there will be differences in the specific activities performed by operators due to differences in safety-related systems, automation, and the availability of improved HSI. The HSI includes displays that integrate information to facilitate assessment of plant state and supervisory monitoring of automated systems, and a computerised procedure system that facilitates execution of the AOPs and EOPs.

Some of the distinctions in equipment type that are important from a design and licensing perspective should be relatively transparent from an operational perspective. In particular, the AP1000 employs passive safety systems that automatically protect the plant in the event of an accident, without the need for immediate operator actions. The AP1000 also employs DiD systems that, if available, can automatically protect the plant for the more probable postulated transients and accidents. If these, DiD, systems are available and operate correctly, they may prevent the need for the operation of the safety-related, passive systems. The AP1000 EOPs integrate the use of the DiD systems and the passive safety systems to maximise the protection of the plant for design basis and beyond design basis accidents. During transients, operators are required to monitor the status of both DiD systems and the passive safety systems, and are procedurally guided in the use of both types of systems.

A design aspect of the AP1000 plant that is different from current plants is in the use of passive safety systems. The passive systems rely on natural forces such as gravity or compressed gases, instead of mechanical forces such as pumps, to perform their functions. As with other automatic systems, operators are responsible for monitoring the availability and operational status of the passive systems. Operators are responsible to verify the operation of, or the need for operation of, the passive systems. When termination criteria are met, operators are responsible for terminating the operation of the systems. Monitoring and control activities associated with passive systems are guided by EOPs.

In the design of the HSI, procedures and training, the passive systems are treated as a type of automated system. The HSI will be designed to support supervisory monitoring and control of the passive systems. While the passive systems are different in how they operate, they do not pose fundamentally different challenges for HSI design or operator supervisory control. In addition, some specific passive systems, such as the accumulators, have been installed in current plants and function identically for the AP1000.

A full description of the AP1000 Concept of Operations (Reference 13.36) includes operation from the MCR, RSR, and local control stations (LCS), addressing normal, abnormal, transient, and emergency operations of the AP1000 plant. Also included are the administrative and business activities such as crew meetings/briefings, accessing plant information via the site-specific local area network, and use of the communication systems. The roles of AP1000 operations staff outside the MCR, RSR, and LCS are also presented

in order to provide a complete view of their roles in the concept of operation for the AP1000 and identify interface and communication channels that the OCS HSI must support.

The roles and responsibilities of the MCR staff are defined in Reference 13.37. This document identifies the roles, responsibilities, and staffing assumptions for the MCR personnel, including both minimal and large staff complement and describes how the expected MCR staff, minimal and large complement, interfaces with the MCR HSI resources.

This description of the concept of operation, along with the conclusion of the allocation of safety functions (Reference 13.32) has been used by OCS and HSI resource designers to develop a coordinated set of functional requirements and design specifications.

13.6.5 Task Analysis

Task analysis provides a systematic method for describing and analysing the way that plant operators interact with SSCs and in operational teams with their co-workers. Task analysis describes the requirements and demands of a task in terms of the actions or cognitive processes necessary for the operator to achieve the task goal.

There have been two main complementary task analysis activities used in the AP1000 HF Engineering programme: Function-based Task Analysis (FBTA) and OSA.

The implementation of these task analysis activities had the following objectives:

- Ensure that human performance requirements equate with human capabilities.
- Provide an input to the development of procedures.
- Provide an input to staffing, training, and communications requirements.
- Provide a basis for design decisions, including the identification of the control, indications, and alarm requirements.

These task analysis activities have been carried out sequentially, and with different but complementary objectives, in order to progressively build confidence that the HSI was sufficient and appropriate to provide the monitoring and control capability necessary to adequately support operators in the delivery and execution of their assigned tasks and safety functions.

- FBTA (Reference 13.38) – The FBTA analysis decomposes and describes selected portions of multiple AP1000 systems that are understood to support a unitary, general function of the plant. This provides a functional perspective on plant operation that supplements the structural perspective offered by the detailed design of individual systems.

- OSA 1 (Reference 13.39) – Focuses on the operational requirements and task demands in terms of the operator actions and/or processes necessary to complete the required AP1000 control and monitoring tasks, abnormal/emergency tasks, and maintenance, testing, surveillance, and inspection tasks.

- OSA 2 (Reference 13.40) – Evaluates the adequacy of the HSI design to support the AP1000 HF program risk-important tasks by identifying and analysing task requirements, time to perform tasks, operational crew staffing and workload.

13.6.5.1 Function-Based Task Analysis (FBTA)

The purpose of the FBTA was to determine and confirm that the instrumentation, controls, alarms, and displays provided via the control systems and operator interfaces were adequate to enable the MCR operators to perform their assigned roles. The FBTA results (Reference 13.41) provide input to the detailed design of the function-based displays.

Results from the FBTA were used to feed into the TSV (Section 13.7.1) in order to:

- Obtain a completeness check on the availability of needed indications, and controls. This includes indications and controls needed for supervisory control of automated systems and manual override.

- Identify issues for tracking and resolution relating to details of plant design or operation.

13.6.5.2 Operational Sequence Analysis 1

A representative sample of plant operator tasks underwent OSA, selected on the basis of the following criteria:

- Representation of the full range of operating modes (for example, start-up, normal, shutdown, abnormal and emergency operations, transient, and low-power conditions).

- Operations including critical human actions and risk-important tasks.

- Representation of the full range of activities involved in an emergency response.

- Operations including MTIS tasks, particularly if a task is identified as risk-important.

With the aim to identify potential limitations on successful task performance that were due to the limits of human performance and capabilities, equipment or software performance and crew communications, each of the scenarios was decomposed into its constituent tasks using approved AP1000 operating procedures.

The results of the analyses of each task have been used to identify the indications, controls and alarms required by the operators and used as a key input into the display development process.

13.6.5.2.1 Criteria for Critical and Risk-Important Human Actions

The deterministic and probabilistic criteria for the identification of critical human actions (Reference 13.35) were negotiated by Westinghouse with the US NRC during development of the AP600 in the mid-1990s. They allowed credit to be taken for the improved safety of the AP600, when compared to current operating plants, and later the AP1000 due to their passive safety features and the non-reliance of ac power for 72 hours. Application of the critical human action criteria, found below, results in the identification of no such actions.

- Deterministic criteria – Any human action that is required to prevent core damage or severe release in licensing DBA.

- PSA criteria – Any one human action that, if assumed to fail, would result in a CDF greater than 1E-4 or a severe release frequency greater than 1E-5.

In order to address the intent of identifying the relevant risk significant human actions,

continued negotiation with NRC resulted in criteria for the identification of risk-important human actions, important for their contribution to CDF and large release. The criteria used to identify risk-important human actions (RIHAs) (Reference 13.35) were the following:

- Risk achievement worth (RAW) – The increase in risk that would result if a single human action were to fail. The CDF and LRF are re-quantified for each human action by setting their failure probability to 1. The RAW value is then calculated as the percentage increase in CDF or LRF due to the human error. For the baseline PSA, a human action is considered risk-important if the CDF or LRF increase is 200 percent; i.e., the RAW is > 3.0. For the "focused" PSA study (with assumed failure of non-safety mitigating features), a human action is considered risk important if the percentage increase is 100 percent; i.e., the RAW is > 2.0. Any value below these criteria is considered to be not risk-important.

- Risk reduction worth (RRW) – The decrease in risk that would result if a human action were made perfectly reliable. The CDF and LRF are re-quantified for each human action by setting their failure probability to 0. The RRW value is then calculated as the percentage decrease in CDF or LRF. For the baseline PSA study, a human action is considered risk-important if the CDF or LRF decreases by more than 10 percent; i.e., the Risk-Reduction Worth is > 1.1. For the "focused" PSA study (with assumed failure of non-safety mitigating features), a human action is considered risk-important if the percentage decrease is 5 percent; i.e., the RRW is > 1.05. Any value below these criteria is considered to be not risk-important.

(RIHAs were however identified for post-accident mitigation and for MTIS support tasks. The basis for the selection and identification of RIHAs is described in Reference 13.35.

Information collected and recorded in the OSA task step relational database included:

- Plant state data required at each step
- Source of the data (e.g., alarm, display, communication)
- Operator Action or decision to be made from the data
- Procedure Steps
- Feedback - Information that provides feedback on the adequacy of actions or decisions
- The required order of tasks, or tasks that need to be done in parallel
- Communication requirements
- Interfaces with other systems

The results of the analyses of each task (Reference 13.43) were used to identify the indications, controls, and alarms required by the operators and used as a key input into the display development process.

13.6.5.3 Operational Sequence Analysis 2

OSA-2 was undertaken on a representative set of operating scenarios that included critical human actions (none), risk-important tasks, and tasks with potential human performance concerns (e.g., anticipated high workload).

After screening the human actions identified in the PSA (Reference 13.44) on the criteria above, OSA-2 was conducted on 19 risk-important tasks and four tasks with potential

human performance concerns. The tasks with human performance concerns were selected by an expert panel on the basis that the tasks were new to control room operations (and therefore had not previously been assessed) and/or had a potentially high operator workload.

The tasks with human performance concerns included:

- Action in response to a data display and processing system failure
- Action in response to the loss of computerised procedures system (CPS)
- Technical Specification (Tech Spec) monitoring
- MCR evacuation

OSA 2 was substantially more detailed in its depth of analysis, building on the OSA 1 analysis, to evaluate the adequacy of the HSI resources available to the operator while conducting risk-important, potentially high workload, tasks. The results from OSA-2 have fed in to the design of procedures and operator training.

OSA-2 addressed four main HF areas:

- Completeness of information – to establish that the information necessary for successful task completion was available.

- Time to perform tasks – to establish that the operators were able to successfully complete tasks within the available time. The time available is based on the thermo-hydraulic calculations used in the PSA model of that time. The time taken was based on assigning to each operator-performed step in the task analysis a generic definition (e.g., check a variable, evaluate a situation, initiate a sequence, etc.) and assigning to that task step the estimated average time to complete (Reference 13.45 Table 2.2-1). Average times had been calculated from the observation of video recordings of operators executing procedure E-0 on a reactor trip or safeguards actuation using the AP1000 control room development facility and the simulator.

- Operator workload – to evaluate the effect of HSI design and task demands, including any concurrent tasks, on operator time-based workload. Time-based workload was derived from dividing time-taken by time-available and multiplying the figure by 100 to yield a percentage. Acceptable workload was considered to be between 50 and 80 percent.

- Operational crew staffing – to verify staffing assumptions. The results of the operator workload assessments and the identification of time constraints are used to review the adequacy of the staffing assumptions, HSI design, task allocation, and work organisation.

The results of OSA-2 (Reference 13.45) concluded that the design of the AP1000 plant supports the successful completion of the 19 risk-important human actions and the four tasks with human performance concerns, with no design changes necessary. The workload was considered to be acceptable for all tasks, with recommendations on operator requirements for one task.

13.6.6 HSI Design

The layout and arrangement of workstations in the MCR (see Figure 13.6) has been

informed by customer input, and by the crew organisation and shift complement described in the AP1000 Main Control Room Staff Roles and Responsibilities (Reference 13.65).

13.6.6.1 HSI Design Guidelines

The design and layout of the control and display features, presented at workstations and on equipment having hard panels or 'soft' VDUs, has been guided by two key documents produced by Westinghouse and based on international Standards, good practice guidance and operating experience.

The first of these HSI design guidance documents (Reference 13.46) is applicable to the HSI resources that are located in the OCS. The focus of the HF input is on the MCR, but the OCS also includes the TSC, the RSR, and the OSC.

The HSI resources include the plant information system, alarm system, computerised procedures, protection and safety monitoring system (PMS) display, soft controls, dedicated controls, diverse actuation system, and the wall panel information system (WPIS). The HSI design guidelines address the HSI resources that are primarily utilised by the MCR operating staff. However, additional users are also considered, such as the shift supervisors, operations management, technical, engineering, maintenance, health physics, and chemistry personnel. The HSI design guideline document includes the following HF guidance:

- Control room design
- VDU-based workstations
- Workstation and console design
- Control room equipment
- Location of controls
- Control and display design
- Alarm systems design
- Computerised procedures
- Communication facilities
- Colour-coding
- Labelling
- Closed Circuit Television Systems
- Working environment
- Display organisation and navigation

The second HSI design guidance document (Reference 13.47) is applicable to the local plant and field operations, local plant control room and operations areas, maintenance workshops, local plant maintenance tasks, and manual activities and includes the following HF aspects:

- Workstation & Console Design
- Movement of Personnel
- Manual Forces
- Location of Controls
- Control and Display Design
- Colour-coding & Labelling
- Annunciator Panels and Auditory Alarms
- Closed Circuit Television Systems
- Working Environment
- Maintainability

The guideline documents are used as a design input directly by the engineers responsible for the development of the OCS operator interfaces and the local plant areas and equipment. The guidelines are applicable across the entire AP1000 project, including peripheral areas that may not be subject to detailed HF analysis, to ensure application of best practice in HSI design, maintain consistency and avoid HF conflicts (such as inappropriate legacy transfer, misdiagnosis, etc.) within and between different operator

interfaces.

The guideline documents have also been used by HF specialists as a tool to provide a systematic means of participating in respective design reviews, and have been used as the basis for the HF design verification, which is described in Section 13.7.2 and more fully in Reference 13.42.

13.6.7 Operation and Control Centres

The objective of the control centres and HSI designs is to provide the operators with an effective means for acquiring and understanding plant data and executing actions to control the plant processes and equipment. The OCS system specification document (SSD) (Reference 13.50) describes the purpose and goals of each control centre and HSI resource, states the main design basis and the rationale supporting engineering design decisions. It covers the design of the MCR, TSC, RSR, operations support centre, local control stations, and the HSI resources (Figure 13.3). The design of each of these control centres is undertaken using the HF Engineering design process as described in the HF Engineering Program Plan (Reference 13.10).

The HF Engineering activities, such as the functional requirements analysis and allocations, FBTA, OSA-1, OSA-2, the engineering test results, operating experience reviews, HSI design guidelines, and the HRA are used by designers to produce the functional requirements, design basis, and design specifications for the individual control centres and HSI resources. The corresponding design specification documents provide greater detail. They document how the requirements as identified in the functional requirements are realised. This includes information on the means, by which the detailed HSI Design Guidelines (Reference 13.46) are applied to the design. The design specification documents typically includes layout drawings, general arrangements, and design descriptions. It is used by the designers as an input to develop the hardware and software implementation documentation, specifications, and verification test procedures.

13.6.7.1 Distributed Control and Information System (DCIS) Displays and Soft Controls

The purpose of the DCIS is to ensure that the operators' understanding of the current plant conditions, equipment, and alarm status is maintained and/or can be readily ascertained. The soft controls enable the operators to control the plant safely under normal conditions and to maintain it in a safe state under accident conditions.

The Data Display and Processing System (DDS) displays and the Plant Control system (PLS) soft controls are part of the DCIS. The displays utilise colour VDU-based workstations to present graphics displays (or mimic displays), trend displays, alarm information, etc. (e.g., Figure 13.4 – further examples of DCIS display screenshots are provided in Figures 13.7 to 13.15). Note: These 'screenshots' are provided for illustrative purposes only. No dynamic data was driving inputs to these displays so no inference to any real-world plant conditions and 'bad' magenta data should be made.)

The DDS displays include physical or system process displays (Figure 13.7), functional displays (Figure 13.8), task displays (Figure 13.9), trend displays, embedded trends, historic data displays, health displays, tagging displays, results from application programs and data processing detail displays. The displays provide dynamic indications of plant parameters and equipment status, including the detailed information required for the monitoring, planning, controlling and obtaining feedback on control actions. The DDS displays provide information on instrumented plant systems and components, including DiD and passive safety systems, functions and components, plus it includes alarm

information.

These VDU-based workstations also provide links to access other human system interfaces such as the CPS and the alarm presentation system (APS) via a windowing system.

The DDS displays provide the mechanism to access the soft controls by selecting a target area (or poke field) on a display (Figure 13.4). The means to access and display the soft controls enables the operator to view the associated graphics displays while undertaking control actions. The DDS displays and soft control displays are accessible via the VDU-based workstations on the operator's and supervisor's consoles in the MCR, although the control functionality is normally 'locked-out' at the supervisor's console.

13.6.7.2 Protection and Safety Monitoring System (PMS) Displays

The purpose of the PMS safety displays is to present information which is important to plant safety as well as provide a limited number of soft control functions. This includes Qualified Data Processing System (QDPS) visual alerts and post-accident monitoring (PAM) variables, and the Reactor Trip System (RTS) and ESF information. The QDPS is provided by the PMS. The PMS displays assist the operators during abnormal and emergency conditions in determining the safety status of the plant and determining if operator action is required to restore the function. Although primarily for use in abnormal or emergency conditions, the associated VDU-based workstations, located at the primary dedicated safety panel (PDSP) in the MCR, are continuously available. The PMS displays provide an overview of the PAM variables, critical safety function displays, RTS and ESF status displays, trends, alerts and detailed data displays. These safety VDU-based workstations are also used to perform RTS and ESF system blocks, resets, Nuclear Instrumentation System calibration functions and ESF component control (for those functions that result in onerous consequences).

The HSI aspects of the design of the PMS displays and soft controls are compatible with the DDS and PLS displays, designed to the same set of HSI/HF guidelines. Designing to the same set of HSI guidelines avoids possible operator errors or delays caused by inconsistent designs between the DDS/PLS displays and the PMS displays. In addition, much of the PMS display information is communicated (via a one-way gateway) to the DCIS and associated VDU-based workstations, where the information is presented via comparable displays.

13.6.7.3 Dedicated Controls

The fixed-position controls are located on the PDSP and the Secondary Dedicated Safety Panel (SDSP) in the MCR. Dedicated controls are also available on the remote shutdown workstation (RSW) panel located in the RSR.

These controls are dedicated to a single function or system level actuation, as typically found on traditional control panels. They provide PMS control functions, including control functions with onerous consequences. Reactor trip, turbine trip, and ESF system level actuations are accomplished using the controls on the PDSP. The ESF system level actuations, resulting in onerous consequences (e.g., automatic depressurisation system [ADS] actuation), are accomplished by actuating one of the controls on the PDSP, plus the corresponding control on the SDSP, simultaneously by two reactor operators (ROs). The RSW panel also provides the controls required for manual reactor trip and the ESF system level actuations.

13.6.7.4 Wall Panel Information System (WPIS)

The purpose of the WPIS is to provide the control room staff with a high-level understanding of the current plant and equipment status via the dynamic display of plant parameters and alarm information. The WPIS facilitates a user group comprehension of the current plant equipment and process status.

The WPIS is positioned in the MCR such that it is visible by the relevant operations personnel and the required text and graphics/symbols are legible by the operators and supervisor while seated at their respective consoles (Figure 13.6). The WPIS presents plant overview and status information, an overview of alarms, major plant parameters, trend displays, equipment and system availability. It also has the capability for the operator to present (or 'post') displays available on the console-based workstations on the WPIS. The WPIS enhances the MCR crew shared situational awareness by:

- Combining and integrating important diverse information that depicts the overall plant status
- Providing "at a glance" overview of plant status
- Identifying major changes in plant state
- Assisting in shift handover by providing a focal point for communication
- Indicate the presence of alarm conditions
- Indicate changes in plant conditions and the rate of change
- Assist in normal plant operations
- Assist in alarm, emergency, and abnormal conditions

The enhanced situational awareness that WPIS provides is particularly advantageous in fault and emergency situations when there may be higher than normal levels of workload, interaction and communication between operators in the MCR.

13.6.7.5 Alarm Presentation System (APS)

The overall purpose of the alarm system is to alert the operators to abnormal plant conditions and to provide them with an understanding of the plant status and behaviour (Reference 13.53).

The alarm system utilises the DCIS VDU-based workstations and the WPIS HSI resources as the means to present alarms and support information to the MCR operators. Alarm information is organised, managed, and presented by the APS. Examples of APS display screens are shown in Figures 13.10, 13.11, and 13.12.

In addition to the APS, the DCIS base alarm system provides detailed contextual information by integrating the alarm indications into the DDS and PLS graphics at the VDU-based workstations at the operator's and supervisor's console. This system also enables the operator to acquire detailed alarm information such as set points, current parameter values, and sorting and filtering of alarm lists.

The APS has been developed in accordance with the internationally recognised standards for the design of alarm systems, EEMUA 191 (Reference 13.51) and International Electrotechnical Commission (IEC) 62241 (Reference 13.52) and with reference to the AP1000 HSI design guidelines for alarm presentation (Reference 13.46 Section 13) where

specific guidance has been provided on the following aspects of alarm system design:

- Alarm categorisation and prioritisation
- Alarm suppression (including standing alarms)
- Minimising nuisance alarms
- Redundant alarms and logic (e.g., in certain operating modes)
- Colour coding and alarm presentation
- Alarm annunciation (visual and auditory)
- Alarm grouping
- ARPs

The APS extends the capabilities provided by the base alarm system providing additional functionality such as alarm suppression, access to alarm response procedures, and alarm grouping. As well as being available on any of the DCIS VDU based workstations on the operator consoles, APS uses the large wall-mounted WPIS to promote early detection and the fast cognitive processing of key alarms by providing fixed areas dedicated to the presentation of alarm information. The WPIS is visible and the labelling easily readable from the RO's, supervisor's and Diverse Actuation System (DAS) panel consoles. An auditory alarm signal will alert the operator to the onset of an alarm.

Alarms are viewed and responded to from the DCIS workstations using the APS as follows:

- The WPIS presents a view of alarms that allows the operators and MCR supervisor to maintain cognisance of the plant conditions at all times. The WPIS also presents a view of alarms common to all operators in the MCA that may be used for review during shift hand-over.

- The operator may use the WPIS as the primary method to identify and correlate high priority alarms and to identify situations in which multiple new alarms are present.

- The operator responds to alarms presented on the WPIS from a DCIS VDU-based workstation at the RO console through the APS support interface.

- ARPs, trend information, detailed parameter and component status information, process diagrams, and logic diagrams are all available using the DCIS VDU-based workstations and APS to assist the operator with diagnosing the alarms and undertaking the necessary compensatory actions.

The APS sorts and organises the alarms from the base alarm system into predefined chronological lists (e.g., unacknowledged alarms, alarm history, un-reset alarms, active user defined alarms, and suppressed alarms) that the operator can select to support the current operations. Any DCIS VDU-based workstation can be used to present the APS support interface and alarm lists. The following information describes key APS functionality that is available to the operators:

- The operators can acknowledge and reset alarms via a pop-up menu accessed from the APS alarm list.

- The operators can obtain information via a pop-up menu accessed from the APS alarm

list.

- The operators can sort alarms by priority, time, system, or operator work station in order to help manage alarms when multiple alarms are present.

- The operators can acknowledge groups of active alarms when presented with multiple new alarms in order to reduce alarm response task workload.

- The APS alarm lists allow the operators and MCR supervisor to be aware of plant conditions. The alarm lists also present a view of alarms that may be used for review during shift handover.

The operators perform alarm-related operations such as acknowledging and resetting alarms from the RO console. The alarm response functions may be divided between the two ROs, with each operator having responsibility for their assigned area. However, any operator assigned to the MCA will be able to monitor and remain cognisant of all alarms.

The MCR supervisor monitors the operators' alarm-related activities from the supervisor's console. Non-routine alarm-related activities such as bypassing an alarm, taking an alarm off scan, or deactivating groups of alarms when a plant function is unavailable, are performed by the operator with the concurrence of the MCR supervisor. The MCR supervisor is cognisant of all alarms and ensures that the RO responds to alarms promptly and in accordance with the ARPs.

The ARPs are electronic presentations of ARP steps, and are retrieved through hot links from the background information menus. Paper copies of the ARPs are available if the electronic versions are not available. Each alarm is provided with an associated ARP and on acknowledgement of the alarm; the operator will open the ARP and follow the procedure steps. Note that in a number of cases, the same ARP applies to more than one alarm indication.

13.6.7.6 Computerised Procedures System (CPS)

The CPS assists the operators in monitoring and controlling the execution of plant procedures. The CPS is accessible via the VDU-based workstations on the consoles in the MCR. The CPS provides navigation links to displays and associated soft controls in the Class 2 control system displays. Examples of CPS display screens are shown in Figures 13.13, 13.14, and 13.15.

The CPS guides operators through plant operating procedures, presenting the status of the procedure steps to the operator. The operators will perform all specified actions in the CPS, with supervision and monitoring from the MCR supervisor.

The CPS provides navigation links to displays in the non-safety control system. Provision of this navigation feature allows the operator to view the procedure step within the physical context of the plant, providing the detailed plant system or component status information. During the execution of emergency operating procedures, the CPS presents the status of the critical safety functions and when applicable directs the operator to the respective function restoration procedure.

In the event that the CPS is unavailable, paper procedures will be used as backup to computerised procedures. These paper procedures include all of the steps, cautions, notes, and features of the computerised procedure and are available in the MCA. In addition, if the CPS becomes unavailable, an online generation of the CPS log will be used to identify

the particular procedure step currently being executed, thereby avoiding place-losing errors in the procedure execution process.

13.6.7.7 Engineering Tests

Formal HF engineering tests were conducted and results documented to provide timely feedback during the HSI design process (References 13.15, 13.16, and 13.17). The engineering tests used rapid prototypes of the MCR consoles, panels, and operator interface designs. These tests were conducted in the AP1000 plant MCR simulator facility with qualified, licensed PWR operators, supplied from participatory utilities, undergoing realistic test scenarios. The first test was focused on the usability of the VDU-based soft controls (Reference 13.16). The second and third engineering tests addressed MCR layout and integration of the user interfaces and their operability and vulnerability to human error (References 13.17 and 13.18).

The engineering tests provided valuable feedback into the early prototype designs due to the differences in the operator interface technology from existing plants and the passive safety systems of the AP1000. The AP1000 MCR provides operator interfaces that are almost entirely comprised of soft controls and display systems (in comparison to a conventional control room layout, containing a relatively large number of dedicated fixed-position controls and displays on panels or control boards positioned around the perimeter of the MCR). The engineering tests provide data via video and digital recordings of operator actions, verbal feedback from the operator subjects and observers via questionnaires, as well as qualitative workload ratings and debriefing sessions.

13.6.7.8 Diverse Actuation System (DAS)

The DAS has been designed to address common mode software failure of the PMS in order to achieve the safety goals of the AP1000 PSA. The DAS provides an independent and diverse means of automatic and manual reactor trip actuation and a selected set of automatic and manual ESF actuations. The specific functions performed by the DAS are selected based on the AP1000 PSA evaluation (i.e., an assessment of the protection system common-mode failure probabilities combined with an event occurrence probability). The DAS is a Class 2 system.

A DAS panel is located in the MCR and comprises the controls for the manual actuation of DAS functions and fixed-position displays for a relatively small number of key parameters. The displays are sufficient for the operator to confirm that a DAS actuation has been initiated and completed. Use of this system will be infrequent, and to prevent inadvertent actuation, the panel control switches are normally kept de-energised, although the displays are continually available. The control switches are enabled from a switch located on the PDSP.

13.6.8 Main Control Room (MCR)

The purpose of the MCR is to provide a seismically qualified and habitable environment (see description of Nuclear Island Non-Radioactive Ventilation System (VBS) at PCSR Chapter 6, Section 6.8.4) for the operators and supervisors to safely, efficiently, and reliably monitor and control plant process during normal, abnormal, and accident conditions. The MCR is designated as an area that remains habitable in the event of an emergency (see description of MCR Emergency Habitability System (VES) at PCSR Chapter 6, Section 6.6.3). It supports operator performance by providing the facilities to interact with other plant personnel, while preventing distractions by non-operations personnel.

It provides a facility that supports the operators in the effective and timely execution of their assigned tasks and responsibilities. Alarms are provided to draw the operator's attention to key indications that may require operator action; displays are provided to enable the operators to determine the plant status; and control facilities are provided to allow the operators to execute control actions. It also provides an interface between plant operations and plant maintenance functions.

The MCR also incorporates the interfaces required for functions such as fire protection and radiation monitoring. In addition, the MCR contains miscellaneous items such as storage space for supplies, procedures, document storage and a drawing laydown area. A table is provided and equipped with a VDU-based workstation to allow access to the DCIS displays and soft controls by a shift manager, reactor engineer, maintenance technician, or auxiliary/field operator without disrupting control room operations. Located in the rear of the MCR are the shift supervisor's office, the operations support area, an operations work area, restrooms, and kitchen facilities.

During emergency conditions, it may be necessary for the MCR to accommodate up to eleven personnel and for the design, including VES, to support this maximum crew compliment. This maximum crew compliment may include two individuals with senior reactor operator licenses, three with RO licenses, an observer from the NRC, an observer from the plant owner's management, and one communicator. Available elsewhere in the plant are two equipment operators. This maximum MCR crew compliment would not assemble until an event occurs and the emergency plan and recall has been invoked and recalled personnel have reported to site.

13.6.9 Remote Shutdown Room (RSR)

The purpose of the RSR is to provide a facility to enable the operators to achieve and maintain safe shutdown following an evacuation of the MCR in the event that it were to become uninhabitable due to fire or smoke.

The RSR houses a single operator console that includes two DCIS VDU-based workstations – or RSW. The console has access to the same HSI resources as the workstations on the MCR reactor operator's console. The RSR is also provided with a dedicated fixed-position switch panel that includes 4 PMS VDUs (one per PMS division) providing the PMS safety displays and accompanying soft controls such as the PMS soft blocks / resets. This remote shutdown safety panel and its operator interface (PMS safety displays and controls) are similar to the MCR PDSP. The familiar design promotes reliable and efficient operator performance.

The site specific emergency plan shall address specific manning of the RSR upon evacuation of the MCR due to uncontrolled fire or smoke in the MCR. However, per the standard AP1000 plant MCR staff roles and responsibilities document (Reference 13.65), the RSR is staffed by a minimum of 1 RO and a control room senior reactor operator (SRO). This allows flexibility for the second MCR RO to immediately lead or be a member of the Fire Brigade, as possibly specified by the fire response portion of the site specific emergency plan. The site specific emergency plan shall include details for fire response, including the specifics of the fire brigade (i.e., content, responsibilities, and actions).

In the improbable event of a fire starting in the MCR that requires evacuation to the RSR, occurring simultaneously with an emergency where the site specific emergency plan invokes a full MCR complement (potentially 11 personnel), then the site emergency plan will likely direct additional personnel, not required in the RSR to achieve and maintain safe shutdown, to the OSC. The mission of the OSC is to provide a habitable area for

operations support personnel and the resources to coordinate the assignment of duties and tasks to personnel outside of the main control room and the TSC in support of plant emergency operation. Additional support personnel as they are recalled by the site specific emergency plan shall be directed to report to the TSC or to the OSC to receive further direction.

The use of the RSR will be infrequent and control capability at the RSW is normally disabled. Control capability is transferred from the MCR to the RSR via a set of control transfer switches. The RSW, consisting of 2 DCIS VDU-based workstations and a MCR PDSP-like switch panel, provides resources to physically accommodate as many as three qualified personnel to directly monitor and control the plant (i.e., one at each DCIS workstation and one at the switch panel). Additionally and as in the MCR, the control supervisor directs and supervises the actions of the ROs.

The maintenance of RSR habitability is provided by the VBS but is not served by the VES. The probable temperature and humidity profiles that might be encountered as the result of prolonged occupation of the RSR, with a subsequent loss of VBS, will be assessed as part of the ongoing RSR development for UK AP1000 design.

A detailed task analysis of the transfer to the RSR, due to a fire in the MCR, and maintenance of the plant in a safe state from the RSW, has been conducted as part of the HEA in support of the GDA submission for the Fire PSA. [

] The result of the human error task analysis of this operator action (HEPO-FI-MCREVAC) for the Fire PSA is found in Reference 13.54. [

]

13.6.10 Local Control Stations

The purpose of local control stations is to provide control and monitoring functions at selected locations outside of the MCR and the RSR for operations and maintenance personnel to carry out plant and equipment control and monitoring activities. Typically these activities are maintenance or other non-routine functions.

There are workstations that are DCIS VDU-based workstations that are connected to the DCIS network. These local DCIS workstations are provided with the displays, capabilities and soft controls required only for designated functions and do not possess general control and display capabilities.

Another type of local control station comprises dedicated fixed-position controls and/or displays. These control stations or panels are varied in size and nature. For example, they may include display meters, valve handles, switches, breakers, indicator lights, pushbuttons, emergency stop controls, electrical panels, etc. Some of these local control stations may be an integral part of an equipment package. These may comprise dedicated fixed controls and/or displays, and may include a standalone VDU-based workstation. An example would be the fuel handling machine.

An additional guidelines document supplements the HSI Design Guidelines document to address the local plant aspects. This document, (Reference 13.47) includes, for example, manual tasks associated with operating valve handles, tool laydown areas, physical access, provision of equipment, equipment labelling, etc.

Refer to section 13.6.12 for a scope description of local controls stations to be included as part of the future HF maintenance assessments to be completed during site licensing.

13.6.11 Plant Layout and Equipment Design

The HF aspects of the plant layout, room layouts and equipment design for operations will vary widely in their importance to safety and operability. Therefore, the appropriate level of HF Engineering involvement is determined on a case-by-case basis.

Design guidelines, HF checklists, and As Low As Reasonably Achievable dose checklists are employed to ensure that the design meets the requirements of a human engineered environment and to assist in ensuring that the workers exposure to radiation is minimised. The HF Engineering input has been largely limited to the application of the relevant AP1000 HSI Design Guidelines (Reference 13.46), supplemented with additional guidelines that address plant layout and equipment design (Reference 13.47). The HF considerations include equipment accessibility, lifting devices, temporary or permanent access platforms, laydown areas, labelling, and the provision of emergency equipment.

13.6.12 Maintenance and Maintainability

The HF supplemental report (Reference 13.56) provides detailed information regarding the maintainability of the AP1000 plant.

As described in Section 4.2.1 of Reference 13.10, Westinghouse adopted a tailored HF Engineering approach to determine HF analysis requirements, categorising HF Engineering areas as core, adjunct or peripheral based on such factors as the degree of human involvement in the task, the nature of the task, task complexity, required speed of operator response, and the potential safety or operational consequences of an operator error. The same framework approach was applied to maintenance to determine the level of HF involvement.

The squib valves are an example of a core maintenance area to which rigorous human factor inputs and methodologies have been applied. An extensive and detailed task analysis of the maintenance and surveillance tasks associated with the ADS Stage 4 and in-containment refuelling water storage tank (IRWST) gravity injection squib valves and the recirculation squib valves was conducted as part of the cognitive-level HEA conducted on the maintenance latent error (MLE) operator action error assessments OPR-011 and OPR-106. The task analysis and HEA pro forma for these two MLE assessments is to be found in Reference 13.54 and further reported in the AP1000 Squib Valve Safety Case (Reference 13.96).

The maintainability case activities addressed by Reference 13.56 include the following:

- Maintainability portion of the constructability, operability, maintainability, inspectability, and testability (COMIT) reviews
- HF maintenance assessment
- Human error prevention with respect to making C&I software changes

Section 3 of Reference 13.56 presents a summary of the purpose, scope, and process of the maintainability reviews and plant layout reviews conducted as part of the COMIT process. The objective of these maintainability and plant layout reviews is to ensure that the plant owner/operator is able to operate and maintain the plant in a safe and efficient manner. The

reviews determine the feasibility of accessing, removing, maintaining, testing, operating and rigging equipment. Where appropriate, changes are identified and submitted as DCPs to ensure adequate ease of maintenance tasks.

Section 4 of Reference 13.10 presents a summary of the purpose, scope, and methodology of the HF maintenance assessment. The objectives of this assessment are to ensure that the applicable HF design guidelines are appropriately applied to the design of local panels and maintenance activities, reduce the possibility of operator/maintainer injuries, avoid human errors in maintenance and local operations tasks that may create a risk to plant safety, and identify HF improvement opportunities that can readily be implemented at the design stage.

The HF maintenance assessment gives priority to local control stations and equipment that have been identified as having a potential impact on safety. The scope of the assessment is as follows:

- Risk-significant SSCs identified in Table 3.3-1 of Reference 13.35 (AP1000 Identification of Critical Human Actions and Risk Important Tasks).
- Local components involved in EOPs.
- Components\tasks associated with potential maintenance errors identified in Appendix C of Reference 13.7.
- Radwaste control room and radwaste local station, including local Ovation™ stations.
- Electrical systems, e.g., electrical rooms, motor control centres.
- C&I cabinets, e.g., component interface module (CIM).
- Other local plant control stations and equipment per the HF engineering programme on case-by-case basis, (e.g., fuel handling equipment and cranes).

As per the methodology presented in Section 4.4 of Reference 13.56, the HF maintenance assessments (local actions, maintenance activities, and associated operator interfaces) are conducted through a review against the guidelines provided by Reference 13.47. Reference 13.56 provides the results of the currently completed HF maintenance assessments. The remaining scope of the HF Maintenance assessments shall be completed during the site licensing.

Finally, Section 5 of Reference 13.56 presents a summary of human error prevention with respect to C&I software development and maintenance. Latent human errors may occur during the development and subsequent maintenance of software for complex C&I systems. Such errors are likely to affect the safety of plant operation in a number of ways. The Westinghouse HF programme, Quality Programme, and the C&I design and software V&V process all contribute to the prevention of human errors and to the identification of such errors prior to any effect on safe plant operation. Section 5 provides a summary of these programmes and processes. Also included is a description of a general process that the plant owner/operator can utilise to prevent the occurrence of human errors while making C&I system software changes.

13.6.13 Development of Procedures

The Westinghouse plant procedure writers group has developed a set of plant operating procedures for the standard AP1000 plant. The site licensee is responsible for the development of the site specific procedures to account for differences between the standard AP1000 and the Moorside site AP1000.

Several HF Engineering activities, completed as part of the HF Engineering program, have provided input to the process of determining the detailed content of plant procedures. These activities include the OER, OSA-1 and OSA-2 tasks analyses, HF engineering tests, the HRA, and the HF V&V activities. While undertaking these activities, valuable information and insights into the plant procedural content requirements are identified. In order to ensure that this procedure-related information is recorded and communicated to the plant procedure development group, an HF Engineering procedure development report has been produced (Reference 13.75).

The plant procedures writer's group developed a writer's guideline document that provides the standards for writing the AP1000 standard plant operating procedures (Reference 13.58). This procedure writer's guideline has taken account and incorporated industry RGP and regulatory standards. It defines the structure, format, style, and conventions to be used in the development of the standard AP1000 plant procedures.

The general process of procedure development includes the creation of a provisional version of the procedure that is reviewed and approved internally to Westinghouse and then issued to the procedure subcommittee of the AP1000 operations committee of the AP1000 Owner's Group (consisting of the participating domestic U.S. AP1000 utilities) for review. Westinghouse addresses the Owner's Group comments and produces the next revision of the procedure. For applicable procedures, a "walk-through" verification utilising the AP1000 simulator is completed to verify general usability of the procedure. Comments and insights from these verification walk-throughs are captured and addressed by the Westinghouse AP1000 procedures group in subsequent revisions to the procedure.

The applicable plant operating procedures are exercised and validated with the HSI during the HF ISV test (Section 13.7.3 and References 13.59 and 13.81). HEDs and HED issues relating to the design and use of procedures are captured and recorded for resolution via the HED resolution process (Section 13.7.4 and Reference 13.60).

13.6.13.1 Procedures

Utilising the procedure writer's guideline document, the Westinghouse procedure writer's group has developed the plant procedures for the standard AP1000 plant, including the following:

- Normal Operating Procedures (NOPs)
  - General Operating Procedures (GOPs); APP-GW-GJP-100s series procedures
  - System Operating Procedures (SOPs); APP-(the three letter system designator)-GJP-100's series procedures
- AOPs; APP-GW-GJP-300s series procedures
- EOPs; APP-GW-GJP-200s series procedures
  - Optimal Recovery
  - Safety Functional Restoration
- Surveillance Test Procedures (STPs); APP-GW-GJP-800s are the general, plant wide surveillance test procedures
- Maintenance procedures; APP-(the three letter system designator)-GJP-800s are the system specific surveillance procedures and maintenance procedures.
- ARPs; APP-(the three letter system designator)-GJP-400s series procedures

- SAMGs; Appendix K of UKP-GW-GGR-201 (Reference 13.84)
- Post 72-hour Operations Procedures; APP-(the three letter system designator)-GJP-720 series procedures

13.6.13.1.1 Normal Operating Procedures (NOPs)

There are two types of NOPs: GOPs and SOPs. The GOPs provide step-by-step instructions for the MCR operators to govern the transition of the plant through the plant operating modes. This set of procedures provides the instructions for moving through all modes of operation from refuelling (mode 6) to 100 percent power (mode 1). Thus, these procedures govern the plant heat-up, reactor start-up, main turbine start-up, excitation of the main generator, synchronisation to the power grid, and power escalation to 100 percent power. Similarly the GOPs include procedures that govern the reduction of power from 100 percent, normal reactor shutdown, and normal cool down and depressurisation to cold shutdown mode (mode 5) and to refuelling mode (mode 6).

A SOP exists for each plant system and provides instructions to the operators on how to align the respective system to perform its design functions. For example; the SOP for the chemical and volume control system (CVS) includes step-by-step instructions on how to establish let-down flow, how to align the system for automatic charging make-up to the RCS, and how to establish purification. The operators utilise SOPs as directed by the GOPs, AOPs, and ARPs.

13.6.13.1.2 Abnormal, Emergency Operating and Alarm Response Procedures

The AOPs provide step-by-step instructions to the MCR operators to respond to plant conditions that have deviated from normal states. These procedures are used to identify the cause of the deviation and to recover from it before the abnormality can escalate to the point where the reactor protection system and the ESFs actuation system are called into effect. In many cases, the normal entry into an AOP is from an alarm and its associated ARP.

The EOPs provide step by step instructions to the MCR operators on how to respond to plant emergency conditions. The EOPs are entered whenever a reactor trip or safeguards actuation has occurred or the plant parameters satisfy the conditions for a reactor trip or safeguards actuation. The EOPs consist of optimal plant recovery procedures and safety function functional restoration procedures. The optimal recovery procedures provide symptom-based response procedures for reactor trip, loss of reactor or secondary coolant, faulted steam generator (SG), and steam generator tube rupture (SGTR). The reactor trip procedure (E-0) is entered first, instructing the operator to manually trip the reactor as an "immediate action" (IA), even if an automatic reactor trip has occurred, and prompting the operator to verify that reactor trip has occurred and that all the safety systems have operated as required. The procedure then steps the operator through several diagnostic steps and based upon plant symptoms the operator is directed to the appropriate optimal recovery procedure. Critical safety functions are monitored through the use of logic trees during execution of the optimal recovery procedures. If a safety function is challenged at any time, the operators immediately transition to the respective function restoration procedure. Upon completion of the function restoration procedure, the operators return to the respective optimal recovery procedure.

The ARPs provide step-by-step instructions to operators on how to respond and recover from an alarm. Each alarm indication has an associated ARP. ARPs may direct the operator to transition to an AOP or NOP, as appropriate.

13.6.13.1.3 Maintenance, Test, Inspection and Surveillance (MTIS) Procedures

The STPs provide step-by-step instructions that govern the conduct of the plant Tech Spec surveillance requirement testing. The frequency of surveillance requirement testing is specified by the plant Tech Spec.

Maintenance procedures provide direction to maintenance personnel on how to conduct maintenance on the respective plant components. These also encapsulate procedures for testing, inspection and surveillance and include the following:

- Tech spec STPs
- Non-technical specification STPs
- Refuelling operational procedures
- Significant maintenance guidelines

13.6.13.1.4 Post-72 Hour Operations Procedures

Post-72 hour operating procedures direct operations to make the necessary alignments to maintain Ancillary Diesel Generators; Passive Containment Cooling; Containment Make-up; Spent Fuel Pool Cooling; and MCR Ventilation, entered when nearing the end of 72-hour's passive and battery-powered safety system installed inventory.

13.6.13.1.5 Procedure V&V

V&V of AP1000 operations procedures ensures adequacy and uniformity in documentation as required by a customer contract or regulatory guidance. Westinghouse administrative procedure APP-GW-GJP-150 specifies how to conduct V&V of operating procedures (Reference 13.101) but ultimately the V&V of procedures will be the responsibility of the owner licensee organisation, because of the specificity of operating procedures to the final, as-built, AP1000 plant, C&I and HSI design configuration and to the operating conduct, legislative and regulatory conditions of the AP1000 host nation.

Verification of procedures is performed to confirm the correctness of the procedure and to ensure that the technical aspects of the plant design are properly incorporated. Verification checks both the written accuracy through proper incorporation of information from the writer's guide (Reference 13.58) and technical accuracy through incorporation of technical plant design information and plant hardware.

Validation of procedures is an evaluation performed to determine the actions specified in the procedures can be followed by the intended users to perform activities, for which the procedure was intended. Validation checks:

- Usability of the procedure to provide sufficient, understandable information to the operator.
- Operational correctness of the procedure, compatible with plant responses, plant hardware, and the available shift manpower.
- Effectiveness of the procedure that it will work as intended.

Validation is conducted using table top, walk and talk through methods and in the AP1000 simulator using qualified personnel to perform control functions in response to scenarios for an observer/review team.

The process for V&V of procedures is an ongoing one, alongside development, enhancement and modification of the plant, C&I, and HSI design. Recent ISV trials conducted for the Standard AP1000 plant design (Reference 13.59) have resulted in the identification of a number of HEDs and HED Issues (13.82), the resolution, of which can be either wholly or partially be attributed to the modification of procedures (13.97). These amendments to procedures, along with approved DCPs, will be re-validated at plant start-up (Reference 13.61).

13.6.13.2 Severe Accident Management Guidelines (SAMGs)

The AP1000 SAMGs were developed to focus on managing the accident after core damage. The guidelines (APP-GW-GJP-5xx series) consist of three major parts. These distinct parts were defined based on in depth investigations of HF considerations, the interfaces with the AP1000 EOPs, the site Emergency Plan (*The Emergency Plan is site specific and the impact on SAMGs of a UK site Emergency Plan would need to be assessed in site licencing*); the possible high level severe accident responses, the potential positive and negative impacts of most actions after core damage, and the progression and chronology of severe accidents (Reference 13.98). SAMGs provide guidance to the MCR operators and emergency response personnel on how to respond to a plant emergency where specific plant parameters have reached a point where core damage may have occurred. The three parts consist of:

- Control Room SAMG
- TSC SAMG
- TSC Severe Challenge Response Guidelines

The Control Room SAMGs consist of two separate guidelines; the appropriate guideline is determined by the status of the TSC at the time the SAMGs are implemented.

- Severe Accident Control Room Guideline Initial Response (SACRG-1 Reference 13.99)
- Severe Accident Control Room Guideline After The TSC Is Functional (SACRG-2 Reference 13.100).

SACRG-1 is initially used by the Control Room staff during limited, rapidly developing accidents, and prior to the TCS being functional. Actions are well defined and prioritised, and presented in two column format similar to the EOPs that will be terminated on identification of core damage.

SACRG-2 is for use by the Control Room staff after the time the TSC is functional and ready to use the TSC SAMG. This guideline provides the Control Room staff with a structured set of activities for use during the time that the TSC is evaluating the plant conditions and the potential responses. This guideline is intended to foster communications between the Control Room staff and the TSC technical staff with the goal of enhancing the Control Room acceptance of the recommendations made by the TSC. Also written in a two-column format, the guideline contains instructions for:

- Monitoring support conditions for implementation of strategies.
- Monitoring the usability of instrumentation readouts being employed in TSC evaluations.
- Monitoring trends in specified key plant parameters to alert the TSC staff to

unexpected changes.

- Evaluating equipment status and availability.
- Identifying potential equipment alignments to meet the TSC accident management objectives.
- Monitoring plant status to ensure that previous actions have not resulted in an unexpected change in plant status.

A Diagnostic Flow Chart specifies the key parameters to be monitored and controlled during a severe accident. The key parameters to be monitored in the Diagnostic Flow Chart include:

- Containment water level
- RCS pressure
- Steam generator water level
- Core Temperature
- Fission product releases
- Containment pressure
- Containment hydrogen

A priority scheme for monitoring plant parameters and evaluating the need to implement a severe accident management strategy has been established, based on a detailed review of severe accident phenomena that may challenge fission product boundaries. If the value of a particular parameter is outside the range defined as a controlled, stable state, the TSC technical staff is directed to evaluate the need to implement strategies to bring the parameter within the range that defines a controlled, stable condition. The evaluation of the need to implement strategies is detailed in a set of seven Severe Accident Guidelines (SAGs). The seven SAGs are:

- SAG-1 (Inject Into Containment)
- SAG-2 (Depressurise The RCS)
- SAG-3 (Inject Into The Steam Generators)
- SAG-4 (Inject Into The RCS)
- SAG-5 (Reduce Fission Product Releases)
- SAG-6 (Control Containment Conditions)
- SAG-7 (Reduce Containment Hydrogen)

In addition, a Severe Accident Status Tree is used to diagnose ongoing fission product releases and challenges to fission product boundaries. The status tree is monitored while using the Diagnostic Flow Chart and evaluation of strategies identified by the flow chart diagnostics is ongoing. If a setpoint value in the status tree is exceeded, all other actions are terminated and a severe accident management strategy must be implemented immediately to deal with the more serious condition. The key parameters in the status tree are:

- Fission product releases
- Containment pressure

- Containment hydrogen
- Containment vacuum

The severe accident management strategies, referenced from the Severe Challenge Status Tree, are contained in a set of four Severe Challenge Guidelines (SCGs). SCGs require more urgent action so, unlike the SAGs, do not call for an evaluation of the benefits and negative impacts associated with the implementation of strategies with respect to the alternative of not implementing any strategy. Compared to the consequences of not responding to a severe challenge, the implementation of any strategy in the guidelines would be beneficial. The four SCGs are:

- SCG-1 (Mitigate Fission Product Releases)
- SCG-2 (Depressurise Containment)
- SCG-3 (Control Hydrogen Flammability)
- SCG-4 (Control Containment Vacuum)

Another important part of the APP-GW-GJP-500 series is the guidance provided to monitor long term activities after a particular strategy is implemented. This is contained in SAEG-1 (TSC Long Term Monitoring). These long-term activities range from identification of the limitations for operation of equipment put into service by the implementation of a strategy, to monitoring tank water levels to permit continued operation of equipment that is put into service to implement a strategy.

The final part of the AP1000 SAMG is the SAMG exit guideline, SAEG-2 (SAMG Termination). When selected parameters in the Diagnostic Flow Chart are less than their set-point values and stable or lowering, the plant is considered to be in a controlled, stable state. At this point, it is not expected that the plant condition will worsen and therefore, no new severe accident management strategies would be required. However, since core damage has occurred, caution should be exercised in performing some subsequent actions due to the high level of fission products possible in various plant systems and structures.

13.6.13.3 Importance of Operating Procedures

It is important to the operating philosophy of the AP1000 plant that tasks are performed in accordance with procedures and that the operators are fully knowledgeable regarding systems, components and structures. As seen in the Sections above, a complete set of procedures has been developed for all plant operating modes and for activities including maintenance, normal operation, abnormal operation and emergencies. These procedures specify how the operators will verify the proper operation of automated systems and intervene manually when needed.

13.6.14 Development of Training Programs

The development of operations training programs is the responsibility of a future licensee organisation. However, by virtue of the implementation of the HF Engineering Program Plan and completion of the HF Engineering activities, there are a number of analyses in which information is derived that is directly applicable to the process of determining the detailed content of the operations training programs. This may, for example, be in the form of identifying tasks where specific skills are required, refresher training requirements, noting where training is required for complex or demanding tasks, or instructing participants on the use of the HSI resources.

These HF Engineering activities have primarily been the OSA-1 and OSA-2 tasks analyses, engineering tests, the HRA, and the V&V analyses. While undertaking these activities, valuable information and insights into detailed operator training requirements are identified. In order to ensure that this training-related information is identified, recorded, and communicated to the group responsible for developing the training programs, an HF Engineering training program development report has been produced (Reference 13.62).

13.6.14.1 Licensed Operator Knowledge and Abilities

As a result of completing HF assessments of operator action errors (Reference 13.54) an assumption has been made that the RO and supervisor in the MCR will have passed licensing examinations (i.e., been granted a DAP certificate) and be conversant with a range of knowledge and abilities similar to those captured in NUREG-2103, "Knowledge and Abilities Catalog for Nuclear Power Plant Operators: Westinghouse AP1000 Pressurised-Water Reactors" (Reference 13.63). This provides the basis for the development of content-valid licensing examinations for ROs and SROs in the US. The examinations developed using this catalogue, along with the Operator Licensing Examination Standards for Power Reactors (Reference 13.64 NUREG-1021), will sample the topics listed in the catalogue. The catalogue is organised into six major sections: 1) Organisation of the catalogue, 2) Generic Knowledge and Ability Statements, 3) Plant Systems grouped by safety functions, 4) Emergency and Abnormal Operating Evolutions, 5) Components, and 6) Theory. This is a new Knowledge and Abilities catalogue developed specifically to address the passive nature of the Westinghouse AP1000 design.

13.6.14.2 Systematic Approach to Training (SAT)

The Westinghouse provided training utilises the INPO and WANO "Systematic Approach to Training Process (SAT)" to develop training materials for the Operations and Technical Support staff personnel. The SAT process includes the use of a Job and Task Analysis (JTA) to address operations-related technical disciplines in the AP1000 Training Program. For each technical discipline, the JTA consists of analyses and documentation to determine the knowledge and skills needed to perform the respective job. NUREG 2103, "Knowledge and Abilities Catalog for Nuclear Power Plants: Westinghouse AP1000 Pressurised Water Reactors" includes the JTA results for MCR operator candidates. This JTA forms the basis for the respective training program. The plant technical data from system/component design basis documents, system descriptions, system drawings, procedures, and safety analysis documentation is then used to produce the necessary training materials that are needed to provide the required knowledge and skills. It is assumed that the Site Licensee will use a SAT and resulting NUREG 2103, "Knowledge and Abilities Catalog for Nuclear Power Plants: Westinghouse AP1000 Pressurised Water Reactors" to develop and implement site specific training.

13.6.15 Staffing

The determination of the final and overall AP1000 staffing requirements is the responsibility of a future licensee organisation. However, the area of staffing levels, crew structures, qualifications, roles and responsibilities for the MCR is a key issue that is addressed by the HF Engineering analyses described in this HF Engineering Program Plan. The HF Engineering activities that have contributed to determining the staffing requirements for the Standard AP1000 Plant include the OER, functional requirements analysis and allocation, task analysis, HRA, the MCR and HSI design, the U.S. Code of Federal Regulations, and the HF V&V assessments.

Based on the results of the analyses conducted in this HF Engineering Program Plan, a

MCR staffing document has been produced (Reference 13.65). This describes the roles and responsibilities for each position of the operating staff in the AP1000 MCR and contributed towards the development of the AP1000 Conduct of Operations document (Reference 13.66)

For normal plant operations, the MCA and the associated HSIs have been designed based upon the following minimum MCR staffing levels (Reference 13.20, Volume 2, Chapter 10):

- One shift supervisor, holding a valid duly authorised person (DAP) certification (SRO), will be part of each shift. This individual is responsible for overall plant operation and will have an office adjacent to the MCA within the MCR. At any time, the shift supervisor may be anywhere within the plant boundary.

- One control room supervisor, holding a valid DAP certification (SRO), will be part of each shift. This individual is responsible for the direct supervision of the ROs in the MCR and their normal station is the MCA, but can be anywhere within the MCR.

- Two qualified ROs will be part of each shift. These individuals are responsible for the operations of the controls in the MCA and are normally located within the MCA. One of these ROs will be at the controls at all times, while the other is within the MCR.

- One individual qualified to provide engineering support as Shift Technical Advisor will be part of each shift. This individual will be normally located in the MCR, but can be anywhere within the plant boundary.

- Two auxiliary operators (AOs) qualified to operate equipment in the plant at local stations shall be part of each shift. These individuals will normally be located at various locations throughout the plant and take direction from the MCR operators.

For emergency operations, the MCA and the associated HSIs are being designed based upon the following maximum MCR staff levels (Reference 13.20, Volume 2, Chapter 10):

- Two individuals with appropriate DAP certificates, the shift supervisor, and the control room supervisor
- Three individuals with RO qualifications
- One engineering SQEP
- Two equipment operators
- One representative from the regulatory body
- One representative from the Plant Owner’s management
- One communications representative

13.6.15.1 Estimated AP1000 Staff Compliment

Determination of the final and overall AP1000 plant staff compliment will ultimately be the responsibility of the site licensee. The estimated or assumed UK AP1000 staff (including site staff and corporate support) is presented in Table 13-2. These 11 staffing areas include 42 detailed staffing functions. These staffing estimates are initial estimates assumed for the UK AP1000 and will be verified and validated by the licensee. The licensee shall consider site location specifics, a more detailed focus on UK regulatory

requirements, and the desired/expected organisational approaches. The personnel and their roles that are needed to man the Emergency Response Organisation, as defined by the site specific Emergency Planning documentation (also the responsibility of the site licensee), shall be drawn from the estimates above. The site specific Emergency Plan shall be considered during the verification/validation of these staffing estimates.

13.6.16 Conduct of Operations

The Conduct of Operations (Reference 13.66), which is classified as an 'Administrative Procedure' within the set of GOPs, provides the standards and guidelines to achieve a high level of performance that contributes to safe, reliable plant operations. The Conduct of Operations governs the behaviour of all operations personnel (MCR operators, field operators), no matter where in the plant they are performing actions (e.g., MCR, RSR, or local to plant).

It sets out the responsibilities of the operations personnel, which include:

13.6.16.1 Responsibilities of the Shift Manager (SM)

The SM acts as the senior management representative on shift and is responsible for the safe operation of the plant at all times. Ensures all individuals conducting business in the MCR do so with a high degree of professionalism and ensure rigorous compliance to standards and requirements. This includes an emphasis on effective use of all human performance tools. During accident situations, the SM shall return to and remain in the control room to direct and oversee the activities of control room operators.

13.6.16.2 Responsibilities of the Shift Supervisor (SS)

The SS (control room supervisor) is responsible for the following:

- Directing the actions of licensed and non-licensed operators in performing plant operations.
- Maintaining a current awareness of plant parameters.
- Ensuring alarms received are prioritised and ARPs are implemented as required.
- Implementing AOPs and EOPs when plant conditions indicate they are required.
- Ensuring a reactor operator is designated as operator at the controls (OATC).
- Being relieved by another SRO qualified as SS prior to leaving the Control Room.
- Conducting observations of plant activities.
- Ensuring Reactivity Management is the highest priority.

13.6.16.3 Responsibilities of the Control Room Reactor Operators (ROs)

The ROs are responsible for the following:

- Monitoring system status to ensure all systems are operating correctly and maintaining plant parameters within system specifications.

- If assigned as OATC, remaining within the area designated as OATC area until relieved by another RO.

- If assigned as Balance of Plant Operator maintains awareness of plant parameters and provides short term relief for the OATC.
- Taking action as necessary to prevent plant safety limits from being exceeded.
- Manually trip or shutdown the reactor, if in their judgment a situation exists that requires prompt action.
- Operating systems as directed by the SS.

13.6.16.4 Responsibilities of the Shift Technical Advisor (STA)

The STA is responsible for the following:

- Provides an oversight function to the crew during off normal conditions.
- During emergency conditions, the STA may assist the SM with oversight of crew emergency response activities while the SM is involved in the Site Specific Emergency Plan.

The Conduct of Operations further details the inherent principles and behaviours expected from an organisation displaying a good safety culture where safety is the overriding priority.

It also reminds operations personnel of their expectations and responsibilities with regards to such factors as:

- Decision making
- Operator at the Controls
- Control Room Access
- MCR Displays
- Operation of Equipment
- Skill of the Craft
- Reactivity Management
- Briefs
- Log Keeping
- Alarm Response
- Alarm Suppression
- Use of the APS
- Manual Control Of Automatic Systems
- Human Performance Tools
- Plant Announcements
- Shift Turnover

The correct and proper use of procedures:

- Procedure Adherence
- Procedure Applicability During Plant Upset Conditions
- Entry Conditions For EOPs And AOPs
- Early Actions
- CPS
- Direction To Perform Response Not Obtained (RNO) Steps
- Notes And Cautions
- Two-Column Procedures
- Continuous Actions
- Critical Safety Functions

- Hardcopy Procedures
- Adverse Containment Conditions

13.6.17 Impact of the United Kingdom Nuclear Worker on the AP1000 Design

13.6.17.1 UK Target Audience Description (TAD)

The AP1000 plant has been designed to physically accommodate the 5th percentile female to the 95th percentile male dimensions based on data initially selected for the U.S. population. A UK anthropometric data set, as well as anthropometry for the adult Chinese population, was compared with the US data set in Reference 13.67 to ensure that the dimensions applied to the AP1000 design are also appropriate for the AP1000 plant worker in the UK. A comparison of the UK and US size data (Reference 13.67, Table 4.6-1) shows the dimensions for the UK 5th percentile female to be generally larger than the US 5th-percentile female, and so encompassed by the US anthropometric data set. For the 95th percentile male, in a number of cases the dimensions for the UK male are slightly larger than for his US counterpart, but still fall within the recommended range for safe operation of controls and visibility of displays as outlined in Reference 13.46. The taller UK male worker is appropriately accommodated by the AP1000 design with respect to physical access, visual access, and design of consoles, panels, and location of controls.

As the utilities will be responsible for recruitment and selection of operators, there is no specific selection criteria developed for the AP1000 plant operators. This is also reflected in the current practices in the UK nuclear industry, which differ between companies and between sites.

Per current US practice, potential ROs are typically hired into a non-licensed operator position if they meet certain national industry selection criteria. Following selection, all licence candidates must complete a rigorous training programme, accredited by the INPO National Academy for Nuclear Training, and then must pass the NRC administered licence exam. To retain the licence, the operator must pass an annual operating exam and a biennial written exam.

There is potential for similar practices to be adopted for UK operators, to ensure that they are SQEPs for the AP1000 plant operation. However, the UK operating utilities may create alternate qualification and hiring requirements through use of the results of the formal JTA (Reference 13.68) in determining the appropriate skills to form the basis of UK national reactor operator selection criteria.

13.6.17.2 UK Nuclear Worker Stereotypes

While there has been international engineering support and participation, the AP1000 plant has been designed primarily by engineers using the characteristics and norms of US operators as the basis. To assess the compatibility of the AP1000 reactor plant design and its potential operation and maintenance by a UK workforce, Westinghouse commissioned a comparative study addressing nuclear worker norms (Reference 13.69). This study sought to address the question of whether the UK operators and maintainers work to a set of population stereotypes and norms that are counter to elements of the AP1000 reactor design, which may increase the risk of human error and negatively impact safety.

The study was conducted in two phases: Phase 1 examined identification and characterisation of nuclear worker population stereotypes in the UK and in the US. This involved a literature review and a series of workshops with subject matter experts to elicit stereotype descriptions. Phase 2 of the project compared the identified UK nuclear worker stereotypes and assessed the AP1000 reactor design against those that varied from the US

stereotype. The analysis was subject to a risk-based review to assess the impact on human error potential.

The Phase 1 study concluded that there was minimal evidence for clear population stereotypes as defined within the study, either from literature or from workshop discussions with operators and HF experts. This phase did identify characteristics of the worker population that may be adaptable subject to good design and interventions such as training. No evidence was found for national variations in population descriptions.

The Phase 2 portion of this work was a qualitative analysis of the stereotypical variations as informed by a parallel quantitative analysis. This assessment concluded that there were aspects of the AP1000 design that were likely to reduce the potential for human error and therefore the population stereotype had no impact. Some characteristics were identified where the US and UK population stereotype variation may have a negative impact on human error potential. Furthermore, a number of low- or moderate-risk areas were identified that were directly relevant to the operation of the plant and therefore were noted for future due consideration by the operating utilities. However, no risk factors were identified that pertained to the design, or changes to the design, of the AP1000 plant.

13.7 HF V&V

The function of the HF V&V activities is to demonstrate that the AP1000 design attains a high standard of HF adequacy and that it conforms to the HF principles as specified in the HF Engineering Program Plan and requirements of the HSI Design Guidelines.

The HF V&V activities include five different analyses: task support verification, design verification, integrated system validation, HED resolution verification, and plant start-up HF engineering design verification.

13.7.1 HF Task-Support Verification

Task support verification was performed in accordance with the plan (Reference 13.70) to confirm that the results of the task analyses (e.g., FBTA, OSA-1, and OSA-2) have been incorporated into the final design. The task support verification assessment includes checking that the plant status information, alarms, and the control functions required by the operators are provided by the HSI resources and are designed compliant with HF good practice. Results of the task support verification assessments are documented in the respective report (Reference 13.72). Noted deficiencies are identified in this report as HEDs. The HF HED resolution and re-verification/re-validation process is described in Section 13.7.5 below.

13.7.2 HF Design Verification

The HF design verification was performed in accordance with the plan (Reference 13.71) to verify that the design of the operations and control centres and HSI resources was done in accordance with the HSI design guidelines (References 13.46 and 13.47) to ensure that the final design meets good HF design principles. The results of the design verification are documented in Reference 13.73. Noted deficiencies are identified in this report as HEDs. The HF HED resolution and re-verification/re-validation process is described in Section 13.7.5 below.

13.7.3 HF Integrated System Validation (ISV)

The HF ISV test was executed per the ISV test plan (Reference 13.59). The HF ISV test

provides a comprehensive human performance assessment of the final design of the AP1000 plant operator interfaces based on realistic operational scenarios within the MCR engineering development AP1000 simulator. The ISV uses performance-based scenarios to determine that the integration of the HSI ensemble (i.e., the hardware, software, plant procedures, communication facilities, work environment, and operating crews) meets performance requirements and supports safe operation of the AP1000 plant. Where performance criteria are not met, HEDs are identified.

The objectives of the ISV test are listed below:

1. Establish the adequacy of the integrated HSI for achieving HF Engineering program goals – The ISV will demonstrate the capability of the AP1000 HSI to support safe, efficient, and effective operations in a wide range of plant modes and conditions, thereby meeting the goals and objectives of the HF Engineering program plan (Reference 13.10).

2. Confirm allocation of function and the structure of tasks assigned to personnel – The ISV will evaluate the capability of crews to perform, in real-time, a broad range of important tasks necessary to respond to the events specified in Section 5.1.1 of Reference 13.59. Data is collected and performance measures are assessed.

3. Validate the EOPs and associated HSI – The ISV will exercise a representative cross-section of the AP1000 EOPs to confirm that the EOPs provide an integrated network of effective and usable instructions for the response to an event, ensuring that operators can reliably bring the plant to safe shutdown conditions following abnormal and emergency events.

4. Confirm the dynamic aspects of the HSI for task accomplishment – The ISV will employ a high fidelity simulator and task environment that provides realistic appearance, behaviour, and real-time responses, so that ISV results may be generalised to actual operations.

5. Evaluate and demonstrate error tolerance to human and system failures – The ISV will employ observers and a representative range of plant operating scenarios to confirm that performance of necessary tasks is highly reliable, that human errors are minimised, and that errors or failures are manageable, should they occur.

6. Establish the adequacy of MCR staffing and of the HSI to support staff to accomplish their tasks – The ISV will assess the sufficiency of AP1000 staffing levels for properly operating the plant in a wide range of conditions, and the sufficiency of control room resources to accommodate these staffing levels and the associated staff activities.

The ISV was performed using [ ] complex performance-based scenarios challenging the integrated system of AP1000. These scenarios were performed to combine the C&I hardware, C&I software, operating plant procedures, communications facilities, and trained operating crews in a simulated AP1000 MCR. The [ ] scenarios included plant heat up and start-up from Mode 5 to 100% power, shutdown and cool down from 100% power to Mode 5, abnormal operations, and emergency operations (Reference 13.81).The ISV scenarios also included the validation of the operator performance assumptions (i.e., execution time windows) stated in the HRA portion of the PSA for those modelled human actions identified as AP1000 risk important human actions (Reference 13.35). The ISV assessed the adequacy of procedures, training, workload, work organisation, and staffing levels. Individual scenarios identify specific objectives, including shift handover, and simulated interactions (e.g., with local operators) that extend beyond the MCR. Aspects of

crew communication and coordination are addressed throughout the ISV.

Consistent with nominal AP1000 plant staffing and operations, ISV test crews consisted of four persons filling the roles of Control Room Supervisor, Reactor Operator (RO-B), Balance-of-Plant Operator (RO-A), and STA. This nominal control room staffing was sometimes increased or reduced per scenario-specific guidance for planned complications.

In situations where AO action was required, a crew member phoned the simulator instructor booth to request the actions to be taken. The limitation was made that there would only be two AOs available for local plant operations. The necessary response was then simulated or role-played according to script by the ISV Staff.

During and after each scenario different performance measures were collected, which included:

- Digital simulator recording of plant performance, obtained at a sample rate of half a second, providing an objective record of operation during the scenario and permitted objective evaluation of pass/fail criteria.

- Observer guides enabled observers to track and record crew behaviour and responses during the scenario. These data were used for both pass/fail and diagnostic criteria.

- Debriefs were conducted after post-trial questionnaires were completed. The ISV Coordinator then led a verbal post-job debrief with participants to collect their feedback about the scenario trial. Additionally, at the conclusion of the crew's participation in the ISV, a final debrief was conducted to capture overall comments. Both debriefs used the established debriefing protocols as guides to promote the free exchange of comments and observations. Feedback from the post-job debriefs was captured by the HF Observer, documented and incorporated in to the comments from the post-trial and final questionnaires.

- Video and audio recording captured the screens and operator expressions at the RO A, B, and C workstations and at the SRO workstation. This video and audio of the MCR area, RSR, and debriefing room was recorded during each scenario using the integral audio/video system.

- Questionnaires were completed by ISV subjects and observers after each scenario trial, and again at the conclusion of testing for a given crew. The questionnaires were administered by computer to facilitate ease of completion, data collection, and data processing.

Questionnaire items addressed the following measures by prompting test participants to provide both quantitative (i.e., numeric ratings) and qualitative (i.e., written comment) responses. Comparisons among scenarios, crew positions, HSI ratings, etc. were made; outliers were identified with respect to average performance and variability, and diagnostic criteria were used as applicable to each of the following:

- Situation Awareness – Rating questions for the situation awareness rating technique (SART) were included on the post-trial questionnaires as the basis for SART results.

- Workload – Rating questions for the subscales of the National Aeronautics and Space Administration (NASA) task load index (TLX) were included on the post-trial questionnaires as the basis for TLX results. (Single numeric values (TLX Omnibus) for

perceived workload during a Scenario were constructed from the self-assessed, average ratings of the six NASA TLX sub-scales – mental demand, effort, frustration level, time demand, performance and physical demand – collected on completion of each scenario).

- Anthropometric and Physiological Factors – Questions on anthropometric and physiological factors were included on the post-trial questionnaire, as a basis for ratings comparable to other HSI.

- Team Performance – Rating questions for the team performance rating technique (TPRT) were included on the post-trial questionnaires as the basis for TPRT results.

- Goal Achievement – Goal achievement questions were included on the post-trial questionnaire to solicit performance ratings and comments, as a basis for comparisons among crews and scenarios.

- Usability – Usability questions were included on the post-trial questionnaire to solicit ratings and comments on the various HSI resources; this gave a basis for comparing and evaluating the resources.

Reference 13.82 provides the results of the AP1000 standard plant HF ISV. The ISV Plan objectives were satisfied through the performance of [ ] scenarios, identifying [ ] HEDs. The integrated system performed acceptably during testing and allowed for the identification of issues and the HEDs. While these HEDs were identified, it was observed that the given plant operations were capable of being performed, necessary tasks were completed such that the health and safety of the public would not be challenged, and that the integrated system supports the safe operation of the plant. These HEDs are resolved and re-verified or re-validated per the HED resolution process as described in Section 13.7.5 below.

13.7.4 Human Engineering Discrepancy Resolution Verification

As described in Sections 13.7.1 through 13.7.3, the HF task support verification, design verification, and ISV have been completed for the standard AP1000 plant. Resultant issues or operator performance concerns have been identified in the respective reports as human error discrepancies (HEDs). The HEDs are entered into the formal HF tracking system (Section 13.5.4 and Reference 13.10 Section 4.2.5), assigned ownership, to be resolved and re-verified or re-validated.

The detailed resolution for each HED Issue is defined through a two-step process. First, a general resolution path for each HED Issue is identified. The resolution paths fall into 3 categories, as follows:

- To Be Corrected – An issue resolution that involves a design change, procedure change, training program change, or an appropriate combination of these three.

- Justify - An issue where the current approach is to justify as acceptable the Issue and respective design/procedure.

- 520 - These are issues deferred to the Plant Start-up HFE design verification as defined by APP-OCS-GEH-520, “AP1000 Plant Start-up Human Factors Engineering Design Verification Plan” (Reference 13.61). These Issues identify a physical aspect of the plant or an aspect of the Control and Instrumentation (C&I) system that can only be verified in the physical plant or actual C&I at the plant.

Second, a detailed resolution plan for each HED Issue is specified by HF and the respective engineering discipline(s). Following agreement between HF and the respective engineering discipline on the detailed resolution plan for the HED issue, the resolution is implemented (i.e., correction made), and the correction is verified or validated, as appropriate, by HF to ensure the HED issue is resolved. Once all the HED issues contributing to (mapped to) an HED are verified/validated as resolved then the HED will be closed.

Each HED issue currently has its general resolution path identified. Discussions with engineering on the detailed resolution plans (corrections) are ongoing and will not be completed for several months. The resolution plans, the implementation of the plans, and the HF verification/validation of the implementations will be documented in the HED resolution verification report (APP-OCS-GER-420, "AP1000 Human Factors Engineering Resolution Verification Report"). The completion date of this report is estimated to be late 2017.

All HEDs, identified through the execution of the HF verification and validation activities, will eventually be resolved (i.e., corrected through design change, procedure change, training program change, or combination, or justified as-is). The resolutions and their HF verification/validation shall be documented via the APP-OCS-GER-420 and APP-OCS-GER-520 reports (future). The HF ISV test results and the implemented resolutions to the HEDs and associated Issues and subsequent verifications/validations will support the HF safety case.

The resolution plan for each HED and HED issue has now been developed (Reference 13.97) and agreed with the appropriate engineering teams and the implementation of the agreed-to resolutions is now in progress.

13.7.5 Plant Start-up HF Engineering Design Verification

An HF Engineering design verification at plant start-up is planned to be executed for the UK AP1000 (Reference 13.61) once plant construction is complete and equipment is installed, although some verification activities cannot be carried out until testing and preparations for plant start-up are underway. The objectives of the plant start-up HF Engineering design verification include:

- Confirm aspects of the OCS/HSI design features that could not be evaluated in other HF V&V activities (specifically the standard plant HF design verification, task support verification, and the ISV).

- Confirm that the as-built in the plant HSIs, procedures, and training conform to the design that resulted from the AP1000 HF program.

- Confirm that all standard plant HF-related issues (including HEDs) documented in the HF Tracking System are verified as adequately addressed or resolved.

There are some aspects of the OCS/HSI design that cannot be evaluated in a simulator or by using design documentation and require the as-built plant. These aspects include lighting, noise, and ambient temperature and humidity of the MCR and RSR. These will be included in the plant start-up verification.

There are DCPs that have been approved for implementation in the standard plant following the commencement and completion of the standard plant HF design verification, task support verification, and ISV activities. In addition, relevant DCPs as the result of feedback from construction, system installation and commissioning activity at AP1000

sites in China and the US will be implemented. Such DCPs, and those that are specific to the UK AP1000 design, will require HF V&V regression. Completion of the regression analysis and activity in order to verify/validate the changed design is part of the plant start-up verification. It is assumed that completion of the UK AP1000 Plant start-up Verification is conducted by the site licensee during site licensing.

13.8 Human-Based Safety Claims (HBSCs)

The process of HFI into the design of the AP1000's SSCs (Section 13.6) and to the human operator's interface with those systems (Section 13.6.6) has been one of an exploration of how the plant works and what it does so that account can be taken of human attributes, environmental and contextual stressors to set up the conditions for operator success in the tasks they must perform.

This Section of the HF chapter identifies human failure events (HFEs) and operator action errors that may serve to impair an engineered system's ability to perform its safety function (Type-A errors) or initiate a fault (Type-B errors), or lead to an operator failing to manually recover the plant to a safe condition post-fault (Type-C errors) – Identification of operator actions important to safety (Section 13.8.1).

The IAEA defines three types of human errors that can occur and contribute throughout the development of a fault sequence (Reference 13.83). These actions are classified and defined as:

- Type-A errors: Interactions where errors in maintenance, testing, inspection or surveillance (MTIS) tasks, made before the occurrence of an initiating event, have the potential to lead to failure or unavailability of a safety related system or mitigating, DiD system when required. This type of error is also referred to as a MLE.

- Type-B errors: Interactions where errors in operation or MTIS tasks have the potential to cause an initiating event. These type of error are also referred to as "Operator-induced initiating events" (OIIEs) or "Maintenance-induced initiating events" (MIIEs).

- Type-C errors: Interactions that occur following an initiating event where errors have the potential to lead to failures of the safety systems to perform one of the required safety functions. This type of error is also referred to as a "Post-fault operator error" (PFOE).

When an operator action important to safety is identified, it is recorded in the HAD for further treatment, tracking, and analysis at an appropriate level and time (Section 13.8.1.3).

The process for identification of operator actions important to nuclear safety has taken place in two main tranches - the first prior to completion of GDA Step 4 and another for the GDA close-out phase. This also coincided with a temporary postponement of the UK's GDA process by Westinghouse between 2011 and 2015. This is only of importance here in order to explain the developments that occurred in the interim period and to explain the terminology that is being used in the rest of this sub-section to describe and to differentiate between the processes for identification and treatment of errors pre- and post-GDA Step 4.

The term 'human failure event' (HFE) is used to describe HBSCs when they have been derived and identified from the PSA, and the term 'operator action error' when they have been identified through systematic examination of the deterministic fault analysis.

Whilst there are very many errors that could be made by operators in the course of their

duties, the design of the plant means that often the consequence of those errors has little or no bearing on nuclear safety in terms of the potential for core damage, radio-active release and dose to the worker or public. The level of HEA detail and effort that a HFE or operator action error receives is in proportion to the risk presented from failure of an operator assigned task or function – Human Error Screening (Section 13.8.2).

For those HFEs and operator action errors with failure consequence exceeding the screening criteria thresholds, HEA has been conducted at an appropriate level and depth of detail.

The depth of HEA that is conducted will be dependent upon the aims of the analysis and the maturity of the design or lifecycle phase of the system at the time of the analyses. Subsequently, HEA has been conducted at different levels of detail on the pre- and post-GDA Step 4 tranches of screened-in HFEs and operator action errors. Kirwan (Reference 13.91) identifies a number of 'levels' of HEA in an "onion framework" that delve successively deeper into the errors, their causes and the subtlety and complexity of their potential impact.

Prior to 2011, some 97 HFEs and operator action errors (Appendix 13A) underwent HEA at a level described by Kirwan as "detailed."

Detailed-level HEA – aims only at the skill- and rule-based levels of behaviour, where a large number of potential errors are yielded and which, following representation, can be quantified and fed into detailed fault and event trees. It is at this level that the causes of errors, known as performance shaping factors (PSFs), and their underlying mechanisms are assessed and recorded, facilitating error-reduction analysis.

Post-2015, with the production of a new PSA model and HBSCs (Reference 13.77), and further identification of operator actions important to safety derived from other fault analysis sources, a further sample (Reference 13.92) of 20 HFEs and operator action errors (Appendix 13B) underwent HEA at a level described by Kirwan as "cognitive".

Cognitive-level HEA – considers the undesirable impacts on the system occurring as a result of mistakes and misconceptions on the part of the operator or the operating team. It is concerned with the potential for misdiagnosis, misconception, diagnostic failure or incorrect judgement to occur.

Further levels of HEA are proposed by Kirwan, but these are considered to be not analysis in more depth but errors occurring in different contextual circumstances, such as maintenance errors, rule violations, or the behaviours of operators in an organisation having a poor safety culture.

The detailed-level and the cognitive-level of HEA have been conducted and presented using a template or "pro forma" that was designed as both a guide to the analyst in the scope and content of the analysis and as a standardised presentation of the analysis data and findings in a consistent and logical format.

The detailed-level HEA pro forma can be found in References 13.7, 13.86, 13.87, 13.88, and 13.90, and the cognitive-level HEA pro forma for the HF-01 sample found in Reference 13.54. APPENDIX 13A and 0 list the source documents and assessment locations for the Detailed-level HEA and the Cognitive-level HEA, respectively. Appendix 13C provides a summary of the cognitive-level HEA results.

A significant part and purpose of conducting HEA in the GDA phase has been to

demonstrate that risk from failure of operator actions important to nuclear safety is reduced ALARP. This principle applies at all levels of risk, extending below the level that may be deemed broadly acceptable. For operator action errors that are deemed to be of lower risk, by virtue of their consequence of failure not exceeding screening criteria thresholds (Section 13.8.2 and Figure 13.5), the ALARP principle is deemed to be adequately demonstrated through compliance with modern standards RGP in the design of affected systems, equipment and the HSI, the result of optioneering design requirement solutions informed by OER, task analysis and the Conduct of Operations (Reference 13.66).

For HFEs and operator action errors where the consequence of their failure exceeds screening criteria thresholds, there has been conducted HEA at a detailed or cognitive level that affords the opportunity to propose improvements to various elements of a system's design that if implemented may demonstrably reduce the risk of failure ALARP.

This too presents another differentiation in terminology used between the detailed-level HEA and cognitive-level HEA. The scope of the detailed-level HEA did not at that time include a full and explicit consideration of the potential cognitive, internal error mechanisms that may reveal the underlying causal factor for an error to occur. Without this cognitive level of error analysis revealing potential internal error mechanisms the proposal of changes to elements of the system's design may be misdirected and therefore ineffective at reducing risk from failure ALARP. For example, there would be little value in improving task lighting if the underlying mechanism for an error were not one's ability to see information on display but that of being able to adequately comprehend what was being seen.

However, for each pro forma completed the result of detailed-level HEA, there have been "ALARP design recommendations" made by 'expert panel' review. The panel included experienced ex-licensed operators and SQEP HF practitioners, who may themselves have been considering internal cognitive decision making processes when making these ALARP design recommendations.

When changes to an element of the system's design were proposed the result of cognitive-level HEA they have been termed "Error Reducing Mechanisms" (ERMs) in order to differentiate their potentially more accurate focuses on the underlying causal factors.

13.8.1 Identification of Operator Actions Important to Safety

The process of identifying operator actions, having the potential to impact nuclear safety if omitted or conducted in error, has been systematic, comprehensive, and extensive. It has considered the requirement for operator action at all stages of the fault progression sequence, including errors of Types A, B and C. The operator action identification process has considered all normal modes of the plant's operation as well as operations in emergency and accident conditions. In addition to the systematic operator action identification processes conducted specifically for GDA (Section 13.8.1.1.2), other sources of fault analysis have been assessed, such as the various Level 1 and 2 PSA models and risk-important human actions (Section 13.8.1.1.1); fault and accident analysis and the fault schedule; internal and external hazards analyses (Section 13.8.1.1.2).

Further identification of operator actions important to safety has resulted from HF integration activities across the project, such as interviewing the technical leads and delivery managers responsible for resolution of GDA Issues that have been raised in other technical and safety areas (Section 13.8.1.2.1), and the supplementary HF review of Class 1 DCPs included in the UK AP1000 DRP for GDA (Section 13.8.1.2.2).

All HFEs and operator action errors when identified are recorded in a HAD. The HAD is an open, living repository for recording, managing and tracking operator actions important to nuclear safety for risk-proportionate HEA and ALARP substantiation (Section 13.8.1.3). The HAD will remain an effective management tool beyond GDA and into site licensing.

13.8.1.1 Identification from Fault Analysis

13.8.1.1.1 Probabilistic Safety Analysis (PSA)

The PSA provides a fully integrated model of the entire plant that can be used to examine the risk from a variety of possible initiating events (e.g., transients, loss of coolant accident [LOCAs], support system failures, etc.). The PSA consistently accounts for both the event frequency and the potential consequences from equipment failures or human errors. The model combines front-line safety systems and support systems in a manner that allows designers to identify the risk significance of important inter-system dependencies. The PSA allows designers to quantify the likelihood of "passive" and "active" failure modes, to examine the significance of single failures and multiple failures, and to determine the risk importance of "safety", "safety related" and "non-safety" systems (Reference 13.77 and 13.85).

PSAs to support new NPP designs have initially been performed on a prototype of the plant design, used early in the design process as an internal analysis tool. The PSA results are used to inform the design and any pertinent design changes. The PSA models and analyses are refined and become more complete as the design matures. During the AP1000's design lifecycle stages and over the GDA process period there have been iterations of the at-power PSA model for internal initiating events, and updates to the flood, fire and shutdown PSAs.

Updates to the PSA are required as the result of significant revisions to the AP1000 design (e.g., upgrades to the C&I architecture); the inclusion of DCPs in the DRP that impact the PSA; improvements to the thermal-hydraulic analysis basis and revised procedures. The HRA is subsequently re-analysed based on latest revisions of the AP1000's design and operation (PCSR Chapter 6) and on the most recent approved revisions of the SSD and Piping and Instrumentation Diagrams.

The at-power PSA model (Reference 13.44, 2007), used during GDA step 3, contained 72 HFEs. Screening of the 2007 PSA HFEs on the basis of their contribution to overall CDF resulted in 21 being selected for detailed HEA. The detailed-level HEA of these 21 errors are reported by 18 pro forma in Reference 13.7. An update to the at-power PSA model was conducted during GDA step 4 (Reference 13.85, 2010) to take account of performance and reliability enhancement afforded by digital C&I and soft HSIs. This update to the at-power PSA resulted in a reduction to the overall CDF and a further 7 HFEs screened-in for HEA because of the lower CDF threshold criteria. The detailed-level HEA pro forma for these 7 errors are reported in Reference 13.86.

Review and screening of the low power and shutdown (LP&SD) PSA model and for the Fire and Flood PSA identified a further 15 HFEs for detailed-level HEA. The pro forma for the 9 HFEs emanating from the LP&SD PSA are reported in Reference 13.88, and the 6 HEA pro forma for Fire and Flood HFEs in Reference 13.87.

A significant, recent, revision to the internal initiating events at-power PSA (2015) has been conducted (Chapter 10). This revision accounts for improved thermal-hydraulic analysis and revised plant procedures that in some cases identify earlier the cues for monitoring and subsequent control actions where simulator tests have resulted in the available time-windows being challenged. This revision has included a re-evaluation of the

Type A pre-initiator actions (given a 'HEPE' prefix to the event ID) and post-initiator actions (given a 'HEPO' prefix to the event ID); additionally, actions modelled in the PSA from the SAA include an 'L2' in the prefix (e.g., HEPO-L2-CNT) to indicate they are part of the Level 2 PSA, which assumes a core damage severe accident (Reference 13.77).

The HRA Guidebook (Reference 13.79) for the revised (2015) at-power PSA gives examples of the MTIS activities performed by plant operations personnel that could result in the unavailability of safety and safety-related SSCs and that have resulted in the identification of 13 (HEPE HFEs) Type A MLEs. These MTIS activities include:

- Realignment of a component or a flow path to normal operating status after completing periodic testing, inspection, or maintenance.
- Removal of jumpers or other temporary system alterations to restore the equipment back to service.
- Calibration and alignment of sensing equipment to ensure proper automatic response to emergency actuation conditions or annunciator activation.

Similarly, Reference 13.79 describes the identification of post-initiator HFEs having been performed in parallel to the PSA systems and accident sequence analyses. Through the representation of potential accident sequences in event trees, analysts identify operator actions that are required to be taken in order to mitigate an accident in accordance with the applicable procedures. As fault tree models are developed; the system analysts identify human actions that are required to place equipment in a state necessary to support the applicable success criteria. This could be an action, such as restarting a pump after a loss of off-site power or repositioning a valve to align an alternate source of water. This process has resulted in the identification of 51 (HEPO HFEs) Type C PFOEs.

These 64 HFEs have been added to the HAD in addition to the HFEs from the superseded PSA. It has not yet been determined what deltas exist or replication there is between these two sets of PSA derived HFEs; therefore, until that exercise is conducted in site-licensing, both sets will remain in the HAD.

The cognitive-level HEA, demonstrated on a sample of operator actions for GDA and reported in Reference 13.54, will be presented to PSA so that the HF team and PSA team can more accurately estimate HEPs for the site licencing phase based on detailed task analysis.

13.8.1.1.2 Design Basis Analysis (DBA)

The nature and scope of the Level 1 and 2 PSAs means that the analyses will be nuclear island and RCS boundary focused, as the source of core damage and large radioactive release, and concerned predominantly with post-fault HFEs. In order to consider more widely other types of HFE, committed earlier in the fault progression sequence, or at site locations with radioactive sources other than the core, a systematic process of human error identification (HEI) was conducted (Reference 13.7 Appendix A). This systematic identification process was executed by multi-disciplinary teams (comprising SQEP systems engineers, maintenance engineers, experienced operators, and HF analysts) using expert judgement to consider, each in turn, the events from the UK Fault Schedule (Reference 13.80), the Composite Fault List, and safety and DiD systems, by answering a set of questions (Table 13-3) designed to prompt and elicit the identification of potential Type A, B and C errors.

This systematic HEI process yielded some further 178 operator and maintainer actions having the potential to affect nuclear safety if omitted or conducted in error. These actions appear in the HAD with an "OPR" prefix to the event ID.

13.8.1.1.3 Beyond Design Basis (BDB)

One of the primary lessons learned from the accident at Fukushima Dai-Ichi was the significance of the challenge presented by a loss of nuclear safety systems following the occurrence of a beyond-design-basis external event. Extreme external events (e.g., seismic events and external flooding) beyond those accounted for in the design basis are highly unlikely but could present challenges to nuclear power plants.

BDB scenarios are by definition very rare, extreme events that could challenge the plant and the crew. The AP1000 plant is a robust, passively safe design that does not require operator action for 72 hours to ensure safety and respond to a design basis station blackout event (i.e., a total loss of ac power).

Human actions taken are directed by the respective emergency operating procedures (EOPs) and ensure optimal plant recovery. However, if the loss of ac power were to extend beyond 72 hours then human action is required to ensure continued cooling and safe shutdown of the plant.

Westinghouse has identified these actions as part of the development of the AP1000 BDB Long-Term Coping Strategy (Reference 13.84 Appendix B) and associated post-72 hour procedures. It is not feasible to identify a priori every possible set of circumstances and plant conditions that can occur in BDB situations, as is the case in severe accident scenarios that are managed via SAMGs. For this reason, the AP1000 BDB Long Term Coping Strategy outlines the objectives and lists the options available for managing the AP1000 plant during a protracted station blackout (SBO) situation.

The development of the AP1000 long-term coping strategy has resulted in 8 operator actions being added to the HAD with a "BDB" prefix to the event ID.

13.8.1.2 Identification from HFI across the AP1000 Project

The AP1000 is a large and multi-faceted socio-technical system, reliant upon human operators for its maintenance and safe operation. For this reason HF becomes a transverse topic across many of the other technical and safety-related project disciplines. In order to extend the 'reach' and integration of HF, HFI-focused activities have been conducted across the other GDA Issue areas.

13.8.1.2.1 HFI across the Other GDA Issues

Through an expert panel assessment process (Reference 13.78), conducted with the respective GDA Issue technical leads and project managers, the primary objectives of this assessment of the other GDA Issues were twofold:

- To identify and define the GDA issues requiring HF support or assessment as part of the issue resolution, and to estimate the level of HF support needed throughout the remainder of the GDA phase; and,

- To identify any claims on operator actions that were being made in safety arguments for the resolution of a GDA issue.

As a result of this expert panel assessment, 32 new operator actions have been identified and added to date that are claimed, or assumed (either implicitly or explicitly), as part of the AP1000 safety case. Each of these has been added to the HAD with an "OPR" prefix.

13.8.1.2.2 HF Review of Approved DCPs

The main objective and purpose of the HF review of DCPs was to enhance the coverage of the GDA human error identification and assessment process by:

- Identifying new operator actions required by the DCP
- Identifying current operator actions affected by the DCP
- Gathering sufficient 'metadata' to facilitate input of the identified and affected operator actions into the HAD for future, risk-proportionate, assessment.

The scope of this DCP HF review is consistent with the AP1000 DRP for the UK GDA, (Reference 13.9). The HF review focused on the identification of new operator actions or current operator actions as affected by DCPs approved by Westinghouse since the previous DRP (Rev 5).

Execution of the DCP HF review process to date (Reference 13.28) identified a further 25 claimed operator actions that have been added to the HAD with an "OPR" prefix and with event ID numbers between 251 and 275.

13.8.1.3 Human Action Database (HAD)

The operator actions important to safety that have been identified to date have been entered into the HAD. The number of actions in the HAD now numbers over 400 HFEs or potential operator action errors (Table 13-4). This number is still subject to some consolidation due to potential duplication (e.g., old and new PSA HFEs) or because of design and task-analysis latency (some actions may already have been designed out) and additions due to ongoing design review and safety substantiation activities (e.g., HFI across the other project technical and safety disciplines and GDA issues).

Many actions in the HAD have now been recorded with a basic set of action 'metadata' that describes the information necessary to make early screening predictions for future detailed HEA or to identify the low-risk actions that may be grouped by similar scenarios and ALARP arguments based on compliance with RGP.

The identification of claims made on the actions of operators is an ongoing one that will continue in parallel with the maturing design and ongoing safety substantiation. For this reason, the HAD will remain an open, living repository for newly identified operator actions important to safety and for the management and tracking of operator actions beyond GDA and in to site licensing.

13.8.2 Risk Proportionate Screening

A screening filter identifies where the major effort in the HEA should be directed. Although many tasks and actions related to system goals have been identified, not all of them will contribute significantly to overall risk if they were failed to be carried out. This may be due to the presence of diverse and reliable backup and DiD systems that adequately compensate for human errors, or because of the trivial nature of the task itself with respect to the overall level of risk involved.

In order to ensure that the 'effort' expended in conducting HEA is proportional to the risk presented from the consequence of failure in the task or action, a method of 'screening' actions for detailed assessment was devised (Figure 13.5).

Approximately 300 actions in the HAD were run through the screening criteria flow chart prior to Westinghouse's resumption of the GDA process in 2015. The HFEs from the most recent PSA (Reference 13.77) and the operator actions identified from the BDB Long-Term Coping Strategy (Reference 13.84), HF Review of DCPs (Reference 13.28) and HFI in GDA Issues (Reference 13.78) have all been added to the HAD subsequent to this first screening exercise.

The final consolidation of HAD entries, the re-screening of post-2011 actions and further cognitive-level HEA of the screened-in actions will be completed during the site licensing phase.

The results of the screening process are described in detail in Reference 13.7, Appendix A. and all the HFEs and operator actions that have been screened-in have been summarised in Appendix 13A with the operator action title and event ID; error identification source; screening node entry point and reference to the supplemental HF safety case document in which the detailed HEA pro forma can be found.

13.8.3 Human Error Analysis (HEA)

There is currently no single, totally comprehensive HEA tool that can deal effectively with skill and rule-based errors, as well as cognitive errors (misdiagnoses), rule or procedure violations, maintenance errors and management failings, and so no techniques which address the full potential impact of human error on a complex socio-technical system. There are, however, a number of HEA tools that can be integrated to provide a highly effective means of identifying a system's vulnerabilities to human error and facilitate identification of appropriately targeted changes that will reduce the risk from human failures ALARP.

13.8.3.1 Detailed-Level HEA

The use of a detailed-level HEA pro forma, executed during GDA steps 3 and 4, standardises the content and presentation of the analyses conducted for each screened-in HFE and human action error.

First, the context in which the operator action is required to be performed is described, both in terms of the operating scenario (the normal operating modes, emergency or accident conditions in which the operator is required to perform some function) and in terms of the specific sequence of events that led up to the need for action and the subsequent consequence of performing the function or conducting the action in error.

Next, the PSFs, both positive and negative, that can affect successful completion of the task are identified, as are the opportunities for the operators to rectify the error or return the plant to a safe state.

For post-fault HFEs, derived from the PSA, the 'stressors' affecting operator performance that are assumed to be present in the task scenario are listed – e.g., long or complex procedures; the time available and estimated time to complete; the cues from the HSI to prompt the appropriate operator response; team support and recovery paths – that, along with the contributory sub-tasks, have informed an estimation of the HEP using the technique for human error rate prediction.

The HEPs for maintenance latent errors going undiscovered until the affected safety or safety-related system is required has been estimated based on combinations of human error assessment and reduction technique (HEART) generic task types that account for the initial, unrevealed maintenance error and the subsequent failure of opportunities to discover the defective system, e.g., alarms, testing, inspection. The HEART-based derivation of HEPs for MLEs is described in Reference 13.7, Section A.5.2, along with the HEP modification tables that take account of the predicted time interval between the tests or maintenance activity that leaves an automatic or manually initiated system unavailable on demand and the alarm, inspection or surveillance process that may reveal its inactive state.

Finally, through a process of multi-disciplinary expert panel, consisting of systems engineers, HSI designers, procedure writers, experienced operators, PSA analysts and HF practitioners, an error reduction analysis was conducted for each HFE and operator action error that underwent detailed HEA. Informed primarily by the PSFs that were found to be important in the deterministic HEA and HRA quantification for PSA, the expert panel proposed potential ALARP design recommendations that were categorised by opportunities to, for example:

- Increase the levels of automation associated with a task to design-out the possibility of error.

- Change the design of the systems affected by the error or contributing to the probability of error by making their operation and maintenance more accessible or less complex, reducing the probability of error in use or, through the addition of sensors, improve the ability of the system to display its condition or operating status.

- Modify the HSI to improve the provision, timely identification and interpretation of system parameters important to safety or to make more intuitive the use of controls and confirmatory system feedback.

- Make improvements to the soft, administrative controls and management barriers - such as specific training objectives; procedure step sequence and presentation; job design and staffing levels - that can prevent or detect errors, reduce workload or stressful error-conducive situations.

This process has resulted in the identification of a number of ALARP design recommendation proposals, recorded in the HEA pro forma found in References 13.7, 13.86, 13.87, 13.88 and 13.90 . The detail and disposition of proposed potential ALARP design recommendations from the HEA pro forma found in Reference 13.7 is documented in Reference 13.93. Where valid ALARP improvement opportunities are found to exist, these will be further evaluated per the Westinghouse design modification and substantiation process (Reference 13.15) during site licensing.

13.8.3.2 Cognitive-Level HEA

The cognitive-level HEA considers the undesirable impacts on the system occurring as a result of mistakes and misconceptions on the part of the operator or the operating team. It is concerned with the potential occurrence of misdiagnosis, misconception, diagnostic failure or incorrect judgement.

This cognitive-level analysis process has demonstrated the application of an HEA methodology that considers the underlying mechanisms of an error and the specific PSFs at the key steps in task analysis when the error is made. In addition, where applicable, it

addresses the potential for the design of procedures and HSIs to cause misdiagnosis of a situation (Section 13.8.3.3) and also for the contribution from contextual, environmental and task design conditions to increase the potential for conditions that may cause operators to behave in violation of procedures (Sections 13.8.3.4).

HEA conducted at a level above the skill- and rule-based levels addresses the internal error mechanism and facilitates the identification and proposal of ERMs that specifically target the underlying error cause to ensure that the risk of failure is reduced ALARP. In this way, the analysis can more credibly justify an argument where, having implemented any ERMs, the risk presented from HFEs and from operator action errors is ALARP.

In order to address the cognitive mechanisms underlying HFEs and operator action errors the cognitive-level HEA process used the cognitive framework proposed in Reference 13.94. This cognitive framework was the synthesis of a comprehensive review of the relevant psychology and behavioural sciences literature to identify five macrocognitive functions: (1) detecting and noticing, (2) understanding and sense making, (3) decision making, (4) action, and (5) teamwork. For each macrocognitive function, the NUREG-2114 researchers identified the proximate causes for cognitive function failure, cognitive mechanisms underlying the failures, and factors that influence the cognitive mechanisms that may lead to human performance errors. Moreover, the research used the information from the literature to infer causal relationships and links between different types of human failures and PSFs.

Because the contextual PSFs at the time when an error occurs in a procedurally driven analysis of a task are potentially more easy to identify or to predict, the cognitive framework proposed in NUREG-2114 was essentially used in reverse for the cognitive-level HEA. If the likely PSFs were ‘known’ or could be more reliably anticipated then the causal relationship to different types of failure could be inferred. A matrix was constructed of the PSFs revealed by the literature to have the strongest influence on each of the five macrocognitive functions (Table 13-5). This in turn also directed the analyst to proposing appropriate ERMs when HEA revealed difficulty in substantiating the claimed level of human reliability or achievability of the task within the available time.

13.8.3.3 Misdiagnosis

Misdiagnosis has traditionally meant the misinterpretation by an operator of data being displayed, potentially failing to identify that the data being presented is wrong or latent, diagnosing the incorrect fault and subsequently taking a wrong or inappropriate, but procedurally driven, course of action. Since the events at Three Mile Island, lessons learned have directed the design of abnormal and emergency operating procedures to a symptom-based construct vice event-based – as is the case for AP1000 AOPs and EOPs.

In a symptom-based procedure system, as long as the operator follows the procedure as written, there is no penalty for an incorrect diagnosis. Procedural selection is not dependent upon a correct diagnosis, but instead depends upon the existing symptoms, which are identified throughout the procedure network.

When in the EOP network, if the symptoms do not match the procedure, the procedure/EOP network eventually guides the crew to the correct procedure, or back to E-0. The CPS also continually monitors plant operating parameters and provides prompts to the operators if criteria are met for entry into any EOP or Critical Safety Function Status Tree (CSFT). Furthermore, the MCR crew composition includes the STA, who monitors the CSFTs and provides expertise to aid the crew in diagnosing and responding to the event. Likewise, AOPs, which are generally entered from alarm response procedures, have

a set of "Symptoms and Entry Conditions" that the operators use to confirm that they are in the proper procedure. Operators would not proceed into a procedure based solely on the presence of one of the symptoms or entry criteria without further confirmatory checks on the status of other symptoms or entry conditions that should be present. These confirmatory checks will often utilise alternative, diverse sensors and displays so that reliance on a single data source to make a diagnostic decision is negated.

The potential for misdiagnosis of an event is further reduced through the adoption by the MCR crew of human performance (HuP) tools, as directed by the Conduct of Operations administrative procedure (Reference 13.66). In particular, those tools are used to promote a 'questioning attitude' and the practice of self-checking and peer-checking, both of which are used to augment the Stop, Think, Act, Review used prior to implementing an action.

13.8.3.4 Design Induced Violation

Rule violation occurs when a person deliberately chooses to deviate from the rules, procedures, instructions, or regulations that govern the safe operation and maintenance of a plant or equipment. In the context of HRA and assessing the potential for human error, rule violations are assumed to occur without malicious intent (sabotage is outside the scope of HRA and error assessment). Instead, HRA is concerned with the potential for plant personnel to deviate from rules or procedures for reasons including convenience (e.g., poor task design), efficiency (optimising, e.g., time saving), routine workarounds (e.g., practices that have become normal and "accepted" or ignored by management), or exceptional violations due to problem solving in unusual situations, among others. Efforts to reduce human error may not adequately address the potential for rule violations, so it is important to understand the causes of violations to be able to adequately design against them and to address the potential for violation in HEA.

13.9 Substantiation of HBSC

The HBSCs, identified as part of the DBA, PSA and SAA, have been substantiated ALARP.

The identification of operator actions important to safety and the HEA of HBSCs has furthered understanding of the human contribution to AP1000 plant safety, both in terms of its reliance on human action and the vulnerability of the plant to potential human failure events in pre-fault and post-fault situations. The substantiation of HBSCs minimises the associated risks to ALARP for the standard AP1000 plant design.

The process of identification of operator actions important to safety has been systematic and comprehensive in its coverage of:

- Plant operating conditions – all modes of operation, including normal, abnormal, emergency, and severe accident conditions.

- Stages of the fault sequence – pre-fault latent errors having the potential to leave safety and DiD systems unavailable on demand (Type-A), operator and maintenance-induced initiating events (Type-B) and actions required post-fault to return and maintain the plant to a safe state or to mitigate the consequence of fault conditions (Type-C).

- Fault analysis –PSA, DBA, BDB and post-72 hour SAA.

This has resulted in the identification of approximately 400 operator actions important to safety being recorded in the HAD, providing confidence that the role of the operator and

reliance on their actions in the maintenance of nuclear safety has been adequately assessed and understood. Some 97 of those ~400 operator actions important to safety have exceeded screening criteria thresholds and have undergone further HEA.

After risk-proportionate screening of the operator actions in the HAD, identified during GDA Steps 3 and 4, a total of 77 detailed-level HEA pro forma were completed for 101 action errors (some detailed-level HEA pro forma addressed more than one action when operator actions were similar or closely tied in a fault sequence or error progression). A breakdown of the HEA pro forma by error-type meant that 28 Type-A MLEs; 12 Type-B MIIEs and OIIEs; and 37 Type-C PFOEs, 5, of which were post-core damage, have been assessed at the detailed-level. The reporting and disposition of these detailed-level HEA pro forma is shown in Appendix 13A.

For the GDA close-out phase and for resolution of the GDA Issue HF-01, samples of 20 operator actions were assessed at a cognitive-level of HEA. The sample was selected to provide diverse coverage of plant operating conditions, fault sequence progression and fault analysis methods. This resulted in the cognitive-level assessment of a further 3 Type-A MLEs; 2 Type-B OIIEs; and 13 Type-C PFOEs, including 2 from the revised 2016 Fire PSA for GDA Issue PS-02. In support of the post-Fukushima Dai-Ichi lessons learned GDA CC-03 Issue, two operator actions identified from the BDB long-term coping strategy were also assessed using the cognitive-level HEA method. The reporting and disposition of these cognitive-level HEA pro forma is shown in Appendix 13B, and a summary schedule of the HEA findings is presented in Appendix 13C.

For specific detail substantiating an individual HBSC, the respective HEA pro forma are reported in numerous documents that comprise the HF safety case for the UK AP1000 Plant. For each operator action that has undergone HEA for GDA, the relevant HF safety case documents are referenced in Appendix 13A and Appendix 13B.

Because the sample of 20 actions that were selected for demonstration of the revised qualitative analysis method (cognitive-level HEA) were selected to provide adequate breadth of content and coverage - in terms of risk significance, fault analysis, error-type and novelty of design - they may also be seen as ‘bounding’ for similar errors and error types. The evidence accumulated to substantiate the risk of failure reduced ALARP for tasks and MTIS activities conducted within the same nuclear safety context bounded by the sample of 20 actions, may also be true for all tasks conducted in this way (i.e., in accordance with conduct of operations and the culture of safety and procedural adherence).

13.9.1 Overall Significance of HFE in the PSA

As discussed in Chapter 10, the UK AP1000 plant PSA assessed that the overall CDF is low. This frequency includes the contribution of human error, particularly post-fault human errors (Type-C) and pre-fault human errors (Type-A) relating to the MTIS e.g., misalignment of manual valves following maintenance performed at-power.

Chapter 10 addresses the relative importance of operator errors on the overall CDF. If no credit is taken for operator actions, the at-power internal events CDF is comparable with CDFs for existing Generation II reactors where credit is taken for operator actions.

Other Type-A errors are included in overall failure rates for UK AP1000 systems derived from AP1000 databases, rather than explicitly modelled in the PSA. Generally, the initiating event frequencies derived from generic operating experience reflect both component and human failure events. In general, Type-B human errors are incorporated into the initiating event frequencies.

Post-fault claims on operator action (Type-C claims) have been identified as part of the PSA. The at-power internal events actions are summarised in Chapter 10. The sampling plan included 11 risk important actions from the at-power internal events PSA model. The criteria for risk important PSA actions are discussed in Reference 13.54.

The analysis undertaken for the generic design has been proportionate to the potential nuclear safety risk and it is therefore unlikely that human error mechanisms that could significantly affect nuclear safety risk have remained unidentified for analysis and assessment. However, the HF led, cognitive-level human error and task analysis that has been conducted for the sample of 20 actions in GDA will be assessed for their impact on the estimation of HEPs that are currently in the PSA model. Cognitive-level HEA will also be performed on the remaining screened-in operator actions during the site licensing phase and used to inform the HEP estimations included in the site-specific PSA models.

13.9.1.1 Substantiation of Pre-Fault/Pre-Initiator Type-A MLE

The revised internal initiating events at-power PSA (Chapter 10) explicitly models Type-A Pre-initiators. The routine actions considered in the PRA involve restoring a component or flow path to normal configuration after completing MTIS and ensuring that the sensing equipment is correctly aligned and calibrated for automatic response to emergency actuation conditions. There are 13 Type-A HFEs (with a 'HEPE' prefix to the event ID) modelled in the PSA. One (HEPE-PCS-XVM-CL-V023) has been included in the HF-01 sample plan for HEA at a cognitive-level. Also included in the sample of 20 are two Type-A operator action errors that relate to MTIS activity on the ADS-4 and IRWST gravity injection squib valves (OPR-011), and recirculation squib valves (OPR-106).

The cognitive-level HEA pro forma for HEPE-PCS-XVM-CL-V023, OPR-106 and OPR-011 are found in Reference 13.54. Extracted from these pro forma are the evidence statements that support the argument for a claim that risk from these MTIS activities is reduced ALARP, subject to further review and disposition of the ERMs identified for consideration in the cognitive-level HEA.

- The AP1000 design and response in this scenario meets recognised RGP
- Operators will have the information and resources they need to successfully fulfil the maintenance activity.
- Plant personnel will be using human performance tools as indicated in the Conduct of Operations (Reference 13.66) sub-section 5.3.16, which include self and peer checking, three way communication, and independent and concurrent verification methods.
- Personnel performing these actions will have the correct knowledge, training, and experience needed for successful completion. Pre-job briefs will be performed, which will involve review of error traps and the application of specific human error reduction tools to avoid them.
- Given that the task is time-consuming and complex, this maintenance activity is considered to be demanding both from a cognitive perspective and from a physical perspective. Various task-support measures reduce the likelihood of error. Among these are IST engineer checks, critical step verification from SQEP engineers and the use of checklists.

From the systematic HEI process executed for GDA Step 4 (Reference 13.7 Appendix

A.2.2), 28 Type-A MLEs were screened in for detailed-level HEA. As a result of these HF assessments a number of common factors promoting successful completion of maintenance tasks on deterministically claimed safety systems were identified:

- Maintenance is performed in accordance with MTIS procedures and permits to work. These include checking for correct alignment before reinstatement.
- Before returning the plant to power after an outage, there is a full check of the operability of all deterministically claimed safety systems.
- In addition, there is a periodic check of the operability of components of these systems during operation.
- Manually operated valves that are normally closed and locked closed are the subject of two-person verification.

MTIS activities associated with risk-significant components are subject to HF assessment in accordance with the Local Panels and Maintainability Human Factors Design Guidelines (Reference 13.47). This addresses the design of MTIS tasks in order to minimise the likelihood of human failures. This document is also referenced in system and equipment specifications for procurement purposes.

For these reasons, and subject to further review and disposition of the ALARP design recommendations identified for consideration in the detailed-HEA pro forma, and by virtue of compliance with RGP in design, Westinghouse has substantiated that the risk from MTIS activity leaving deterministically claimed safety and DiD systems unavailable on demand is reduced ALARP for GDA.

13.9.1.2 Substantiation of Pre-Fault Type-B Operator or MIIE

From the systematic HEI process executed for GDA Step 4 (Reference 13.7 Appendix A.2.2), 12 Type-B OIIEs and MIIEs were screened in for detailed-level HEA. Also, included in the GDA Issue HF-01 sample plan were two Type-B OIIEs that have undergone cognitive-level HEA. These assessments identified the following evidence to support the arguments and claims that the tasks can be successfully accomplished:

- Operators will be trained and available to perform the task.
- Operators will use and follow procedures, which provide appropriate guidance for the task.
- Maintenance activities will be properly prepared, organised, and executed.
- Refuelling operations are pre-planned and undertaken in accordance with specific refuelling procedures
- Operators will have all tools and equipment necessary to perform the task, and tools and equipment are fit for purpose and appropriately maintained.
- The AP1000 plant design and response in maintenance scenarios meets recognised RGP.
- The design of the refuelling machine (RFM) reduces the potential for human error and

incorporates previous operating experience.

13.9.1.3 Substantiation of Type-C Post-Fault Operator Errors

In total, 45 Type-C post-fault operator errors underwent HEA – 32 having detailed-level HEA and 13 cognitive-level HEA.

In the event of a fault, the operators in the MCR are required and automatically prompted to follow a set of symptom-based EOPs to address any failures in automatic systems and optimally recover the plant to a stable and safe state. The HF design of the MCR and of the EOPs support a number of factors promoting successful completion of tasks that apply to all post-fault errors. These are summarised as follows:

- The Conduct of Operations governs use and verbatim adherence to procedures, operations personnel roles and responsibilities, command, control, and communication in the MCR, crew briefings and shift turnovers, HuP tools and implementation, operations management and leadership, decision making, and safety culture. The Conduct of Operation ensures a healthy nuclear safety culture of all operations personnel at the plant by describing the responsibilities and behaviour required.

- Operators will be fully trained and exercised in the use of EOPs.

- In the event of a fault, there is no requirement for the operator to make a diagnosis of the event, apart from following the steps in the symptom-based EOPs.

- EOPs will be available when needed on the CPS. Hard copies will also be available in the MCR as a backup to CPS. The CPS assists the operators in monitoring and controlling the execution of procedures. The CPS is accessible via the DCIS VDU-based workstations and provides navigation links to the relevant control system displays. The CPS automatically assesses and presents the status of each step and automatically executes parallel monitoring, alerting the operator to important plant information when it needs attention.

- Alarms are both visual and auditory and are presented on the DCIS VDU-based workstations at the RO and control room supervisor consoles. In addition, the alarms are presented at a fixed location on the wall panel information system. All alarms are conspicuous, clear in meaning and easily accessible for detailed alarm information.

- The control room supervisor and ROs will communicate directly with each other, as all are located in the MCR.

- If the STA is established, this person will provide a redundant source of advice and checking of critical safety function status to the MCR team.

13.9.2 Substantiation of HBSC in BDB and SAA

Two BDB, post 72-hour, operator actions and three PSA-derived Level 2 (post-core damage) operator actions underwent HEA at a cognitive-level, whilst 5 HFEs that were post-core damage received HEA at a detailed level.

The BDB actions involved a beyond design basis seismic event and tsunami that causes a SBO scenario exceeding 72 hours in duration, but without a concurrent reactor accident situation. Extracted from the BDB assessments are the following arguments to support the

claim that the operator tasks to extend long term coping can be carried out successfully:

- Necessary onsite equipment is available, and SSCs remain functional following the event.
- Operators necessary to conduct the task are available, both onsite and offsite.
- Operators will follow procedures, be adequately trained for the task and for the site emergency plan, have sufficient time to complete the task, and will have the necessary tools and equipment for the task.
- The site-specific emergency plan will ensure provision of care for all staff, including potable water, food, respite, personal protective equipment (PPE), medical care, and psychological care.
- The AP1000 design and response in BDB scenarios meets recognised RGP.

The three Level 2 actions all involved operator tasks post-core damage. From the cognitive level HEA conducted on these actions, the following arguments support the claim that the actions to respond to a severe accident can be completed successfully:

- Procedures have been verified to provide appropriate guidance for the task.
- Operators necessary to complete the task are available and adequately trained.
- Operators will follow procedures.
- The HSI has been verified to support the task.
- Workload is adequate and there is sufficient time to carry out the task.
- The design of the AP1000 Plant and response in this scenario meets RGP, and any discrepancies will be resolved.

13.9.3 Operator Actions with Low Risk Consequence – ALARP Justification

Whilst there are many potential errors that could be made by operators or plant staff in the course of their duties, the design of the AP1000 Plant means that often the consequences of those errors have little to no impact on nuclear safety in terms of the potential for core damage or radioactive release. This is the case for a large number of the operator actions currently in the HAD, which do not exceed the screening criteria thresholds that would be used to trigger further, more detailed, risk-proportionate, human error analysis.

The term ‘ALARP’ is used to express the concept to reduce risks SFAIRP and it is a concept that must be applied at all levels of risk, extending below the level that may be deemed broadly acceptable. In simple terms it is a requirement to take all measures to reduce risk where doing so is reasonable.

An overall ALARP justification requires a balanced argument containing elements of, (i) compliance with RGP, (ii) demonstration of optioneering, and (iii) quantitative and qualitative assessment (see section 13.2.2).

13.9.3.1 Relevant Good Practice (RGP)

The RGP element of an ALARP justification argument requires that the design solutions that are used to meet safety standards are (i) consistent with application of industry

accepted Codes, Standards and Practices in the UK, (ii) have applied the latest, proven technology, and (iii) have used applicable testing.

13.9.3.1.1 Accepted Codes, Standards and Practices

The list of HF standards and guidance (Table 13-1) that have been used to shape and inform the design of AP1000's safety and DiD systems (Section 13.6.12), the control and display HSIs (Section 13.6.6), control centres (Section 13.6.7) and the operating procedures (Section 13.6.13) were then, and remain, both internationally and industry recognised RGP. In particular the execution and management of a recognised HF Engineering programme (Reference 13.14) applied throughout the AP1000 design phases has ensured that consideration of the inherent strengths and weaknesses of the human operator have been accommodated to ensure successful execution of assigned tasks to maintain nuclear safety (Reference 13.10). The standards and guidance comprising RGP for the HFI in design have undergone an assessment of equivalency to recognised UK standards and are appropriate to the HFI activity and commensurate with the associated risks.

13.9.3.1.2 Use of Proven Technology

The recognition by workers, maintainers, operators (Section 13.6.2.2) and ultimately by the safety case of the use of proven technology, combined with an inherently safe design philosophy for AP1000 (Section 13.6.1) will contribute considerably to the safety and ease of operations and to an HF argument for risk of human failure reduced ALARP.

13.9.3.1.3 Use of Applicable Testing

RGP may be confirmed through utilisation of applicable test results in demonstrating the suitability of the design or operational practice. The progressive application of HF task-support verification (Section 13.7.1) and HF design verification (Section 13.7.2), culminating in integrated system validation tests (Section 13.7.3) provides evidence in demonstrating RGP as related to MCR and RSR HF design implementation. Such test results verify assumptions on relevant human action times through direct simulation and analysis of operator practices. This validation then establishes RGP for these assumptions.

13.9.3.2 Optioneering

The appropriate consideration of different options is an inherent part of the design and design change process. Key in the design process for HF has been the functional analysis and allocation of function process that is described and the results reported in Reference 13.32. Similarly, the DCP process and other design change driver mechanisms, such as Engineering and Design Coordination Reports and Requests for Engineering Change, incorporate opportunity for technical, operational and safety disciplines affected by a proposed design change to challenge and propose alternative solutions as a part of the acceptance or rejection decision (Reference 13.15).

13.9.3.3 Risk Assessment

A risk assessment was conducted for all of the ~400 operator actions that currently reside in the HAD as part of the screening for detailed-level and cognitive-level HEA. The level of risk presented by failure of each action was assessed against threshold criteria relating to such factors as the contribution of the failure to initiating event frequency or core damage frequency or potential effect on passive or DiD systems (Section 13.8.2 and Figure 13.5).

13.10 Conclusion

The AP1000 plant design has undergone a comprehensive and systematic programme of HF Engineering activities that together provide the evidence to support the HF basis for safety (i.e., the HF safety claims) for GDA.

- There has been a systematic, through-life, approach to HFI within the design, assessment and management of systems and processes.
- The allocation of safety actions between humans and engineered SSCs has been substantiated and validated.
- A systematic approach has been taken to identify human actions important to safety operating in normal modes and in abnormal, emergency and accident conditions.
- The administrative controls needed to keep the facility within its operating rules for normal operation or return the facility back to normal operations have been systematically identified.
- Proportionate human error analysis has been carried out for tasks important to safety.
- Workspaces in which operations and maintenance activities are conducted have been assessed to support reliable task performance.
- Suitable and sufficient user interfaces have been provided at appropriate locations to provide effective monitoring and control of the facility in all normal operating modes, fault and accident conditions.
- Procedures have been produced, verified and validated that support reliable human performance during activities that could impact on safety and a systematic approach to training assumed for operators. HF V&V activities have been completed, HEDs identified, with resolutions being identified and implemented.
- HF V&V activities have been completed, HEDs identified, with resolutions being identified and implemented.
- The staffing levels and number of competent personnel needed to operate the facility safely in all its operational states has been estimated.
- Proportionate analysis has been conducted of human actions and administrative controls that are necessary for safety as part of the DBA, PSA and SAA aspects of the safety case.
- The consideration and disposition of ERMs and ALARP design recommendations that were made in the HEA.

Further, the substantiation of human-based safety claims for GDA and the safe, efficient operation of the plant have been predicated on a number of general assumptions that will need to be adopted by a future licensee organisation or require further substantiation of alternatives. These assumptions relate to:

- Adopting a conduct of operations that governs use and verbatim adherence to procedures, defines the operations personnel their roles and responsibilities towards

effective command, control, and communication, and the use of HuP tools, where appropriate, as normal working practice.

- Having sufficient trained personnel being available to conduct operations, maintenance and safety important tasks and that the training of those personnel is based on a SAT that for licensed operators adopts a syllabus akin to that of the NUREG-2103 Knowledge and Abilities Catalog (Reference 13.63).

- Having a culture on the nuclear licensed site where operations, management and leadership see safety-first at the heart of everything they do.

The HF design of the AP1000 Plant has been based upon a set of internationally recognised Standards and Codes and on industry experience and guidance that can be deemed as RGP in the UK.

The design evolution of AP1000 is consistent with the ONR's expectations for the demonstration of ALARP with respect to new commercial reactor designs. A level of safety that is no less than a comparable facility in operation or being constructed has been demonstrated. Additionally, experiences of earlier designs and, in particular, the HF lessons learned from accidents at other NPP around the world have been considered in the design evolution of the AP1000.

Acknowledged future work in the HF safety case substantiation for GDA has been identified and will need to be further progressed during the site licensing phase. These future work areas are:

- Completion of the resolution process currently in progress for the HED and HED issues arising from the HF verification and validation activity conducted for standard AP1000 plant design.

- When appropriate, commencing the standard AP1000 plant start-up HF verification activity described in Reference 13.61.

- Complete HEA process at a cognitive-level for all screened-in, risk-significant operator actions, as demonstrated on a sample of actions for GDA. Provide the HEAs to PSA to serve as human reliability analysis input for the PSA updates to be completed during the Site Licensing.

- Complete HEA process of MTIS activity on SSCs that provide safety function

For the reasons presented above, and with acknowledgement to the aforementioned assumptions, issues and future HF substantiation areas; the role of the operator in ensuring nuclear safety is understood, and the risk to nuclear safety arising from human failure has been identified and reduced ALARP for the standard AP1000 plant design in GDA.

18	BS IEC 61772 (2009) – Nuclear Power Plants –Control Rooms – Application of Visual Display Units
19	BS IEC 61227 (2008) – Nuclear Power Plants – Control Rooms – Operator Controls
20	BS IEC 60965 (2009) – Nuclear Power Plants – Control Rooms – Supplementary Control Points for Reactor Shutdown without Access to the Main Control Room

Table 13-2 Estimated/Assumed UK AP1000 Staff (including site staff and corporate support)

Staffing Area	1st Unit	Total with 2nd Unit	Total with 3rd Unit
Plant Management	17	28	38
Plant Operations	77	144	201
Plant Maintenance	109	176	224
Plant Engineering	45	68	84
Plant Safety	51	77	102
Plant Licensing	2	3	4
Plant Administration	49	72	97
Environmental	2	2	3
Radiation Protection	25	37	51
Waste Management	11	18	24
Training	23	29	32
Totals	411	654	860

Table 13-3 Questions used to elicit the identification of potential operator errors

Type and Source of Error	Questions to elicit identification of potential errors
Maintenance latent errors for passive safety systems and DiD systems.	• What maintenance errors can be performed on the system or respective components that would prevent or degrade the system/component from performing its safety or mitigating function? • Use the plant Tech Specs and associated surveillance requirements as a list or required maintenance activities when answering question "a." above. • Consider improperly performed corrective maintenance when answering question "a." above. • Consider errors performed on any support systems of the respective passive safety system or DiD system that would degrade or prevent the system from performing its mitigating function. • From your extensive plant operating experience and training experience, recall and identify any human action/error that resulted in a maintenance latent error. If possible, identify the "operating experience" report and enter it into the HAD field.
Operator induced initiating events and maintenance induced initiating events from fault schedule events.	• What are the operator errors/actions that when performed would initiate the event/fault? • What are the maintenance errors that when performed would initiate the event/fault? • When answering the questions above, refer to the Fault Schedule (Reference 13.3) or to PCSR Chapter 8 and 9 to better understand the event. • Systematically consider each plant operating mode as the initial plant condition when answering the above questions. • Consider the GOPs (i.e., plant mode change procedures) when answering question "a." above. • Refer to associated plant Tech Spec surveillance requirements when answering question "b." above. • From your extensive plant operating experience and training experience, recall and identify any human action/error that resulted in an operator induced initiating event or maintenance induced initiating event. If possible, identify the "operating experience" report and enter it into the HAD field.
Post-fault operator errors from fault schedule events.	• What error can the operator make that prevents or degrades a passive safety system or a defence in depth (DiD) system from performing its mitigating function? • Refer to the appropriate EOP to identify potential operator errors during the execution of the procedure. • From your extensive plant operating experience and simulator training experience, recall and identify any human action/error performed during the execution of the appropriate EOP.

Table 13-4 Identification Source and Error Type of Human Action Database entries

Operator action or HFE identification source	Number in HAD	Type A MLE	Type B MIIE	Type B OIIE	Type C PFOE	HEA Pro forma
Early PSA HFEs (Reference 13.44 and 13.85)	72		2	2	68	21 (DL) *
New PSA HFEs (HEPE) (Reference 13.77)	13	13				1 (CL) **
New PSA HFEs (HEPO) Reference 13.77)	51				51	13 (CL)
Systematic HEI process UK AP1000 Fault Schedule (Reference 13.80)	178	77	15	73	13	44 (DL) 4 (CL)
Systematic HEI process Composite Fault List (PCSR Rev 0. 2011 Chapter 8)	41	6	11	24		10 (DL)
AP1000 BDB Long-Term Coping Strategy (Reference 13.84)	8					2 (CL)
HF Review of Class 1 DCPs in the AP1000 DRP for GDA (Reference 13.28)	25					
HFI across the other GDA Issues (Reference 13.78)	32

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
001	ADN-MAN01 (LPM-MAN02)	Operator fails to manually actuate the Automatic Depressurisation System before core damage (Operator fails to recognise the need for RCS depressurisation during a LOCA)	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
002	ADN-REC01 (LPM-REC01)	Operator fails to manually actuate the Automatic Depressurisation System post-core damage Operator fails to recognise need for reactor coolant system depressurisation during small LOCA	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
003	ATW-MAN03	Operator fails to manually trip the reactor through Protection and Safety Monitoring System in one minute	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
004	ATW-MAN05	Operator fails to manually trip the reactor through Protection and Safety Monitoring System in seven minutes	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(CAN-MAN0S) CIC-MAN01	Operator fails to locally close manual valve CAS-V204 to isolate containment	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
005	CIB-MAN00	Operator fails to Diagnose Steam Generator Tube Rupture	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
006	CIB-MAN01	Failure to Close Main Steam Isolation valve on a Ruptured Steam Generator	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
007	CIC-MAN01 (CAN-MANOS)	Operator fails to Isolate Containment	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
008	CIT-MAN0S	Operator fails to Isolate Containment	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
009	CMN-REC01	Operator fails to Actuate Core Makeup Tank	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
010	CVN-MAN00	Operator fails to Align	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
011	CVN-MAN03	Operator fails to Start Chemical and Volume Control System Pump B	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
012	DUMP-MAN01	Operator fails to Operate Steam Dump Valves	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
013	LPM-MAN01	Operator fails to Recognise the Need for Reactor Coolant System Depressurisation during a small LOCA or loss of high pressure heat removal system (Modes 1-5)	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(LPM-MAN02) ADN-MAN01)	Operator fails to recognise the need for Reactor Coolant System depressurisation during a medium loss-of-coolant accident. (Modes 1-4)	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(LPM-REC01) ADN-REC01	Operator fails to Recognise the Need for Reactor Coolant System Depressurisation during a small loss-of-coolant accident or transient with loss of the passive residual heat removal system, and successful operation of the core makeup tanks after core damage (Mode 3 – Hot Standby)	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
014	REC-MANDAS	Operator fails to Diagnose of an Event Through DAS Signals or Perform an Activity by Operating DAS Controls	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
015	REN-MAN04	Operator fails to Initiate Recirculation (LOCA and IRWST level signal failure)	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
016	RHN-MAN01	Operator fails to Align Normal Residual Heat Removal System	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
017	VLN-MAN01	Operator fails to Actuate Hydrogen Control System	at-power PSA APP-GW-GL-022 (Node 2 Post-Core Damage)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
018	VWN-MAN01	Operator fails to Align Standby Chiller	at-power PSA APP-GW-GL-022 (Node 2 CDF risk increase >1%)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
019	OPR-009 (OPR-091; OPR-092; OPR-094; OPR-095; OPR-096; OPR-097)	Incorrect maintenance leads to PRHR failing to provide a heat sink	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
020	OPR-010 (OPR-127)	Maintenance error leads to CMTs failing to inject when required following reactor trip	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
021	OPR-011	Maintenance error leads to ADS failing to vent RCS when required	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
022	OPR-068	Mispositioned Component Interface Module (CIM) prevents control signal from reaching an actuated PMS component	Systematic HEI Node 5b CDF increasing factor of DiD system (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
023	OPR-069	DC Power left de-energised to ADS valves	Systematic HEI	HF Program for the UK

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
			Node 3 Passive Safety System (MLE)	UKP-GW-GL-042, Rev 1, Appendix C
024	OPR-070	Outlet valve left closed erroneously on safety injection accumulator	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
025	OPR-071 (OPR-074)	Accumulator levels allowed to rise to point where they are unavailable.	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
026	OPR-072 (OPR-073)	Operator erroneously allows accumulators to drain to the point that not enough water available for injection	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-073) OPR-072	Operator erroneously allows accumulator pressure to decrease too low	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-074) OPR-071	Operator erroneously allows pressure in accumulator to go too high.	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
027	OPR-079	Foreign Material is erroneously left in IRWST	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
028	OPR-080	Operator incorrectly adjusts Accumulator boron concentration such that it is too low	Systematic HEI Node 3 Passive Safety System	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
			(MLE)	
029	OPR-081	Operator erroneously allows IRWST boron concentration to decrease below limits	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
030	OPR-082	Operator allows Level in the IRWST to decrease below limits	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
031	OPR-084	Foreign material left in ADS lines following maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
032	OPR-085 (OPR-107; OPR-112; OPR-113)	Operator leaves IRWST outlet valve closed	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-091) OPR-009	PRHR Heat Exchanger becomes air-bound	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-092) OPR-009	PRHR HX not vented or refilled following maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-094) OPR-009	Opening of PRHR outlet manual isolation valve following system maintenance is omitted	Systematic HEI Node 3 Passive Safety System	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
			(MLE)	
	(OPR-095) OPR-009	PRHR inlet motor operated valve left closed following maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-096) OPR-009	Maintenance error leads to failure of a PRHR air operated outlet isolation valves to open when required	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-097) OPR-009	Operator inadvertently closes PRHR inlet MOV PXS-V101	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
033	OPR-099	Operator incorrectly executes the CMT discharge valves operability test	Systematic HEI Node 5a Initiating Event Frequency (OIIE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
034	OPR-106	Maintenance error leads to failure of Recirculation squib valves	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-107) OPR-085	PXS-V121A/B are left closed after maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
035	OPR-109	IRWST level instrumentation miscalibrated or made inoperable, preventing automatic transfer to sump recirculation	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
	(OPR-112) OPR-085	Maintenance error leading to Containment sump motor operated suction valves being left closed.	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-113) OPR-085	Maintenance error leads to check valves in containment recirculation path being unable to open	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
036	OPR-115 (OPR-116)	Maintenance leads to Passive containment cooling system (PCS) motor operated outlet valves left closed	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-116) OPR-115	Maintenance leads to Passive containment cooling System air operated valves fail to open when demanded	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
037	OPR-118 (OPR-121)	Failure to maintain PCS storage tank within required temperature band.	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-121) OPR-118	Operator fails to maintain PCS storage tank above minimum level	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
038	OPR-122 (OPR-123)	Maintenance error leads to inability to monitor PCS storage tank level	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-123)	Calibration error leads to PCS failing to actuate	Systematic HEI	HF Program for the UK

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
	OPR-122	on high containment pressure via PMS	Node 3 Passive Safety System (MLE)	UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-127) OPR-010	Operator leaves CMT isolated following maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
039	OPR-129	CMT not vented or refilled following maintenance	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
040	OPR-130	Improper Latching of a Fuel Assembly	Systematic HEI Node 3 Fuel handling (OIIE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
041	OPR-131	The operator Improperly Seats the Fuel Assembly Within the Core	Systematic HEI Node 3 Fuel handling (OIIE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
042	OPR-132	Foreign Material Left Behind in the Core	Systematic HEI Node 3 Fuel handling (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
	(OPR-137) OPR-174	Improper maintenance leads to Pressuriser Code Safety Valve Failing to Lift at set point pressure	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
043	OPR-138	Operator fails to maintain proper boron concentration in the PXS tanks	Systematic HEI Node 3 Passive Safety System (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
044	OPR-142	Master Diverse Actuation System (DAS) Disable Switch for manual DAS actuation left	Systematic HEI Node 5b CDF increasing factor of	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
		in disable position	DiD system (MLE)	
045	OPR-144	Operator fails to return a DAS function to its normal, ready configuration following Channel Operational Testing or Channel Calibration	Systematic HEI Node 5b CDF increasing factor of DiD system (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
046	OPR-174 (OPR-137)	Maintenance error results in PZR Safety Valve incorrect opening set point (valve opens prematurely)	Systematic HEI (Node 2 CDF risk increase >1%) (MLE)	HF Program for the UK UKP-GW-GL-042, Rev 1, Appendix C
047	ATW-MAN11	Operator fails to Recognise the Need for Manual Boration	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
048	CVN-MAN02	Operator fails to Align Chemical and Volume Control System	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
049	HPM-MAN01	Operator fails to Diagnose Need for High Pressure Heat Removal	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
050	PRI-MAN01	Operator fails to Isolate Failed Passive Residual Heat Removal Heat Exchanger	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
051	PRN-MAN01	Operator fails to Align Passive Residual Heat Removal System	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6

APPENDIX 13A DETAILED-LEVEL HEA ACTIONS (cont.)

Screened-in Human Failure Events and Operator Action Errors with Detailed-Level Human Error Analysis Pro forma				
Serial No.	**Event ID**	**Human Failure Event or Operator Action Error**	**HFE or Operator Action Error Source document (Screening Node and Error Type)**	**Location of detailed HEA Pro forma**
052	PRN-MAN02	Operator fails to Align Passive Residual Heat Removal System	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
053	PRN-MAN03	Operator fails to Align/Control Passive Residual Heat Removal System Operation	PSA Update UKP-GW-GLR-102 (Node 2 CDF risk increase >1%)	HF Safety Case as reflecting the PSA Update UKP-GW-GL-069, Rev 0, Section 6
054	CRDET	Control room operators fail to respond to the fire protection system alarms and notify	Fire PSA (Chapter 56) APP-GW-GL-022 (Node 2 Fire or Flood)	HF Safety Case as reflecting the Fire/Flood PSA UKP-GW-GL-070, Rev 0, Section 4
055	FLISM	Auxiliary personnel fail to isolate or mitigate the flood	Flood PSA (Chapter 57) APP-GW-GL-022 (Node 2 Fire or Flood)	HF Safety Case as reflecting the Fire/Flood PSA UKP-GW-GL-070, Rev 0, Section 4
056	OPA-01	Operator fails to deactivate the PMS division involved in a fire	Fire PSA (Chapter 56) APP-GW-GL-022 (Node 2 Fire or Flood)	HF Safety Case as reflecting the Fire/Flood PSA UKP-GW-GL-070, Rev 0, Section 4

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE

Human Error Analysis Sample - Summary Schedule	
Human Action Identifier	**BDB-005**
Location (s) of Action	This is a manual valve lineup that will be performed at several locations. Room 00304, Room 00371 Room 12213, Room 12211 Room 12306, Room 12354, Room 12351
Person(s) Performing Action	Licensed Reactor Operator 1 Local Equipment (auxiliary) Operator
Task	Operator conducts post-72 hour operation of Containment Cooling
Tools/Equipment	PCCWST level, PCS-LT010/011 PCCAWST level, PCS-LT037 SFP Level, SFS-LT019B/C SFP Emergency Makeup Flow rate, PCS-FIT039 PCS Recirculation Pump Discharge Flow rate, PCS-FIT030
SSC	Passive Containment Cooling System (PCS) Spent Fuel Pool (SFP)
Error Description	Operator fails to refill the PCCWST and / or the SFP or fails to adjust flow to the containment distribution buckets.
Performance Shaping Factors	Training Communication Availability of tools

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Error Mechanism	Communication errors; these will be combated by the use of 3 way communication and reinforced with training. Local operators may feel under pressure to establish PCCWST and SFP makeup quickly if site clearance and arrival of the temporary pump were delayed, resulting in missing or short-cutting PCS component alignment precondition checks prior to connecting and starting pump. However, this assessment assumes that the offsite equipment arrives within 24 hours, and given that there will be enough people to handle the high workload of site clean-up and recovery, it is not expected that there will be motivation to take short cuts.
Consequence	Failure of Containment Cooling
Recovery	There are no procedural based recovery opportunities due to the simple nature of the actions required of the operators. However, suction and discharge hose connection failure would likely be revealed immediately to local operator in vicinity of temporary pump with recovery opportunity before pump damage or containment and/or SFP overheating. The failure to establish flow due to PCS component alignment may not be revealed until PCCWST level low indications and established in time before containment and SFP temperature rise
Error Likelihood	The likelihood of unrecovered error is considered to be low, given the assumptions made in the assessment. The action consists of simple, manual tasks, the operators conducting the task will have clear objectives and procedures, have plenty of time, and will not have high workload. This action is judged to be feasible and likely to be performed successfully. The operators will have been trained on and know how to operate the equipment needed to complete this action. The procedures are straight forward. Given the assumptions made in this assessment, it is expected that operators will be able to complete this task successfully. It is assumed that offsite equipment will arrive in a timely manner, the plant is able to clear a path to the PCCAWST and the connection flanges, there is sufficient SQEP to perform the task, that the operators will have clear objectives and procedures, and that there is enough time to complete this action.
Corrective Action / Recommendation	1) Supply two hoses with the off-site pump. One terminating at both ends with male connectors and one terminating at both ends with female connectors. Then make the PCCAWST outlet and pump suction connectors both male and the Pump discharge and Class 1 PCS flange both female. Hoses cannot then be cross-connected. 2) The specification of the self-powered, off-site pump should include a requirement for local panel and connection task-lighting to reduce risk of error in night-time operation.

Human Action Identifier	BDB-006
Location (s) of Action	This is a manual valve line up that will be performed at several locations. Room 12351, Room 12701, Room 12553,
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operator makes up to the SFP by gravity drain from the PCCWST
Tools/Equipment	SFS-LT019B (SFP Lvl B) SFS-LT019C (SFP Lvl C)
SSC	Passive Containment Cooling System (PCS) Spent Fuel Pool (SFP) Passive Containment Cooling Water Storage Tank (PCCWST)
Error Description	Failure to refill the spent fuel pool post 72 hours
Performance Shaping Factors	HSI Design; Training; Communication; Stress; Time Pressure
Error Mechanism	Communication errors; these will be combated by the use of 3 way communication and reinforced with training.
Consequence	Inadequate mass of water in SFP. Failure of proper MCR communication with LO could lead to uncovering of fuel in the SFP.
Recovery	There are no procedural based recovery opportunities due to the simple nature of the task required of the operators. There are two knowledge based recovery opportunities that could occur at the end of this action; there is a flow indicator after valve V0045, which, if the operator checks, could indicate insufficient/no flow or, the MCR crew could notice the level changes of the PCCWST and/or SFP are not what is expected with successfully established flow.
Error Likelihood	The likelihood of unrecovered error is considered to be low, given the assumptions made in the assessment. The action consists of simple, manual tasks, the operators conducting the task will have clear objectives and procedures, have plenty of time, and will not have high workload. This action is judged to be feasible and likely to be performed successfully. The operators will have been trained on and know how to operate the equipment needed to complete this action. The procedures are straight forward. Given the assumptions made in this

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	assessment, it is expected that operators will be able to complete this task successfully.
Corrective Action / Recommendation	To reduce the risk to operators in navigating to room 12701, the procedure will be updated to provide alternative means of directing operators to take certain routes from room 12351 to room 12701 during a SBO.
Human Action Identifier	**HEPE-PCS-XVM-CL-V023**
Location (s) of Action	Valve/Piping Penetration Room 12306
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operators complete a valve cycling test of the PCS Manual Valve PCS-PL-V023 (Recirculation Return Isolation)
Tools/Equipment	PCS-FT030
SSC	Passive Containment Cooling System (PCS)
Error Description	PCS Manual Valve PCS-V023 unintentionally left closed.
Performance Shaping Factors	HSI Design Training Task Complexity Procedures
Error Mechanism	Population stereotypes dictate the expectancies of certain control behaviours (e.g., one expects that when a valve is turned counter clockwise, flow will increase). Violating population stereotypes can lead to errors. The valves will be controlled based on population stereotypes, and any plant worker dispatched to align valves will be trained in their operation. Retention of motor skills is influenced by several factors associated with practice including amount of practice and practice schedule; the AO will be well practiced in opening valves.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Manual control issues will be reduced by designing the valves to be opened within the human physiological limitations or providing tools to do so. The valves involved in this action are manual valves and thus designed to be operated manually. There is no time pressure and the tasks are simple (open/close manual valves).
Consequence	If the recirculation isolation valve is closed no recirculation is possible (chemistry concern). Failure to open valve PCS-PL-V023 would result in the inability to recirculate through the 2 recirculation pumps (PCS-MP 01A and PCS-MP 01B), recirculation heater (PCS-MB 01), and chemical addition tank (PCS-MT 02), removing an alternate source for PCS cooling to the PCS distribution bucket.
Recovery	The auxiliary operator could identify that the valve PCS-PL-V023 was unintentionally left in closed position when initialling on Passive Containment Cooling System Valve Stroke Test (APP-PCS-GJP-806) Attachment 2 step 5.11 that the valve PCS-PL-V023 was opened. The auxiliary operator could identify that the valve PCS-PL-V023 was unintentionally left in closed position when initialling and circling it is open on Passive Containment Cooling System Valve Stroke Test (APP-PCS-GJP-806) Attachment 5 regarding step 5.11 that the valve PCS-PL-V023 is open. The independent verifier could identify that the valve PCS-PL-V023 was unintentionally left in closed position when initialling on Passive Containment Cooling System Valve Stroke Test (APP-PCS-GJP-806) Attachment 2 step 5.11 that the valve PCS-PL-V023 was opened. Step 5.18 for procedure APP-PCS-GJP-806 requires the PCCWST be placed in recirculation via procedure APP-PCS-GJP-101, which requires the starting up of the recirculation pumps (PCS-MP 01A and PCS-MP 01B), which would result in a low flow indication from APP-PCS-FT-030, which would cause an automatic trip of the recirculation pumps and heater (PCS-MB 01) to prevent damage. An auxiliary operator would be dispatched to identify any valves out of normal position.
Error Likelihood	This is a routine action that the AOs will perform hundreds of times. Provided the AOs are following procedures as they are required to do, they will be initialling and having an independent verifier initialling that the valve PCS-PL-V023 is left open at the ending of the procedure, a low workload, and they have been trained to test valves, it is expected that operators will be able to complete this task successfully. The likelihood of unrecovered error of this action is very low. See Chapter 10 for the PSA quantification of the HEP for this action.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Corrective Action / Recommendation	None
Human Action Identifier	**HEPO-ADS4-C1**
Location (s) of Action	Main Control Room (MCR)
Person(s) Performing Action	Main Control Room Crew
Task	Operator depressurises the RCS using the ADS Stage 4 valves.
Tools/Equipment	RCS-V004A/B/C/D
SSC	Reactor Coolant System (RCS)
Error Description	Operator fails to depressurise the RCS with the ADS Stage 4 on low CMT level.
Performance Shaping Factors	Procedures; Training; HSI Design; Task Complexity; Attention
Cognitive Processes	Detect CMT Narrow Range Level (less than 61.9%). Understand the significance of the CMT Narrow Range Level. Detect that ADS stage 4 has not actuated automatically. Understand the significance of ADS Stage 4 not actuating. Determine the correct actions to take in this situation. Actuate ADS Stage 4 using manual back-up PMS switches.
Consequence	The purpose of opening the ADS stage 4 valves is to depressurise the RCS sufficiently to allow for gravity injection of the IRWST. With only the stage 1 to 3 valves open the RCS pressures may be too high to support gravity injection. If ADS stage 4 is not successfully actuated within the 15-minute time window, irreversible core damage is expected to happen at 36 minutes after the cue.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Recovery	There is a CMT lower narrow range level alarm on PMS if the operator fails to see the cue of low CMT level. Operators may diagnose why cooling does not happen at the expected rate and realise that ADS stage 4 has not been actuated. At that time the action can be completed
Error Likelihood	This assessment indicates that this action is feasible within the PSA time window. It is not likely that errors will occur as the operators are trained in this scenario, the interface provides cues, alarms, and indications that are clear and unambiguous, the task steps are clearly guided by procedures, and the procedures are assessed to be of high quality. The likelihood of unrecovered failure of this action is low; see Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from resolution of HED issues associated with this action.
Human Action Identifier	**HEPO-COG-CONT**
Location (s) of Action	MCR
Person(s) Performing Action	MCR crew
Task	Operator diagnoses high containment pressure when the pressure reaches or exceeds 59 PSIG.
Tools/Equipment	PCS-PT005, PCS-PT006, PCS-PT007, PCS-PT008 PCS-PT012, PCS-PT013, PCS-PT014
SSC	PCS
Error Description	Operator fails to diagnose high containment pressure when the pressure reaches or exceeds 59 PSIG.
Performance Shaping Factors	Procedures Training HSI Design

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Task Complexity Attention Stress Staff Structure
Cognitive Processes	Detection, recognition and understanding of the containment pressure alarms, diagnosing high containment pressure.
Consequence	There will be no consequences unless PMS and DAS also fail, as either PMS or DAS will actuate Containment Cooling
Recovery	There is an alarm High-2 Containment pressure when the pressure reaches 6.2 psig, There are four (PCS-PT005/6/7/8) priority alarms and the outlet valves to the Passive Containment Cooling Water Storage Tank (PCCWST) will automatically open. In addition there will be peer checks.
Error Likelihood	Unrecovered failure of this action is considered very unlikely. It is unlikely that the operator will either fail to detect high containment pressure, nor understand the significance as the containment pressure and the status of the Containment CSF is present on many interfaces including the WPIS. In addition, procedures guide the operator to look for and assess this parameter, procedural adherence is a requirement, the operator is trained to diagnose high containment pressure, and the monitoring of the critical safety functions is likely to be the dedicated task of the STA. Peer checking will add another line of defence. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None
Human Action Identifier	**HEPO-COG-CORE COOLING**
Location (s) of Action	MCR
Person(s) Performing Action	MCR Crew

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Task	Diagnosis of inadequate core cooling in a large loss of coolant (LOCA) accident scenario.
Tools/Equipment	5th hottest CETs (Red and Orange path) Sub-Cooling Margin (Orange path)
SSC	Reactor System (RXS)
Error Description	Operator fails to diagnose inadequate core cooling
Performance Shaping Factors	Procedures; Training; Staff Structure; HSI design; Task Complexity; Attention ;Stress
Cognitive Processes	Detection of CET, understanding of what high CET means, diagnosis of inadequate core cooling
Consequence	Core cooling is required to prevent core damage. The consequence of the operator failing to diagnose inadequate core cooling is that they would not enter procedure FR-C.1 "Response to Inadequate Core Cooling". This could mean that actions in FR-C.1 may not be implemented (e.g., turning on the hydrogen igniters or flooding the reactor cavity). This could lead to a reactor vessel failure and a molten core concrete interaction
Recovery	This is a time sensitive action. Completing this action after the available time window may not be effective but will not have a negative impact.
Error Likelihood	Having considered the potential errors, it is considered NOT likely that this action would fail. It is directed by procedures in a rigorous fashion and the task is a fundamental part of the operators' training. Clear indications are present on the interface, and the STA is dedicated to the task of monitoring the CSFs. See Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	Further research should be conducted to determine if it is beneficial to provide a means of alerting the operators to a recent red path condition on the critical safety function trees, which may have reverted back to an orange path. This would beneficial to alleviate the possibility in which the plant conditions could oscillate, across the boundary, of a red and orange path, before an operator notices. However care must be taken to ensure a solution does not create worse errors.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Resolution of HED issues associated with this action.
Human Action Identifier	**HEPO-F1-ADSDIS**
Location (s) of Action	Auxiliary Building I&C Room 12213
Person(s) Performing Action	Equipment (auxiliary) operators
Task	Operator opens breakers to prevent spurious ADS Stage 4 actuation. A fire in a PMS Division cabinet in one of the Class 1E I&C Rooms requires that the Operator takes action to remove power from the safeguards actuation circuits to prevent spurious actuation of the Stage 4 Automatic Depressurisation System (ADS) Squib Valves.
Tools/Equipment	ECS-EC-121-2M (Div A Battery Charger Bkr) ECS-EC-121-2C (Div A Regulating Xfmr Bkr)
SSC	Main AC Power System (ECS) Fire Protection System (FPS) PMS
Error Description	Failure to remove power to the affected PMS Division I&C cabinet through de-energising the battery bus by isolating the batteries and isolating the affected I&C cabinets.
Performance Shaping Factors	Audible and visual Fire Alarm cues in the MCR Symptom-based Fire Response procedures presented on CPS Communication between MCR crew and Auxiliary Operators
Cognitive Processes	Correctly read Fire panel. Execute desired action correctly communicate correct fire location. Information recall – working memory and attention – Step 7 - Implement the correct attachment for fire response.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Team communication –Local (auxiliary) operators correctly perceive information from MCR about breaker location or identification Execute required response/action – Local (auxiliary) operators open the correct breakers
Consequence	The consequence of failure to de-energise a PMS Division ADS4 cabinet within 30 minutes of a fire in an I&C room is the possibility of spurious actuation of the ADS4 Squib Valves. However this would require that fire-induced hot shorts generate sequential 'arming' and 'firing' signals, emanating from separate I&C cabinets, within a short time-window (i.e., if a 'firing' signal does not follow 'arming' signal within a certain time then the system will 're-set', requiring that another, time-dependant, sequential arming and firing signal sequence is spuriously generated).
Recovery	Failure in the MCR to communicate to site and to the fire brigade the correct area/zone or room affected by a fire may first be revealed to them by local site personnel who are evacuating or by first-responders attending the area/zone or room reporting that no fire is evident. Failure of the local (auxiliary) operators to open the correct breakers for the fire affected Division PMS cabinet would be revealed primarily by the relevant Division safety display monitor on the PDSP in the MCR not going dark and no audible and visual PMS alarm on the APS as expected. There is also likely to be an unexpected alarm coincident with the local (auxiliary) operators reporting the breakers open.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be very low. See Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	1) Reinstate manual reactor trip in Revision 3 of AOP-305 2) The list of rooms on pages 2-3 of Attachment 2 AOP-305 (Rev 2) are presented sequentially (except for the 50xxx rooms that appear in the middle of the list of 40xxx rooms) in 4 columns. Each column extends over both pages. Normal reading and page scanning expectation is to go from top to bottom of column 1 on page 1 and then to top of column 2 on page 1, etc. Currently, Attachment 2 lists the room numbers and attachment cross-reference sequentially in columns from top of column 1 on page 1 to the bottom of column 1 on page 2 and back to the top of column 2 on page 1, etc. Presentation of look-up tables in this way increases search times for the attachment cross-reference and the probability of making cross-referencing errors.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Resolution of HED issues associated with ISV Scenario 5 OPA-1 action
Human Action Identifier	**HEPO-FI-MCREVAC**
Location (s) of Action	MCR (Fire Zone 1242 AF 01).
Person(s) Performing Action	MCR Crew
Task	Main control room evacuation due to fire Temporary evacuation of the Main Control Room (MCR) is required because the outbreak of a fire and smoke in the MCR is making the MCR uninhabitable. The operators evacuate to the Remote Shutdown Workstations (RSW) located in the Remote Shutdown Room (RSR) on the floor below to establish and maintain safe shutdown conditions until the MCR can be made habitable again.
Tools/Equipment	RSW Transfer Switch Panel Self -Contained Breathing Apparatus (SCBA) can prolong the time available to operators to conduct operations in the MCR before becoming uninhabitable.
SSC	Operation and Control Centres System (OCS)
Error Description	Failure to evacuate MCR and transfer control to the RSR to establish and maintain safe shutdown.
Performance Shaping Factors	Human System Interface and System Response Workplace and Workstation Adequacy Training Task and Work Load
Cognitive Processes	Detect fire/smoke in the MCR, understand its significance, knowledge of procedure to follow, follow procedure
Consequence	Reactor at power with no one in the control room.
Recovery	Reactor can be tripped from RSR.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Error Likelihood	The likelihood of unrecovered failure of this action is considered very low. No credible failure paths were identified for this task/action. Failure to identify an alarm and source of the fire causing the alarm were not deemed credible when a fire emanates from an MCR that is permanently occupied by trained, licenced operators. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	The site Licensee shall define policies and procedures to respond to an on-site fire during Site Licensing. There will be a room designated as an 'assembly area' for fire fighters. This may contain lockers for the on-shift fire-fighter's clothing and kit with a changing, forming-up and briefing area and direct communication with the MCR. There will be portable, hand-held devices available to facilitate communication between the MCR and the Fire Fighting crew and with locally dispatched auxiliary operators having a range sufficient to cover all fire assembly points, fire areas/zones and rooms containing nuclear safety important SSCs. Doors to rooms that contain systems, equipment and components providing or supporting a nuclear safety, security or power generation function and that are not frequently or routinely occupied will be normally locked and only accessible to duly authorised and appropriately qualified and trained personnel. Resolution of HED issues associated with this ISV Scenario 7 action.
Human Action Identifier	**HEPO-INJ**
Location (s) of Action	MCR
Person(s) Performing Action	MCR Crew
Task	Actuate IRWST injection
Tools/Equipment	PXS-V123A/B PXS-V125A/B PXS-V121A/B

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
SSC	Passive Core Cooling System (PXS)
Error Description	Operator fails to actuate IRWST injection
Performance Shaping Factors	Procedures Training HSI design Task Complexity Attention
Cognitive Processes	Detect that IRWST injection has not actuated automatically (procedurally prompted). Detect that PMS IRWST injection has failed (procedurally directed). Correctly execute DAS IRWST injection, a simple manual task (procedurally directed). Confirm that IRWST injection was performed correctly. Follow procedures
Consequence	If operator fail to open the In-containment Refuelling Water Storage Tank (IRWST) injection valves manually from the Diverse Actuation System (DAS) Panel and nothing further is attempted then core damage would occur. However, the chances that the nuclear operators would attempt nothing else are highly unlikely from a human action standpoint as strict adherence to procedures and peer checking is expected per Conduct of Operations. Additionally in APP-GW-GJP-201 (E0, Step 5) the implementation of [Site specific procedure (Event Classification] occurs. This action notifies the Technical Support Centre and Emergency off-site facility which will be aware of any undue changes or issues from the Main Control Room (MCR). Additionally the alignment and injection of RNS is attempted to negate core damage.
Recovery	Peer checking is part of the Conduct of Operations, as is SRO supervision and the practice of crew briefs, any of which, could recover a failure of this action. The PRA does not credit recovery for this step. Recovery actions are available in FR-C.1 (Response to Inadequate Core Cooling) but this is after core damage and therefore only appropriate to be credited in the Level 2 PRA.
Error Likelihood	Unrecovered failure of this action is very unlikely. It is not likely that errors will occur as the operators are

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	trained in this scenario, the interface provides cues and indications that are clear and unambiguous, the task steps are clearly guided by procedures, and the procedures are assessed to be of high quality. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from resolution of HED issues associated with this action.
Human Action Identifier	**HEPO-L2-CAVFLD**
Location (s) of Action	MCR
Person(s) Performing Action	MCR Crew
Task	Operators recognise the need and manually open the containment recirculation valves to flood the reactor cavity after core damage in a large loss of coolant accident (LOCA) scenario with indications of inadequate core cooling.
Tools/Equipment	PXS-V117A, PXS-V118A, PXS-V120A PXS-V117B, PXS-V118B, PXS-V120B
SSC	RCS
Error Description	Operator fails to flood RV cavity for IVR on loss of core cooling cue
Performance Shaping Factors	Procedures Training HSI design Task Complexity Attention Stress

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Cognitive Processes	Detect CET higher than 1200F, recognise CSFT red path, follow procedures, recognise the need for reactor cavity flooding, execute the reactor cavity flood correctly, and confirm flood occurred successfully.
Consequence	Since there is already core damage, the consequences are vessel damage, if water is not released around the vessel to help lower the temperature.
Recovery	Step 3 in FR-C.1 directs the operators to Actuate Safeguards. If the operators had already actuated safeguards, technically the need to “initiate reactor cavity flooding” should not be needed as the plant’s passive safety features should already be in effect.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be low. While the action involves higher workload and stress, the HSI design, procedures, task complexity, and training will drive this action towards success. While the initial conditions of this action are different from those of scenario 12 for the ISV, the action of interest was performed successfully in all trials, which shows that it is possible for operators to complete this action. This combined with the majority of the PSFs leading to success of the action; it seems unlikely that a human error will occur to prevent this action from being successfully completed. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from the resolution of the HED issue (ISV-51 and Issue ID ISV-07-07) associated with this task.
Human Action Identifier	**HEPO-L2-CNT**
Location (s) of Action	MCR
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operator manually isolates containment
Tools/Equipment	Containment isolation valves
SSC	Containment System (CNS)

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Error Description	Operator fails to manually isolate containment
Performance Shaping Factors	Procedures, Training, HSI Design, Attention, Stress
Cognitive Processes	Follow procedures, successfully ensure all containment isolation valves are closed, confirm with peer check.
Consequence	Since there is already core damage, the consequences could be a release associated with the accident progression provided additional actions to prevent this are not taken.
Recovery	Step 7 of FR.C-1 will also have the operators perform this action (manual containment isolation), which the operators will reach if they transition out of E-0 via the Foldout Page. If the operators did transition out of E-0 but failed to perform this action (manual containment isolation), they could, depending on the failure, be directed to "Return To Procedure And Step In Effect" (as in F-0 Step 7), which allows them to reach Step 13 of E-0.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be very low. While the level of stress the operator is experiencing is a negative PSF, the HSI design, procedures, task complexity, and training will drive this action towards success. While the initial conditions of this action are different from those of scenario 17 for the ISV, the action of interest was performed successfully in all trials, which shows that it is possible for operators to complete this action. This combined with the majority of the PSFs leading to success of the action; it seems unlikely that a human error will occur to prevent this action from being successfully completed. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from resolution of HED issues associated with manual isolation of containment action in ISV Scenario 17.
Human Action Identifier	**HEPO-L2-H2I**
Location (s) of Action	MCR
Person(s) Performing Action	Licenced Reactor Operator 2

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Task	Operator manually actuates the hydrogen igniters in a large loss (LOCA) of coolant scenario.
Tools/Equipment	VLS-AE001/2/3
SSC	Containment Hydrogen Control System (VLS)
Error Description	Operator fails to manually actuate hydrogen ignitors
Performance Shaping Factors	Training, HSI Design, Task Complexity, Attention, Time Pressure, Procedures
Cognitive Processes	Follow procedures, recognise that PLS actuation of hydrogen igniters failed, successfully actuate hydrogen igniters via DAS, and confirm hydrogen igniter actuation. Operators already know they are in a core damage scenario and have initiated reactor cavity flooding, so the significance and importance of this task are fully understood.
Consequence	The PSA assumes containment failure once the hydrogen level reaches detonation conditions.
Recovery	There is an alarm when the hydrogen concentration reaches 3%. In Severe Accident Control Room Guideline (SACRG-1), APP-GW-GJP-501, Rev 0, in Step 5 the text states "Determine if Hydrogen Igniters should be in service: 5a) Check hydrogen concentration (less than 10%), 5b) Turn on both groups of Hydrogen Igniters. If the hydrogen igniters fail then the Response Not Obtained (RNO) column 5b) instructs the operator to Actuate DAS Containment Hydrogen Igniters.
Error Likelihood	Unrecovered failure of this action is considered to be of very low likelihood. Turning on the hydrogen igniters is a simple task and there is the potential for recovery if the operator initially fails to carry out the task. The main PSFs are workload and stress but the procedures give sufficient guidance to allow us to deduce that this failure is unlikely. See Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from the resolution of the HEDs associated with RIHAs VLN-MAN01 and DAS-VLN-MAN01 actions in ISV Scenario 17.
Human Action Identifier	**HEPO-OFILL**

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Location (s) of Action	MCR
Person(s) Performing Action	MCR Crew
Task	Operator successfully isolates RCS makeup flow from CVS and SFW flow prior to ruptured Steam Generator overfill.
Tools/Equipment	SGS-LT001-1-MED, SGS-LT011-1-MED SGS-LT005-1-MED, SGS-LT013-1-MED
SSC	Protection and Safety Monitoring System (PMS)
Error Description	Operator fails to isolate ruptured SG (on High-3 NR SG level—PMS backup)
Performance Shaping Factors	Audible and visual Alarm cues in the MCR, HSI Design Training; Procedures; Time Pressure; Communication; Workload
Cognitive Processes	Detect ruptured SG NR level above 72.8%, recognise and understand the significance of failure of isolation of the ruptured SG, follow procedures, make correct decisions, successfully execute manual valve closures. Operators will have already diagnosed the situation as a SGTR event, and will be watching ruptured SG NR level.
Consequence	The operator failure to isolate RCS makeup flow from CVS and SFW flow to the ruptured SG without ADS manual actuation could lead to steam generator overfill, potentially resulting in Containment-bypass sequences and a significant increase in the offsite radiological consequences. If the primary-to-secondary leakage continues for a significant time, the Steam Generator may become filled and water may enter the steamline. If the leakage continues, Containment is bypassed and fluid may be released through the secondary side safety valves to the atmosphere. Moreover, due to the presence of water, these valves may not be capable of reclosing and will remain stuck open.
Recovery	A SRO/STA review on operators' actions could potentially help them identifying the error in recognising the ruptured SG overfill and the error in failing to isolate SFW and CVS before the ruptured SG NR level reaches

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	95% of span. The available time for this human action is deemed short, as it is based on the bounding PSA scenario. However, even if that PSA bounding scenario occurs, E 3 foldout page criteria for ADS will be met sooner in the scenario evolution: operators will manually actuate ADS, thus lengthening the time window. It has to be noted that in case of both Ruptured SG isolation and SFW/CVS isolation failure, core damage can be prevented by RCS depressurisation via the ADS valves and IRWST or RNS injection/recirculation. This has been demonstrated in ISV test Scenario 15 results, as the MCR crews prevented SG overfill by depressurising the RCS using ADS stage 1-3 (RIHA ADF MAN01) that terminated the filling of the ruptured SG before overfilling instead of isolating RCS makeup flow from CVS and SFW flow to the ruptured SG. The depressurisation of the RCS terminates the primary-to-secondary leakage and prevents a Steam Generator overfill event. HEPO OFILL may not be recovered this way, but SG overfill is successfully prevented.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be low. Workload, stress and time pressure have been identified as negative PSFs, but a good HSI design, knowledge/experience/training and clear procedures have been identified as positive PSFs, reducing the likelihood of error. Given that this action is a backup of PMS automatic isolations and that it is required after the failure when attempting to isolate the ruptured SG, the likelihood of requiring MCR crew to perform this action is already reduced. Moreover, it is not likely that this error will occur given that the operators are trained in this scenario, the interface provides clear indication of the status of the ruptured SG NR level, the task steps are guided specifically by symptom-based procedures, and SRO surveillance is provided. See Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	In the previous revision (Rev. 5) of EOP E-3, which was used for the PSA HRA (as documented in HRA Notebook, APP-PRA-GSC-321 Rev. C), the verification of the ruptured SG level (i.e., Check Ruptured SG(s) Narrow Range Level – LESS THAN 82%) was positioned in Step 6, right after the SG isolation actions from the Main Steam line and from ruptured SG drains (E 3 Steps 3 through 5). It was just a “check” step. Currently, this step has been transformed into a “continuous/monitor” step and its set point has been lowered, from 82% of span to 72.8% of span. However, this step has been moved from Step 6 to Step 17. Therefore, in order to make sure that the timely, automatic PMS isolation of RCS makeup flow from CVS and SFW flow to the ruptured SG has occurred, it is recommended to move current Step 17 so that it is encountered by the MCR crew at an earlier stage in the procedure. Resolution of HED issues associated with RIHA CIB-MAN01 in ISV Scenario 15 and isolation of ruptured SG as part of ISV Scenario 14.

Human Action Identifier	HEPO-PRHR-GT
Location (s) of Action	MCR
Person(s) Performing Action	MCR crew
Task	Operator manually actuates PRHR after automatic actuation failure post reactor trip without safeguards actuation.
Tools/Equipment	PXS-PRHT, PRHRHX Outlet Temp Filtered PXS-FT49A/B, PRHR HX Flow
SSC	PXS
Error Description	Operator fails to actuate Passive Residual Heat Removal (PRHR) during an event without a Safeguards signal
Performance Shaping Factors	HSI Design Training Communication
Cognitive Processes	Monitoring of the CSFT, recognition and understanding of a heat sink red path, following procedures, communicate within the MCR crew, manually actuate PRHR.
Consequence	Failure of this task could ultimately result in damage to the core.
Recovery	The EOP ES-0.1 Reactor Trip Response procedure is being performed concurrently with monitoring of Critical Safety Functions (EOP F-0) and will eventually (Step 25 RNO) instruct the operator to throttle PRHR although this may not occur in the time to core damage postulated by the PSA.
Error Likelihood	The likelihood of unrecovered failure of this task is considered to be very low. Given the positive impact of the PSFs, the training and experience levels of the operators, the presence of the STA in monitoring the CSFTs, the procedurally driven resolution method, and modern standards HSI design, this task is deemed to be achievable in

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	the available time. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None
Human Action Identifier	**HEPO-RNSINJ**
Location (s) of Action	MCR
Person(s) Performing Action	MCR Crew
Task	Operator aligns the normal residual heat removal (RNS) for injection from the cask loading pit (CLP).
Tools/Equipment	SFS-LT022 RNS-FT001A/B
SSC	RNS
Error Description	Operator fails to align RNS for injection
Performance Shaping Factors	Procedures, Training, HSI design
Cognitive Processes	
Consequence	RNS is a support system and although it would be helpful to use it, if it is not possible, there is no safety consequence. RNS failure does not lead to core damage but rather is used as DiD.
Recovery	There is no real recovery for RNS. Peer checking is provided. SRO also provides supervision. From the PRA standpoint no recovery was credited for this step. Recovery actions are available in FR-C.1 (Response to Inadequate Core Cooling) but this is after core damage.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be low. Due to a design change, any actuation of ADS (automatic or manual) always transitions to ES 1.3 and ADS Stages 1-3 Actuation Response.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	The most current procedures have been changed to reflect the DCP. Due to the DCP and updated procedure changes PRA issued a revised set of critical human action steps to HF for the Human Action HEPO-RNSINJ. Although the actions were relatively simple, the operators were required to transition to several procedures to complete the action. The workload was considered medium, although the action was not complicated. The PRA time window for HEPO-RNSINJ was 24 minutes, developed prior to the design change. The HF analysis time for the human action was 30.97. However, in the ISV trials for Scenario 11 all four crews completed the action and two of the four crews did meet the PRA time of 24 minutes. Based on this assessment it seems unlikely that a human error will occur to prevent this action from being successfully completed. It should also be noted that the PSA time window has been calculated using conservative considerations. The PSA time window calculated was based on the upper bound of a MLOCA break size. This time window would be significantly longer for smaller and more likely break sizes. A modified time window based on a smaller break size and consideration for procedures improvements are also anticipated to result in a time window that can be achieved. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	None aside from the resolution of ISV issues related to alignment of RNS from CLP and then from IRWST to the RCS from ISV Scenario 11.
Human Action Identifier	**HEPO-RRWSTISO**
Location (s) of Action	MCR
Person(s) Performing Action	MCR crew
Task	Operator successfully isolates IRWST recirculation following spurious IRWST recirculation squib valve(s) actuation.
Tools/Equipment	PXS-V117A/B; PXS-LT054 & PXS-LT055
SSC	PXS
Error Description	Operator fails to isolate IRWST recirculation following spurious recirculation actuation

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Performance Shaping Factors	Training, HSI Design, Stress, Time Pressure, Task Complexity
Cognitive Processes	Detect and understand the IRWST level and Containment Sump Level High alarms and the associated level indications, follow procedures, successfully close PXS valves.
Consequence	The operator failure of isolating the IRWST inventory leakage into the Containment floodable region would render the IRWST unavailable. In consequence, IRWST passive injection and PRHR long term cooling can no longer be considered available as mitigation means: IRWST would not contain enough water inventory for passive injection and the PRHR heat exchanger would not be operable as the IRWST water level is below the required level for its correct operation. The unavailability of the IRWST inventory would leave operators with only the secondary side heat removal systems to be used for the mitigation of this event (MFW and SFW systems).
Recovery	Various alarms will appear in the MCR indicating a leak into the Containment floodable region and the IRWST level alarm will help the identification of the leakage. Peer/supervisor check is expected.
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be very low. The likelihood of not recognising the IRWST leak is low: IRWST level alarms will be triggered, Containment sump alarms will be triggered, progressively showing the IRWST level drop and Containment flooding. Error of omission (action not attempted) is considered low as the main error mechanisms linked to this type of error is related to misdiagnosis and non-expectation of cues. Despite this fact, the ample available time reduces the probability of failing the action. For the accomplishment of this human action, a few indicators in MCR are required to identify and diagnose the event, the stress level is low, there is not a significant time pressure, the task is simple and only a single control action is to be performed. See PCSR Chapter 10 for the PSA quantification of the HEP for this action.
Corrective Action / Recommendation	Within seconds of the initiating event, the WLS Containment sump level alarm is received. Alarm Response Procedure APP-WLS-GJP-401, is used to treat this alarm. It directs the operator to AOP-340 “Response to a RCS Leak”. This procedure does not mitigate the faulted PXS recirculation condition because it directs the operators to look for a RCS leak only. The ALARP discussion has identified a recommended procedure change of both ARP-APP-WLS-GJP-401 and AOP-340 in order to include indications of other types of leaks that could occur in fluid systems located in Containment, apart from a RCS leak.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	Repetitive steps have been identified in Alarm Response Procedure used to accomplish the Containment Recirculation line isolation, APP-PXS-GJP-401. The associated instructions for the primary cue, level transmitters PXS-LT054 and PXS-LT055, direct the operator to close Containment Recirculation isolation MOVs per Step 3. Similar instructions are repeated in steps 4 and 6. Moreover, instructions for PXS LT054 and PXS LT055 are not exactly the same although they are redundant level transmitters. The ALARP discussion has identified a recommended a simplification of level transmitters PXS-LT054 and PXS-LT055A related procedure steps, including identical steps for both transmitters.
Human Action Identifier	**OPR-011**
Location (s) of Action	Rooms 11206, 11300, 12206, and 11207
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operators maintain ADS stage 4 and IRWST injection valves and return them to service.
Tools/Equipment	1. Static Protector Plug(s) 2. Hand held, Battery Powered, Digital Volt Meter 3. Keys for ILC cabinets A01, A03, B01, B04, C01, C02, D01 and D04 4. Keys for the following cabinets: • DAS-JD-001 (Processor Cab 1) • DAS-JD-003 (Squib Valve Cab) • PMS-JD-SVCA01 (Squib Valve Controller Cab Div A) • PMS-JD-SVCB01 (Squib Valve Controller Cab Div B) • PMS-JD-SVCC01 (Squib Valve Controller Cab Div C) • PMS-JD-SVCD01 (Squib Valve Controller Cab Div D)
SSC	ADS

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Error Description	Maintenance error leads to failure of ADS Stage 4 and IRWST gravity injection squib valves
Performance Shaping Factors	Team Work, Communication, Time Pressure, Tooling and PPE, Access, Training, HSI design, Procedures
Cognitive Processes	Correctly determine which tests are required for which valves, correctly and unambiguously record outcomes of tests and inspections, apply correct levels of force when connecting or disconnecting electrical connecters at the valve, correctly reconnect the cabling from PMS/DAS SVCs to the squib valve igniters after installation in the pipeline, correctly restore PMS/DAS SVC to service, correctly and completely perform visual inspections of the valves, detect and understand the significance of any fault in the valve, follow procedures, apply proper force to components during disassembly and reassembly, remove, disassemble, and reassemble items in the correct order, apply the correct text, properly handle squib valve cartridges, ensure proper hoist connections, properly use the hoist, properly disconnect the valve from the flanges, properly perform electrical continuity checks, use properly calibrated tools (e.g., multimeter), correctly record measurements, proper communication amongst team members. Work planning and use of checklists and human performance fundamentals is of primary importance for this task.
Consequence	Failure to successfully complete specific maintenance tasks may result in a failure of the squib valves to actuate. This could potentially lead to one of the four flow paths required to vent the RCS not functioning. In this eventuality, the three remaining flow paths that are unaffected would be sufficient to depressurise the RCS to allow the IRWST to drain to the RCS. In addition to this ADS stage 1-3 will be sufficient to depressurise the RCS providing further redundancy for this system. Failure of IRWST injection valves to actuate would result in failure to inject the contents of the IRWST into the RCS or failure to place the RCS and Containment sump on recirculation. In this eventuality, the three remaining flow paths that are unaffected would be sufficient to inject the IRWST into the RCS.
Recovery	Co-worker peer review, Independent Verification (when indicated by the procedure) and Concurrent Verification (when indicated by the procedure) performed by SQEP engineers
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be low, due to the training, work planning, collective recognition of the safety significance of the squib valves, use of procedures and checklists, peer checks, and independent verification. A number of recommendations for improvements to this task are identified below. An HEP for this action will not be calculated until site licensing.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Corrective Action / Recommendation	1) Since IRWST Injection squib valves (i.e., PXS-V123A/B, PXS-V125A/B) need to be removed in order to access and maintain the Containment Recirculation Squib valves (i.e., PXS-V1183A/B, PXS-V120A/B), it is recommended to include in APP-PXS-GJP-804 procedure a statement in "precautions and limits" section alerting the operator that the activity he/she is about to perform could require the removal of other squib valves. 2) There is the potential for the IST engineer to make a selection error and chose either wrong valves to be tested and / or chose the wrong tests to be undertaken on the right valves and vice versa. There is no IV identified for the test selection process in the current revision (i.e., Rev. 0) of the MTIS procedure and therefore, including IV of the test selection process is raised as a suggested improvement from this assessment. 3) There also exists the possibility for an administration error to occur when undertaking the maintenance activities locally either at the valves location in-situ or on the Maintenance Floor. Therefore, it is recommended to add a verification step during the results recording process to ensure that the documented results are correct and comprehensible for other maintenance operators. 4) It is recommended that the Site specific Maintenance procedure includes all IVs and CVs as instructed in the current MTIS procedure (APP-PXS GJP-804, Rev. 0) as well as including all Vendor's Manual (APP PV70 VMM 001, Rev. 1) recommendations, cautions and documentations requirements for critical steps. Moreover, it is also recommended that the site licensee's maintenance procedure will include a step to check the CIMs LEDs indications to ensure proper restoration. 5) Since both IRWST injection and Containment Recirculation squib valves need to be maintained at least once every two years for all valves on a rotational basis, it is recommended to adapt the site specific maintenance schedule to synchronise the maintenance activities requiring valves removal for those pairs of IRWST injection and Containment Recirculation squib valves located one above the other at the same time. 6) In order to prepare the working area in the PXS room, transporting all required tools and equipment, it is recommended to use the personnel hatch versus the equipment hatch itself, as this will avoid transportation/handling of equipment on top of the IRWST injection squib valves, which could damage them. 7) The current maintenance procedure (APP-PXS-GJP-804, Rev. 0) provides checklists to follow when undertaking maintenance activities. The checklists do not contain a high degree of detail. Moreover, the

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	In-Service Inspection Data Sheet, where results are recorded requires the maintenance operator to circle a box to record if the test was Satisfactory or not ("SAT/UNSAT" box). Circling this box may easily be completed in a manner that may not be clear to another operator and it is likely that this particular design element of the checklist could increase the likelihood of a latent maintenance error. A redesign of this element of the checklist is recommended in order to avoid misinterpretation of the results. 8) In order to minimise the risk of omitting or forgetting to reconnect the PMS/DAS SVCs cabling after maintenance and reinstallation, it is recommended that the Site specific Maintenance procedure includes an IV step to check that the electrical connection has been properly restored to the squib valves igniters. 9) The time taken to remove the worst case valves is currently unknown. Further assessment is required to understand if the time available during maintenance is sufficient to enable the maintenance operators to complete this task. 10) It is recommended to study the feasibility of fitting the hydraulic system to the flange studs located closest to the room wall in order to ensure proper valve removal from the pipeline. 11) It is recommended to study the feasibility of removing the IRWST injection valves flange studs with the current room layout.
Human Action Identifier	**OPR-099**
Location (s) of Action	Rooms: 12305, 12304, 12301, and MCR
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operator executes the CMT discharge valves operability test.
Tools/Equipment	PXS-V002A/B; PXS-V014A/B; PXS-V015A/B PMS-MTCD01; PMS-MTCB01; PMS-JD-ILCA01
SSC	Core Makeup Tank (CMT)
Error Description	Operator incorrectly executes the CMT discharge valves operability test

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Performance Shaping Factors	Procedures, HSI Design, Task Complexity, Attention, Task Preparation, Time Pressure, Training
Cognitive Processes	Follow procedures, select the correct valve, correctly use independent verification, correctly close the valves, and return them to proper alignment.
Consequence	Failure to close the CMT inlet isolation first and opening the CMT discharge isolation valves results in the flow of highly borated and cooler CMT fluid into the reactor coolant. Failing to close the CMT discharge isolation extends the time period, during which the fluid injection would continue, and therefore the severity of the consequences. If not identified and corrected promptly an automatic reactor trip will result. Safeguards actuation occurs about 3 minutes or less after both CMT valves are left open.
Recovery	Peer check and independent verifier signature for the critical subtasks are opportunities for recovery. The plant transient initiated by inadvertent CMT flow would result in multiple alarms in the MCR. Such alarms would be expected to include Control Rod Motion audible, Pressuriser Level Low alarms, CMT High Temperature alarms, Steam line Pressure Low alarms and Cold Leg temperature low alarms. The operator or the control room supervisor would be expected to investigate and correct the cause of these alarms.
Error Likelihood	The likelihood of unrecovered failure of this task is considered to be low. Workload is considered low, as no other actions are required to be performed before this one. Stress level is also considered to be low as this is a maintenance action. Time pressure is not significant, as this is a maintenance action with no time requirements. All of the valves linked to failure of this action have valve positions indications in the MCR, leading to successful completion. An HEP for this action will not be calculated until site licensing.
Corrective Action / Recommendation	None
Human Action Identifier	**OPR-106**
Location (s) of Action	Rooms 11206, 11300, 12206, and 11207
Person(s) Performing Action	Local Equipment (auxiliary) Operator
Task	Operators maintain Containment Recirculation squib valves and return them to service.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Tools/Equipment	1. Static Protector Plug(s) 2. Hand held, Battery Powered, Digital Volt Meter 3. Keys for ILC cabinets A01, A03, B01, B04, C01, C02, D01 and D04 4. Keys for the following cabinets: • DAS-JD-001 (Processor Cab 1) • DAS-JD-003 (Squib Valve Cab) • PMS-JD-SVCA01 (Squib Valve Controller Cab Div A) • PMS-JD-SVCB01 (Squib Valve Controller Cab Div B) • PMS-JD-SVCC01 (Squib Valve Controller Cab Div C) • PMS-JD-SVCD01 (Squib Valve Controller Cab Div D)
SSC	PXS
Error Description	Maintenance error leads to failure of recirculation squib valves
Performance Shaping Factors	Communication, Time Pressure, Training, Access, HSI Design, Procedures
Cognitive Processes	Correctly determine which tests are required for which valves, correctly and unambiguously record outcomes of tests and inspections, apply correct levels of force when connecting or disconnecting electrical connecters at the valve, correctly reconnect the cabling from PMS/DAS SVCs to the squib valve igniters after installation in the pipeline, correctly restore PMS/DAS SVC to service, correctly and completely perform visual inspections of the valves, detect and understand the significance of any fault in the valve, follow procedures, apply proper force to components during disassembly and reassembly, remove, disassemble, and reassemble items in the correct order, apply the correct text, properly handle squib valve cartridges, ensure proper hoist connections, properly use the hoist, properly disconnect the valve from the flanges, properly perform electrical continuity checks, use properly calibrated tools (e.g., multimeter), correctly record measurements, proper communication amongst team members. Work planning and use of checklists and human performance fundamentals is of primary importance for this task.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Consequence	Failure to successfully complete this test would render unavailable the Containment Recirculation squib valves undergoing maintenance. This unavailability reduces the capabilities for the establishment long term recirculation from the Containment sump to the Reactor when required for the mitigation of certain accidents. As the IRWST Injection squib valves will be removed to perform a full maintenance on the Containment Recirculation squib valves, the potential for a common cause failure during maintenance on both types of valves may occur, potentially rendering unavailable IRWST Injection valves as well. This is initially limited to the valves being worked on during that particular outage.
Recovery	Co-worker peer review, Independent Verification (when indicated by the procedure) and Concurrent Verification (when indicated by the procedure) performed by SQEP engineers
Error Likelihood	The likelihood of unrecovered failure of this action is considered to be low, due to the training, work planning, collective recognition of the safety significance of the squib valves, use of procedures and checklists, peer checks, and independent verification. A number of recommendations for improvements to this task are identified below. An HEP for this action will not be calculated until site licensing.
Corrective Action / Recommendation	As per OPR-011
Human Action Identifier	**OPR-131**
Location (s) of Action	Containment
Person(s) Performing Action	Refuelling SRO
Task	The operator seats the fuel assembly within the Reactor Vessel (RV).
Tools/Equipment	PPE – full body coveralls will be worn by the SROs during normal refuelling operations.
SSC	Fuel Handling and Refuelling System (FHS)
Error Description	Operator improperly seats the fuel assembly within the core.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
Performance Shaping Factors	Communication; Time Pressure; Training; PPE; HSI Design; Procedures
Cognitive Processes	Select proper operational mode for the refuelling machine, ensure interlocks are operational, follow procedures, detect fuel assembly position on the interlock display, and ensure fuel assembly is properly seated before releasing from the refuelling machine gripper.
Consequence	If the FA is improperly seated onto the RV assembly support floor and guide pins AND is erroneously released by the RFM or the operator it could move from its vertically upright position impacting the side of the RV vessel or another FA. This could potentially damage the FA (or the one impacted) resulting in a release of radioactive material. At this point the SRO would contact the Main Control Room (MCR) to sound the containment evacuation alarm and suspend refuelling activities. Ultimately, this error would potentially lead to an increased outage time for the plant.
Recovery	Concurrent Verification occurs throughout the refuelling process and SROs are able to check each other's actions and key system status indicators e.g., interlock displays throughout the process.
Error Likelihood	The likelihood of unrecovered failure of this task is considered to be extremely low. The refuelling SROs are SQEP, are fit for duty and are highly trained and experienced in undertaking refuelling activities. The HSI is designed according to good RGP and AP1000 HF guidelines. There are also numerous safety related interlocks that prevent an SRO from releasing a fuel assembly into the RV if it is not properly seated within the RV. The workload of the crew is deemed to be medium and no significant negative performance shaping factors have been identified that will increase the likelihood of human error in this scenario. Based on the positive influence of the PSFs, the prevention and recovery mechanisms, as well as the training and SQEP levels of the SRO crew, this scenario, during normal operations is deemed extremely unlikely. However, during recovery operations i.e., a major PLC malfunction the likelihood of a human error based failure increases.

APPENDIX 13C COGNITIVE-HEA ACTIONS SUMMARY SCHEDULE (cont.)

Human Error Analysis Sample - Summary Schedule	
	This increase in risk can be mitigated by introducing IV during the crucial stage of inserting a FA into the RV when operating in this mode. This has been identified as an improvement. An HEP for this action will not be calculated until site licensing.
Corrective Action / Recommendation	Site specific procedures specifically identify the points, at which IV should occur, if the SROs put the FA down in the RV in interlock override mode

14 AP1000 PLANT ALARP EVALUATION

14.1 Introduction

This chapter summarises and consolidates the results and conclusions of the following fault analysis and hazards safety case chapters in Volume 3 of the AP1000 Pre-Construction Safety Report (PCSR):

- Fault and Accident Analysis (Chapter 8)
- Internally initiated faults (Chapter 9)
- Probabilistic safety assessment (PSA) (Chapter 10)
- Internal hazards (Chapter 11)
- External hazards (Chapter 12)
- Human factors (Chapter 13)

Each of the above preceding chapters has its own results and conclusions, but there are some overall results and conclusions for the AP1000 plant design that are better suited to be discussed collectively. This collective presentation allows for an assessment of the AP1000 design against the requirement that the risks from its operation should be ALARP.

The results and conclusions of the fault and accident analyses demonstrate that the dose and frequency targets given in the Office for Nuclear Regulation (ONR) safety assessment principles (SAPs) (Reference 14.2) are met by the design and operation of the plant, and that the risks associated with plant operation are ALARP. These demonstrations are the subject of the rest of this chapter.

Section 14.2 discusses the classification and categorisation of systems, structures, or components (SSCs) identified in the various chapters of the fault and accident analysis and the claims made on them. These claims lead to requirements placed on the individual SSCs in terms of performance, reliability, separation and segregation, seismic withstand, and other survivability requirements. These requirements are the starting point for the engineering substantiation that is the subject of Volume 4.

Section 14.3 discusses the limits and conditions cited in the various chapters of the fault and accident analysis.

Section 14.4 lists the emergency instructions and operator actions identified in the fault and accident analyses. The corresponding operator errors (the failure of operators to fulfil these actions) are analysed in Chapter 13, which also contains a human factors as low as reasonably practicable (ALARP) assessment.

Section 14.5 is a compilation of information from the preceeding chapters of this volume to provide comparisons with the public and worker risk targets from the ONR SAPs that apply to the safety case as a whole.

Section 14.6 summarises the risk-reduction and ALARP arguments for the AP1000 plant, compiled from various sources. These sources demonstrate implementation of numerous design enhancesments over the life of the AP1000 design program. The implementation of the identified measures leads to the conclusion that, in the areas of severe accidents and human errors, the risks from the AP1000 plant are ALARP.

Section 14.7 provides an assessment to demonstrate that the total plant risk has been lowered to the point that it is very difficult to identify further cost-effective risk reduction measures.

The overall conclusion of this chapter is that risk-reduction and ALARP assessments have been carried out systematically and comprehensively to a sufficient degree to demonstrate that the risks associated with the AP1000 design and operation are considered to be ALARP.

14.2 Requirements on Systems, Structures, and Components from the Fault and Accident Analysis

The safety case developed in this volume of the PCSR identifies a number of SSCs as being important for safety. The categorisation and classification of the SSC is determined using the methodology in Section 5.2. The classification of SSCs defines the quality requirements placed on those SSCs during design, manufacture, and through life.

For the faults discussed in Chapter 9, the performance of the identified SSCs is analysed, and the analysis in the safety case confirms that these performance requirements are adequate for design basis (DB) targets to be met.

Generic component failure data parameters from Table 10-34 and Table 10-35 are used as an input to the AP1000 plant PSA discussed in Chapter 10. The engineering substantiation in Chapters 15 through 23 provides evidence that the design supports those assumptions.

In addition to performing their assumed safety functions, each SSC has to perform its function in the environment created by the events they are designed to mitigate. For example, SSCs designed to mitigate the consequences of a loss-of-coolant accident (LOCA) must be able to provide the required functionality in the elevated temperature and humidity associated with a LOCA. The environmental requirements for SSCs in normal and abnormal conditions are discussed in Section 5.8.

In addition to the above, there are also requirements driven by internal and external hazards evaluations, including separation, segregation, and seismic capacity. These requirements are derived from the internal hazards assessment (Chapter 11) and the external hazards assessment (Chapter 12).

14.3 Limits and Conditions Identified in the Safety Case

The limits and conditions identified or implied by the design basis accident analyses in Chapter 9 are presented in Reference 14.4. Section 5.6 and Reference 14.3 describe the process for the development of limits and conditions.

14.4 Emergency Actions Identified in the Safety Case

In some DB and other accidents, there is sometimes a requirement that operators should perform certain actions, either to manually initiate or realign a safety system (for example, manually activating CMT injection) or for their own protection (for example, to evacuate a particular area upon the activation of an area activity alarm).

In all of these cases, the required operator action is the subject of written operator procedures, supported by appropriate training and review. . Human Factors has been involved in the development of plant normal, abnormal, and emergency operating procedures, as described in Chapter 13, and Human Factors will continue to be involved in the development of site-specific procedures and procedure revisions to ensure error-likely situations are identified and mitigated.

The design basis accident analyses presented in Chapter 9 require a limited number of such operator actions. These operator actions have been entered into the Human Factors Human

Action Database (HAD), which is described in Chapter 13. The HAD is an open, living repository for recording, managing, and tracking operator actions important to nuclear safety. During site licensing, actions in the HAD will be screened for risk significance, and actions identified as risk significant will receive risk-proportionate human error analysis via the methodology established during GDA.

14.5 Comparison with Public and Worker Targets

14.5.1 Introduction

The SAPs (Reference 14.2) give a number of dose targets relating to normal operation, to fault sequences, and to societal risk. Targets 1, 2, and 3 relate to normal operation and as such are addressed separately in Chapter 24.

The dose targets relating to fault sequences are as follows:

- Target 4 – Design basis faults sequences, any person
- Target 5 – Individual risk of death from accidents, any person on the site
- Target 6 – Frequency dose targets for any single accident, any person on the site
- Target 7 – Individual risk to people off the site from accidents
- Target 8 – Frequency dose targets for an individual facility, any person off the site
- Target 9 –Total risk of more than 100 deaths

Each target defines a basic safety level (BSL) and a basic safety objective (BSO). It is relevant good practise that any new facility should meet the BSOs wherever possible. The BSO is a benchmark that reflects modern nuclear safety standards and expectations. In all cases, new facilities should meet the BSLs and demonstrate that risks are ALARP.

The comparison with Target 4 uses the results of the DB assessment given in Chapter 9 for all faults. The comparison with the probabilistic targets (Targets 5 to 9) uses the results of the PSA presented in Chapter 10 and is supplemented by additional probabilistic assessments cited in Chapters 8 and 9 as necessary. During GDA, the PSA work used to demonstrate meeting the SAP Targets is focused on the internal events at-power modelling. During site licensing, this comparison would be expanded to include various other models, including the low power and shutdown PSA, seismic PSA, maintenance activities, and the spent fuel pool PSA.

14.5.2 Comparison with SAP Targets

14.5.2.1 Target 4 – Design Basis Faults Sequences, Any Person

Target 4 gives a set of targets for the effective dose received by any person from a DB fault sequence. The targets are:

Onsite

BSL: 20 mSv for initiating event frequencies exceeding 10^{-3}/yr
200 mSv for initiating event frequencies between 10^{-3}/yr and 10^{-4}/yr
500 mSv for initiating event frequencies less than 10^{-4}/yr and 10^{-5}/yr

BSO: 0.1 mSv

Offsite

BSL: 1 mSv for initiating event frequencies exceeding 10^{-3}/yr
10 mSv for initiating event frequencies between 10^{-3}/yr and 10^{-4}/yr
100 mSv for initiating event frequencies less than 10^{-4}/yr and 10^{-5}/yr

BSO: 0.01 mSv

Chapter 9 demonstrates that these targets are met for DB fault sequences. Most fault analyses support the BSOs; however, there are some limited events that are above the BSO but support the BSL with a conservative amount of margin. Some of the largest radiological consequences would be further refined during site licensing and would be expected to be reduced, as discussed in Chapter 9.

14.5.2.2 Target 5 – Individual Risk of Death from Accidents, Any Person on the Site

Target 5 gives an individual risk of death for a person on the site from the sum total of accidents on the site. The individual risk of death is given as follows:

- BSL 10^{-4}/yr
- BSO 10^{-6}/yr

A risk figure for core damage releases can be conservatively derived from the Level 1 PSA results for comparison with this target, using a risk factor of 1, i.e., equating the total frequency of core damage with the risk of death to some worst-located individual onsite. This is clearly conservative because not all events with core damage will result in a release from the containment (as demonstrated by the Level 2 PSA results), and not all releases will result in high enough doses to cause death. Chapter 10 gives this frequency as 8.4E-07/yr, which is the total core damage frequency (CDF) for at-power internal events, internal flooding, and internal fire. The BSO is achieved even making this conservative assumption.

14.5.2.3 Target 6 – Frequency Dose Targets for Any Single Accident – Any Person on the Site

Target 6 gives targets for predicted frequency for any single accident on the site that could give an effective dose to a person on the site as follows:

Effective Dose (mSv)	Predicted Frequency per Annum	
	BSL	BSO
2-20	10^{-1}	10^{-3}
20-200	10^{-2}	10^{-4}
200-2000	10^{-3}	10^{-5}
>2000	10^{-4}	10^{-6}

On the same basis as for Target 5, a conservative derivation can be made of the frequency of accidents resulting in greater than 2000 mSv to the most exposed individual, by equating this to the CDF. As noted for Target 5, the total CDF for at-power internal events, internal flooding, and internal fire is 8.4E-07/yr, which therefore achieves the BSO for this dose band of Target 6. This simplified derivation assumes that no sequences without core damage can cause a dose to any person onsite of greater than 2000 mSv.

14.5.2.4 Target 7 – Individual Risk to People Off the Site from Accidents

Target 7 gives an individual risk of death for a person off the site from the sum total of accidents on the site. The individual risk of death is given as follows:

- BSL 10-4/yr
- BSO 10-6/yr

The sum of the large release frequency (LRF) for at-power internal events, at-power internal flooding and at-power internal fire is 7.4E-8/yr. Since the dose to the reference individual from any large release is calculated to be well above 20,000 mSv, the risk of death is effectively one, so large releases contribute 7.4E-8/yr towards the risk of death. . This gives a conservative total risk estimate of 743E-8/yr, more than an order of magnitude below the BSO for this target.

A cruder but more demonstrably conservative approach is to use the same principle as with Target 5, and to note that the risk from releases following core damage is bounded by the CDF of 4.6E-7, which is below the BSO.

14.5.2.5 Target 8 –Frequency Dose Targets for an Individual Facility – Any Person Off the Site

Target 8 gives targets for predicted frequency for any single accident on the site that could give an effective dose to a person off the site as follows:

Effective Dose (mSv)	Predicted Frequency per Annum	
	BSL	BSO
0.1-1	1	10^{-2}
1-10	10^{-1}	10^{-3}
10-100	10^{-2}	10^{-4}
100-1000	10^{-3}	10^{-5}
>1000	10^{-4}	10^{-6}

Section 10.23 compares Target 8 BSO with the CDF and LRF values for the at-power PSA results (Internal Events, Internal Flooding, and Internal Fire). Section 10.23 demonstrates margin to the Target 8 BSO.

14.5.2.6 Target 9 – Total Risk of More than 100 Deaths

Target 9 is the societal risk target for the total risk of 100 or more fatalities:

- BSL 10^{-5}/yr
- BSO 10^{-7}/yr

The total risk of 100 or more deaths is not a parameter directly calculated in the DB or PSA analysis. Furthermore, this parameter will be highly site-specific and cannot be calculated precisely in a generic assessment. Nevertheless, a simplified assessment can be made that assumes that all large releases will result in more than 100 fatalities, either immediate or eventual, and no other events (including all events outside the reactor, since the

inventory of radioactive material is very small elsewhere) will result in that number of fatalities. In this case, the LRF approximates to the total risk of 100 or more deaths. Section 10.23 demonstrates margin to the Target 9 BSO.

14.5.3 Conclusion of Comparison with Public and Worker Targets

This section has brought together the results of various analyses to provide a comparison with the dose and risk targets given in the SAPs. The results show that in most cases the calculated doses and risks are below the BSO of the relevant frequency and dose band target. In the small number of cases where this is not so, the doses or risks are still below the BSL with margin.

During site licensing, these targets would need to be evaluated once again to incorporate additional probabilistic and deterministic evaluations that have not yet been completed, such as the spent fuel pool PSA, maintenance activities and faults, as well as additional aspects of the reactor PSA, such as the low power and shutdown model. Generally speaking, the additional PSA models are expected to contribute less to the total CDF and LRF than the existing at-power models, and as such would not compromise the demonstration of meeting the risk targets. Additionally, many of the maintenance and spent fuel pool activities to be evaluated are not driven by plant-specific unique features, and as such would reflect the same results as existing operating units which support these risk targets, and may be slightly better if reflecting more recent relevant good practice.

14.6 Assessment That Risks Are As Low As Reasonably Practicable

This section uses the results of the fault and accident assessment chapters in addition to information from other chapters of the PCSR to demonstrate that there are no further reasonably practicable improvements to the AP1000 design that could be implemented and therefore the overall plant risk has been reduced ALARP.

The discussion of ALARP begins with relevant good practice. The AP1000 design has evolved through the use of proven fuel and major reactor component designs, including reactor vessel (RV), reactor internals, control rod drive mechanisms, reactor coolant pumps (RCPs), steam generators (SGs), and pressuriser. Proven major components reduce the chance of leakage or failures that would affect normal plant operation, possibly resulting in plant transients or forced outages with their associated impact on safety system challenges and occupational radiation exposures. Innovative design solutions have been used to reduce the complexity of engineered safety systems to make them significantly more reliable than those used in the previous generations of pressurised water reactor (PWRs). The use of Class 2 systems to provide defence in depth is also a best practice. These features of the AP1000 design are discussed in detail in Chapter 6 of this PCSR.

Chapter 5 summarises the codes and standards used for SSCs of each class. The relevant chapters of Volume 4 – Engineering Substantiation give further details of codes and standards used in the design of the AP1000 plant and justify the claim that these codes and standards demonstrate conformance with relevant good practice in their respective areas, and that they are met by the design:

- Chapter 16, Civil Engineering
- Chapter 17, Mechanical Engineering
- Chapter 18, Essential Electrical Systems
- Chapter 19, Control and Instrumentation
- Chapter 20, Structural Integrity

- Chapter 21, Reactor Chemistry
- Chapter 22, Fuel System, Nuclear and Thermal Hydraulic Design
- Chapter 23, Containment and Nuclear Ventilation Systems

The discussion of ALARP continues by examining options for reasonably practicable measures to reduce risk. This section reviews major design decisions taken during the evolution of the design from the previous generation of PWRs, giving a brief explanation of why certain features were selected and others were rejected, to demonstrate that the evolution process has resulted in a sufficiently optimised design from the point of view of safety.

Following this, the section discusses a number of exercises that have been carried out to identify potential risk reduction measures. These exercises constitute a systematic and comprehensive approach to risk reduction.

The ALARP assessment for the AP1000 design presented therefore consists of a number of inputs from different phases of the development and assessment of the design. Many of these exercises have been aimed at overall risk reduction and optioneering, and may not have included explicit risk-reward evaluations in the United Kingdom (UK) context of ALARP, but they have led to many risk-reduction measures being incorporated into the design that contribute to achieving an overall plant risk judged to be ALARP.

In this section, risk-reduction and ALARP arguments for the AP1000 plant are compiled from various sources:

- Review of major design decisions
- Use of PSA to inform the AP1000 design
- Severe accident mitigation design alternative (SAMDA) process
- Reliability assurance programmes
- Fault and hazard analysis
- Changes implemented in the UK specific design
- Human factors ALARP assessment
- ALARP issues raised in the GDA process

The final part of the ALARP assessment is to evaluate the options identified in terms of cost and benefit to show that the cost of any further improvements to the design would be grossly disproportionate to the risk reduction achievable.

14.6.1 Review of Major Design Decisions

A discussion of major design decisions dating back to the earlier AP600 design and its development into the AP1000 design is contained in Appendix 6A. In that discussion, the advantages and disadvantages of a number of design alternatives are reviewed with an assessment of their contribution to overall risk reduction.

These design choices fall under the following headings:

- Residual heat removal
- Containment design
- Control room systems
- Primary system design
- Duty systems

Additionally, Section 9.8.3 provides a detailed description of AP1000 design features specifically to address plant safety during shutdown modes.

Many of the options considered under the above headings were considered as part of the development of the AP600 design; however, the conclusions of those exercises apply equally to the AP1000 plant and the design choices have been carried over to its design. More detailed consideration of the major design choices and the rationale for them is presented in Appendix 6A. Addtionally, this information is detailed in Reference 14.1.

Westinghouse developed the AP1000 design to have an electric power production capability comparable with existing nuclear power stations but with a level of risk more than an order of magnitude lower than the best reactors currently operating. Current nuclear power stations have achieved an acceptable level of risk by evolving ever-increasing complexity with respect to their engineered safety features (ESFs), but this complexity is subject to the law of diminishing returns. If those same approaches (i.e., additional complexity) are taken to the extreme when developing a new design, very low levels of risk might be achievable; however, it would be at a price so high that it is no longer economical to build the nuclear power station.

Westinghouse has taken an alternative approach in designing the AP1000 plant. The complexity of the design is reduced by making the ESFs passive rather than active to the maximum degree feasible, thereby achieving a very high level of reliability and a simplified design. The basic design uses the concepts of inherent safety, fault tolerance, passive safety features, and defence in depth to produce a design that has significantly lower risks than earlier PWR designs.

14.6.2 Use of PSA to Inform the Design

The plant PSA was used throughout the AP1000 design program to review a number of areas to gain insight into risk-significant issues, leading to the implementation of a number of risk-reduction measures that significantly contribute to risk being ALARP for the plant as a whole. Appendix 10A provides historical information which specifically examined the following groups of design features:

- Design Improvements Introduced as a Result of the AP600 Design PSA
- Review of Defence-in-Depth Systems
- AP1000 Design Enhancements Implemented Based on PSA Insights

The total plant core damage and large release frequencies incorporating the examined design enchancements are demonstrated to support all applicable SAP Targets, as discussed in detail in Section 14.5. As such, the PSA was an invaluable tool in the development of the AP1000 plant design, and its use and overall results and conclusions support the claim of the overall plant risks being reduced ALARP.

14.6.3 Severe Accident Mitigation Design Alternatives Process

The SAMDA process was a United States (US) national programme specifically aimed at assessing candidate design alternatives to reduce the risk from severe accidents. As part of this process, an evaluation of candidate modifications to the design was conducted to evaluate the potential for such modifications to provide significant and practical improvements in the radiological risk profile. This process is entirely consistent with the ONR SAP (Reference 14.2) requirement to use severe accident analysis to consider further risk-reducing measures.

The process used for identifying and selecting candidate design alternatives included a review of SAMDAs evaluated for other plant designs. Several alternative designs evaluated previously for other plants were excluded from the present evaluation because they have already been incorporated or because they were not applicable to the AP1000 design. These include the following:

- Hydrogen ignition system (Already incorporated)
- Reactor cavity flooding system (Already incorporated)
- Reactor Coolant System (RCS) depressurisation (Already incorporated)
- RV exterior cooling (Already incorporated)
- RCP seal cooling (AP1000 uses sealless pumps)

Candidate design alternatives were selected based upon those evaluated for other plant designs as well as suggestions from design personnel. Additional candidate design alternatives were selected based upon an assessment of the plant PSA results. The following 15 design alternatives were finally selected for further evaluation:

- Diverse containment recirculation valves
- RNS located inside the containment
- Self-actuating containment isolation valves (CIVs)
- Improved reliability of the diverse actuation system (DAS)
- Diverse in-containment refuelling water storage tank (IRWST) injection valves
- SG safety valve flow directed to the IRWST
- SG shell-side passive heat removal system
- Chemical and volume control system (CVS) upgraded to mitigate small LOCAs
- Ex-vessel core catcher
- Secondary containment filtered ventilation
- Passive containment spray
- Filtered containment vent
- Increase of SG secondary side-pressure capacity
- High-pressure containment design
- Active high-pressure safety injection system

Two design changes additional to those identified in the SAMDA process were also considered for inclusion in the AP1000 design:

- Larger accumulators
- Larger fourth-stage ADS valves

14.6.3.1 Results of the Severe Accident Mitigation Design Alternative Process

An evaluation of these alternatives was performed using a bounding methodology, such that the potential benefit of each alternative is conservatively maximised. As part of this process, it was assumed that each alternative performs beyond expectations and completely eliminates the corresponding severe accident sequence. In addition, the capital cost estimates for each alternative were intentionally biased on the low side to maximise the risk-reduction benefit. This approach maximises the potential benefits associated with each alternative.

The results for the AP1000 plant show that despite the significant conservatism employed in the evaluation, only one of the alternatives evaluated (diverse containment recirculation valves) provides risk reductions that are cost-beneficial. A second (improved reliability of the DAS) was rejected in the SAMDA process but has subsequently been included in the UK design to increase availability during maintenance.

The results also show that even a conceptual "ideal SAMDA", one that reduces the total plant radiological risk to zero, would not be cost-effective. This is due primarily to the already low-risk profile of the AP1000 design.

14.6.3.2 Diverse Containment Recirculation Valves

The SAMDA alternative consists of changing the containment recirculation valve design so that two out of the four lines use diverse valves. In the AP600 design, each of the four lines contained a squib valve, two of the lines contained check valves, and the other two lines contained motor operated valves (MOVs). To provide diversity, the squib valves in two of the lines would be made diverse, thereby reducing the frequency of core melt by eliminating the common-cause failure (CCF) of the containment recirculation.

The four AP600 plant recirculation squib valves were of the "low-pressure" type and were a part of a single common-cause group. In the AP1000 plant, two of these valves that are in series with non-return valves are designated to be of the "high-pressure" type, in a common-cause group with the same design of valves on the IRWST injection lines. Thus, the CCF mode that fails the four recirculation lines in the AP600 plant is eliminated and replaced with the product of two CCF modes, one applicable to the group of six high-pressure squib valves and the other to the two low-pressure squib valves. This design change reduces the likelihood of recirculation failure.

To estimate the benefit from this SAMDA, the core damage sequences resulting from a failure of containment recirculation are assumed to be averted. Core damage sequences resulting from failure of containment recirculation correspond to PSA CDF at long term following failure of water recirculation to the RV after successful gravity injection.

14.6.3.3 Improved Reliability of the Diverse Actuation System

This potential design improvement consists of improving the reliability of the DAS, which actuates ESFs and allows the operator to monitor the plant status. The design change would add a third C&I cabinet and a third set of DAS instruments to allow the use of two-out-of-three logic instead of two-out-of-two logic.

This design improvement was rejected in the SAMDA process but has since been incorporated in the UK design to prevent a single failure from causing actuation during maintenance operations. This is considered best practice.

14.6.3.4 Potential Design Improvements Not Taken forward in the Severe Accident Mitigation Design Alternative Process

Table 14-1 gives the capital cost estimates in US dollars and UK pounds for each rejected alternative assessed in the SAMDA process. A dollar/pound exchange rate of 1.5 has been assumed. Each design alternative is discussed in turn and the argument given as to why the risk-reduction benefit is not commensurate with the capital cost.

Locate the Normal Residual Heat Removal System inside the Containment

This potential design improvement consists of placing the entire RNS and piping inside the containment pressure boundary. Doing so would prevent containment bypass due to ISLOCAs of the RNS. In previous PSAs of current-generation nuclear power plants, the ISLOCA is the leading contributor to plant risk because of large offsite consequences. A failure of the valves that isolate the low-pressure RNS from the high-pressure RCS causes the RNS to overpressurise and fail, releasing reactor coolant outside the containment, where it cannot be recovered for recirculation cooling of the core. The result is core damage and the direct release of fission products outside the containment.

In the AP1000 plant, the design of the RNS is already substantially enhanced over that of currently operating PWR plants: the AP1000 plant is designed with a higher design pressure and an additional isolation valve is provided. In the AP1000 plant PSA, no ISLOCAs contribute significantly to the CDF (Chapter 10), therefore, locating the RNS of the AP1000 plant inside the containment would provide virtually no risk-reduction benefit and so was not investigated further in terms of its cost.

Self-Actuating Containment Isolation Valves

This potential design improvement consists of improved containment isolation provisions on all normally open containment penetrations. The category of "normally open" is limited to normally open pathways to the environment during power and shutdown conditions, excluding closed systems inside and outside the containment, such as the RNS and CCS.

The design alternative would be either to add a self-actuating valve or to enhance the existing isolation valve inside containment to provide for self-actuation in the event that containment conditions indicate a severe accident. Conceptually, the design would be either an independent valve or an appendage to an existing fail-closed valve that would respond to post-accident ambient conditions within the containment: for example, a fusible link would melt in response to elevated ambient temperatures and close the valve.

The benefits of this potential design alternative are evaluated by generously assuming that it eliminates the containment isolation failure release category. This does not include induced containment failures that occur at the time of the accident, such as in cases of vessel rupture or anticipated transient without trip (ATWT). Thus, the component of the LRF and the component of collective dose due to failure of containment isolation events can each be set to zero. This potential design alternative ameliorates the consequences of a core damage event but has no effect on reducing its frequency. Given the low contribution of containment isolation failure to the LRF (approximately 5% of the total, Chapter 10), there is an ALARP case for not including this potential design alternative.

Improved Reliability of the Diverse Actuation System

This improvement consisting of improving the reliability of DAS by adding a third division of the control and instrumentation (C&I) system allowing for 2 out of 3 actuation logic rather than 2 out of 2 was rejected in the US SAMDA process but is included in the UK design. For additional information, please see Chapter 19.

Diverse In-Containment Refuelling Water Storage Tank Injection Valves

This potential design improvement consists of changing the IRWST injection valve designs so that two of the four lines use diverse valves. Each of the four lines is currently isolated by

a squib valve in series with a non-return valve. To provide diversity, the valves in two of the lines would be provided by a different vendor.

For the non-return valves, alternate vendors are available; however, it is questionable if non-return valves from different vendors would be sufficiently different to be considered diverse unless the type of non-return valve was changed from the current swing disk check to another type. The swing disk type is preferred for this application and other types are considered to be less reliable.

Squib valves are specialised valve designs for which there are few vendors. A vendor might not be willing to design, qualify, and build a reasonable squib valve design for this AP1000 plant application, given that they would only supply two valves per plant. As a result, this potential design improvement is not really practicable because of the uncertain availability of a second squib valve supplier and the uncertain reliability of another non-return valve type.

The cost estimate for this potential design improvement assumes, however, that a second squib valve vendor does exist and that this vendor provides only the two diverse IRWST squib valves.

The cost impact does not include the additional first-time engineering and qualification testing that would be incurred by the second vendor. Such costs would be expected to be up to or even exceeding £1M.

This change would reduce the frequency of core melt by eliminating the CCF of the IRWST injection.

The contribution to CDF from failure of IRWST injection valves is 8.1E-8/yr during power operation (see Chapter 10) and 3.3E-8/yr at shutdown (Chapter 10). Given the costs above, there is an ALARP case for not including this potential design alternative.

Steam Generator Safety Valve Flow Directed to the In-Containment Refuelling Water Storage Tank

This potential design improvement consists of providing all the piping and valves required for redirecting the flow from the SG safety and relief valves to the IRWST. An alternate, lower-cost option of this potential design improvement consists of redirecting only the first-stage safety valve to the IRWST. This system would prevent or reduce fission product release from bypassing the containment in the event of an SGTR event.

The cost-benefit analysis for this design alternative is essentially the same as for the diverse IRWST injection valves with the same conclusion that there is an ALARP case for not including it.

Steam Generator Shell-Side Passive Heat Removal System

This potential design improvement consists of providing a passive safety-significant heat removal system to the secondary side of the SGs. The system would provide closed-loop cooling of the secondary side using natural circulation and stored water cooling.

This would prevent a loss of primary heat sink in the event of a loss of starup feedwater (SFW) and the passive residual heat removal (PRHR) heat exchanger (HX). A perfect secondary heat removal system would eliminate transients from each of the release categories. To evaluate the benefit of this potential design improvement, the frequencies of all

the transient sequences are subtracted from the overall frequency of each of the release categories and the risk is recalculated.

Chemical and Volume Control System Upgraded to Mitigate Small Loss-of-Coolant Accidents

The current design of the CVS for the AP1000 plant is capable of supplying pressurised water at a rate sufficient to keep the reactor core covered in the event of an RCS leak of a magnitude within the very small LOCA category. The CVS can provide sufficient makeup of the reactor coolant in the event of a failure of a small line of 0.97 cm (3/8 inch) or less. Only one CVS pump would be needed for this duty.

The CVS is regarded as an active duty system, which supports normal operations, and acts as a first line of defence to reduce the unnecessary actuation and operation of the safety systems. The AP1000 plant includes several active systems that provide defence-in-depth capabilities for RCS makeup and decay heat removal. These active systems are the first line of defence to reduce challenges to the passive systems in the event of plant transients.

The potential design-improvement-proposed system is intended to enhance its capability so that it could intervene following a small or intermediate LOCA, such as would result from an RCS leak or a tube leak within the PRHR HX, to keep the core covered during such LOCAs.

This increase in capability would be achieved by means of the following SAMDA enhancements:

- Connections provided from the IRWST containment recirculation to the CVS
- A second line added from the CVS makeup pumps to the RCS

A perfect, upgraded CVS is assumed to prevent core damage in the following release categories: RCS leak, PRHR HX tube ruptures, small LOCA, and intermediate LOCA. The CVS is assumed to have perfect support systems (power supply and component cooling) and to work in all situations regardless of the CCFs of other systems.

Ex-Vessel Core Catcher

This potential design improvement consists of designing a structure in the containment cavity or using a special concrete or coating that will inhibit core-concrete interaction even if the debris bed dries out. A perfect core catcher would prevent core-concrete interaction for all cases; however, the AP1000 plant incorporates a wet cavity design in which ex-vessel cooling is used to maintain the core debris in the vessel to prevent ex-vessel phenomena such as core-concrete interaction. Consequently, containment failure due to core-concrete interaction is not considered in detail for the AP1000 plant large-release PSA.

For cases in which RV flooding fails, it is assumed that containment failure would occur due to ex-vessel steam explosion or core-concrete interaction. This containment failure is assumed to be an early containment failure (ECF) (due to ex-vessel steam explosion) even though core-concrete interaction and basemat melt-through would be a late containment failure. To conservatively estimate the risk reduction of an ex-vessel core catcher, this design change is assumed to eliminate the ECF release category.

Secondary Containment Filtered Ventilation

This potential design improvement consists of providing the middle and lower annulus of the secondary concrete containment with a passive annulus filter system for filtration of elevated

releases. The passive filter system would be operated by drawing a partial vacuum on the middle annulus through charcoal and high-efficiency particulate air (HEPA) filters. The partial vacuum is drawn by a diffusion pump with motive flow from compressed gas tanks.

The secondary containment would then reduce particulate fission product release from any failed containment penetrations (containment isolation (CI) failure). To evaluate the benefit from such a system, this design change is assumed to eliminate the CI release category.

Passive Containment Spray

This potential design improvement involves adding a passive safety-significant spray system and all associated piping and support systems to the AP1000 plant containment.

A passive containment spray system would result in risk benefits in the following ways:

- Scrubbing of fission products could be done, primarily for CI failures.
- Assuming appropriate timing, containment spray could be used as an alternate means of flooding the RV and debris-quenching should vessel failure occur.
- Containment spray could also be used to control containment pressure for cases in which the passive containment cooling system (PCS) has failed.

To envelop these potential risk benefits, the risk-reduction evaluation will assume that containment sprays are perfectly effective for each of these benefits with the exception of fission product scrubbing for containment bypass. Thus, the risk reduction can be conservatively estimated by assuming that all release categories except containment bypass are eliminated.

Filtered Containment Vent

This potential design improvement consists of placing a filtered containment vent and all associated piping and penetrations into the AP1000 plant containment design. The filtered vent could be used to vent the containment to prevent catastrophic overpressure failure, and it would also provide filtering capability for source term release. With respect to the AP1000 plant PSA, the possible scenario in which the filtered vent could result in risk reduction would be late containment overpressure failures. Other containment overpressure failures occur because of dynamic severe accident phenomena, such as hydrogen burn and steam explosion.

The late containment failures for the AP1000 plant are failures of the PCS. Analyses have indicated that for scenarios with PCS, air cooling might limit the containment pressure to less than the ultimate pressure; however, for the large-release PRA, failure of the PCS is assumed to result in containment failure based on an adiabatic heatup.

To conservatively consider the risk reduction of a filtered vent, the use of a filtered vent to preclude a late containment failure will be evaluated. A decontamination factor (DF) of 1000 will conservatively be assumed for each PRA Level-1 accident classification, even though it is realised that the dose due to noble gases will not be impacted by the filtered vent because 100 percent of the noble gas fission products will still be released. The risk reduction is therefore equal to the DF assumed because the PRA CDF accident classification frequencies do not change.

Increase of Steam Generator Secondary Side Pressure Capacity

This potential design improvement consists of increasing the design pressure of the SG secondary side and safety valve setpoint to the degree that an SGTR will not cause the secondary system safety valve to open. The design pressure would have to be increased sufficiently so that the combined heat capacity of the secondary system inventory and the PRHR system could reduce the RCS temperature to below T_{sat} for the secondary design pressure.

Although specific analysis would have to be performed, it is estimated that the design pressure would have to be increased by tens of bar (several hundred psi). This design would also prevent the release of fission products that bypass the containment via the SGTR.

High-Pressure Containment Design

This potential design improvement consists of using the massive high-pressure containment design in which the design pressure of the containment is approximately 20 bar (300 psi) for the AP1000 plant containment.

The massive containment design has a passive containment cooling feature much like the AP1000 plant containment. The high design pressure is considered only for prevention of containment failures due to severe accident phenomena, such as steam explosions and hydrogen detonation. A perfect high-pressure containment design would reduce the probability of containment failures but would not reduce the frequency or magnitude of the release from an unisolated containment (containment isolation failure or containment bypass). To estimate the risk reduction of a high-pressure containment design, this design is assumed to eliminate the containment failure release categories. This design change was not incorporated since it is judged that the likely cost is disproportionate to the risk reduction that would be achieved.

Active High-Pressure Safety Injection System

This potential design improvement consists of adding a safety-significant active high-pressure safety injection pump and all associated piping and support systems to the AP1000 design. A perfect high-pressure safety injection system would prevent core melt for all events except excessive LOCA and ATWT. To estimate the risk reduction, therefore, only the contributions to vessel rupture and ATWT need to be considered. Including an active high-pressure safety injection system would contravene the fundamental design objective of the AP1000 plant that all safety systems should be passive. It would require a high-pressure safety injection pump or pumps and all associated piping, ac power supplies, and support systems. All equipment would have a high safety classification. This would be very expensive and would not provide any significant risk reduction; therefore, this design change was not incorporated.

Larger Accumulators

Increasing the size of the accumulators would result in a significant increase in cost that would be greater than the cost threshold established by the perfect SAMDA evaluation. To have any benefit in the PRA, the accumulators would have to be increased in size sufficiently to change the large LOCA success criteria from two of two accumulators to one of two accumulators.

Westinghouse estimates that the accumulator tanks would have to be increased in size from 56 to 112 m^3 (2000 to 4000 ft^3) and the hardware costs associated with this change would be significant. Such a size increase would also likely result in a change to the design of the direct vessel injection (DVI) piping subsystem.

Note that the most recent large LOCA analysis shows that the current accumulator size can in fact prevent core melt using only one accumulator, so this change should not be considered.

The design of this piping system was established early in the AP1000 plant design program, and any change in the DVI piping would result in significant piping reanalysis of the DVI piping. Westinghouse estimates the redesign costs associated with the changes in hardware and piping redesign to be significantly greater than the cost threshold established for the perfect SAMDA discussed above; therefore, this design change was not incorporated.

Larger Fourth-Stage Automatic Depressurisation System Valves

Increasing the size of the fourth-stage ADS valves would result in a significant increase in cost associated with redesigning the AP1000 plant loop piping and fourth-stage piping configuration. The AP1000 plant ADS valves were already increased in size compared with the AP600 plant valves by more than the ratio of the power uprate of the AP1000 plant. To have any benefit in the PRA, the fourth-stage ADS valves would have to be increased in size sufficiently to change the LOCA success criteria from three of four valves to two of four valves.

To accommodate such a change, Westinghouse estimates that the fourth-stage ADS valves would have to increase in size from 356 to 457 mm (14 to 18 inches); the associated piping would also increase accordingly. In addition, the common fourth-stage inlet piping that connects to the hot leg would have to increase in size from 457 to at least 508 mm (18 to 20 inches). This would require a significant redesign of the squib valve and would also result in redesign of the ADS stage 4 piping, which in turn would impact the design of the reactor coolant loop piping.

Such a redesign would require Westinghouse to perform additional confirmatory testing of the passive core cooling system (PXS) to verify that the behaviour of the passive safety systems was not adversely impacted. Westinghouse estimates the cost of this change to be significantly higher than the cost threshold of the perfect SAMDA. This design change was therefore not incorporated.

14.6.4 Reliability Assurance Programmes

The AP1000 plant reliability assurance programme (RAP) described in Chapter 5 represents a dual-stage approach to the design and operation of the AP1000 plant to provide increased confidence in plant reliability and the corresponding safety of the public. The first stage of the RAP is the design stage, referred to as the design reliability assurance programme (D-RAP). The second stage of the RAP is referred to as the operational reliability assurance programme (O-RAP).

The AP1000 plant D-RAP is implemented as an integral part of the AP1000 design process to provide confidence that reliability is designed into the plant and that the important reliability assumptions made as part of the AP1000 plant PSA will remain valid throughout its lifetime.

Reliability of AP1000 plant SSCs will be ensured by applying operational phase reliability assurance activities (OPRAAs), which are contained in various operating plant programmes.

The OPRAAs comprise site administrative, maintenance, operational, and testing programmes to enhance operational phase reliability throughout the designed plant life.

In addition to this, the AP1000 plant designers have systematically reviewed the reliability of SSCs other than the Class 1 systems, particularly those providing defence in depth. This programme, the AP1000 reliability programme for non-Class 1 systems with safety importance (ANSIS), has systematically reviewed the availability controls relevant to these Class 2 SSCs to ensure their reliability in operation.

These programmes are primarily aimed at the reliability of SSCs throughout the plant life. This systematic approach to reliability contributes to risk minimisation and is a contribution to the overall ALARP argument.

14.6.5 Changes Implemented in the UK Design

As part of licensing the AP1000 plant in the UK, a number of design alternatives have been incorporated for the UK AP1000 design. The ALARP implications of these changes are discussed in the relevant chapters of the PCSR.

14.6.6 As Low As Reasonably Practicable Conclusions

The design philosophy for the AP1000 has been to take the best of the proven design features from the previous generation of PWRs and to substantially improve the safety through the use of innovative passive engineered safety systems with defence in depth provided by more traditional systems. This approach constitutes good practice and has led to a design whose risks are very low.

Further, it is clear that the designers of the AP1000 plant have systematically sought ways of further reducing risk during every phase of development from the original AP600 concept to the fully developed AP1000 design. Risk reduction has been an intimate and natural part of the design and risk evaluation process.

The designers have also used appropriate analysis tools such as the accident analyses, PSA and severe accident assessments to systematically identify potential risk-reduction measures, many of which have been implemented in the design on the basis that they are the ALARP option or that they constitute good practice.

During the course of the development of this PCSR, systematic fault studies have been performed, beginning with a systematic, auditable, and comprehensive identification of faults followed by systematic DB and probabilistic assessments. For each fault analysed, further ALARP measures were sought, and specific implementation of changes are noted throughout Chapter 9. The total plant risk has been lowered to the point that it has become very difficult to find further cost-effective plant improvements, especially since the benefit threshold is so low.

The conclusion from this section is that risk-reduction and ALARP assessments have been carried out systematically and comprehensively to the point that there are no further reasonably practicable improvements that could be implemented and, therefore, risk has been reduced ALARP.

14.7 Summary of AP1000 Plant ALARP Assessment

This chapter ssynthesises the results and conclusions from the internally initiated faults (Chapter 9), PSA (Chapter 10), internal and external hazards assessments (Chapters 11 and

12), and the human factors assessments (Chapter 13). These assessments have identified the SSCs that are important for safety and the requirements placed upon them by the safety case in terms of performance and reliability.

Operator actions identified in the DB analysis (Chapter 9) or the PSA (Chapter 10) are collected into the HAD, screened for risk significance, and for a sample of actions, analysed for human error potential as discussed in Chapter 13.

With all these identifications in place, the results of the various analyses have been compared with the dose and risk targets given in the ONR SAPs. The results show that in most cases the calculated doses and risks are below the BSO of the relevant frequency and dose band target. In the small number of cases where this is not so, the doses or risks are still below the BSL with adequate margin.

Finally, this chapter has brought together the various ALARP assessments, including historical and individual ALARP evaluations coming from the fault and hazard analyses, to demonstrate that the risks from the AP1000 design and operation are ALARP.

Table 14-1 Estimated Costs of Improvement Options

	Estimated Cost of the Design Alternatives	US $	£
1	Locate the RNS inside the containment.	Virtually no risk-reduction benefit and so was not investigated further in terms of its cost	
2	Self-actuating CIVs	$33,000	£22,000
3	Improved reliability of the DAS	$470,000	£313,000
4	Diverse IRWST injection valves	$570,000	£380,000
5	SGTR safety valve flow directed to the IRWST	$620,000	£413,000
6	SGTR shell-side passive heat removal system	$1,300,000	£867,000
7	CVS upgraded to mitigate small LOCAs	$1,500,000	£1,000,000
8	Ex-vessel core catcher	$1,660,000	£1,110,000
9	Secondary containment filtered ventilation	$2,200,000	£1,470,000
10	Passive containment spray	$3,900,000	£2,600,000
11	Filtered containment vent	$5,000,000	£3,330,000
12	Increase of SGTR secondary-side pressure capacity	$8,200,000	£5,470,000
13	High-pressure containment design	$50,000,000	£33,300,000
14	Active high-pressure safety injection system	Extremely expensive, also contravenes a fundamental design objective	
15	Larger accumulators	Significant increase in cost	
16	Larger fourth-stage ADS valves	Significant increase in cost

ZVS	excitation and voltage regulation system

15 ENGINEERING SUBSTANTIATION

15.1 Introduction

The purpose of Volume 4 of the Pre-Construction Safety Report (PCSR) is to provide the evidence that the systems making up the AP1000 standard design meet the requirements placed on them by the safety case presented in other parts of the PCSR.

This chapter lists the sources of claims on systems, structures, or components (SSCs) in the safety case and the requirements on SSC performance that are implied by them. The chapter then introduces the chapters of Volume 4, which provide evidence that the SSCs identified in the fault assessments (Volume 3) can meet the requirements arising from the claims made on them in the safety case.

These requirements come from the following sources:

- Performance requirements from the transient analysis performed as part of the design basis (DB) assessment
- Survivability and operability requirements arising from the need to operate in normal plant environmental conditions and the environmental conditions following a design basis accident (DBA)
- Reliability requirements from the probabilistic assessment of DB faults and the probabilistic safety assessment
- Separation and segregation requirements from the internal hazards assessment
- Seismic qualification requirements arising from the external hazards assessment
- Quality requirements for design, manufacturing, installation, commissioning, maintenance, and testing
- Durability requirements related to expected plant service life

The purpose of the engineering substantiation volume is to provide the evidence that these requirements are met by the SSCs as designed and by the way they are tested and maintained throughout the life of the plant.

The requirements on the SSCs from the safety case are detailed in the engineering schedule (Reference 15.1) and summarised in the tables in Appendix 15A. These tables will be further developed during site-specific licensing to form the basis of the maintenance schedule.

15.2 Performance Requirements

The transient analysis performed as part of the DB assessment to demonstrate that system limits such as departure from nucleate boiling ratio or pressuriser level are not exceeded assumes that the various systems claimed in the analysis, whether as the principal means of providing each safety function or as the alternate means (in the case of frequent faults) or SSCs providing defence in depth, meet certain performance requirements. These performance requirements will depend on the safety function being provided but will be given in terms of physical parameters such as flow rate, fluid pressure, fluid capacity, or reactivity worth.

15.3 Survivability and Operability Requirements

Chapter 5 provides an overview of the equipment qualification requirements for defined SSCs. Equipment qualification requirements are based on design requirements and location of the SSC within the plant. For SSCs that are required to operate following a DBA, the defined SSCs must be able to perform their intended function in the environmental conditions corresponding to their location following an accident. These requirements are implemented through a defined environmental qualifications programme.

15.4 Reliability Requirements

Accident sequences are discussed in Chapter 8. The frequency of the sequence is the initiating event frequency multiplied by the probabilities of failure of each of the SSCs making up the sequence.

The demonstration that reliability requirements are met involves the use of analysis or operational data plus assessment of dependent failures (common-cause failures). Section 5.9 discusses equipment reliability in more detail.

15.5 Separation and Segregation Requirements

Selected systems identified in the safety case have redundant equipment to meet single-failure criteria. Where survivability of the redundant equipment is threatened by such events as internal hazards, protection is achieved by providing the appropriate level of separation or segregation of the redundant equipment. Reference 15.3 defines the separation criteria for SSCs.

15.6 Seismic Qualification

Chapter 5 provides an overview of seismic categorisation. Certain SSCs identified in the safety case are required to operate after a seismic design basis event. Class 1 SSCs are classified as seismic Category I (C-I), which implies the requirement that the SSC does not fail and it can perform its intended function after a design basis earthquake.

Other SSCs are not required to operate during or after a design basis earthquake but do have the requirement to retain their structural integrity. Such SSCs are designated as seismic Category II (C-II).

Where the failure of an SSC in a design basis earthquake has the capacity to adversely affect a Class 1 SSC or incapacitate a plant operator in the control room, there is a higher requirement on its structural integrity. Such SSCs are referred to as seismic C-II/C-I and apply seismic C-II requirements.

Seismic qualification substantiates the seismic withstand of SSCs appropriate to their seismic classification. Reference 15.2 defines the seismic design criteria that apply to SSCs that must be seismically designed.

15.7 Quality Requirements

The classification methodology described in Chapter 5 is the means used to capture the safety significance of SSCs. This has implications for the standard of design, manufacturing, construction, maintenance, and testing to be used, and the appropriate codes and standards become requirements on the corresponding SSCs.

15.8 Durability Requirements

The design life of the AP1000 plant is 60 years. Many components will have to be repaired or replaced during the lifetime of the plant; however, this is not possible for some SSCs, particularly civil structures. For these, the necessity of retaining structural integrity or functionality over a 60-year lifetime will place requirements on the design, construction, or maintenance of the SSC. Both pre-operational and in-service inspection and testing requirements are defined to support the defined reliability claims on SSCs.

15.9 Substantiation

Substantiation of the claims made on SSCs in the safety case involves providing arguments and evidence to show that the design and operation of SSCs meet the requirements that come from normal operations and the safety case as described above.

For convenience in this PCSR, this substantiation is given by engineering discipline in the remaining chapters of this volume.

15.9.1 Civil Engineering

In Chapter 16, the claims made on the AP1000 plant civil structures are substantiated. This includes normal and abnormal (accident) loads and loading from design basis earthquakes and other external hazards.

15.9.2 Mechanical Engineering

In Chapter 17, the claims made on the AP1000 plant mechanical systems are substantiated. In particular, the claims made on the performance and reliability of the Class 1 protection systems and the Class 2 systems claimed as defence in depth are substantiated.

15.9.3 Electrical Systems

In Chapter 18, the claims made on the Class 1 and standby Class 2 electrical systems in terms of loading and reliability are substantiated, along with claims on normal alternating current systems during normal operation.

15.9.4 Control and Instrumentation

In Chapter 19, the claims made on the Class 1 protection system, the Class 2 diverse actuation system (DAS), the Class 2 functionality provided by part of the normal operations control system, and other control and instrumentation systems are substantiated.

15.9.5 Structural Integrity

In Chapter 20, the structural integrity classification and supporting claims for plant components are defined. The chapter primarily focuses on components with the potential to have a structural integrity classification of High Safety Significant or High Integrity.

15.9.6 Reactor Chemistry

In Chapter 21, the claims made on primary circuit chemistry in relation to reactivity control, primary circuit activity levels, corrosion resistance, and prevention of stress corrosion cracking are substantiated. Also, the corresponding claims on the secondary (steam raising) system are also substantiated.

15.9.7 Fuel Design

In Chapter 22, the claims made on the fuel design relating to performance in accident conditions such as clad ballooning and pellet-clad interactions are substantiated.

15.9.8 Containment and Ventilation

In Chapter 23, the claims made in relation to radioactivity retention and containment by the containment and ventilation systems are substantiated.

APPENDIX 15A
ENGINEERING SCHEDULE

The DB analysis presented in Chapter 9 identifies the SSCs required to provide the safety functions necessary to meet the DB requirement that the DB targets (SAP Target 4) should be met, and that adequate diversity should be provided for each safety function. The analysis also identifies SSCs provided in the design to achieve defence in depth.

The classification scheme given in Chapter 5 for SSCs is used to identify those SSCs that play an important part in ensuring nuclear safety. This in turn helps to define the quality requirements placed on those SSCs during design and manufacture, and through life. In particular, the safety class of a given SSC can be used to determine which codes, standards, and seismic design considerations are appropriate to the design and manufacture of that SSC, and to specify examination, maintenance, inspection, and testing (EMIT) regimes for that SSC.

Further, for each SSC identified in the safety case, transient and other analyses lead to performance requirements and reliability requirements that will be appropriate to the importance of the SSC to safety.

This appendix lists the AP1000 SSCs claimed in the safety case, principally in Chapter 9, Fault and Accident Analysis. The safety function and category provided by each SSC is given along with its safety classification. The listing corresponds to the list given in Reference 15A.1.

Table 15A-1 contains the categorisation and classification of the AP1000 mechanical SSCs.

Table 15A-2 contains the categorisation and classification of the AP1000 electrical SSCs.

Table 15A-3 contains the categorisation and classification of the AP1000 control and instrumentation (C&I) SSCs.

Table 15A-4 contains the categorisation and classification of the AP1000 structural SSCs.

These tables will be developed as the safety case is developed to a site-specific PCSR, and will eventually contain a complete set of requirements for each SSC, and form the basis of the maintenance schedule.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Component Cooling Water System (CCS) Location: Auxiliary Building and Turbine Building (cont.)								
Balance of system components are Class D & E					C	The balance of the system provides Category C functions such as: • Removing nuclear heat from the reactor coolant during normal operation (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation). Failure of this function would result in a short-term power manoeuvre, thus affecting nuclear safety. • Support plant reactivity control during normal operation. • Providing long-term support of Category A or B functions.	3	The CCS provides cooling to equipment that supports normal power operation, whether by removing nuclear heat (cooling of the RCP for example), controlling the reactivity (cooling of the CVS letdown HX for example), or providing long-term support of Category A or B functions (WLS RCDT HX, for example).
Condensate System (CDS) Location: Turbine Building								
–	Feedwater Heaters	E	NNS	ASME Section VIII	C	Removing nuclear heat from the reactor during normal operations. Failure of this function can result in a short-term power manoeuvre, thus affecting safety.	3	The feedwater heaters provide required heat removal and thermal efficiency improvements to support normal power operation. If a tube leak occurs in a feedwater heater, the heater train is bypassed and power must be reduced.
CDS-ME-05	Deaerator	E	NNS	ASME Section VIII	C	Removing nuclear heat from the reactor during normal operations.	3	Mechanical failure of deaerator internal components could create a blockage of suction lines from the deaerator to feedwater pump. This would cause the deaerator level to rise above the allowable level.
–	Condensers	E	NNS	ASME Section VIII	C	Removing nuclear heat from the reactor during normal operations. Failure of this function can result in a short-term power manoeuvre, thus affecting safety.	3	The main condenser must accommodate the steam loads and drain flows specified for normal power operation. On a significant tube leak in a condenser shell, the bank of tubes containing the leak would have to be isolated resulting in a reduction in power.
–	Feedwater Heater Drain Coolers	E	NNS	ASME Section VIII	C	Removing nuclear heat from the reactor during normal operations. Failure of this function can result in a short-term power manoeuvre, thus affecting safety.	3	If a tube leak occurs in a drain cooler, the heater train is bypassed and power must be reduced.
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Condenser Tube Cleaning System (CES) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Turbine Island Chemical Feed System (CFS) Location: Turbine Building								
–	CFS Chemical Distribution Package	E	NNS		C	Provide long-term support of Category A functions.	3	The CFS injects chemicals into selected plant secondary systems to maintain control of the secondary water chemistry. This includes chemistry control of SWS, which performs Category A functions.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Condenser Air Removal System (CMS) Location: Turbine Building								
–	Condenser Vacuum Breakers	E	NNS	ANSI 16.34	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Balance of system components are Class D					C	Control of levels of radioactivity released to the environment.	3	The CMS and the gland seal system (GSS) discharge into the turbine island vents, drains and relief system (TDS). The exhaust from the TDS into the turbine island vent is continuously monitored for radiation. No credit is taken for absorption of noble gases along the release pathway during steam generator tube rupture.
Containment System (CNS) Location: Containment								
CNS-MV-01	Containment Vessel	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	The containment vessel, the hatches, and the spare penetrations must not leak, in order to maintain containment integrity. These SSCs provide the principal means of providing this safety function.
CNS-MY-Y01	Equipment Hatch	B	I	ASME III, MC				
CNS-MY-Y02	Maintenance Hatch	B	I	ASME III, MC				
CNS-MY-Y03	Personnel Hatch – 110.744 m (135′-3″)	B	I	ASME III, MC				
CNS-MY-Y04	Personnel Hatch – 102.184 m (107′-2″)	B	I	ASME III, MC				
–	Spare Containment Penetrations	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
Condensate Polishing System (CPS) Location: Turbine Building								
–	Condensate Polishing Loop	E	NNS	M/f Std	C	Provides long-term support of a Category A safety function.	3	The CPS helps maintain a noncorrosive environment within the CDS, FWS, and SGS to meet the plant water chemistry guidelines.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Chemical and Volume Control System (CVS) Location: Containment, Auxiliary Building, and Annex Building								
CVS-ME-01	CVS Regenerative Heat Exchanger	D	NNS	ASME VIII/ TEMA	C	Control of the level of radioactivity within the reactor coolant.	3	The CVS purification function provides a means for control of the radioactivity contained within the reactor coolant.
CVS-ME-02	CCS Letdown Heat Exchanger	D	NNS	ASME VIII/ TEMA				
CVS-MP-01A/B	Pumps	D	NNS	Hydraulic Institute Stds	A	Maintaining reactor coolant inventory. Controlling subcritical reactivity of the fuel in the reactor core during normal operation and accident conditions.	2	The CVS makeup pumps provide a supplemental source of RCS inventory makeup. This function is contained with the RAP and is considered important to safety. The CVS makeup pumps provide coolant to the pressuriser spray line.
CVS-MT-01	Boric Acid Storage Tank	D	NNS	API 650				

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Chemical and Volume Control System (CVS) Location: Containment, Auxiliary Building, and Annex Building (cont.)								
CVS-MT-02	Boric Acid Batching Tank	E	NNS	ASME VIII	C	Provide long-term support of Category A or B functions	3	Provides support for the BAST which performs a Category A function.
CVS-MT-03	Chemical Mixing Tank	E	NNS	ASME VIII	C	Provide long-term support of Category A or B functions	3	Contains hydrazine solution required to provide a 10 ppm concentration in a cold, water solid RCS for scavenging oxygen.
CVS-MT-05	Air Intrusion Prevention Tank	D	NNS	ASME VIII	B	Prevention of the release of radioactive waste material from onsite storage facilities	2	This tank is used with the radioactive waste processing system for pre-shutdown operations. This system is designed to prevent the release of radiation.
–	Demineralisers	D	NNS	ASME VIII	C	Control of the level of radioactivity within the reactor coolant.	3	The CVS purification function provides a means for control of the radioactivity contained within the reactor coolant. This function is not subject to increased availability controls and is not important to safety.
–	Filters	D	NNS	ASME VIII				
–	Valves Providing CVS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34	A	Maintaining reactor coolant inventory.	2	The CVS makeup pumps provide a supplemental source of RCS inventory makeup. This function is contained with the RAP and is considered important to safety.
CVS-PL-V001	RCS Purification Stop	A	I	ASME III-1	A	Prevention of the release of radioactive material through the boundary of the RCS.	1	These valves provide the principal means of isolating the CVS from the RCS.
CVS-PL-V002	RCS Purification Stop	A	I	ASME III-1				
CVS-PL-V003	RCS Purification Stop	C	I	ASME III-3				
CVS-PL-V030	Cation Bed Control Valves	D	NNS	ASME B16.34	C	Removal of nuclear heat from the reactor coolant during normal operation. Control of radioactivity to support normal power operation.	3	The CVS cation bed is used weekly to remove specific chemical contribution in the coolant to maintain compliance with chemistry control guidelines for the coolant. Failure of these valves will result in a potential impact to power production.
CVS-PL-V040	Resin Flush IRC Isolation	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
CVS-PL-V041	Resin Flush ORC Isolation	B	I	ASME III-2				
CVS-PL-V042	Flush Line Containment Isolation Relief	B	I	ASME III-2				
CVS-PL-V045	Letdown Containment Isolation IRC	B	I	ASME III-2				
CVS-PL-V046	Letdown Pressure Instrument Root	B	I	ASME III-2				
CVS-PL-V047	Letdown Containment Isolation ORC	B	I	ASME III-2				
CVS-PL-V058	Letdown Line Thermal Relief Valve	B	I	ASME III-2	A	Maintaining the integrity of containment.	1	This valve protects the containment boundary between the inboard and outboard containment isolation valves on the CVS letdown line from thermal overpressurisation.
CVS-PL-V059	Letdown Isolation Valve for WLS RCDT	D	NNS	ASME B16.34	C	Removal of nuclear heat from the reactor coolant during normal operation.	3	Flow path is required to support degasification of the reactor coolant to support normal plant operation.
CVS-PL-V065	H2/Zinc Addition IRC Shutoff Valve	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Chemical and Volume Control System (CVS) Location: Containment, Auxiliary Building, and Annex Building (cont.)								
CVS-PL-V067	CVS Makeup Return Line Bypass Check Valve	A	I	ASME III-3	A	Maintaining the integrity of the reactor coolant system pressure boundary.	1	The makeup return line spring-assisted check valve functions to protect the RHX from overpressure due to thermal expansion. If a leak were to occur upstream of this valve, it would remain closed to preserve reactor coolant pressure boundary and therefore performs a safety-related function.
CVS-PL-V080	RCS Purification Return Line Check Valve	C	I	ASME III-3	A	Prevention of the release of radioactive material through the boundary of the RCS.	1	These valves provide the principal means of isolating the CVS from the RCS.
CVS-PL-V081	RCS Purification Return Line Stop Valve	A	I	ASME III-1				
CVS-PL-V082	RCS Purification Return Line Check Valve	A	I	ASME III-1				
CVS-PL-V084	Auxiliary Pressuriser Spray Line Isolation	A	I	ASME III-1				
CVS-PL-V085	Auxiliary Pressuriser Spray Line	A	I	ASME III-1				
CVS-PL-V090	Makeup Line Containment Isolation	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment. Control of core reactivity during normal operation and accident conditions.	1	The isolation valves are the principal means of fulfilling the safety function. Provides a principal means of isolation of dilution flow to reduction of RCS boron concentration.
CVS-PL-V091	Makeup Line Containment Isolation	B	I	ASME III-2				
CVS-PL-V092	Zinc Injection Containment Isolation ORC	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
CVS-PL-V094	Zinc Injection Containment Isolation IRC	B	I	ASME III-2				
CVS-PL-V095	Zinc Injection Cont Isolation Test Connection Valve	C	I	ASME III-3				
CVS-PL-V096	Zinc Injection Containment Isolation Test Connection	B	I	ASME III-2				
CVS-PL-V100	Makeup Line Containment Isolation Relief	B	I	ASME III-2				
CVS-PL-V115	Makeup Pump Suction Header 3-way Blend Valve	D	NNS	ASME B16.34	C	Removal of nuclear heat from the reactor coolant during normal operation.	3	Failure of this valve will result in boration of the primary coolant and a reduction in plant power generation.
CVS-PL-V136A	Demineralised Water System Isolation	C	I	ASME III-3	A	Control of core reactivity during normal operation and accident conditions.	1	Provides a principal means of isolation of dilution flow to reduction of RCS boron concentration.
CVS-PL-V136B	Demineralised Water System Isolation	C	I	ASME III-3				
CVS-PL-V215	Hydrogen Injection Containment Isolation Test Valve IRC	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
CVS-PL-V216	Hydrogen Injection Containment Isolation Test Connection Valve IRC							
CVS-PL-V217	Hydrogen Injection Containment Isolation Check IRC	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
CVS-PL-V218	Hydrogen Injection Containment Isolation Test Connection							
Chemical and Volume Control System (CVS) Location: Containment, Auxiliary Building, and Annex Building (cont.)								
CVS-PL-V219	Hydrogen Injection Containment Isolation ORC							
–	Zinc Addition Equipment	E	NNS	-	C	Controlling the level of radioactivity within the reactor coolant.	3	The CVS provides a means of adding liquid zinc acetated solution to the RCS to reduce the potential of crud-induced power shifts and radiation fields.
–	Hydrogen Addition Equipment	E	NNS	-	C	Provide long-term support of Category A or B functions.	3	The CVS provides hydrogen to the RCS during normal operations to eliminate free oxygen and minimise corrosion of the fuel and primary surfaces.
CVS-PY-C01	Demineraliser Resin Flush Line Containment Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
CVS-PY-C02	Letdown Line Containment Penetration	B	I	ASME III, MC				
CVS-PY-C03	Makeup Line Containment Penetration	B	I	ASME III,MC				
CVS-PY-C04	Zinc Injection Line Containment Penetration	B	I	ASME III-MC				
CVS-PY-C05	Hydrogen Add Line Containment Penetration	B	I	ASME III, MC				
–	Remaining Class D CVS SSCs	D	NNS	ASME B16.34	C	Control of the level of radioactivity within the reactor coolant.	3	The CVS purification function provides a means for control of the radioactivity contained within the reactor coolant. This function is not subject to increased availability controls and is not important to safety.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Circulating Water System (CWS) Location: Turbine Building and Pump Intake Structure								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Standby Diesel Fuel Oil System (DOS) Location: Diesel Generator Building and Yard								
–	Fuel Oil Transfer Package	D	NNS	M/f Std	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions.	2	The onsite diesel generators have been identified as important to safety. These SSCs provide standby power for supplementary decay heat removal functions. This does not represent the principal means of decay heat removal.
–	Fuel Oil Storage Tanks	D	NNS	API 650				
–	Fuel Oil Day Tanks	D	NNS	ASME VIII				
–	Valves Providing DOS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
–	Ancillary Diesel Generator Fuel Tank	D	Note 2	ASME VII	B	Reducing the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident.	2	The ancillary diesel generators and fuel tanks reduce the probability that offsite SSCs would be needed to support post 72 hour actions required to maintain safe shutdown.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Demineralised Water Treatment System (DTS) Location: Turbine Building								
–	Primary Demineralisation Package	E	NNS	-	C	Provide long-term support of Category A or B functions.	3	The DTS receives treated water from RWS, processes this water to remove ionic impurities, and provides demineralised water to the DWS, which performs Category A functions.
–	Secondary Primary Demineralisation Package	E	NNS	-				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Demineralised Water Transfer and Storage System (DWS) Location: Various								
–	Condensate Storage Tanks	D	NNS	API 650	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions.	2	DWS supplies a water source for the SFW pumps, which serve to remove decay heat after reactor trip.
–	Valves Providing DWS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
DWS-PL-V241	DWS Containment Penetration Thermal Relief Valve	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment	1	The isolation valves are the principal means of fulfilling the safety function.
DWS-PL-V244	Demineralised Water Supply Containment Isolation – Outside	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	These valves isolate the DWS piping that penetrates the containment barrier. This containment flow path is normally locked closed, and it is only opened when demineralised water is required inside containment.
DWS-PL-V245	Demineralised Water Supply Containment Isolation – Inside	B	I	ASME III-2				
DWS-PL-V248	Containment Penetration Test Connection Isolation	B	I	ASME III-2				
DWS-PY-C01	Containment Demineralised Water Supply Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
Balance of system components are Class E					C	Provide long-term support to Category A or B safety functions.	C	The DWS provides initial fill and makeup to the primary side RCS through the CVS. The DWS contains equipment to deoxygenate demineralised water and condensate. The DWS provides initial fill and makeup to the spent fuel pool through the CVS. The DWS provides water to humidifiers in the HVAC systems.

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Fuel Handling and Refuelling System (FHS) Location: Containment and Auxiliary Building								
FHS-FH-01	Refuelling Machine	D	II	AISC	A	Protecting against internal/external hazards that would directly and inevitably result in loss of one of the other Category A safety functions.	2	The water in the spent fuel pool and designated makeup sources provide the principal means of protecting the spent fuel against damage. However, all handling systems are significant contributors to this protection: they are not allowed to fail and damage safety-related equipment.
FHS-JL-01	Refuelling Machine Control Panel	D	II	M/f Std				
FHS-FH-02	Fuel Handling Machine	D	II	AISC				
FHS-FH-04	New Fuel Elevator	D	II	AISC				
FHS-FH-05	Fuel Transfer System	D	II	AISC				
FHS-JL-03	Fuel Transfer System Control Panel Inside Containment	D	II	M/f Std				
FHS-JL-04	Fuel Transfer System Control Panel Outside Containment	D	II	M/f Std				
FHS-FH-52	Spent Fuel Assembly Handling Tool	D	II	AISC				
FHS-FS-01	New Fuel Storage Rack	D	I	M/f Std	A	Controlling subcritical reactivity of the fuel in the reactor core and the spent nuclear fuel in the spent fuel pool and associated structures during normal operations and accident conditions.	2	This SSC is a significant contributor to the cooling and reactivity control of the spent fuel. Principal means of performing these functions are associated with the spent fuel pool and the coolant contained within.
FHS-FS-06	In-containment Fuel Storage Rack	D	I	M/f Std	A	Controlling subcritical reactivity of the fuel in the reactor core and the spent nuclear fuel in the spent fuel pool and associated structures during normal operations and accident conditions.	2	This SSC is a significant contributor to the cooling and reactivity control of the spent fuel. Principal means of performing these functions are associated with the pit and the coolant contained within.
FHS-FS-21 FHS-FS-22 FHS-FS-23 FHS-FS-24 FHS-FS-25 FHS-FS-26 FHS-FS-27 FHS-FS-28	Spent Fuel Storage Rack	D	I	M/f Std	A	Controlling subcritical reactivity of the fuel in the reactor core and the spent nuclear fuel in the spent fuel pool and associated structures during normal operations and accident conditions. Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	2	This SSC is a significant contributor to the cooling and reactivity control of the spent fuel. Principal means of performing these functions are associated with the spent fuel pool and the coolant contained within.
FHS-MT-01	Spent Fuel Pool	C	I	ACI 349	A	Controlling subcritical reactivity of the fuel in the reactor core and the spent nuclear fuel in the spent fuel pool and associated structures during normal operations and accident conditions. Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	1	Spent fuel pool represents the principal means of providing this safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Fuel Handling and Refuelling System (FHS) Location: Containment and Auxiliary Building (cont.)								
FHS-MT-02	Fuel Transfer Canal	C	I	ACI 349	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating). Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	These SSCs provide for maintaining inventory of coolant in the spent fuel pool to provide cooling and reactivity control of the spent fuel. Additionally, the cask loading pit provides an alternate suction source for the cooling water to various support systems. Therefore, integrity of these volumes is considered a principle function.
FHS-MT-03	Refuelling Cavity	C	I	ACI 349				
FHS-MT-05	Spent Fuel Cask Loading Pit	C	I	ACI 349				
FHS-MT-06	Spent Fuel Cask Washdown Pit	C	I	ACI 349				
FHS-MY-Y01	Spent Fuel Transfer Gate	C	I	M/f Std				
FHS-MY-Y02	Spent Fuel Cask Loading Pit Gate	C	I	M/f Std				
FHS-MY-Y03	Permanent Cavity Seal Ring	C	I	M/f Std				
FHS-PL-V001	Fuel Transfer Tube Isolation Valve	C	I	ASME III-3				
FHS-PL-V001	Fuel Transfer Tube Isolation Valve	C	I	ASME III-3	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
FHS-FT-01	Fuel Transfer Tube	B	I	ASME III Class MC				
FHS-PY-B01	Fuel Transfer Tube Blind Flange	B	I	ASME III-2				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	Does not contribute to maintaining nuclear safety as determined by the safety case.
Fire Protection System (FPS) Location: Various								
FPS-PL-V045	PCS to FPS Isolation Valve	F	NNS	ANSI B16.34	C	Ensures proper firefighting and sprinkler system supply from seismically qualified source and allows maintenance of PCS and/or FPS.	3	This normally open valve ensures Non-RCA side of Auxiliary Building is supplied with adequate supply of firefighting and sprinkler operation.
FPS-PL-V050	Fire Water Containment Supply Isolation – Outside	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of maintaining containment isolation.
FPS-PL-V051	Fire Water Containment Test Connection Isolation	B	I	ASME III-2				
FPS-PL-V052	Fire Water Containment Supply Isolation – Inside	B	I	ASME III-2				
FPS-PL-V702	FPS Containment Penetration Thermal Relief Valve	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
FPS-PY-C01	Fire Protection Containment Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
FPS-PL-V441	Auxiliary Connection to CCS Isolation	D	NNS	ANSI B16.34	C	Provide long-term support of a Category A or B safety function.	3	This connection allows a fire protection standpipe to furnish water to cool a normal residual heat removal pump and heat exchanger following a fire that disables the normal CCS cooling function.
FPS-MS-01A/B	Fire Protection Pump Package Units	F	NNS	M/f Std	B	Function that provides a backup to a Category A safety function.	3	The fire protection pumps provide an alternative means to provide cooling water to multiple sources such as the PCCWST, the spent fuel pool, and the RNS heat exchangers.
–	Automatic sprinklers for SWS pumps, CCS pumps, and startup feedwater pumps	G	NNS	-	GNS	No nuclear safety implications.	GNS	Protection from internal hazards is train-separation where required based on risk-analysis.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Fire Protection System (FPS) Location: Various (cont.)								
–	Containment standpipe and suppression system components. Includes all FPS components inside reactor containment with the exception of those used for containment isolation and containment spray	F	NNS	ANSI B31.1	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Auxiliary Building Standpipe and Non-1E Equipment Penetration Room Preaction Sprinkler System Components	F	NNS	ANSI B31.1	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Balance of system components are Class E, F, and G					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Main and Startup Feedwater System (FWS) Location: Turbine Building								
FWS-MP-03A/B	Startup Feedwater Pumps	D	NNS	Hydraulic Institute Standards	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	The SFW pumps provide a mode of decay heat removal using steam dump to the atmosphere or the main condenser. These pumps are included in the RAP and are important to safety.
–	Valves Providing SFW AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
FWS-MS-01A/B/C	Main Feedwater Pump Packages (Includes Main Feedwater Pump, Main Feedwater Booster Pump, Speed Increaser, and associated Lube Oil equipment)	E	NNS	Hydraulic Institute Standards	C	Removing nuclear heat from the reactor during normal operations.	3	The main feedwater pumps provide the motive power for main feedwater flow.
FWS-ME-06A/B	6th Stage Feedwater Heaters	E	NNS	ASME Section VIII	C	Removing nuclear heat from the reactor during normal operations.	3	The feedwater heaters provide required heat removal and thermal efficiency improvements to support normal power operation.
FWS-ME-07A/B	7th Stage Feedwater Heaters	E	NNS	ASME Section VIII	C			
–	Valves and instrumentation supporting normal power operation of the AP1000 MFW function	E	NNS	Mfg. Std	C	Removing nuclear heat from the reactor during normal operations.	3	The main feedwater function supports continued normal plant operation and removal of power operation nuclear heat.
Balance of main and startup feedwater system components are Class E					GNS		GNS	
Gland Seal System (GSS) Location: Turbine Building								
System components are Class D					C	Removing nuclear heat from the reactor during normal operations. Failure of this function can result in a short-term power manoeuvre, thus affecting safety.	3	The GSS is a system necessary for power generation and can affect the availability of the AP1000 generating unit since it is a vital part of maintaining main condenser vacuum and backpressure on the main turbine during plant operation.
Generator Hydrogen and CO2 Systems (HCS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Heater Drain System (HDS) Location: Turbine Building								
HDS-MP-01A/B	MSR Shell Drain Pumps	E	NNS	Hydraulic Institute	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	If there is a loss of function in a MSR shell drain pump, 50% of the MSR shell drain to the deaerator is lost which will result in a reduction in power production.
–	MSR Shell Drain Tank Normal Drain Path Control Valves	E	NNS	ANSI B16.34	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	If one of these valves failed to a closed position during full power operation, 50% of the MSR shell drain is lost.
–	Feedwater Heater Drain Path Control Valves	E	NNS	ANSI B16.34	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	If one of these valves failed to a closed position during full power operation, 50% of the MSR shell drain is lost.
–	MSR 2nd Stage Reheater Drain Tank Normal Drain Path Control Valves	E	NNS	ANSI B16.34	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	If one of these valves failed to a closed position during full power operation, 50% of the MSR shell drain is lost.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Hydrogen Seal Oil System (HSS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
In-core Instrumentation System (IIS) Location: Containment								
–	IIS Guide Tubes	A	I	ASME III-1	A	Prevention of the release of radioactive material through the boundary of the RCS.	1	Provides the principal means of fulfilling the safety function.
–	Thimble assemblies	B	I	M/f Std	B	Instrumentation used to monitor Category A safety functions (but not required to facilitate actuation).	1	The thimble assemblies provide the structure for mounting of the in-core instrumentation channels. The individual channels are classified separately.
Main Turbine and Generator Lube Oil System (LOS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Mechanical Handling System (MHS) Location: Various								
MHS-MH-01	Containment Polar Crane	C	I	NUREG-0554 supplemented by ASME NOG-1	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating). Preventing the release of radioactive material through the boundary of the RCS.	1	Provides the principal means of fulfilling the safety function. The polar crane protects against load drops on the RCS or on any irradiated fuel assemblies, regardless of location in the transfer canal or vessel.
MHS-MH-02	Cask Handling Crane	C	I	NUREG-0554 supplemented by ASME NOG-1	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	1	Provides the principal means of fulfilling the safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Mechanical Handling System (MHS) Location: Various (cont.)								
MHS-MH-05	Equipment Hatch Hoist	C	I	NUREG-0554 supplemented by ASME NOG-1	A	Prevention of the release of radioactive material through the boundary of the RCS.	1	Provides the principal means of fulfilling the safety function.
MHS-MH-06	Maintenance Hatch Hoist	C	I	NUREG-0554 supplemented by ASME NOG-1				
MHS-MH-16	Filter Cask Portable Handling Device	D	NNS	M/f Std	B	Preventing the release of radioactive waste material from onsite radioactive waste systems.	3	The filter cask provides the principal means of fulfilling the safety function. The filter cask portable handling device is a significant contributor to the safety function.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	Does not contribute to maintaining nuclear safety as determined by the safety case.
Main Steam System (MSS) Location: Turbine Building								
–	Moisture Separator Reheaters (MSR)	E	NNS	ASME Section VII	C	This component is important to power production reliability. Single failure of an MSR during power operation will result in a reduction in plant power production.	3	If an MSR reheater section must be taken out of service due to a tube leakage, plant power production must be reduced per turbine generator vendor requirements. A tube leak in the MSR is not expected to cause low-pressure turbine parameters to reach the trip setpoint before operator action can be taken to isolate the reheater section.
MSS-PL-V001 MSS-PL-V002 MSS-PL-V003 MSS-PL-V004 MSS-PL-V005 MSS-PL-V006	Turbine Bypass Control Valves	E	NNS	M/f Std	C	Remove nuclear heat from the reactor coolant during normal operation. If one or more of these valves are failed to the closed position and unable to be opened, the plants availability to survive a full load rejection without a reactor trip is challenged, thus affecting nuclear safety.	3	Single failure of a turbine bypass control valve during power operation could result in a reactor trip. The valves are credited as back-up to the MSIVs, and the valves are required to prevent a reactor trip during a Level A transient.
MSS-PL-V015A/B	MSR 2nd Stage Reheat Supply Steam Isolation Valves	E	NNS	M/f Std	C	Remove nuclear heat from the reactor coolant during power operation. Failure of either of these valves to their closed position during power operation will result in a loss of reheat steam to 2nd stage of the MSR, which will result in a reduction in plant power per turbine generator vendor requirements.	3	V015A/B valves are fail-closed, air-operated valves that serve as isolation valves in the 2nd stage MSR reheat steam supply. These valves are also credited as backup to the MSIVs.
–	Extraction Non-Return Valves	E	NNS	M/f Std	C	Remove nuclear heat from the reactor coolant. Failure of the air assist on one of these valves would push the valve to a partially closed position during power operation which may cause a small reduction in plant power.	3	These valves are partially closed, air-assisted check valves in the extraction steam supply lines to the FW heaters and 1st Stage MSRs. Single valve failure may result in a reduction in plant power production.
–	Main Steam Delivery Valves and Piping	E	NNS	-	C	Removing nuclear heat from the reactor coolant during normal operation.	3	The MSS delivers steam from the SGS to the MTS and to and from the moisture separator reheaters during normal operation.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Main Turbine System (MTS) Location: Turbine Building								
MTS-MG-01	High-Pressure Turbine	E	NNS	M/f Std	C	This component is important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Failure of high-pressure turbine will result in immediate unit trip
–	Low-Pressure Turbines	E	NNS	M/f Std	C	This component is important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Failure of low-pressure turbine will result in immediate unit trip.
MTS-PL-V001A/B MTS-PL-V003A/B	Turbine Main Stop Valves	E	NNS	M/f Std	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Single valve failure will result in a reduction in plant power if not remedied. The failure of this valve to operate on demand requires a plant shutdown if not remedied within 72 hours.
MTS-PL-V002A/B MTS-PL-V004A/B	Turbine Control Valves	E	NNS	M/f Std	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Single valve failure will result in a reduction in plant power if not remedied. The failure of this valve to operate on demand requires a plant shutdown if not remedied within 72 hours.
–	Turbine Reheat Stop Valve	E	NNS	M/f Std	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Single valve failure will result in a reduction in plant power if not remedied.
–	Turbine Intercept Valves	E	NNS	M/f Std	C	These components are important to power production reliability. Failure of this component would result in a short-term power manoeuvre, thus affecting nuclear safety.	3	Single valve failure will result in a reduction in plant power if not remedied.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Passive Containment Cooling System (PCS) Location: Containment Shield Building and Auxiliary Building								
PCS-EH-02	Ancillary Water Storage Tank Heater	D	NNS	M/f Std.	B	Reduce the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident.	3	Supports the operation of a Class 2 component (PCS-MT-05). This component reduces the probability that offsite SSCs would be needed to support post 72 hour actions.
PCS-MT-01	Passive Containment Cooling Water Storage Tank	C	I	ACI 349	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material containment.	1	Provides the principal means of fulfilling the safety function.
PCS-MT-03	Water Distribution Bucket	C	I	M/f Std				
PCS-MT-04	Water Collection Troughs	C	I	M/f Std				
PCS-MY-Y01 PCS-MY-Y02 PCS-MY-Y03 PCS-MY-Y04 PCS-MY-Y05	PCS Water Storage Tank Screens	C	I	M/f Std				
PCS-MT-05	Passive Containment Cooling Ancillary Water Storage Tank	D	II	API 650	B	Reduce the probability of requiring the use of offsite SSCS to maintain Category A safety functions after 72 hours following an accident.	2	Provides the principal means of fulfilling the safety function. This component reduces the probability that offsite SSCs would be needed to support post 72 hour actions.

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Passive Core Cooling System (PXS) Location: Containment (cont.)								
PXS-PY-R02A	Accumulator Tank A Orifice	C	I	ASME III-3	A	Maintaining reactor coolant inventory. Control of core reactivity during normal operation and accident conditions	1	Provides the principal means of fulfilling the safety function.
PXS-PY-R02B	Accumulator Tank B Orifice	C	I	ASME III-3	A	Maintaining reactor coolant inventory. Control of core reactivity during normal operation and accident conditions.	1	Provides the principal means of fulfilling the safety function.
PXS-PY-R04A	Core Makeup Tank A to RCDT	B	I	ASME III-2	A	Maintaining reactor coolant inventory. Control of core reactivity during normal operation and accident conditions.	1	Provides the principal means of fulfilling the safety function.
PXS-PY-R04B	Core Makeup Tank A to RCDT	B	I	ASME III-2	A	Maintaining reactor coolant inventory. Control of core reactivity during normal operation and accident conditions.	1	Provides the principal means of fulfilling the safety function.
PXS-PY-R05	PXS Leak Test Subsystem Orifice	D	NNS	ASME B31.1	C	Provide long-term support of Category A or B functions.	3	Supports operation of Class 1 and Class 2 SSCs.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Reactor Coolant System (RCS) Location: Containment								
RCS-MB-01	Steam Generator 1	A	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions. Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Provides the principal means of fulfilling the safety function of maintaining the integrity of the RCS pressure. The RCS function of decay heat removal is not a principal means of satisfying the safety function.
RCS-MB-02	Steam Generator 2	A	I	ASME III-1				
RCS-MP-01A	SG 1 Reactor Coolant Pump	A	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions. Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Provides the principal means of fulfilling the safety function of maintaining the integrity of the RCS pressure. Pump coast down time is credited within design basis analysis. The RCS function of decay heat removal is not a principal means of satisfying the safety function.
RCS-MP-01B	SG 1 Reactor Coolant Pump	A	I	ASME III-1				
RCS-MP-02A	SG 2 Reactor Coolant Pump	A	I	ASME III-1				
RCS-MP-02B	SG 2 Reactor Coolant Pump	A	I	ASME III-1				
RCS-MV-01	Reactor Vessel	A	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions.	1	Provides the principal means of fulfilling the safety function.
RCS-MV-02	Pressuriser	A	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions. Mitigating reactor coolant overpressure during normal operation and accident conditions.	1	Provides the principal means of fulfilling the safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Reactor Coolant System (RCS) Location: Containment (cont.)								
–	Pressuriser heaters	A/D	NNS	ASME III-1 ANSI B31.1	A/C	Maintain integrity of the RCS boundary. Maintaining the RCS pressure in the operating band. Since the control of RCS pressure during normal operation prevents reactor trips and the actuation of Category A and Category B functions, these normally operating duty systems are recognised as being important to safety.	1/3	The pressuriser heaters sheath is part of the RCS boundary. This is the heaters only class 1 function. The heaters are configured in 5 groups. A control group is sized to accommodate steady-state heat losses. Backup heater capacity is provided to produce the minimum heat required to maintain subcooled RCS pressure during standby operations.
–	SG Shells	B	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions. Removing of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Provides the principal means of fulfilling the safety function for the release of radioactive material from the containment. The SG shell function of decay heat removal is not a principal means of satisfying the safety function.
–	SG Channel Head Divider Plates	B	I	ASME III-1	A	Maintaining the integrity of the RCS pressure boundary; including mitigating RCS overpressure during normal operations and accident conditions.	1	Provides the principal means of fulfilling the safety function.
–	SG Tube Bundle Support Assemblies	C	I	ASME III, NG	A	Protecting against internal/external hazards that would directly and inevitably result in loss of a principal means to fulfil one of the other Category A safety functions	1	Provides the principal means of fulfilling the safety function.
–	SG Steam Flow Limiting Venturies	B	I	ASME III, NG	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment.	1	Provides the principal means of fulfilling the safety function.
–	SG Feedwater Distribution Ring Supports	B	I	ASME III, NG	A	Protecting against internal/external hazards that would directly and inevitably result in loss of a principal means to fulfil a Category A safety function. Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Provides the principal means of fulfilling the safety function of protecting against internal/external hazards that would directly and inevitably result in loss of a principal means to fulfil a Category A safety function. The SG feedwater distribution ring support function of decay heat removal is not a principal means of satisfying the safety function.
RCS-PL-V001A	First Stage ADS	A	I	ASME III-1	A	Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions). Preventing the release of radioactive material through the boundary of the RCS.	1	Provides the principal means of fulfilling the safety function.

Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Raw Water System (RWS) Location: Yard, Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Reactor System (RXS) Location: Containment								
–	Fuel Assemblies	C	I	M/f Std	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions). Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating). Protecting against internal/external hazards that would directly and inevitably result in loss of one of the other Category A safety functions.	1	Provides the principal means of fulfilling the safety function.
–	Control Rod Clusters	B	I	M/f Std	A	Control of core reactivity during normal operation and accident conditions.	1	Provides the principal means of fulfilling the safety function.
RXS-MI-01	Reactor Upper Internals	C	I	ASME III, NG	A	Protecting against internal hazards that, as part of a sequence of failures, could result in loss of a Category A or B safety function. Removing the nuclear core decay heat from the reactor core during normal and accident conditions.	1	The upper internals restrain the top of the fuel assemblies from vertical and horizontal movement. The upper internals provide a protective path for the fixed in-core flux detectors and core exit thermocouples. The upper internals provide the flow path for flow exiting the core to establish the required circulation for decay heat removal.
RXS-MI-02	Reactor Lower Internals	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions. Removing the nuclear core decay heat from the reactor core during normal and accident conditions.	1	Provides protection, alignment, and support for the core.
RXS-MI-10	Fasteners	D	NNS	-	B	Protecting against internal hazards that, as part of a sequence of failures, could result in loss of a safety function.	3	Includes fasteners and pins that do not provide direct load carrying capabilities of core support structures.
RXS -MI-11	Threaded Structural Fasteners	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Provide direct load carrying capabilities of core support structures.
RXS-MI-20	Lower Core Support Plate	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions. Removing the nuclear core decay heat from the reactor core during normal and accident conditions.	1	The lower core support assembly supports the core and the attached internal structures. Provides directional and metered control of reactor coolant flow through the core. Provides restraint and alignment of the core.
RXS-MI-21	Secondary Core Support	D	NNS	-	B	Functions that provide a backup to a Category A safety function.	3	In the event of an abnormal downward vertical displacement of the internals following a hypothetical failure, the secondary core support limits the dynamic force imposed on the reactor vessel.
RXS-MI-22	Vortex Suppression Plate	D	II	-	C	Removing nuclear heat from the reactor coolant during normal operation.	3	The lower plenum vortex-suppressor plate is positioned in the vessel's lower plenum to suppress flow vortices formed by reactor coolant flow reverser in this region.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Reactor System (RXS) Location: Containment (cont.)								
RXS-MI-23	Core Shroud Assembly	D	II	-	B	Functions that provide a backup to a Category A safety function.	3	The core shroud allows cooling water (i.e., bypass) to flow through the cavity between the core barrel and core shroud lateral panels while providing distance between the core and the RV. This distance protects the RV from detrimental radiation effects by limiting total exposure.
RXS-MI-24	Radial Supports (4)	C	I	ASME III, CS	A	Protecting against internal/external hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Restricts the lower end of the core barrel from rotational or translations movement and provides a load path for the lower core support plate horizontal loadings, while allowing for radial and axial displacements of the core barrel and lower core support plate.
RXS-MI-25	Core Barrel	C	I	ASME III, NG	A	Removing the nuclear core decay heat from the reactor core during normal and accident conditions.	1	Directs flow from the RV inlet nozzles through the downcomer annulus, through the flow skirt, and into the lower plenum.
RXS-MI-26	Core Barrel Nozzle	C	I	ASME III, NG	A	Removing the nuclear core decay heat from the reactor core during normal and accident conditions.	1	Provides the passageway for the reactor coolant from the core to the RV outlet nozzle projection.
RXS-MI-27	Head and Vessel Pins	D	II	-	B	Functions that provide a backup to a Category A safety function.	3	Pins provide an alignment guide and assist in the proper orientation and assembly of the lower internals, upper internals, and reactor vessel closure head.
RXS-MI-28	Lower Support Plate Fuel Alignment Pins	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Locates the bottom of the fuel assembly nozzle.
RXS-MI-29	Core Barrel Hold Down Spring	C	I	-	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Provides a preload to limit axial movement of the upper and lower core support assemblies during operation.
RXS-MI-50	Upper Support	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Provides the vertical restraint, lateral restraint, and lateral alignment to the top of the core through its main components.
RXS-MI-51	Upper Core Plate	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Transfers core loads to the upper support columns and compresses the fuel assembly springs creating a preload.
RXS-MI-52	Support Columns (42)	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Transfers vertical and lateral reaction loads to the upper support subassembly.
RXS-MI-53	Guide Tube Assemblies (69)	C	I	ANSI B31.1	A	Controlling subcritical reactivity of the fuel in the reactor core during normal operations and accident conditions.	1	The guide tube assemblies sheath and guide the control rod drive shafts and control rods.
RXS-MI-54	Upper Support Plate Fuel Alignment Pins	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Engage the top of the fuel assemblies.
RXS-MI-55	Upper Core Plate Inserts	C	I	ASME III, NG	A	Protecting against internal hazards that could directly and inevitably result in loss of one of the other Category A safety functions.	1	Provides the alignment plate engagement gaps.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Reactor System (RXS) Location: Containment (cont.)								
RXS-MI-56	Safety Injection Deflector	D	II	ANSI B31.1	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions.	2	Prevents cold water from the DVI nozzle from impinging directly on the core barrel and directs the water downward.
RXS-MI-58	Head Cooling Nozzles	D	II	ANSI B31.1	B	Plant process control function that maintains variables with the limits assumed in the safety analysis.	3	The AP1000 RV is designed for maximum operating temperatures in accordance with applicable design codes. A contributing function to reduce susceptibility to fatigue of dissimilar metal welds and nozzle penetrations is the use of a reduced temperature closure head design (relative to the core exit temperature). The head cooling nozzles control RV inlet bypass flow to the closure head for this purpose.
RXS-MI-80	Reactor Vessel Flow Skirt	D	II	ASME III NG	A	Removing the nuclear decay heat from the reactor during normal operations and accident conditions.	2	The flow skirt provides a uniform core inlet flow distribution.
RXS-MN-01	Reactor Vessel Cavity Reflective Insulation	D	II	-	A	Functions provided to minimise the consequences of severe accidents in accordance with the plant design basis.	2	During severe accidents involving reactor cavity flooding, the RVLIS shall remain intact and provide a specified annulus with the outer surface of the reactor vessel and allow water in the reactor cavity to enter the bottom of the annulus for cooling of the reactor vessel. The RVLIS shall also allow the free discharge of steam from the top of the annulus.
–	Integrated Head Package CRDM Forced Air Cooling System	E	II	-	GNS	No nuclear safety implication.	GNS	The CRDM coiling system maintains the temperature of the coins contained within the coil stack below the specified design limit during normal operations and hot standby.
–	Integrated Head Package Radial Arm Hoist	E	II	AISC N690	C	Provides long-term support of a Category A or B safety function.	3	The radial arm hoist is provided for stud tensioning activities.
–	Integrated Head Package CRDM Seismic Support	C	I	ASME III NF	A	Protecting against an internal hazard that could directly or inevitably result in the loss of a principal means of fulfilling a Category A safety function.	1	Provides the principal means of seismically supporting the CRDM.
–	Integrated Head Package Lifting Rig	C	I	AISC N690	A	Protecting against an internal hazard that could directly or inevitably result in the loss of a principal means of fulfilling a Category A safety function.	1	The lifting rig removes the IHP during refuelling.
–	Integrated Head Package Integral Cable Support System (1E Cables)	C	I	IEEE 344	A	Protecting against an internal hazard that could directly or inevitably result in the loss of a principal means of fulfilling a Category A safety function.	1	The cable support system provides support to Class 1 cables.
RXS-MY-Y01	Integrated Head Package Shroud	C	I	ASME III NF	A	Permanently installed structure to provide shielding per the plant design basis.	1	The shroud provides shielding that reduces dose rates in the areas of the head assembly.
–	Integrated Head Package Service Structure	E	II	AISC N690	C	Provides long-term support of a Category A or B safety function.	3	The service structures include all handrails, ladders, platforms, and bridges that allow access for maintenance and inspection.
–	CRDM Pressure Housing (Latch Housing and Rod Travel Housing)	A	I	ASME III-NB	A	Prevention of the release of radioactive material through the boundary of the RCS.	1	Components are part of the primary coolant pressure boundary.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Reactor System (RXS) Location: Containment (cont.)								
–	CRDM Latch Assembly	C	I	M/f Std	A	Control of core reactivity during normal operation and accident conditions.	1	The control of core reactivity is performed by the RCCA neutron absorber material; the CRDMs are used in a support function for the positioning of the RCCAs to support power operation. The only safety related function of the latch assembly is that it be capable of releasing the drive rod when electrical power is cut to the coil stack assembly before and after an SSE event. The latch assembly is classified as Non-Code because it does not have a nuclear safety-related pressure retaining function.
–	CRDM Drive Rod Assembly	D	NNS	M/f Std	B	Plant process control function that maintains variables with the limits assumed in the safety analysis.	3	The control of core reactivity is performed by the RCCA neutron absorber material; the CRDMs are used in a support function for the positioning of the RCCAs to support power operation.
–	CRDM Coil Stack Assembly	D	NNS	M/f Std	B	Plant process control function that maintains variables with the limits assumed in the safety analysis.	3	The control of core reactivity is performed by the RCCA neutron absorber material; the CRDMs are used in a support function for the positioning of the RCCAs to support power operation.
–	CRDM Flux Rings	D	NNS	M/f Std	B	Plant process control function that maintains variables with the limits assumed in the safety analysis.	3	The flux rings direct the magnetic energy from the coil stack assemblies to actuate the latch assembly latches to hold or move the drive rod assembly and RCCA/GRCA.
–	CRDM Flux Ring Locking Straps	E	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	CRDM Rod Travel Housing Eyebolt	D	NNS	M/f Std	B	Protecting against internal hazards that could, as part of a sequence of failures, result in the loss of a safety function.	3	The eyebolt is used to lift and handle the rod travel housing during installation onto the reactor vessel head prior to plant operation.
–	CRDM Guide Sleeve	D	NNS	M/f Std	B	Plant process control function that maintains variables with the limits assumed in the safety analysis.	3	The guide sleeves guide the drive rod into the latch assembly following an outage. The failure during movement could affect the operation and integrity of the CRDM assembly.
RXS-MY-Y01	Irradiation Tube Plug Seat Jack	E	GNS	M/f Std	C	Providing support of a Category A or B function.	3	Specimen tubes are required to maintain integrity to prevent debris intrusion into the core and interfere with Category A functions.
-	Incore Instrumentation QuickLoc Assembly 1	A	I	M/f Std.	A	Maintaining the integrity of the reactor coolant pressure boundary.	1	Principal means of fulfilling the safety function.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Sanitary Drainage System (SDS) Location: Various								
–	Main Control Room Isolation Valves	C	I	ASME III-3	A	Maintaining habitability of the main control room.	1	The isolation valves are the principal means of isolating the main control room envelope during VES operation.
Balance of system components are Class P					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

SFS-ME-01A	Spent Fuel Pool Heat Exchanger A	D	NNS	ASME VIII	B	The SFS heat exchanger provides a backup or alternate method to the Category A function to remove heat from the spent fuel pool.	2	SFS provides a supplemental function of spent fuel pool heat removal.
SFS-ME-01B	Spent Fuel Pool Heat Exchanger B	D	NNS	ASME VIII				
SFS-MP-01A	Spent Fuel Cooling Pump A	D	NNS	Hydraulic Institute Standards	B	The SFS cooling pump provides a backup or alternate method to the Category A function to remove heat from the spent fuel pool.	2	SFS provides a supplemental function of spent fuel pool heat removal.
SFS-MP-01B	Spent Fuel Cooling Pump B	D	NNS	Hydraulic Institute Standards				
–	Valves Providing SFS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	2	SFS provides a supplemental function of spent fuel pool heat removal. This function is considered important to safety.
SFS-PL-V024A	Spent Fuel Pool Level Instrument Isolation	C	I	ASME III-3	A	Functions required to provide information and control capabilities that allow specified manual actions necessary to reach the nonhazardous stable state.	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V024B	Spent Fuel Pool Level Instrument Isolation	C	I	ASME III-3				
SFS-PL-V024C	Spent Fuel Pool Level Instrument Isolation	C	I	ASME III-3				
SFS-PL-V028	Cask Washdown Pit Level Instrument Isolation Valve	C	I	ASME III-3	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V031	SFS Refuelling Cavity Drain to SGS Compartment Isolation	C	I	ASME III-3	A	Maintaining reactor coolant inventory Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Drain pathway provides a principal flow path for natural circulation cooling during an accident. Drain is closed during refuelling to preserve reactor canal inventory.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Spent Fuel Pool Cooling System (SFS) Location: Auxiliary Building, Containment (cont.)								
SFS-PL-V032	SFS Refuelling Cavity Suction Isolation	C	I	ASME III-3	A	Maintaining reactor coolant inventory. Removing decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V058	SFS Containment Isolation Valve V034 Test	C	I	ASME III-3				
SFS-PL-V033	SFS Refuelling Cavity Drain to Containment Sump Isolation	C	I	ASME III-3	A	Maintaining reactor coolant inventory.	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V034	SFS Suction Line Containment Isolation Valve	B	I	ASME III-2	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment. Preserve IRWST inventory.	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V035	SFS Suction Line Containment Isolation Valve	B	I	ASME III-2				
SFS-PL-V038	SFS Discharge Line Containment Isolation Valve	B	I	ASME III-2				
SFS-PL-V037	SFS Discharge Line Containment Isolation Valve	B	I	ASME III-2	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment.	1	Provides the principal means of fulfilling the safety function.
SFS-PL-V048	SFS Containment Penetration Test Connection Valve	B	I	ASME III-2				
SFS-PL-V056	SFS Containment Penetration Test Connection Isolation Valve	B	I	ASME III-2				
SFS-PL-V067	SFS Containment Isolation Relief Valve	B	I	ASME III-2				
SFS-PL-V039	SFS Suction Line from IRWST Isolation	C	I	ASME III-3	A	Removing the nuclear core decay (or residual) heat from the reactor coolant during normal operations and accident conditions (includes those SSCs that provide the heat sink removal of decay heat from the reactor coolant).	1	The IRWST provides the heat sink for the PRHR HX, which removes the nuclear core decay heat from the reactor coolant during accident conditions. The PXS is the principal means to fulfil this decay heat removal Category A function. This valve provides support for refuelling operations to fill, drain, cool and purify the refuelling cavity and IRWST
SFS-PL-V040	SFS Fuel Transfer Canal Drain Isolation	C	I	ASME III-3	A	Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).	1	Provides the principal means of fulfilling the safety function.

Balance of System Components are Class E					GNS			

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Secondary Sampling System (SSS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Service Water System (SWS) Location: Turbine Building and Yard								
–	Service Water Cooling Tower Fans	D	NNS	M/f Std	A	Removing the nuclear core decay (or residual) heat from the reactor coolant during normal operations and accident conditions (includes those SSCs that provide the heat sink removal of decay heat from the reactor coolant). Maintaining spent fuel integrity such that significant radioactive release does not occur as a result of overheating.	2	SWS supports the CCS defence in depth functions of decay heat removal and spent fuel cooling.
–	Service Water Cooling Tower	D	NNS	M/f Std				
SWS-MP-01A/B	Service Water Pumps	D	NNS	Hydraulic Institute Std				
–	Valves Providing SWS AP1000 Equipment Class D Function	D	NNS	ANSI B16.34				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Turbine Building Closed Cooling Water System (TCS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Turbine Island Vents, Drains and Relief System (TDS) Location: Turbine Building								
–	Piping and components that provide the path from the GSS and CMS to atmosphere and rad monitor	D	NNS	ANSI B3 1.1	C	Monitoring of radioactivity released to the environment.	3	The CMS and the GSS discharge into the TDS. The exhaust from the TDS into the turbine island vent is continuously monitored for radiation.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Radiologically Controlled Area Ventilation System (VAS) Location: Auxiliary Building and Annex Building								
–	CVS and RNS Pump Room Coolers	L/R (D)	NNS	M/f Std	C	Providing long-term support of Category A or B functions.	3	These components support normal operation of the RNS pumps and CVS make-up pumps by maintaining the pump rooms within their design temperature range. Unavailability of coolers would not lead to immediate loss of supported SSCs; time is available for remedial action to be taken.
VAS-MD-D700 VAS-MD-D705	Dampers for the HEPA filter pathway	C	I	ASME AG-1	A	Controlling the levels of radioactivity released to the environment.	1	Filtered exhaust for the VAS may be provided by the VFS during abnormal conditions.
–	Fire Dampers	D	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas.
VAS-MS-101	HEPA Filters	D	I	ANSI N509	A	Controlling the level of radioactivity released to the environment.	2	HEPA filtration is located on the VAS subsystem serving the fuel handling area to capture potential airborne particulates containing radioactivity.
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	B	Control of levels of radioactivity released to the environment.	3	The VAS provides HVAC to radiologically controlled areas and provides for the means of filtering and monitoring of environmental releases.
–	Air Handling Units	L	NNS	M/f Std				
–	Filters	L	NNS	UL 900				
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class L								

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Nuclear Island Non-radioactive Ventilation System (VBS) Location: Auxiliary Building and Annex Building								
–	Battery Rooms Exhaust Fans	D	NNS	AMCA	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis.	2	Maintains the temperature in the electrical rooms and the main control room during normal operation. Maintains proper airflow in the battery rooms to prevent hydrogen building during battery charging.
–	PCS Room Heaters	D	NNS	M/f Std	C	Provide long-term support of Category A or B functions.	3	The PCS room heaters maintain proper conditions to facilitate the proper operation of the PCS makeup function after 72 hours.
–	Combination Fire/Smoke Dampers	D	NNS	UL-555	A	Protecting SSCs from internal/external hazards that could result in the loss of a principal means of fulfilling a Category A safety function.	2	Fire/smoke dampers are provided to prevent fire or smoke spread between areas of the plant that could impact a safety function.
–	Fire Dampers	E	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas.
–	Dampers Providing AP1000 Equipment Class D Function	D	NNS	ANSI / AMCA500	A	Maintaining habitability of the main control room and maintains design temperatures in the equipment rooms.	2	VBS provides a supplementary ventilation function to preserve habitability and SSC function. This has been determined to be important to safety.
–	Dampers in Lines Isolating Radioactive Contamination	R	NNS	ASME-509	C	Control of levels of radioactivity entering the plant from the environment.	3	Dampers are used to control the intake of radioactivity.
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	VBS Radiation Monitoring Package	C	I	M/f Std	A	Maintaining habitability of the main control room.	1	VBS contains two skid mounted MCR radiation monitoring packages consisting of radiation detectors, local radiation processors, and sampling components to continuously measure and record the radioactive materials in the MCR main supply air duct and actuate VBS supplemental air filtration and VES operation.
–	MCR/CSA Supplemental Air Filtration Units	D	NNS	ASME AG-1	A	Maintaining habitability of the main control room.	2	VBS provides a supplementary ventilation function to preserve habitability and SSC function of the CSA in support of the MCR.
–	MCR Isolation Valve	C	I	ASME III-3	A	Maintaining habitability of the main control room.	1	The isolation valves are the principal means of fulfilling the safety function.
–	Valves Providing VBS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34	A	Maintaining habitability of the main control room and maintains design temperatures in the equipment rooms.	2	VBS provides a supplementary ventilation function to preserve habitability and SSC function. This has been determined to be important to safety.
–	Other Air Handling Units	D	NNS	M/f Std	A	Maintains design temperatures in the equipment rooms containing Class 1 electrical and C&I equipment.	2	VBS provides a ventilation function to support operation of Class 1 SSCs
–	Filters	D	NNS	UL 900				
–	Fans, Ductwork	D, L or R	NNS	SMACNA				
–	Ancillary Fan	D	Note 2	ANSI/ AMCA 210, 211, 300	B	Reduce the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident.	2	MCR ancillary fans allow for post-72 hour ventilation of the MCR. This function has been determined to be important to safety. This component reduces the probability that offsite SSCs would be needed to support post 72 hour actions.
Balance of system components are Class L					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Containment Air Filtration System (VFS) Location: Auxiliary Building and Annex Building								
VFS-PY-C01	Containment Supply Duct Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
VFS-PY-C02	Containment Exhaust Duct Penetration	B	I	ASME III, MC				
VFS-MY-Y01	Containment Air Supply Debris Screen	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment. Control of levels of radioactivity released to the environment.	1	The debris screens are structurally designed to withstand the maximum pressure differential assuming that they are blocked with debris generated by a LOCA. This is the Class 1 function of the screens. The debris screens support a Class 2 function of controlling radioactive release.
VFS-MY-Y02	Containment Air Exhaust Debris Screen	C	I	ASME III-3				
VFS-PL-V003	Containment Purge Supply Containment Isolation Valve	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
VFS-PL-V004	Containment Purge Supply Containment Isolation Valve	B	I	ASME III-2				
VFS-PL-V007	RCS Ejector Discharge Isolation	C	I	ASME III-3				
VFS-PL-V008	ILRT Vent Discharge Isolation	B	I	ASME III-2				
VFS-PL-V009	Containment Purge Discharge Containment Isolation Valve	B	I	ASME III-2				
VFS-PL-V010	Containment Purge Discharge Containment Isolation Valve	B	I	ASME III-2				
VFS-PL-V006 VFS-PL-V012 VFS-PL-V015	Containment Penetration Test Valves	C	I	ASME III-3				
VFS-PL-V101	Containment Air Supply Line Test Connection	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
VFS-PL-V202	Containment Atmosphere to Filtration Units Isolation	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
VFS-PL-V587	Filtration Units to Containment Atmosphere Manual Isolation	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
VFS-PL-V800 A/B	Vacuum Relief Containment Isolation	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment. Provides containment vacuum relief.	1	The isolation valves are the principal means of fulfilling the safety function.
VFS-PLV803 A/B	Vacuum Relief Containment Isolation Check Valve	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
–	Valves Providing VFS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34	C	Control of levels of radioactivity released to the environment. Monitoring of radioactivity released to the environment.	3	VFS provides the means to release and monitor gaseous effluent.
–	Dampers in Lines Isolating Radioactive Contamination	R	NNS	ASME-509	C	Control of levels of radioactivity released to the environment.	3	Dampers are used to control the release of radioactivity.
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Containment Air Filtration System (VFS) Location: Auxiliary Building and Annex Building (cont.)								
–	Fire Dampers	E	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas.
–	Supply Air Handling Units	L	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
	HEPA Filters	R	NNS	ASME AG-1	B	Controlling the level of radioactivity released to the environment.	3	HEPA filtration captures potential airborne particulate containing radioactivity.
–	Air Exhaust Filtration Units (other than HEPA filters)	R	NNS	ASME AG-1	C	Control of levels of radioactivity released to the environment. Monitoring of radioactivity released to the environment	3	VFS provides the means to release and monitor gaseous effluent.
–	Fans, Ductwork	L or R	NNS	SMACNA or ASME AG-1	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Balance of system components are Class L and Class R								
Health Physics and Hot Machine Shop HVAC System (VHS) Location: Annex Building								
–	Annex Bldg Exhaust Radiation Package	E	NNS	M/f Std	C	Monitoring the level of radioactivity released into the environment.	3	The system exhaust is provided with a radiation monitor to record and alarm release of radioactive effluent.
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Fire Dampers	E	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas in the annex building.
–	HEPA Filters	R	NNS	ANSI N509	B	Controlling the level of radioactivity released to the environment.	3	HEPA filtration is provided in or at the individual machine tools.
–	Air Handling Units w/ Filters	L	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class E or Class L								
Containment Hydrogen Control System (VLS) Location: Containment								
–	Hydrogen Igniters	D	NNS	M/f Std	B	Functions provided to reach and maintain safe state for beyond DBAs as specified in the station operating procedures.	2	Hydrogen igniters are identified as important to safety per the ANSI process and are the principal means of beyond design basis hydrogen mitigation.
VLS-MY-E01A	Catalytic Hydrogen Recombiner A	D	NNS	M/f Std	B	Plant process control function that maintains process variables within safety analysis limits.	3	Hydrogen recombiners are provided for hydrogen mitigation during DBAs. The principal means of hydrogen mitigation is the design of the containment and the amount of free volume. The recombiners are provided for additional level of defence against hydrogen accumulation.
VLS-MY-E01B	Catalytic Hydrogen Recombiner B	D	NNS	M/f Std				
Balance of system components are Class E or Class L					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Radwaste Building HVAC System (VRS) Location: Radwaste Building								
–	HEPA Filters	R	NNS	ANSI N509	B	Controlling the level of radioactivity released to the environment.	3	HEPA filtration is located on the VRS discharge line to capture potential airborne particulate containing radioactivity.
–	Radwaste Bldg Exhaust Radiation Package	E	NNS	M/f Std	C	Monitoring the level of radioactivity released into the environment.	3	The system exhaust is provided with a radiation monitor to record and alarm release of radioactive effluent.
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Fire Damper	E	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas in the radwaste building.
–	Air Handling Units	L	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Filters	L	NNS	UL 900				
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class E or Class L								
Turbine Building Ventilation System (VTS) Location: Turbine Building								
–	Shutoff, Isolation, and Balancing Dampers	L	NNS	ANSI / AMCA500	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Fire Dampers	D	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas in the turbine building.
–	Air Handling Units w/ Filters	L	NNS	M/f Std, UL-900	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class L					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Containment Leak Rate Test System (VUS) Location: Auxiliary Building								
VUS-PL-V015	Main Equipment Hatch Test Connection	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The identified valves and hatches form part of the primary containment boundary.
VUS-PL-V016	Maintenance Equipment Hatch Test Connection	B	I	ASME III-2				
–	Personnel Hatch Test Connections	B	I	ASME III-2				
VUS-PL-V023	Fuel Transfer Tube Test Connection	B	I	ASME III-2				
–	Electrical Penetration Test Isolation Valves	B	I	ASME III-2				
–	Spare Penetration Test Connection	B	I	ASME III-2				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Central Chilled Water System (VWS) Location: Various								
VWS-MS02 and -MS03	Air Cooled Chiller MS02 and MS03	D	NNS	M/f Std	C	Provide long-term support of a Category A or B function.	3	The VWS provides a source of chilled water to the VBS supply air handling units that are used to maintain the MCR and Class 1 electrical room passive heat sink temperatures within their normal design temperature range. The VWS provides chilled water to the VAS pump room unit coolers which support operation of the RNS and CVS pumps.
VWS-MP02 and –MP03	Pumps	D	NNS	M/f Std				
VWS-MT-04	Tanks	D	NNS	ASME VIII				
VWS-MT-05	Air Cooled Chiller Chemical Add Tank	D	NNS	ASME VIII				
–	Valves Providing VWS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
VWS-PY-C01	Containment Chilled Water Supply Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
VWS-PY-C02	Containment Chilled Water Return Penetration	B	I	ASME III, MC				
VWS-PL-V053	Containment Penetration Thermal Relief Valve	C	I	ASME III-3	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
VWS-PL-V057	Containment Penetration Thermal Relief Valve	C	I	ASME III-3				
VWS-PL-V058	Fan Coolers Supply Containment Isolation	B	I	ASME III-2				
VWS-PL-V062	Fan Coolers Supply Containment Isolation	B	I	ASME III-2				
VWS-PL-V080	VWS Containment Isolation Relief Valve	B	I	ASME III-2				
VWS-PL-V082	Fan Coolers Return Containment Isolation	B	I	ASME III-2				
VWS-PL-V086	Fan Coolers Return Containment Isolation	B	I	ASME III-2				
VWS-PL-V424	Containment Penetration Test Connection	B	I	ASME III-2				
VWS-PL-V425	Containment Penetration Test Connection	B	I	ASME III-2				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Annex/Auxiliary Building Nonradioactive Ventilation System (VXS) Location: Auxiliary Building and Annex Building								
–	Air Handling Unit Fans Providing AP1000 Equipment Class D Function	D	NNS	AMCA	C	Provide long-term support of Category A or B functions.	3	These components support operation of ZOS by maintaining the diesel bus switchgear rooms and battery charger rooms (containing dc switchgear) within their design temperature range.
–	Dampers Providing VXS AP1000 Equipment Class D Function	D	NNS	ANSI / AMCA500				
–	Exhaust Fan Providing Ancillary Diesel Room Ventilation	D	NNS	AMCA	C	Provide long-term support of Category A or B functions.	3	These components support operation of ZOS by maintaining the diesel bus switchgear rooms and battery charger rooms (containing dc switchgear) within their design temperature range.
–	Fire Dampers	D	NNS	UL-555 or UL-555S	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas in the diesel generator building, which contains equipment supporting Class 2 safety functions.
–	Air Handling Units	L	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Filters	L	NNS	UL 900				
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class E or Class L								
Hot Water Heating System (VYS) Location: Various								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Diesel Generator Building Heating and Ventilation System (VZS) Location: Diesel Generator Building								
–	Unit Heaters Providing AP1000 Equipment Class D Function	D	NNS	UL-1025; NFPA 70	C	Provide long-term support of Category A or B functions.	3	The equipment maintains ambient temperature within the diesel generator rooms and the electrical equipment service modules to ensure equipment operation and reliability during periods of diesel generator operation.
–	Fans Providing AP 1000 Equipment Class D Function	D	NNS	AMCA				
–	Dampers Providing VZS AP1000 Equipment Class D Function	D	NNS	AMCA				
–	Fire Dampers	D	NNS	UL-555	B	Protecting against internal/external hazards that could, as part of a sequence of failures, result in loss of one of the safety functions, for example preventing fire spread.	3	Fire dampers are provided to prevent fire spread outside of the designated fire areas in the diesel generator building, which contains equipment supporting Class 2 safety functions.
–	Air Handling Units	L	NNS	M/f Std	GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
–	Filters	L	NNS	UL 900				
–	Fans, Ductwork	L	NNS	SMACNA				
Balance of system components are Class E								

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Gaseous Radwaste System (WGS) Location: Auxiliary Building								
–	Gas Cooler	D	NNS	ASME VIII/ TEMA	B	Prevention of the release of radioactive waste material from onsite storage facilities.	2	This is a radioactive waste processing system which is considered a plant storage/treatment facility. This system is designed to prevent the release of radiation.
–	Sample Pumps	D	NNS	M/f Std				
–	Guard and Delay Beds	D	NNS	ASME VIII				
–	Moisture Separator	D	NNS	ASME VIII				
–	Valves Providing WGS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
Liquid Radwaste System (WLS) Location: Containment, Auxiliary, and Radwaste Buildings								
–	Heat Exchangers, WLS and CCS Side	D	NNS	ASME VIII/ TEMA	B	Prevention of the release of radioactive waste material from onsite storage facilities.	2	This is a radioactive waste processing system which is considered a plant storage/treatment facility. This system is designed to prevent the release of radiation.
–	Pumps	D	NNS	M/f Std				
–	Tanks	D	NNS	ASME III without Code Stamp				
–	Degasifier	D	NNS	ASME VIII				
–	Ion Exchangers	D	NNS	ASME VIII				
–	Filters	D	NNS	ASME VIII				
–	Pulse Dampers	D	NNS	M/f Std				
–	Leak Chase Collection Pots	D	NNS	ASME VIII				
–	Vapour Condenser	D	NNS	ASME VIII TEMA-C	B	Prevention of the release of radioactive waste material from onsite storage facilities.	2	This is a radioactive waste processing system which is considered a plant storage/treatment facility. This system is designed to prevent the release of radiation.
–	Valves Providing WLS AP1000 Equipment Class D Function (local drain valves in Radwaste Building)	D	NNS	ANSI 16.34				
WLS-PL-V055	Sump Discharge Containment Isolation IRC	B	I	ASME III-2	A	Prevention of the release of radioactive material from the containment.	1	The isolation valves are the principal means of fulfilling the safety function.
WLS-PL-V057	Sump Discharge Containment Isolation ORC	B	I	ASME III-2				
WLS-PL-V058	WLS Containment Isolation Relief Valve	B	I	ASME III-2				
WLS-PL-V067	RCDT Gas Outlet Containment Isolation IRC	B	I	ASME III-2				
WLS-PL-V068	RCDT Gas Outlet Containment Isolation ORC	B	I	ASME III-2				

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Liquid Radwaste System (WLS) Location: Containment, Auxiliary, and Radwaste Buildings (cont.)								
WLS-PL-V071A	CVS Compartment to Sump	C	I	ASME III-3	A	Protecting SSCs from internal/external hazards that would directly and inevitably result in the loss of a principal means of fulfilling a Category A safety function.	1	During a DBA, it is necessary to prevent premature flooding of the PXS compartment and the CVS compartment. The drain line from each of these compartments to the sump has two check valves in series. These check valves prevent reverse flow through the drain lines which could cause premature cross flooding.
WLS-PL-V071B	PXS A Compartment to Sump	C	I	ASME III-3				
WLS-PL-V071C	PXS B Compartment to Sump	C	I	ASME III-3				
WLS-PL-V072A	CVS Compartment to Sump	C	I	ASME III-3				
WLS-PL-V072B	PXS A Compartment to Sump	C	I	ASME III-3				
WLS-PL-V072C	PXS B Compartment to Sump	C	I	ASME III-3				
–	PXS & CVS Compartment Drains	C	I	M/f Std				
WLS-MY-Y34	Containment Sump Stilling Well	D	I	M/f Std	B	Functions that continuously monitor the availability of Category A safety functions for proper operation or to alert control room staff of their failures.	2	Supports monitoring a Category A safety function; the sump instruments are the primary means for monitoring the Category A safety function. Although they are classified as Safety Class 2 based on their function, these components are designed Seismic Category I because they ensure sump level sensors (which detect leakage) remain functional when subjected to safe shutdown earthquake.
WLS-MY-Y35	Containment Sump Stilling Well	D	I	M/f Std				
WLS-MY-Y36	Containment Sump Stilling Well	D	I	M/f Std				
WLS-PY-C02	Reactor Coolant Drain Tank WLS Connection Penetration	B	I	ASME III, MC	A	Prevention of the release of radioactive material from the containment.	1	Each containment penetration provides a principal means of maintaining containment integrity.
WLS-PY-C03	Containment Sump Pumps Combined Discharge Penetration	B	I	ASME III, MC				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Radioactive Waste Drain System (WRS) Location: Auxiliary Building								
–	Pumps	D	NNS	M/f Std	B	Prevention of the release of radioactive waste material from onsite storage facilities.	2	This is a radioactive waste processing system which is considered a plant storage/treatment facility. This system is designed to prevent the release of radiation.
–	Drains	D	NNS	M/f Std				
–	Leak Chase Collection Pots	D	NNS	ASME VIII				
–	Pulse Dampers	D	NNS	M/f Std				
–	Valves Providing WRS AP1000 Equipment Class D Function	D	NNS	ANSI 16.34				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Solid Radwaste System (WSS) Location: Auxiliary Building								
–	Pumps	D	NNS	M/f Std	B	Prevention of the release of radioactive waste material from onsite storage facilities.	2	This is a radioactive waste processing system which is considered a plant storage/treatment facility. This system is designed to prevent the release of radiation.
–	Tanks	D	NNS	ASME VIII				
WSS-MV-03	Resin Fines Filter	D	NNS	ASME VIII				
–	Valves Providing WSS AP1000 Equipment Class D Function	D	NNS	ANSI B16.34				
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-1. AP1000 UK Categorisation and Classification of Mechanical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category	Safety Function(s) Provided by the SSC	UK Safety Class	Justification of the Safety Class
Waste Water System (WWS) Location: Various								
WWS-PL-V506	MCR WWS Isolation Valve	C	I	ASME III-3	A	Maintaining habitability of the MCR.	1	The isolation valves are the principal means of isolating the MCR envelope during VES operation.
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Onsite Standby Power System (ZOS) Location: Diesel Generator Building								
ZOS-MS-05A/B	Diesel Generator Engines	D	NNS	M/f Std	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	The onsite diesel generators have been identified as important to safety. These SSCs provide standby power for supplementary decay heat removal functions. This does not represent the principal means of decay heat removal.
–	Diesel Generator Starting Units	D	NNS	M/f Std				
–	Diesel Generator Radiators	D	NNS	CAGI				
–	Diesel Generator Silencers	D	NNS	API 661	GNS	No nuclear safety implications.	GNS	The silencers do not support the Class 2 function of the standby diesels as they are designed for occupational noise abatement. This class assumes no credible failure mode can result in exhaust path restrictions that affect diesel operation.
–	Valves Providing ZOS Diesel Generator Engines AP 1000 Equipment Class D Function	D	NNS	ANSI 16.34	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	The onsite diesel generators have been identified as important to safety. These SSCs provide standby power for supplementary decay heat removal functions. This does not represent the principal means of decay heat removal.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Notes:

1. Component performs a safety-related function equivalent to **AP1000** equipment Class C. The component is constructed using the standards for Class R and a quality assurance program in conformance with 10 CFR Part 50 Appendix B.
2. The equipment is generally of rugged construction and the seismic design requirements are limited to the anchorage of the equipment and layout review to preclude failure due to seismic interactions.

Table 15A-2. AP1000 UK Categorisation and Classification of Electrical SSCs

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Main AC Power System (ECS) Location: Various								
–	RCS switchgear	C	I	ANSI/NEMA/UL/ NEC IEEE 323, 344, 382 10 CFR 21	A	Prevention of the release of radioactive material through the boundary of the RCS. Control of core reactivity during normal operation and accident conditions.	1	Principal means of reactor shutdown and core reactivity control.
–	Bus ES-1 and ES-2	D	II	ANSI/NEMA/UL/ NEC IEEE242, 317,336	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	Buses support power delivery associated with the ZOS. This is considered a function important to safety.
–	Ancillary Diesel Generators	D	Note 2		B	Reduce the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident. Prevention of the release of radioactive material from the containment.	2	Ancillary diesels provide for alternate power generation for post-72 hour operation and supplement the function of containment heat removal. This component reduces the probability that offsite SSCs would be needed to support post 72 hour actions.
–	Equipment associated with connection to ZBS	E	NNS		C	Power for normal operations to support removing nuclear heat from the reactor is provided via the ECS.	3	ECS is the principal means of providing plant power during normal operations.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Class 2 DC and Uninterruptible Power Supply System (EDS) Location: Various								
–	EDS Equipment supporting AP1000 Class D Function	D	NNS	ANSI/NEMA/UL/ NEC IEEE141, 242, 336,450, 484, 485, 944, 946	B	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	Supports control power and monitoring instrumentation, as well as hydrogen igniters which are only required in a beyond DBA, providing diverse means of hydrogen dispersion to catalytic converters.
-	EDS Battery Monitors	E	NNS	IEEE 1491	C	Functions to monitor the availability of the batteries.	3	Principal means to fulfil the safety function.
Communication Systems (EFS) Location: Various								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Grounding and Lightning Protection System (EGS) Location: Various								
System components are Class E					C	EGS provides hazard protection of plant SSCs required for removal of nuclear heat during operations.	3	EGS is the principal means of providing earthing and lightning protection.
Special Process Heat Tracing System (EHS) Location: Various								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-2. AP1000 UK Categorisation and Classification of Electrical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Plant Lighting System (ELS) Location: Various								
–	Emergency Lighting, MCR and Remote Shutdown Workstation	D	II	Industry Standard	A	Maintaining habitability of the MCR.	2	Provides control room lighting in the event of loss of normal power.
-	Fuel Handling Area Emergency Lighting	D	II	Industry Standard	A	Allow placement of fuel in a safe location	2	Enables recovery actions.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Cathodic Protection System (EQS) Location: Various								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Class 1E DC and UPS System (IDS) Location: Various								
–	Batteries, Chargers, UPS	C	I	IEEE 323, 344, 382	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions). Prevention of the release of radioactive material from the containment. Prevention of the release of radioactive material through the boundary of the RCS. Control of core reactivity during normal operation and accident conditions. Maintaining habitability of the MCR. C&I systems required to automatically actuate or provide manual actuation (where this is the only means of actuation) for SSCs delivering other Category A functions.	1	Provides the principal means of fulfilling the safety function. Segregation of four systems. Redundant bank of batteries and associated monitoring.
–	Battery Monitoring System	E	II	ANSI/NEMA/UL/ NEC	C	Functions to monitor the availability of the Class 1 batteries.	3	Provides the principal means of fulfilling this safety function.
Balance of system components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Plant Security System (SES) Location: Various								
–	Access control system	E	NNS	Industry Standard	C	Functions that provide access control to the nuclear power plant.	3	Provides the principal means of fulfilling the safety function.
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Table 15A-2. AP1000 UK Categorisation and Classification of Electrical SSCs (cont.)

Tag Number	Description	AP1000 Class	Seismic Category	Principal Design Code	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Closed Circuit TV System (Nuclear Operations) (TVS) Location: Various								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Main Generation System (ZAS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Transmission Switchyard and Offsite Power System (ZBS) Location: Yard								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.
Onsite Standby Power System (ZOS) Location: Yard								
–	Class D Function of the ZOS	D	NS	ANSI/NEMA/UL/ NEC IEEE242, 317,336	A	Removal of decay heat from the reactor coolant during normal operation and accident conditions (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation and accident conditions).	2	Diesels only required in the event of loss of grid connections, and only in the event of an accident requiring use of the containment cooling system. 72 hour grace time, following loss of AC supplies, before diesels are required. This gives time to restore grid connection or connect portable, engine-driven generators to the safety-related connection.
Excitation and Voltage Regulation System (ZVS) Location: Turbine Building								
System components are Class E					GNS	No nuclear safety implications.	GNS	SSCs are not designed or considered in the application of a safety function.

Notes:

1. The principal design codes and standard provided in this table are associated with the AP1000 standard plant design. As deemed appropriate, corresponding IEC standards will be supplemented in place of the listed design standard.

2. The equipment is generally of rugged construction and the seismic design requirements are limited to the anchorage of the equipment and layout review to preclude failure due to seismic interactions.

Table 15A-3. AP1000 UK Categorisation and Classification of C&I SSCs

System Function or Equipment	Applicable IEC Standards	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Protection and Safety Monitoring System (PMS)					
Reactor Trip Functions	60880 61513 61226 60987	A	PMS initiates functions required to reach the nonhazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Initiates reactor trip when plant conditions reach specified limits.	1	PMS is the primary C&I system to initiate a reactor trip.
Engineered Safety Features	60880 61513 61226 60987	A	PMS initiates functions required to reach the nonhazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Actuates engineered safety features to limit the consequences of DBAs.	1	PMS is the primary C&I system to initiate engineered safety functions such as containment isolation, decay heat removal, and safety injection.
Diverse Actuation System (DAS)					
Reactor Trip Functions	61513 61508 61226	A	DAS initiates functions required to reach the nonhazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Initiates reactor trip when plant conditions reach specified limits.	2	DAS is the diverse C&I system to initiate a reactor trip.
Engineered Safety Features	61513 61508 61226	A	DAS initiates functions required to reach the nonhazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Actuates engineered safety features to limit the consequences of DBAs.	2	DAS is the diverse C&I system to initiate engineered safety functions such as containment isolation, decay heat removal, and safety injection.
Plant Control System (PLS)					
Reactor Power Control	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	PLS monitors the neutron flux and reactor core outlet temperatures and automatically controls the reactivity to maintain a proper magnitude and distribution of fission energy production during startup and power production.

System Function or Equipment	Applicable IEC Standards	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Plant Control System (PLS) (cont.)					
Rod Control	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	The PLS controls movement of the control rods during plant startup and power production.
Pressuriser Pressure and Level Control	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	PLS monitors and controls RCS pressure to maintain the pressure within the design limits and provides for the proper system pressure during power production. PLS maintains pressuriser level during heatup and cooldown and in the event of a minor RCS leakage to maintain reactor coolant inventory.
Steam Generator Water Level Control	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	PLS monitors and controls the steam generation process to maintain an adequate water level inside the steam generators during power production. PLS controls steam generator level to maintain heat removal from the RCS.
Steam Dump Control	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	PLS controls the steam dump valves to provide a rapid steam generator load demand upon loss of electrical load transients to match reactor power with steam demand during power production. PLS controls the steam dump valves to dissipate residual heat and core decay heat during reactor shutdown.
Rapid Power Reduction	61513 62138 61226 60987	B	Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis.	2	PLS initiates a rapid insertion of negative reactivity upon loss of electrical load transient to match reactor power with steam demand during power production.

Balance of Plant Controls	61513 62138 61226 60987	C	The balance of the PLS provides monitoring and control functions that are important to plant startup, power production, and shutdown.	3	The balance of the PLS provides monitoring and control functions that are important to plant startup, power production, and shutdown.
Operation and Control Centre System (OCS)					
Hardware required for Manual Reactor Trip and Manual Engineered Safety Features for PMS Reactor Trip and ESF Displays for PMS	60880 61513 61226 60987	A	Required to provide information and control capabilities that allow specified manual actions necessary to reach the nonhazardous stable state.	1	The OCS provides the primary hardware used to manually initiate and monitor Class 1 SSCs.
Hardware required for Manual Reactor Trip and Manual Engineered Safety Features for DAS Reactor Trip and ESF Displays for DAS	61513 62138 61226 60987	A	Required to provide information and control capabilities that allow specified manual actions necessary to reach the nonhazardous stable state.	2	The OCS provides the human interface design as well as the location and mounting arrangement for the operator interface equipment necessary to support defence in depth safety functions.
Hardware required for Post-accident Monitoring System Functions from PMS and RMS	60880 61513 61226 60987	B	Required to provide information that allows specified manual actions necessary after the nonhazardous stable state has been reached to prevent a DBA from leading to unacceptable consequences, or mitigate the consequences.	2*	*The Qualified Data Processing System provides displays of Category 1 post-accident monitoring system variables. This hardware will be implemented as Class 1.
Software required for Post-accident Monitoring System Functions from PMS and RMS	61513 62138 61226 60987	B	Required to provide information that allows specified manual actions necessary after the nonhazardous stable state has been reached to prevent a DBA from leading to unacceptable consequences, or mitigate the consequences.	2	The software that supports the Qualified Data Processing System, the principal means of providing the operator post-accident monitoring information.
Balance of Operator Displays and Controls	61513 62138 61226 60987	C	Provide continuous or intermittent monitoring and control capabilities for normal operation.	3	The OCS provides the human interface design as well as the location and mounting arrangement for the operator interface equipment necessary to support normal plant operations.

Table 15A-3. AP1000 UK Categorisation and Classification of C&I SSCs (cont.)

System Function or Equipment	Applicable IEC Standards	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Main Turbine Control and Diagnostics System (TOS)					
Turbine Control	61513 62138 61226 60987	C	The TOS supports removing nuclear heat from the reactor during normal operation. Failure of this system can result in a power manoeuvre thus affecting nuclear safety.	3*	*The TOS provides the primary means of controlling the turbine generator. It supports such functions as turbine trip and overspeed protection. Due to its importance to power production and equipment protection this system will be implemented as a Class 2 system.
In-core Instrumentation System (IIS)					
Core Exit Temperature Measurements used by PMS for Post-Accident Monitoring	60880 61513 61226 60987	B	Required to provide information that allows specified manual actions necessary after the nonhazardous stable state has been reached to prevent a DBA from leading to unacceptable consequences, or mitigate the consequences.	2*	*Core exit temperature measurements are not used for reactor trip or engineered safety feature functions. Some of the measurements are inputs to the PMS system for post-accident monitoring. These sensors are implemented as Class 1 as identified in the applicable IEC standards column.
Balance of Core Exit Temperature Measurements	61513 62138 61226 60987	B	Required to provide information that allows specified manual actions necessary after the nonhazardous stable state has been reached to prevent a DBA from leading to unacceptable consequences, or mitigate the consequences.	2	The core exit temperature measurements are provided to DAS for display and monitoring of post-accident core cooling. The purpose of providing core exit temperature measurements to DAS is to provide information to the reactor operator to monitor core cooling as a basis for manual actuation of the ADS during post-accident conditions.
Core Flux Measurements	61513 62138 61226 60987	C	Provides continuous monitoring of Category B function (reactor power control) to indicate the continued availability for operation and alert control room staff.	3	The IIS provides online neutron flux data. This data is used to generate a 3-D indication of the core power distribution.
Special Monitoring System (SMS)					
Digital Metal Monitoring	61513 62138 61226 60987	C	Monitor for the occurrence of and alert personnel to take mitigating actions for abnormal events.	3	The SMS provides plant personnel with information pertaining to the presence and general location of loose parts or abnormal structural conditions in the RCS.
Reactor Coolant Pump Vibration Monitoring	61513 62138 61226 60987	C	Monitor for the occurrence of and alert personnel to take mitigating actions for abnormal events.	3	The primary purpose of the reactor coolant pump vibration monitoring system is to provide early detection of abnormal vibration levels of the reactor coolant pumps to avoid or mitigate damage.

Table 15A-3. AP1000 UK Categorisation and Classification of C&I SSCs (cont.)

System Function or Equipment	Applicable IEC Standards	UK Safety Category of the Function Provided by the SSC	Safety Function(s) Provided by the SSC	UK Safety Class of the SSC	Justification of the Safety Class
Radiation Monitoring System (RMS)					
Containment High Range	60880 61513 61226 60987	A	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment.	1	There are four trains for the containment high range radiation detectors which measure the containment area radiation. Inputs from the RMS provide radiation signals to PMS for processing. When a predetermined setpoint is exceeded on the high range detectors, PMS will isolate containment.
MCR HVAC	61513 62138 61226 60987	A	Maintaining habitability of the MCR.	1	The MCR supply duct is monitored for particulates, iodines, and noble gas. Inputs from the RMS provide radiation signals to PMS. When a predetermined setpoint is exceeded on the noble gas channel, PMS will initiate the supplemental air filtration system. When a predetermined setpoint is exceeded on the particulate or iodine channel, PMS will isolate the MCR and initiate VES.
Balance of System Functions	61513 62138 61226 60987	C	Monitoring radioactivity released into the environment.	3	Radiation detection signals from the RMS to PLS are used to process various plant control functions such as valve control, pump operation, as well as pressure and flow control functions.

16 CIVIL ENGINEERING

16.1 INTRODUCTION

The AP1000 nuclear power plant, including its civil engineering aspects, has been designed with the intent that it can be constructed and operated at a wide range of potential sites throughout the world. In particular, the design has specifically addressed construction at any potential location within the eastern and central United States (US), demonstrating a capability for withstanding a wide range of different environments and site conditions more onerous than would be present at potential AP1000 plant sites in the United Kingdom (UK).

The AP1000 design is founded on international nuclear safety practices and needs to be demonstrated as safe in the UK, taking into account UK-established nuclear safety practices consistent with the safety assessment principles (SAPs) (Reference 16.1) considered by the UK Nuclear Regulator when making licensing decisions. The international civil engineering case is, on many occasions, more demanding than needed to satisfy UK requirements. This is because of the more benign environments at potential sites in the UK compared with those at the potential locations considered in the design (see Chapter 12, External Hazards). However, the absence of a prescriptive regulatory regime in the UK means that it is necessary to present the evidence that underpins the AP1000 design within a new logical framework that is consistent with the UK regulatory approach.

This chapter describes the civil engineering design of the AP1000 plant structures for a set of environmental conditions established by site interface parameters shown in Table 16-3. It justifies the AP1000 design assuming a site defined by the site interface parameters. Chapter 12 demonstrates that the UK sites are expected to be bounded by these interface parameters.

Once a specific site is decided upon for an AP1000, a site characterisation evaluation against the current plant design will set the design limits for that project.

This chapter addresses the expectations of the UK Regulator for the justification of the civil engineering structures. It makes extensive reference to relevant Westinghouse design documentation.

The civil engineering structures have been designed for rapid construction by making maximum use of offsite fabricated steel modules, which are subsequently filled with concrete when located onsite, rather than conventional, cast-in-place, reinforced concrete. Instead of fixing reinforcement bars and pouring concrete between shuttering, concrete is placed between two steel plates to form a module wall; these plates provide the reinforcement and act as shuttering. This form of construction, called steel-concrete composite (SC) construction, is unconventional in the UK for nuclear power station construction. Therefore, the justification for SC structures has been considered in particular detail. The design reports for the enhanced shield building and the response to RI-AP1000-02 provide justification of the design approach (References 16.3, 16.4, 16.39, 16.40, and 16.41). The civil engineering design and safety justification has proceeded in accordance with criteria developed for the AP1000 design that are recorded in a number of documents.

16.1.1 Purpose

The civil engineering structures are required to provide structural support to the structures, systems, or components (SSCs), including supporting systems, that enable safe nuclear power generation. Loads from normal operations, fault conditions, maintenance activities,

construction, and decommissioning must be safely transferred from each SSC attached to the civil engineering structure to a foundation of suitable strength and rigidity.

In addition to providing structural support, the civil engineering structures need to act as suitable barriers. Examples of barrier functions are the retention of liquids, protection from the weather, radiation shielding, prevention of the spread of fire and the control of accidentally generated missiles so that they do not cause significant harm. This chapter addresses all these barrier functions with the exceptions of the radiation shielding, which is addressed in Chapter 24; and fire resistance, which is addressed in Chapter 11.

An earthquake causes vibrations that will pass through the civil engineering structures and cause the SSCs that make up the nuclear power plant to experience dynamic loads. In addition to demonstrating seismic integrity, the civil engineering structures need to be suitably analysed for the seismic motions at SSC support points to be defined. The SSCs can then be analysed to determine seismic responses.

Nuclear safety functions placed on the civil engineering structures are addressed by demonstrating that the civil structures will withstand the loads arising from normal operations, internal hazards, external hazards, and internal plant faults. The structures need to be appropriately constructed and shown not to suffer any significant deterioration through life. The evidence needed to support a nuclear safety function depends on the significance of the safety function with regards to nuclear safety.

Safety functions are categorised according to safety importance of the contribution made by an SSC in meeting the function classified. The categorisation and classification process is explained in Chapter 5. The approach to the justification of the civil engineering structures takes into account the category and class assigned to a structure. The nuclear island houses the SSCs of greatest safety significance, and therefore the nuclear island civil engineering structures are assigned Category A safety functions and are Class 1. They are justified to withstand the most severe hazards using the most reliable methods adopted for the plant civil engineering structures.

The objective of this chapter is to provide evidence that the designs of the civil engineering structures deliver the necessary nuclear safety functions in an appropriate manner, depending on the safety function category and the civil engineering class. The level of information provided is commensurate with the safety significance of the structure. The nuclear island structures, which house the Class 1 safety systems, are reported in most detail.

16.1.2 Scope

This chapter is limited to addressing the following civil engineering structures that have been assigned nuclear safety functions.

- Containment internal structures
- Shield building
- Auxiliary building
- Nuclear island foundation
- Annex building
- Diesel generator building
- Radwaste building
- Turbine building
- SWS (service water system) cooling towers

This chapter addresses the effects of normal operations, internal plant faults, internal hazards, external hazards, and life cycle engineering for the above structures. Safety functions are categorised and the role of an SSC in meeting this function is classified as explained in Section 16.3. Structures are assigned a seismic category depending on the performance required following an earthquake. Sections 16.4 and 16.5 include explanations to justify that the hazards, codes, and standards considered in the design are appropriate for each civil engineering structure, depending on the safety function, class, and seismic category.

The containment vessel itself is outside the scope of this chapter, as this is considered to be a vessel justified in Appendix 20K. Equipment design is outside the scope of this chapter. The interface between civil engineering structures and internal equipment occurs at the support point. Items encasted in concrete are considered to be part of the civil engineering structure whereas any protrusions for the purpose of supporting equipment are justified as part of the equipment justification.

16.1.3 Format

The evidence needed to support construction in the UK exists and has been documented as part of the generic AP1000 design and licensing process. As noted previously, this chapter presents this information within a framework compatible with the UK regulatory regime. This chapter utilises the information in the AP1000 criteria documents and summaries of the global analyses. Other equally important references referred to are the design report for the AP1000 enhanced shield building (Reference 16.3) and the response to RI-AP1000-02 (Reference 16.4, 16.39, 16.40, and 16.41). Detailed technical information, tabulations, and figures in these documents are referenced within this chapter without being reproduced.

16.1.4 Structural Descriptions and Layouts

General descriptions of the structures identified in Section 16.1.2 are presented in Section 6.11. More detailed civil/structural information is provided in this chapter.

Figures 16-1 and 16-2 show the general arrangements of an AP1000 plant and the locations of systems within the civil engineering structures. For the generic design, it is assumed that the north/south axis runs parallel with the longitudinal axis of the turbine building. The radwaste building is located to the south of the auxiliary building and the turbine building is located to the north.

The details of the major structures are given in References 16.48 through 16.86. The plant was originally designed to US customary units with grade level defined as 100'-0". This PCSR uses metric units and the grade level is taken as +100.000 m.

16.1.5 Interfaces

The internal and external hazards assessments (Chapters 11 and 12) define events that lead to loads being placed on the civil structures. Normal operations and fault conditions also place loads on the civil engineering structures.

16.1.5.1 Normal Operations and Internal Plant Faults

The civil engineering structures are required to support the vessels, pipework, cable trays, mechanical plant, and electrical equipment during normal operations. If internal faults occur in the plant, additional demands can be placed upon the civil engineering structures. Loads relating to normal operations and internal plant faults have been considered as explained in Section 16.7.

16.1.5.2 Internal Hazards

The requirements have been identified for the walls and floors forming the rooms contained within the nuclear island to act as barriers against relevant internal hazards. This information has been presented in the form of a barrier matrix (Reference 16.9). PCSR Chapter 11 identifies claims with respect to the civil engineering structures. The civil engineering design criteria address loads arising from the following internally generated hazards:

- Flooding
- Fire
- Pressure part failure (PPF)

The layout and the structural design for the loads specified in Reference 16.6, including requirements for radiation shielding and for the external hazards, provide inherent protection for other internal hazards. The justification of adequately designed barriers against internal hazards is provided in Chapter 11. The provision of barriers for radiation shielding is considered in Chapter 24.

16.1.5.3 External Hazards

Chapter 12 derives magnitudes of external hazard events appropriate to the AP1000 plant UK generic safety case. The events considered are typical upper-bound events, which will need to be confirmed in UK site-specific studies. Chapter 12 compares these events with the external hazards addressed by the design. The responses of the civil engineering structures to external hazards are considered in Section 16.4.

16.2 SITE CHARACTERISTICS

The site-related parameters for which the plant has been designed are given in Chapter 4; those affecting the civil engineering structures are shown in greater detail in Table 16-3. These parameters reflect potential bounding site characteristics for possible worldwide AP1000 plant sites. In the UK context, these site parameters and conditions represent the envelope beyond which additional validation would be required.

In general, the sources of the site parameters and conditions presented in Chapter 4 are irrelevant to the UK justification. What is required is a demonstration that the parameters and conditions associated with any particular UK site at which a plant is to be built will not fall outside this envelope. If parameters and conditions fall outside this envelope, then further justification will be required to demonstrate that the design is acceptable. The demonstration that site-specific data falls within the acceptable envelope will be addressed during site licensing.

Although UK site-specific data is not available for GDA submissions, it is often possible, using general data for potential plant locations in the UK, to show the margins that exist

between potential natural hazards in the UK and those for which the plant has been designed. Chapter 12 (External Hazards) presents such comparisons.

16.3 UK CATEGORISATION AND CLASSIFICATION APPLIED TO THE CIVIL ENGINEERING STRUCTURES

A method for the categorisation of safety functions and classification of SSCs has been developed and is presented in Chapter 5. Structures are also assigned a seismic category depending on their required performance during and following a seismic event. The seismic categories are discussed in the following sections.

16.3.1 Seismic Category I

Seismic category I (C-I) structures have both functional and integrity requirements placed upon them. The main seismic functional requirement is to respond to an earthquake in a manner that can be defined so that an SSC that relies on the structure for support can be seismically justified. Other functional requirements may also need to be justified, such as providing a substantially watertight barrier during and following a seismic event.

16.3.2 Seismic Category II

If failure of a structure (not classed as C-I) can result in an unacceptable interaction with a Class 1, C-I SSC, or another seismic category II (C-II) SSC, or cause an incapacitating injury to occupants of the control room, then the structure is designated as C-II. C-II structures are justified as having appropriate integrity but provision of functionality is not required.

16.3.3 Seismic Category Non-Nuclear Seismic

All UK Class 2 and 3 structures for which failure can be accepted, allowing for all reasonably possible modes of failure, are designated as seismic category non-nuclear seismic (NNS). Even though a structure has been assigned as NNS, a seismic justification is undertaken. This is because a plant could be located in a seismic zone where normal industrial practice would be to provide some form of seismic protection to all new structures. For the standard plant these structures are designated as seismic category III (C-III).

16.3.4 AP1000 Structures

The functional and integrity requirements for C-I structures are met by ensuring full compliance with the codes and standards referred to in Section 16.5.1. C-II structures are designed to the same codes and standards as C-I to conservatively ensure no unacceptable adverse interaction with a Category A safety function.

In the UK, civil engineering structures have been categorised according to their safety function and have been classified according to their significance in delivering this function. The seismic categories assigned to the AP1000 structures are shown in Table 16-1.

The nuclear island structures house SSCs that provide the principal means of delivering the Category A safety functions. These functions must be delivered to achieve and maintain a safe, stable state for 72 hours from the initiating event for design basis accidents (DBAs). The primary civil engineering structures that make up the nuclear island are designated as A1 and C-I (A1 refers to a Category A safety function and Class 1 contribution to this safety function in accordance with Chapter 5).

The first bay of the turbine building, the diesel generator building, and the SWS cooling towers contain active systems that deliver Category A functions. The systems in these structures provide an alternative means of delivering the functions provided by the Class 1 components. These Class 2 components make a significant contribution to delivering Category A safety functions but are not the principal means of achievement. Therefore these structures are designated as A2. The first bay of the turbine building is C-II to prevent adverse interaction with the nuclear island. The remaining structures housing Class 2 components are assigned to the NNS category. The turbine building north of the first bay closest to the nuclear island is C3 and NNS.

Immediately adjacent to the nuclear island, the annex building is of multi-storey construction, with the potential for undesirable interactions with the nuclear island; therefore, this multi-storey area of the annex building is C-II. The remaining single-storey area of the annex building, of lightweight construction, is Class general non-safety (GNS) and seismic category NNS.

Areas of the annex building contain SSCs that need to support Category A safety functions after 72 hours following an accident. Hazard protection in excess of that afforded by designing to normal industrial standards is deemed necessary to ensure equipment availability post-72 hours.

The radwaste building is Category B3 because the function of the equipment in the building is not nuclear safety-significant. It is seismic category NNS because seismic failure of the building would not be of any consequence for the functioning of the systems within the nuclear island.

16.4 DESIGN BASIS EXTERNAL HAZARDS

The magnitudes of external hazards in the UK are generally enveloped by those specified for the design (see Chapter 12). This section considers whether the designs of the civil engineering structures are conservative with regard to their responses to naturally occurring hazards defined by the site interface parameters. Only natural hazards are discussed in this chapter because manmade external hazards, originating from outside the nuclear site boundary (excluding malicious aircraft impact), are a site-specific issue to be addressed during site-specific licensing. Detailed information on the loads arising from external hazards is provided in Sections 16.7 and 16.8.

16.4.1 A1 Civil Engineering Structures – Nuclear Island

The external hazards that the nuclear island structures have been designed to withstand are shown in Table 16-3. In the UK, natural hazards are included in the design basis unless conservatively they have a predicted frequency of less than 1 in 10,000 year (Reference 16.1). The AP1000 design considers both severe operating events with a frequency of about 1 in 50 year as well as extreme environmental events with a frequency of about 1 in 10,000 year. In some cases, such as snow, design is based only on the severe condition since the load factors or allowable stresses and the load combinations used in the design are sufficient that these loads are more limiting than the extreme condition with unit load factor or allowable stresses up to yield.

This report uses the terminology from ACI 349 (Reference 16-15) and AISC N690 (Reference 16-24) to differentiate between the recurrence frequency of the hazards.

- Severe environmental loads are those that could infrequently be encountered during the plant life. These include the severe design wind and snow. The magnitudes correspond to the values that would be applicable to a commercial building at the same location.

- Extreme environmental loads are those which are credible but are highly improbable. These include the tornado and the SSE.

Chapter 12 compares the natural hazards for which the nuclear island structures have been designed with the natural hazards applicable in the UK using generic UK data. The natural hazards most likely to challenge the civil engineering structures are wind, extreme snow, tornadoes, and earthquakes.

16.4.1.1 Design Wind

The AP1000 plant is designed for the design wind (Reference 16.6) in accordance with ASCE 7 (Reference 16.20). The design wind is specified as a basic wind speed of 64.8 m/s (145 mph) with an annual probability of occurrence of 0.02 based on the most severe location in the United States identified in Reference 16.20 (wind speeds in the UK are generally lower as discussed in Chapter 12). This wind speed is the 3 second gust speed at 10.06 m (33 feet) above the ground in open terrain (Reference 16.20, exposure C). Higher winds with a probability of occurrence of 0.01 are used in the design of the nuclear island by using an importance factor of 1.15.

Velocity pressure exposure coefficients and gust response factors are calculated according to Reference 16.20 for exposure C, which is applicable to shorelines in hurricane prone areas. The topographic factor is taken as unity.

The design wind loads calculated as described above are considered as a severe environmental condition with appropriate load factors for concrete design and allowable stresses for steel design. Loads and load combinations are shown in Tables 3 and 4 of Reference 16.6.

16.4.1.2 Tornado

The nuclear island is designed for the design basis tornado (Reference 16.6) specified as follows:

- Maximum wind speed – 134.1 m/s (300 mph)
- Maximum rotational speed –107.3 m/s (240 mph)
- Maximum translational speed – 26.8 m/s (60 mph)
- Radius of maximum rotational wind from centre of tornado – 45.8 m (150 ft)
- Atmospheric pressure drop – 13.8 kPa (2.0 psi)
- Rate of pressure change – 6.9 kPa/s (1.2 psi/sec)

It is estimated that the probability of wind speeds greater than the design basis tornado is between 10^{-6} and 10^{-7} per year for an AP1000 plant at a "worst location" anywhere within the contiguous United States.

The exterior walls and roof of the nuclear island are designed to protect the nuclear island

against damage from the tornado missiles shown in Table 16-3.

Chapter 12 identifies that the tornadoes considered in the design are far more onerous than what could occur in the UK. The concrete is designed to ACI-349-01, which is acceptable UK practice (see Section 16.5.1.5); therefore, it can be concluded that the international design follows a very conservative approach with respect to tornadoes in the UK.

16.4.1.3 Snow

The AP1000 plant is designed for deep snow loads associated with a 1 in 50 year event (Reference 16.6) in accordance with ASCE 7 (Reference 16.20). The nuclear island roof is constructed from reinforced concrete at least 200 mm thick and is designed to resist a ground snow load of 3.6 kN/m^2 (75 lb/sq. ft) (Reference 16.6, Section 5.2.2B) using ultimate load factors of 1.4 and 1.7 for dead and live loads, respectively (Reference 16.6, Table 3). Snow is considered to be a live load as explained in Section 16.7.4.2; therefore, the auxiliary building roof provides a rugged barrier.

A study of the effects of automobiles acting as missiles during a tornado has been made (Reference 16.13). This study considered an 1814-kg (4000-lb) vehicle impacting the roof with a vertical velocity of 33 m/s (74 mph) with the vehicle assumed to be a soft missile impacting a rigid target. Noting this, if snow or icicles were to slide off the sloping roof of the shield building and impact the roof of the auxiliary building, it is to be expected that the effects on the roof would be bounded by the postulated vehicle impact.

16.4.1.4 Earthquake

The AP1000 standard plant is designed for a safe shutdown earthquake (SSE) defined by the US Certified Seismic Design Response Spectra (CSDRS) scaled to 0.3g zero period acceleration (ZPA). The response spectra are based on USNRC Regulatory Guide 1.60 (Reference 16.31) with additional amplification at 25 Hz. The horizontal and vertical spectra are shown in Figures 1 and 2 of Reference 16.7 for various damping values (the horizontal spectrum is shown in Figure 12C-1 for 5% damping). The horizontal and vertical components of the ZPA have been taken to be the same with both scaled to 0.3g for the SSE.

The AP1000 plant will be demonstrated to satisfy all seismic design acceptance criteria using the site-specific input. This demonstration may include a combination of comparisons of ground motion and soil conditions, and site specific analyses. The nuclear island has been designed to the CSDRS for a wide variety of soil conditions. It is therefore expected that the site specific demand will be lower than the standard plant design basis.

It is not expected that there will be significant changes for the AP1000 plant in the UK. The basic design will retain the existing design and hence retain the margins inherent in the enveloping parameters of the standard plant seismic design. Where design changes are required for other reasons, the revised design will be demonstrated to satisfy site-specific requirements.

16.4.2 A2 Civil Engineering Structures

The nuclear island houses the Class 1 passive safety components that have a low frequency of failure per demand. When designed to resist the same hazard, a single passive safety system will be more reliable than a single active safety system because the passive safety systems are of a simple design based on the application of the fundamental laws of physics. To benefit from this, it is deemed reasonable for the backup systems to be less reliable than those with

Class 1 components; therefore, the backup systems do not need to be designed to withstand hazard loadings as onerous as those specified for the design of the Class 1 components.

A2 civil engineering structures have been designed to withstand the same onerous extreme events as A1 only if their failure when subjected to such an event could cause an adverse interaction with an A1 system. When such a failure would not cause an adverse interaction, justification of A2 SSCs against natural hazards is only considered necessary from the point-of-view of investment protection and as low as reasonably practicable (ALARP), because the Class 1 components housed in the A1 nuclear island structure are capable of mitigating DBAs.

A2 structures may be C-II or seismic category NNS. Table 16-2 explains the logic behind the external hazard events addressed by the design and gives the underlying reasoning.

For A2 structures designated as C-II, the seismic motion used for the integrity justification is the same as the one used for C-I structures to provide the necessary consistency.

For A2 structures designated as seismic category NNS, the design is based on less onerous external hazard events than the 1 in 10,000 year events normally expected to be considered in the UK (Reference 16.1). The approach for each A2 structure is explained below with respect to the more significant natural hazards for the civil engineering design.

16.4.2.1 Turbine Building (A2 and C3)

The first bay of the turbine building on the side of the building closest to the nuclear island, south of grid line 11.2, is A2 and C-II. This houses Class 2 equipment associated with the component cooling and service water systems (CCS and SWS, respectively). The turbine building, apart from the first bay, is a C3 structure and is seismic category NNS. A seismic gap separates the A2 first bay from the C3 area.

The first bay of the turbine building has a 610-mm-thick (24 inches) reinforced concrete wall around its perimeter with reinforced floors and roof (References 16.67 through 16.74)It is, therefore, a relatively rigid and strong structure resistant to external hazards.

The C3 area comprises the main turbine hall with three floor levels and a basement below. The C3 area contains no equipment assigned a safety function. The roof to this area is generally at a level of 144.2 m (473.1 feet), whereas the roof of the first bay is considerably lower, at the same level as the turbine building operating deck at 118.59 m (380.1 feet).

The NNS area of the turbine building is more flexible and less hazard-resistant than the first bay. It is a steel-framed structure. A seismic gap is provided between the first bay and the rest of the turbine building. The robust nature of the first bay means that if some interaction were to occur, the first bay would act as a partial barrier to prevent damage to the Class 1 components in the nuclear island. The Turbine Building NNS area is on a stable foundation media so that the basemat beneath the Turbine Building does not endanger the first bay.

The approaches to tornado, extreme wind, extreme snow, and earthquake are explained in the sections that follow.

16.4.2.1.1 Tornado

Tornadoes must not lead to collapse of the turbine building onto the nuclear island; however, it is unnecessary for the Class 2 equipment housed in the first bay to be protected from tornadoes. The design approach to tornadoes is as follows:

- The reinforced concrete walls of the first bay of the turbine building are designed to withstand the same tornado wind loading as the nuclear island following the American Concrete Institute (ACI) design criteria presented in ACI 349-01 (Reference 16.15), which is appropriate to the UK. This ensures that tornado loading could not cause the first bay to collapse onto the nuclear island. The first bay is not designed to withstand tornado missile loads as they would lead to local effects that could not credibly lead to gross failure of the first bay. Local damage could cause some elements of the structure to be blown against the nuclear island; however, the resulting missiles would be enveloped by those considered for the tornado design of the nuclear island, presented in Table 16-3.

- The C3 area of the turbine building is designed to withstand the same tornado wind loading as the first bay, but different criteria are applied. First, it is acceptable for the cladding to be blown off. The objective of the design is to demonstrate that the heavy elements of the C3 area of the turbine building (floors and structural steel-frame components) will not collapse or become tornado borne missiles (see Reference 16.6, Sections 6.2.1 and 6.3.2 for the assumptions to be made about the building area and its contents being considered as projected into the wind). Second, the C3 area of the turbine building is designed to the industrial codes and standards identified in Section 16.5.2.

Chapter 12 identifies that the tornadoes considered in the design are far more onerous than what could occur in the UK. The concrete is designed to ACI-349-01, which is acceptable UK practice (see Section 16.5.1.5); therefore, it can be concluded that the international design follows a very conservative approach with respect to tornadoes in the UK.

16.4.2.1.2 Extreme Wind

The turbine building is designed for the 1 in 50 year design wind in accordance with ASCE 7 (Reference 16.20). No damage is permitted under this condition. The building is not evaluated for the 1 in 10,000 year event since this wind is enveloped by the tornado. Extreme wind must lead to neither collapse of the turbine building onto the nuclear island nor damage to the first bay sufficient to affect Class 1 components.

How the design addresses the 1 in 50 year design wind is explained in Reference 16.6, Section 5. The main part of the turbine building structure, which envelopes the C3 area, is designed to withstand the same wind loading as applied to the nuclear island except that the importance factor is reduced from 1.15 to 1.0 (an importance factor is US terminology and is a factor applied to the wind loading to take into account the importance of a building). The American Institute of Steel Construction (AISC) allowable steel stresses presented in AISC S335 (Reference 16.16) are increased by 33 percent (Reference 16.6, Table 8) for the natural hazards considered in the design of Category NNS structures. The magnitude of the wind considered is similar to the UK 1 in 10,000 year wind as shown in Chapter 12. The design criteria with respect to wind loads is similar to the criteria followed in the UK in the past when using a permissible stress code (i.e., stresses up to yield are acceptable for tension members). Considering that it is not necessary for the Class 2 equipment to be justified to withstand 1 in 10,000 year events, the case against extreme wind for the turbine building is adequate for the UK. The protection provided by the first bay provides additional assurance. Note that the main part of the turbine building is being redesigned for the 50 Hz turbine in the

UK; the structural design will use UK design codes to provide margin similar to that provided by the US codes.

The design against tornado, which is far more onerous than an extreme wind, demonstrates that an extreme wind could not cause an adverse reaction between the first bay of the turbine building and the nuclear island.

16.4.2.1.3 Snow

Design snow loads are explained in Reference 16.6, Section 5.2.2. The roof over the entire area of the turbine building is designed to withstand the same snow loading as applied to the nuclear island (see Section 16.4.1.1) except that the importance factor is reduced from 1.2 to 1.0. For uniform snow conditions, this is conservative for the UK as discussed in Chapter 12.

Chapter 12 identifies snow drifting or snow sliding off the shield building roof as potential hazards, which are relevant to the A2 first bay of the turbine building. This will be constructed of at least 200-mm-thick (7.87 inches) reinforced concrete slab, which should be more than capable of resisting such events. If the roof slab were to fail, only the Class 2 components would be affected and there would be no potential for damage to the Class 1 components.

16.4.2.1.4 Earthquake

The A2 first bay of the turbine building is designed to withstand the same earthquake as the A1 nuclear island. A seismic gap between the turbine building first bay and the nuclear island and between the turbine building first bay and the C3 portion of the turbine building is provided above grade.

The C3 portion of the turbine building is qualified against the seismic ground motion specified in the 1997 Uniform Building Code (UBC) (Reference 16.17). The UBC seismic motion is for US Zone 3 with an importance factor of 1.0. This input is higher than that used on other NNS buildings in order to reduce the risk of the upper part of the turbine building collapsing onto the first bay and the nuclear island. Note that the main part of the turbine building is being redesigned for the 50 Hz turbine in the UK; the structural design will use seismic input and design codes to provide margin similar to that provided by the UBC design.

16.4.2.2 Diesel Generator Building and SWS Cooling Towers

The diesel generator building and SWS cooling towers are located so that there is no potential for their collapse to lead to any adverse reaction with the Class 1 components located in the nuclear island. These buildings contain Class 2 equipment. The buildings are seismic category NNS.

16.4.2.3 Annex Building (A2/GNS)

The annex building comprises a multi-storey part east of the auxiliary building (between gridlines E-I1 and 2-13); and a single-storey lightweight part, mainly housing offices, north and east of this (between gridlines A-D and 8-13, and between gridlines A-G and 13-16). The building arrangement is shown in References 16.62 through 16.64 and 16.87 through 16.96. The multi-storey part of the annex building is adjacent to the nuclear island; it is of relatively heavy construction with a potential interaction hazard with the nuclear island; therefore, the multi-storey part is C-II. The single-storey part is classified as GNS. The multi-storey part of the annex building is designed to suffer no adverse reaction from collapse of the GNS part, so the GNS part is not discussed further in this chapter.

The multi-storey part of the annex building contains SSCs that need to maintain Category A safety functions 72 hours after a DBA. The SSCs required to support Category A safety functions after 72 hours are protected from hurricanes. The boundary of the room in the multi-storey part of the annex building housing the ancillary diesels and their supporting equipment provides hurricane protection.

The design approach to external hazards acting on the annex building is conservative in the UK context as identified in the sections that follow.

16.4.2.3.1 Earthquake

The A2 annex building is designed to withstand the same earthquake as the A1 nuclear island. A seismic gap between the annex building and the nuclear island and between the annex building A2 and the C3 portion is provided above grade.

16.4.2.3.2 Wind

The annex building is designed for the 1 in 50 year design wind in accordance with ASCE 7 (Reference 16.20). No damage is permitted under this condition. The building is not evaluated for the 1 in 10,000 year event since this wind is enveloped by the tornado.

The annex building has been designed for the same 1 in 50 year wind loading as the nuclear island structures except that the importance factor has been reduced from 1.15 to 1.0, based on Reference 16.6, Section 5.2. Chapter 12 points out that the 1 in 50 year design wind load would be similar to a UK 1 in 10,000 year wind loading. Wind loads are combined with other loads conservatively in the AP1000 design as identified in Reference 16.6, Tables 5 and 6 (i.e., a load factor of 1.7 has been used for concrete structures and permissible stress criteria have been used for steel structures that include inherent margins). In the UK, common nuclear practice is to allow structures to be stressed close to their ultimate limit states under extreme external hazards (i.e., a load factor of 1.0 or 1.05 is used for concrete structures and permissible stresses for steel structures are enhanced so that tensile stresses are allowed to approach yield). The 1 in 50 year severe wind used in the AP1000 design is similar to the UK 1 in 10,000 year extreme wind, so the overall approach to extreme wind is conservative.

16.4.2.3.3 Tornadoes and Hurricanes

The A2 portion of the annex building adjacent to the nuclear island is designed to withstand the same tornado loading as the nuclear island, but the cladding, but not the concrete walls, is permitted to be blown from the building by a tornado. The walls and ceiling of the annex building room housing the ancillary diesel generators are designed to remain in place under hurricane wind loading and to protect the equipment from hurricane missiles. The wall to the nuclear island, at the interface with the annex building, is designed to withstand the full effects of a tornado.

Chapter 12 reports that the tornadoes considered as part of the international design are very conservative compared with potential UK tornadoes. The precise performance of a particular structure under the design tornado loading is not of concern in the UK because such a large tornado is not predicted.

16.4.2.3.4 Snow

The annex building has been designed for the same snow loading as the nuclear island structures (see Section 16.4.1.1) except that the importance factor has been reduced from 1.2 to 1.0 (Reference 16.6, Section 5.2). For uniform snow loading, this reduction does not affect the conclusion in Chapter 12 that the uniform snow loading addressed by the AP1000 design is conservative when compared with possible snow accumulation at potential UK sites. The AP1000 plant is designed for deep snow associated with a 1 in 50 year event. The roof is designed to resist a ground snow load of 3.6 kN/m^2 (75 lb/sq. ft.) (Reference 16.6, Section 5.2.2B) using ultimate load factors of 1.4 and 1.7 for dead and live loads, respectively (Reference 16.6, Table 3). Snow is considered to be a live load as explained in Section 16.7.4.2. Also see Section 12B.2.

16.4.3 B3 Civil Engineering Structure – Radwaste Building

Compared with the nuclear island structures, the radwaste building is a small, lightweight structure. Three methods are used to demonstrate that a potential radwaste building impact on the nuclear island during a seismic event will not impair its structural integrity (Reference 16.45):

- The maximum kinetic energy of the impact during a seismic event considers the maximum radwaste building and nuclear island velocities. The total kinetic energy is considered to be absorbed by the nuclear island and converted to strain energy. The deflection of the nuclear island is less than 0.51 cm (0.2″). The shear forces in the nuclear island walls are less than the ultimate shear strength based on a minus one standard deviation of test data.

- Stress wave evaluation shows that the stress wave resulting from the impact of the radwaste building on the nuclear island has a maximum compressive stress less than the concrete compressive strength.

- An energy comparison shows that the kinetic energy of the radwaste building is less than the kinetic energy of tornado missiles for which the exterior walls of the nuclear island are designed.

The equipment located in the radwaste building is not required to function following any credible hazard. The building is designed for the same snow and design wind loads discussed in Section 16.4.2.1 above in relation to the C3 area of the turbine building. The radwaste

building is designed to the UBC seismic requirements, Zone 2A with an importance factor of 1.25 (Reference 16.6, Section 5.2.4). Note that the building is being redesigned and the structural design will use UK design codes to provide margin similar to that provided by the US codes.

Return periods of natural hazards needing to be considered in the design of the B3 civil engineering structures are not well defined in the UK. The expectation is that the approach will reflect the importance of the structure to nuclear safety. A reasonable baseline is the natural hazards and their frequencies of occurrence that would be considered for the design of conventional UK industrial structures. The radwaste building exceeds this baseline by a good margin as it has been designed to withstand more onerous international environments. Conventional UK industrial structures are not normally designed to withstand earthquakes unless the consequences of their failure are particularly significant.

16.5 APPLICABLE CODES, STANDARDS AND METHODOLOGIES

16.5.1 A1 Civil Engineering Structures

For A1 structures, the adopted codes and standards should lead to a clearly conservative design under all DBEs (design basis events), with no sudden change in response to BDB (beyond design basis) events of either increasing magnitude or lower frequency. The preference is for nuclear-specific codes and standards to be adopted when appropriate codes and standards are available. For innovative design features not covered by established codes, appropriate design methodologies, specifications, or testing are used.

16.5.1.1 Seismic Analysis Codes

The American Society of Civil Engineers (ASCE) standard ASCE 4-98 (Reference 16.18) was specified for the seismic analyses of the nuclear island (Reference 16.6, Table 2), which are presented in detail in Reference 16.32. ASCE 4-98 is a well-established nuclear-specific standard regularly referred to in the UK for determining appropriate assumptions and methodologies when undertaking seismic analyses of major new nuclear facilities. This is noted in Reference 16.19. Information specific to seismic analysis of AP1000 plant structures is presented in Reference 16.7.

16.5.1.2 Wind and Tornado Loading

ASCE 7-98 (Reference 16.20) was used when determining wind and tornado loads under the defined wind and tornado hazards as explained in Reference 16.6, Section 5.2.3 and Reference 16.12. Reference 16.19 provides some comparisons between ASCE 7-98 and the later versions of the code, concluding that the use of ASCE 7-98 should be appropriate.

The 1 in 50 year wind loads addressed by the AP1000 design are similar to the 1-in-10,000 wind loads for a UK environment. The application of the design codes incorporates margins in excess of those normally considered necessary in the UK. For instance, Table 3 in Reference 16.6 shows that an ultimate load factor of 1.7 has been applied to the wind loading, when in the UK an ultimate load factor of 1.0 or 1.05 would normally be used when considering 1 in 10,000 year wind loads. The margin of 1.7 is conservative and allows for any differences in the US and European wind codes when determining wind loads from wind speeds; hence, the choice of wind code is not critical to the justification of the nuclear island for a UK site.

16.5.1.3 Methodology for Justifying Missile Barriers and Protective Structures

The empirical relationships used for design of missile barriers and protective structures are the modified National Defence Research Committee (NDRC) Formula for concrete, and either the Ballistic Research Laboratory (BRL) or Stanford relationship for steel. Full details are provided in Reference 16.6, Section 4.3.

In the UK, current practice would be to use the R3 Impact Assessment Procedure (Reference 16.21) to evaluate the effects of missiles on structures. This procedure includes the BRL relationship for steel so the AP1000 design use of this relationship is aligned with UK nuclear practice.

16.5.1.4 Methodology for Evaluating Effects Associated with Postulated Rupture of Piping

For the AP1000 design, barriers and shields constructed of either steel or reinforced concrete are provided to protect essential equipment, including instrumentation, from the effects of jet impingement resulting from postulated pipe breaks (Reference 16.6, Section 4.2). Barriers differ from shields in that they may also resist the impact of the whipping pipes. Barriers and shields include walls, floors, and structures specifically designed to provide protection from postulated pipe breaks. Dynamic effects are evaluated using the elastic or elastic-plastic methods presented in "Introduction to Structural Dynamics" by Biggs (Reference 16.22), a standard dynamic analysis text often referred to in the UK.

16.5.1.5 Reinforced Concrete Design Code

ACI 349-01 (Reference 16.15) has been used for the design of the reinforced concrete, taking into account the supplementary requirements in Reference 16.6, Section 6.2.1.

ACI 349-01 is a nuclear-specific code that is fully applicable for determining reinforcement and concrete requirements for A1 structures when demonstrating load-resistance capabilities. The design of anchorages (Reference 16.15, Appendix B) and the provision of reinforcement to provide ductility (Reference 16.15, Chapters 12 and 21) ensure a safe design with no unacceptable step changes in response.

Reference 16.19 compares ACI 349-01 with ACI 349-06 and concludes that the AP1000 applied design provides a basis for the structural safety of the plant.

16.5.1.6 Specification of Materials and Detailing of Reinforcement for Reinforced Concrete

The concrete and reinforcement specified for construction of the AP1000 plant are addressed in Reference 16.6, Sections 7.1 and 7.2. Self-consolidating concrete (SCC) is specified to ACI 237R-07 (Reference 16.23). Design to ACI 349-01 is based on the presumption that materials and workmanship will be specified in accordance with US standards, appropriate for nuclear application, as indicated in Reference 16.6, Section 7. Such standards would not naturally be followed in the UK, where reference to the Europe-wide harmonised technical specifications for materials, workmanship, and testing would be expected. Using a consistent set of US nuclear standards has the advantage of addressing the full intent of ACI 349-01. Reference 16.42 provides the metrication plan for the AP1000 plant; including definition of the extent to which metrication shall apply and to what level of detail metrication shall reach into the design, procurement, licensing, construction, testing, information & configuration management, operation and maintenance of AP1000 plants deployed in the UK. For this document, metrication is defined as the act of adopting metric (SI) units in the design, procurement, construction, operation, and decommissioning phases of an AP1000 plant.

16.5.1.7 Structural Steelwork Design Code

The AISC design criteria for nuclear structures, presented in ANSI/AISC-N690-1994 (Reference 16.24), have been followed for the design of the structural steelwork. The supplementary requirements in Reference 16.6, Section 6.2.2 have been taken into account. This is a nuclear-specific code applicable to the design of steelwork for A1 structures for resisting loads.

ANSI/AISC-N690-1994 (Reference 16.24) has been used for the design. Reference 16.19 compares ANSI/AISC-N690-1994 with ANSI/AISC-N690-2006 and concludes that the AP1000 applied design criteria provide a basis for the structural safety of the plant. In addition, the seismic detailing in the older version of the code is not consistent with the latest recommendations in AISC 341 (Reference 16.25). The shortfall against modern standards is not considered to be of such significance to the A1 structures that the established AP1000 design process should be changed.

The analysis and design of cold-formed steel structures conform to the American Iron and Steel Institute (AISI) code.

16.5.1.8 Specification of Materials and Detailing of Structural Steelwork

Structural steel and associated materials are used as identified in Reference 16.6, Sections 7.3 to 7.9. Basic materials used in the structural and miscellaneous steel construction in the AP1000 design conform to the ASTM standards listed in Reference 16.6. Construction assurance is discussed in more detail in Section 16.19.

16.5.1.9 Steel-Concrete Composite Modular Construction

Steel-Concrete Composite Modules are constructed from concrete and structural steelwork. Justification of the design methodology for SC modular construction is presented in References 16.3 and 16.4. ACI 349 is used as guidance in the design of SC structures. For example, ACI 349 is used to guide member dimensions, plate thicknesses, and strength calculations. To validate this approach, first principle engineering mechanics justifications have been developed and detailed analysis and confirmatory testing has been completed as described in References 16.3 and 16.4.

16.5.2 A2 Civil Engineering Structures

The Class 1 equipment located within the nuclear island structures is the principal means for ensuring nuclear safety. These components are highly reliable. It is appropriate to take credit for this by not making the reliabilities of the Class 2 components be as high as would be required if they had to reduce risks to meet the UK probabilistic criteria. Thus, the structures containing the Class 2 components do not need to be designed to the nuclear-specific codes and standards that are used for the design of the nuclear island.

In accordance with the AP1000 Safety Categorisation and Classification methodology presented in Chapter 5, nuclear codes and standards are applied to Class 1 SSCs, and Class 2 nuclear codes and standards are applied to Class 2 SSCs where appropriate Class 2 nuclear codes and standards exist. Within the context of civil engineering, Class 2 nuclear codes and standards do not exist either in Europe or the US. In the US, codes and standards are either nuclear-specific or normal industrial standard. To design A2 structures to the US nuclear-specific codes and standards would be to ignore the safety advantage of having very reliable Class 1 components; therefore, it is acceptable to design the A2 structures to

robust industrial standards with identified supplemental requirements. Designing Class 2 structures to robust industry codes and standards with the appropriate supplemental requirements supports the overall design reliability requirements. The approach to codes and standards for Class 2 structures, together with the underlying reasoning, is included in the summary information in Table 16-2. This is discussed further in the sections that follow for each A2 building.

16.5.2.1 Turbine Building – First Bay

The first bay of the turbine building is C-II and is designed to ACI 349-01 (Reference 16.15) and ANSI/AISC-N690-1994 (Reference 16.24) as used for the A1 structures described above.

16.5.2.2 Diesel Generator Building and SWS Cooling Towers

The Class 2 diesel generator building and SWS cooling towers are seismic category NNS and are designed to industrial standards. Reinforced concrete elements are designed to ACI 318-99 (Reference 16.26) and structural steel to AISC S335 (Reference 16.16), as used for the C3 area of the turbine building. Seismic analysis and design are based on Reference 16.17. Note that these structures are being redesigned and the structural design will use UK design codes to provide margin similar to that provided by the US codes.

16.5.2.3 Annex Building

The A2 areas of the annex building are designed to the same codes and standards as the A1 nuclear island structures as explained in of Reference 16.6, Section 6.2.1. The remaining GNS area is designed to normal industrial standards.

16.5.3 B3 and C3 Civil Engineering Structures

B3 and C3 structures are designed to normal industrial standards. By definition, failure of a B3 or C3 structure will not have any safety implications with respect to either Class 1 or Class 2 SSCs. Use of normal industrial standards for structures where failure has no nuclear safety implications is acceptable practice in the UK.

16.5.3.1 Turbine Building

The C3 area of the turbine building is designed to ACI 318-99 (Reference 16.26) for concrete structures and AISC S335 (Reference 16.16) for steel structures. These are normal industrial standards as is appropriate for a C3 structure (Reference 16.1, guidance to Principle ECS.3).

Under tornado loading, the acceptance criteria are based on ACI 318 for concrete structures using a load factor of 1.0 and AISC S335 for steel structures with stresses enhanced by 70 percent (Reference 16.6, Tables 5 and 6). It is acceptable for some cladding to be blown from the building and for cladding rails to fail, provided that they do not become detached from the main structural frame (Reference 16.6, Section 6.2.1). The adopted load factor and stress enhancement are chosen so as to remove any margin on the tornado load that allows for loading uncertainties. This is consistent with the normal practice of removing loading margins when considering the effects of extreme loads on normal industrial structures. It is considered acceptable under such extreme conditions for the structure to be damaged and close to collapse, but collapse must not occur.

Seismic analysis and design is to UBC 1997 (Reference 16.17). This is a normal industrial standard for structures sited in seismic regions of the world. Further detail is provided in Reference 16.7.

Note that the C3 area of the turbine building is being redesigned and the structural design will use UK design codes to provide margin similar to that provided by the US codes.

16.6 DESIGN ASSURANCE

Design quality processes that provide an equally high level of assurance for the design justifications for all the civil engineering structures, regardless of the safety class, are followed. The general approach to quality assurance and independent reviews is presented in Chapter 3. When issues arise that might need special consideration, for instance, the design approach falls outside the scope of the adopted codes and standards, expert independent external advice is sought. An example is the expert panel set up to advise on the design of SC construction. The independent experts, suitably qualified and experienced persons (SQEPs), were drawn from a variety of organisations to determine a best-engineering practice approach as described in Reference 16.3.

16.7 ANALYSIS (EXCLUDING SEISMIC), LOADS, AND LOAD COMBINATIONS

16.7.1 Load Identification and Reconciliation Process

Plant structures have been designed and analysed for normal operational loads and design basis loads arising from internal hazards, external hazards, and internal plant faults.

Initially, system and equipment loads are postulated for the civil and structural design. At a later stage, as the design of the systems and equipment progresses, the loads acting on the civil structures may be revised. The structural designer is responsible for ensuring that any revised loading is appropriately allowed for in the design. For example, preliminary interface loads were defined for the reactor coolant loop supports. When the interface loads were finalised, the structural designer reconciled them with the initial postulated loads.

Loads from small items of equipment are frequently included as uniformly distributed loads derived by making conservative assumptions. When the actual arrangements are decided, a reconciliation exercise is undertaken to confirm that the uniform loads assumed in the design bound the loads from the equipment present.

Loads from major items of equipment not included as uniformly distributed loads are recorded in vessel and equipment specifications, such as the Reactor System Interface Control Document (Reference 16.27).

16.7.2 Analysis Approach

Analyses are undertaken using general-purpose structural analysis codes, as described in the civil/structural design criteria (Reference 16.6). The structural systems analysed are described in Section 8 of the same document.

The dynamic effects from the impulsive and impact loads as a result of pipe rupture, tornado-induced missiles, and other such accidents are addressed using one of the following methods:

- Applying an appropriate dynamic load factor to the peak value of the transient load

- Using impulse, momentum, and energy balance techniques
- Performing a time-history dynamic analysis

Elastoplastic behaviour is assumed by applying appropriate ductility ratios unless excessive deflections could cause an adverse interaction with a Class 1 system. Dynamic increase factors, appropriate for the strain rates involved, are applied to the static material strengths of steel and concrete when determining section strength.

Material properties assumed for the design justification are presented in Reference 16.6, Section 7 and Table 9. The concrete compressive strength, as defined in ACI 349-01 (Reference 16.15) and ACI 318-99 (Reference 16.26), is taken as 27.6 N/mm^2 (4000 psi) generally, and 41.4 N/mm^2 (6000 psi) for portions of the shield building.

16.7.3 Load Combinations

For concrete structures, individual loads are combined by multiplying the loads by a factor and combining them with other factored loads. The factors are in accordance with ACI 349-01 (Reference 16.15) with supplemental requirements as cited in Reference 16.6, Section 6.2.1 and take into account uncertainties, the frequency of the loading, and acceptable structural responses. The resulting member forces are checked against the ultimate limit state criteria presented in ACI 349-01.

Steel structures are designed to the permissible stress code in ANSI/AISC-N690-1994 (Reference 16.24) with supplemental requirements as cited in Reference 16.6, Section 6.2.2. All load factors are set to unity and permissible code stresses are applied for all normal operation conditions. For less frequent events, the permissible stresses are enhanced by a stress limit coefficient, with the value depending on the frequency of the loading and acceptable structural responses.

The load combinations considered are presented in the civil/structural design criteria report (Reference 16.6) as follows:

- C-I concrete structures – Table 3
- C-I steel structures – Table 4
- C-II concrete structures – Table 5
- C-II steel structures – Table 6
- Seismic category NNS concrete structures – Table 7 (identified as seismic Category III (C-III) structures)
- Seismic category NNS steel structures – Table 8 (identified as C-III structures)

In these tables, each load case is designated by a letter; for ease of reference, the designated letters are included in the following section titles relating to load cases.

16.7.4 Normal Design Loads

Normal operational loads conservatively reflect the maximum loads expected during the design life. The civil engineering structures are not vulnerable to damage as a result of

repeated application of normal operating loads. The case for "through-life" safety of the civil engineering structures is presented in Section 16.18.

Normal practice in the UK would be to justify structures against external hazards with return periods of slightly greater duration than the design life of the facility. Such external hazards reflect operational basis events and are considered to occur several times and in combination with other operational loads. The margins required are more onerous than those applicable to the less frequent DBEs; however, the AP1000 design does not include such a justification. Instead, a conservative approach is followed with respect to the justification against the less frequent DBEs such that the design justification criteria for DBEs bounds that for operational basis events.

16.7.4.1 Dead Loads (D) and Liquid Loads (F)

Dead loads arising from small items of equipment are addressed by uniformly distributed loads derived using conservative assumptions. Specific large-item loads are included when appropriate; e.g., the dead load from the vertical support to the steam generator (SG). These loads are recorded in the appropriate design specifications as explained in Section 16.7.1 above.

The Civil/Structural Design Criteria report (Reference 16.6) provides information on the dead loads and liquid loads (combined and factored as if they were dead loads). Dead loads include all permanent piping and equipment loads. The following loads are summarised in Reference 16.6:

- Section 5.2.1 presents the dead loads considered generally for the design of the civil engineering structures. The weight of normal concrete is taken as 23.6 kN/m^3 (150 lb/ft3).

- Appendix A identifies the additional uniform loads included to cater for the dead loads from permanently attached small items of equipment appropriate for the design of the turbine building.

- Appendix B identifies the hydrostatic loads to be considered in the design of the in-containment structures that account for the water inventory and its location during various plant operations.

- Appendix C identifies the hydrostatic loads to be considered for the structural design of the fuel handling area.

- Section 5.2 indicates that differential settlement is included as a dead load for the design of C-I steel structures.

16.7.4.2 Live Loads (L)

Live loads include snow loading, movable equipment loads, and other loads that vary in intensity and occurrence. Live loads arising from small items of equipment are frequently addressed by uniformly distributed loads derived using conservative assumptions. Specific large-item live loads are included; e.g., the live loads associated with operation of refuelling equipment. These loads are recorded in specifications as explained in Section 16.7.1.

The following loads are summarised in Reference 16.6:

- Section 5.2 identifies the live loads considered generally in the civil engineering design. Tables 16-4 to 16-7 of this chapter present these in metric units.

- Appendix A identifies the live loads specific to the turbine building.

- Appendix B identifies the live loads specific to the in-containment structures.

- Section B.4 of Appendix B identifies that loads due to operation of the spargers are addressed as live loads (the operation of the spargers and the resulting automatic depressurisation system (ADS) load cases, ADS1 and ADS2, are also explained in this section, together with an explanation of how these loads are combined with seismic loads).

- Section 5.2.2 (E) identifies that loads occurring during construction are temporary live loads. Section 5.2.8 of Reference 16.6 identifies that stresses are increased by a third for such temporary live loads.

16.7.4.2.1 Concrete Placement Loads

Information on wet concrete placement loads acting on the steel faceplates to the walls of the structural modules is provided below (Reference 16.46). An explanation is provided as to why the resulting stresses are not combined with the stresses associated with post construction load combinations.

The steel faceplates of the structural wall modules, designed for the hydrostatic pressure of the concrete, act as concrete forms. The concrete placement loads are 1050 pounds per square foot determined in accordance with ACI-347. The bending stress in the faceplate due to this hydrostatic pressure of the concrete is approximately 89.63 MPa (13 ksi), based on the assumption of a continuous faceplate, or 137.89 MPa (20 ksi) based on the assumption of simple spans. The minimum yield strength of material for the faceplates is 344.74 MPa (50 ksi). The stress is well below the allowable, since the plate is designed to limit the out-of-plane deflection. After the concrete has gained strength, these stresses remain in the steel; however, since the average residual stress is zero and since the concrete no longer requires hydrostatic support, the ultimate strength of the composite section is not affected, and the full steel plate is available to carry other loads as described below.

The steel plates and the concrete act as a composite section after the concrete has reached sufficient strength. The composite section resists bending moment by one face resisting tension and the other face resisting compression. The steel plate resists the tension and behaves as reinforcing steel in reinforced concrete. The composite section is underreinforced so that the steel would yield before the concrete reaches its strain limit of 0.003 in/in. As the steel faceplates are strained beyond yield to allow the composite section to attain its ultimate capacity, the modest residual bending stress from concrete placement is relieved, since the stress across the entire faceplate in tension is at yield. The small residual strain induced by the concrete placement loads is secondary and has negligible effect on the ultimate bending capacity of the composite section. The stresses in the faceplates resulting from concrete placement are therefore not combined with the stresses in the post-construction load combinations.

16.7.4.3 Static Earth Pressures (H)

Static earth pressures are evaluated using standard geotechnical relationships; soil profiles consistent with those assumed in the seismic design are used. Static earth pressures are

combined and factored in the same way as live loads. When considering sliding stability, resistance is considered to be provided by sliding resistance at the bottom of the basemat with no account taken of passive soil resistance.

16.7.4.4 Normal Operating Loads (To) and Equipment Reactions (Ro)

Normal operating live loads comprise thermal loads (To) and their effects, plus piping and equipment reactions (Ro). These are assigned the maximum values associated with normal operations or shutdown conditions, based on the most critical transient or steady-state condition. Operating loads of a minor nature are addressed within the uniformly distributed loads, derived using conservative assumptions. Specific operating loads are included when appropriate and for all large items of equipment such as the frictional loads, associated with thermal expansion, at the supports to the major vessels. These loads are recorded in specifications as explained in Section 16.7.1.

The approach for determining the operating thermal loads is presented in Reference 16.6, Section 5. Reference 16.6, Section 10.3 indicates that thermal analyses are performed to evaluate the effects of thermal gradients. Reference 16.6, Section B.4 identifies the normal thermal loads addressed within the design of the in-containment structures. Reference 16.6, Sections C.3 and C.4 identify the normal thermal conditions addressed by the design for the fuel handling area structures. ADS1 leads to hydrodynamic loads on the boundaries to the in-containment refuelling water storage tank (IRWST). Section 16.7.4.2 above identifies that these loads, arising as a result of operation of the spargers, are considered to be live loads (L). Reference 16.6, Appendix B indicates that ADS2 leads to temperature transients that affect the boundaries to the IRWST. These temperature transients are considered as a normal thermal load (To).

16.7.5 Loads Arising from Internal Plant Faults and Internal Hazards

Chapter 11 reviews all internal hazards, and from the findings presented in Chapter 11, it is concluded that flooding (including temperature effects), internal missiles, dropped loads, explosions, fire and postulated PPF are considered in the civil engineering design, either in applicable load combinations or on a case-by-case basis

Building collapses are also a potential internal hazard catered to by designing the buildings so that their responses to hazards will not lead to any adverse response to the Class 1 equipment located in the nuclear island.

It is possible for an item of equipment to experience loads in excess of normal loads as a result of an internal plant fault. Such accidents are considered in load combinations where margins are substantially reduced because of the low frequency of such postulated events. For instance, when designing concrete, all load factors may be reduced to unity with the exception of accident pressure (Pa) (Reference 16.6, Table 3).

16.7.5.1 Temperature Effects (T_a)

The barrier matrix (Reference 16.9) identifies the temperature ranges for compartments within the nuclear island that are addressed in the design of the walls and slabs forming the compartment. Reference 16.6, Section 10.3, identifies the thermal analyses to be undertaken to evaluate the effects of thermal gradients. Reference 16.6, Section B.4, identifies the accidental thermal transients addressed by the design of the in-containment structures. Reference 16.6, Appendix C.5, identifies the accident thermal conditions addressed by the design for the fuel handling area structures.

16.7.5.2 Flooding (D and L)

Table 11-1 identifies the compartments within the nuclear island for which flooding is a potential internal hazard. For each compartment, the potential maximum depth of stagnant water as a result of an abnormal operational occurrence is given. Reference 16.6, Section 5.2, identifies that liquid loads are treated as dead loads (D), except for external pressures from groundwater, which are treated as live loads (L).

Site flooding could also affect equipment if it is located below the site flood level. The design of the basement walls to withstand extreme flood loads and the provision of a watertight barrier up to plant grade level, which is above the maximum design site flood level, ensure that flooding of the nuclear island from external sources does not occur.

16.7.5.3 Postulated Pressure Part Failure and Other Accidents (P_a, T_a, R_a, Y_r, Y_j, and Y_m)

Pressure part failures for which it is considered reasonable to postulate failure are all associated with the rupture of piping. Other accidents that can cause accidental loads to be applied to the civil engineering structures arise from loss of cooling accidents (LOCA) and safety relief valve (SRV) operation. These postulated accidents lead to the types of load described in the following sections.

Accident Pressure Load (P_a)

A postulated pipe break can lead to a differential pressure across a subcompartment, compartment, or building wall or slab. Determination of the pressure loads (including dynamic effects) is discussed in Reference 16.10. [

]

Accident Thermal Load (T_a)

The civil engineering design considers thermal loads as a result of temperature gradients caused by postulated pipe breaks. Determination of subcompartment temperatures is discussed in Reference 16.10. Accidental thermal transients addressed by the design of the in-containment structures are presented in Reference 16.6, Section B4. Accidental thermal conditions addressed by the design of the fuel handling area structures are presented in Reference 16.6, Section C5.

Accident Pipe Reaction (R_a)

Piping and equipment reactions generated by the postulated break including Ro (see Section 16.7.4.4) are considered under thermal conditions. The determination of pipe reactions generated by postulated breaks is discussed in Reference 16.10.

Reaction from Pipe Rupture (Y_r)

Loads on structures generated by the reactions from the broken high-energy pipe during a postulated break are addressed by the civil engineering design. Determination of the loads is discussed in Reference 16.10 which indicates that pipe whip restraints are provided when appropriate to transfer the restraint load to the main civil engineering structure.

Jet Impingement (Y_j)

Jet impingement loads on the structure generated by a postulated break are addressed by the civil engineering design. Determination of the loads is discussed in Reference 16.10 which indicates that barriers and shields are provided to protect against the effects of jet impingement resulting from postulated pipe breaks.

Missile Impact Load (Y_m)

Missiles can be generated as a result of a postulated break, which is addressed in a way similar to impact from pipe whipping. Determination of the loads is discussed in Reference 16.10.

16.7.6 Loads from External Hazards

Table 16-3 presents the parameters associated with external hazards and ground conditions applied to the design of the plant. UK site-specific studies should demonstrate that these parameters envelope conditions at UK sites.

16.7.6.1 Wind and Hurricanes (W)

The approach followed for determining the wind and hurricane forces on structures is explained in Reference 16.6, Section 5.2.3 and in Reference 16.12. Table 16-3 presents the loads addressed by the design.

16.7.6.2 Tornadoes (W_t)

The approach followed for determining the tornado effects on C-I structures is explained in Reference 16.6, Section 5.2.33 and in Reference 16.12. Table 16-3 presents the loads addressed by the design.

For C-II structures, the approach is modified as indicated in Reference 16.6, Section 6.2.1. The approach for the seismic category NNS turbine building structures (identified as C-III structures in Reference 16.6) is presented in Reference 16.6, Section 6.3.2. It is acceptable for external cladding, when provided, to be blown off a building; however, other structural elements forming the building envelope, such as reinforced concrete walls and roofs, are designed to withstand tornado loading as explained in Reference 16.6, Section 6.2.1.

16.7.6.3 Missiles

The approach to missile protection against externally and internally generated missiles is presented in Reference 16.6, Section 4.3. Table 16-3 presents the loads addressed by the design. Tornado missile loads (W_m) are combined with tornado wind loads (W_w) and pressure differential loads (W_p) as shown in Reference 16.12.

16.7.6.4 Water Level (Flood) Design

The plant is to be sited at a level so that flooding resulting from an event external to the plant site is no more severe than an onsite flooding event as discussed in Section 16.7.5.2. The determination of this level is a site-specific issue. It is also for the site-specific safety case to present the arguments that adequate margins exist with respect to flooding from sources external to the site (i.e., there are no step changes in consequences as a result of slightly lower frequency events than the DBEs).

16.7.6.5 Temperatures

The external building temperatures addressed when considering internal plant faults and internal hazards take into account the extreme temperatures presented in Table 16-3. It is for the site-specific cases to demonstrate that the temperatures considered envelope the extreme temperatures at the site, taking into account such factors as global warming, elevation, solar gain, and location in the UK.

16.8 SEISMIC ANALYSIS

16.8.1 Input Motions for Seismic Analysis of Category I and II Structures (E_s)

The seismic input motion used for the standard plant seismic design and analyses for C-I and C-II structures is explained in Chapter 12. The SSE is the CSDRS with peak vertical and horizontal ground accelerations set at 0.3g. References 16.7 and 16.32 describe the derivation of the CSDRS together with the justification of the design time histories produced to represent the CSDRS. The CSDRS is a free field ground response spectra applied at finished grade level (Reference 16.6, Section 2.2).

As the specific UK sites where plants might be located have not been determined, C-I and C-II structures have been analysed for the SSE for six possible soil profiles. The intention is that licence applicants will demonstrate that the ground conditions at a particular site are bounded by the soil profiles assumed in the analysis or alternatively that the design analyses utilising seismic demands developed for the UK site-specific conditions meet applicable codes and standards.

16.8.2 Analysis of Seismic Category I and II Structures

The structures that make up the nuclear island are all C-I. Reference 16.32 summarises the types of models and analysis methods used in the seismic analyses of the nuclear island, as well as the type of results obtained and where they are used in the design. This is discussed further in Section 16.8.3 below.

The first bay of the turbine building and the multi-storey portion of the annex building adjacent to the nuclear island are C-II structures. Reference 16.7 presents details of how these were modelled and analysed. Enveloped foundation response spectra were developed using results from the Soil Structure Interaction (SSI) studies summarised in Reference 16.32.

Seismic analyses are undertaken using appropriate analysis methods. Reference 16.32 describes the role of each of the analysis methods and the important assumptions. The analyses determine the seismic force distribution for use in the design of the nuclear island structures and in-structure seismic responses (accelerations, displacements, and floor response spectra). In-structure seismic responses are used for the analysis and design of seismic subsystems, when more detailed local evaluations of seismic responses are undertaken. Details of the computer modelling and methods followed are provided in Reference 16.32. Fluid and structure interaction effects are allowed for in the design. The criteria for determining the live loads to be taken as present in the seismic analysis are presented in Reference 16.6, Section 5.2.4.1.

When undertaking SSI, as described in Reference 16.32, it is impractical to include detailed representation of all of the nuclear island structural elements. Some floor slabs, walls, miscellaneous steel platforms, and framings are analysed as subsystems. Reference 16.7

describes the procedures and methods used when seismically analysing such civil engineering subsystems.

Exterior walls, below grade, are designed for two cases: first for dynamic earth pressures calculated in accordance with ASCE 4-98 (Reference 16.18), and second to resist full passive earth pressure.

Seismic loads are combined with other loads as shown in Reference 16.6, Tables 3 to 6.

16.8.3 Nuclear Island Seismic Analysis Models

An overview of some of the important features of the seismic analysis and reference to additional reports that present more detailed information is provided in Reference 16.32. The important models, which vary in complexity, are summarised below:

- **NI10 Dynamic Model** – This model was used for an ANSYS fixed-base finite element time history analysis undertaken to determine time histories at important locations in the structure. Substructuring was used to reduce the computer analysis time. The mesh finite element size used was typically about 3 m (10 feet).

- **Nuclear Island Stick Model** – Stick models were used for SSI sensitivity studies using the SASSI software. Six different ground conditions were analysed: a hard rock site and five sites with different ground stiffnesses as identified in Reference 16.32. The presence of adjacent buildings was investigated and it was concluded that the effects of these on the nuclear island seismic response was small; therefore, subsequent 3-D SASSI computer analyses of the nuclear island were performed with adjacent buildings excluded. A stick model was also used to investigate the effects of foundation liftoff from the underlying subgrade. This was found to increase the subgrade pressure by a maximum of 4 to 6 percent close to the west edge of the basemat, with insignificant effects beneath the rest of the basemat.

- **NI20 Dynamic Model** – This model has fewer nodes and elements than the NI10 model, with a typical finite element mesh size of about 6.1 m. Based on this model, 3-D SSI analyses were undertaken using the SASSI software, again for five different soil profiles. Acceleration time histories and floor response spectra were obtained. In addition, this model was used to determine the maximum bearing pressure, which occurred for the hard rock condition.

- **NI05 Static Model** – This model has more nodes and elements than the NI10 model with a typical finite element mesh size of about 1.4 m (5 feet). This model was used to calculate design member forces and moments using response spectra analysis.

Justification of structural elements proceeds at the following three levels:

- Level 1 determines the enveloping seismic response for the nuclear island structures taking into account SSI.

- Level 2 uses the more detailed NI05 model to evaluate element/member forces and deformations using the Level 1 response spectra.

- Level 3 applies appropriate design code clauses to the Level 2 force actions (i.e., axial tension/compression, in-plane and out-of-plane shears, torsions, and out-of-plane moments – including interactions of these effects) to evaluate capacity margins.

The standard plant dynamic analyses generate one set of in-structure responses for each soil profile. These in-structure responses are enveloped to obtain the seismic design envelope (design member forces, nodal accelerations, nodal displacements, and floor response spectra), which are used in the standard plant design and analysis of C-I structures, components, and seismic subsystems to ensure high confidence that a safe plant may be constructed at a specific site. Seismic in-structure spectra are given in Reference 16.32 for the following six key locations:

- Containment internal structures at the reactor vessel supports, elevation of 100 m (100'-0").
- Containment internal structures at the operating deck level, elevation of 110.44 m (134.25').
- Auxiliary shield building northeast corner at the control room floor level, elevation of 105.03 m (116.5').
- Auxiliary shield building at the corner of fuel building roof, elevation of 124.14 m (179.19').
- Auxiliary shield building roof area, elevation of 169.31 m (327.41').
- Steel containment vessel adjacent to the polar crane, elevation of 137.80 m (224').

16.8.4 Seismic Input Motions and Seismic Analysis of Category NNS Structures (Eq)

Seismic category NNS structures are analysed using the seismic methods in UBC 1997 (Reference 16.17). Further supplementary requirements are presented in Reference 16.6, Section 6.3.1. Section 16.4.2 of this chapter identifies the seismic input motions against which seismic category NNS structures have been justified. Seismic loads are combined with other loads as shown in Reference 16.6. Reference 16.6 (Section 5.2.4.1, Tables 7 and 8) identifies that seismic category NNS structures do not need to be designed for an earthquake vertical component.

Note that the NNS structures are being redesigned and the seismic analyses will use UK methodology to provide margin similar to that provided by the US codes.

16.9 DESIGN REQUIREMENTS OTHER THAN STRENGTH

16.9.1 Water Retaining Barriers

Reinforced concrete walls and slabs designed to ACI 349-01 (Reference 16.15) may not provide a watertight boundary as there is potential for water to flow through small cracks and joints formed during construction. To ensure a watertight boundary when one is required, an additional waterproof layer is provided. The passive containment cooling water storage tank (PCCWST) is provided with a leaktight stainless-steel barrier. A waterproof membrane is provided around the basemat to the nuclear island; this will be a site specific design. Walls and floors of the in-containment structures and auxiliary building internal structures exposed to water are constructed using stainless-steel plate. Leak chases are provided for pools inside containment and in the auxiliary building that are filled with borated water. The leak chases are provided to prevent borated water from getting behind the various pool liner plates and potentially corroding the structural elements behind the pool liners. The leak chases for the pools inside containment are part of the liquid radwaste system (WLS). The leak chases for

the pools outside of containment are part of the radioactive waste drain system (WRS). Reference 16.14 describes a leakage assessment and potential corrosion impact of leakage from the pools within the fuel handling area on the associated structure. This document also presents evidence that the current design of the AP1000 plant fuel handling provides capabilities of detecting a long term leak from the pools, pits and canals within the fuel handling area.

Some floor slabs in the nuclear island might become flooded as a result of an accident. The use of structural floor modules and metal decking to support the weight of wet concrete during construction provides confidence that any leakage through these slabs would be insignificant and would not be detrimental to Class 1 equipment.

16.9.2 Deflection Limits

Reference 16.6, Section 11.3, presents the deflection limits applied to different structural elements as part of the design.

16.9.3 Separation between Buildings

Reference 16.6, Section 12, presents the criteria followed for determining the gaps between building superstructures.

16.9.4 Doors within Walls Required To Act as a Barrier

The approach to doors within walls, excluding those in the containment vessel wall, required to act as a barrier is explained below:

- Doors are not generally designed to retain water, because under accident conditions it is assumed that water will flow under the door.

- Doors are not generally designed to resist pressures from accidental pressure releases. Such pressures will quickly diminish with distance. On a case-by-case basis, it is considered whether a door could act as a missile and whether a target exists with a safety function, or if a door can be challenged by a DB externally generated pressure pulse. If necessary, protection is provided.

- Exterior doors to the annex building and first bay of the turbine building are designed to withstand either wind loading or hurricane loading appropriate to the building barrier through which they pass.

- There are no exterior doors to the shield building or the auxiliary building. Access to the nuclear island is only via the buildings that surround the nuclear island. The doors leading into the nuclear island are typically heavy-duty security doors. On a case-by-case basis, it is considered whether one of these doors could act as a missile and whether a target exists with a safety function. If necessary, missile protection is provided.

16.9.5 Fire Resistance

Chapter 11 describes the internal fire hazards analysis. The AP1000 design civil engineering structures have been justified as either meeting or exceeding the fire resistance requirements for internal fires.

16.10 SHIELD BUILDING

The shield building, including its significant features, is described in Reference 16.3. The shield building, shown in Figure 16-4 of this chapter, is a C-I structure that provides shielding, protects the containment from external DBEs, and has functions associated with the design of the passive containment cooling system (PCS). The cylindrical shield building surrounds the containment vessel and shares a common basemat with it and the auxiliary building. A light coloured coating is provided on the exterior portions of the SC structure of the shield building. The cylindrical section of the shield building structurally supports the roof and the PCCWST. From a structural perspective, the shield building includes a number of key structural features as shown in Figure 16-3. The shield building design is extensively described and justified in Reference 16.3.

16.10.1 Shield Building Key Structural Features

16.10.1.1 Shield Building Cylindrical Wall

The cylindrical wall has a nominal outside radius of 22.1 m (72 feet) and thickness of 0.91 m (3 feet). This wall is generally constructed using SC construction. SC construction comprises two external 19-mm (0.75 inches) steel plates forming permanent shutters that act compositely with the concrete poured between them. The cylindrical wall section below the auxiliary building roof line on the west side of the plant is constructed using conventional reinforced concrete.

The concrete used for the SC-constructed walls is either standard concrete or self-consolidating concrete based on the region of the building and constructability assessments. The faceplates are made of American Society of Testing Materials (ASTM) A572 Grade-50 steel, which acts as concrete reinforcement. The thickness of the steel faceplate precludes failure modes such as thermal, creep, and fatigue. The material specification was chosen to improve the overall strength and ductility of the SC portion of the structure so that the design capacity has significant margin when compared with demand during DBEs. The SC is made fully composite by the provision of 152-mm-long (6 inches), 19-mm-diameter (0.75 inches) [ ] shear studs welded to the inner surfaces of the faceplates and 19-mm-diameter (0.75 inches) [ ] reinforcement tie bars that are welded at both ends to the faceplates and pass through the concrete core. The SC construction form is shown in Reference 16.3, Figures 3.1-1 and 3.1-2. In locations along the edges of the panels (Reference 16.3, Figure 3.1-2), tie bars may be mechanically connected, or replaced with pairs of deformed hooked bars or T-headed bars connected to opposing sides of the panels. The use of hooked bars, T-headed bars or mechanically connected tie rods facilitates alignment of panels for welding. These alternate connections provide shear capacity between the face plates and concrete at least equal to the shear capacity of the tie bars.

16.10.1.2 Steel-Concrete Composite/Reinforced Concrete Connections

Where the shield building connects to the auxiliary building, specially designed connections are provided. To ensure continuity between reinforced concrete and SC construction, the steel plate modules are anchored to the reinforced concrete basemat and walls by mechanical connections. The connectors provide for the direct transfer of forces from the reinforcement in conventional reinforced concrete to the SC faceplates.

At the horizontal connection that occurs on the bottom of the lowest SC section, each vertical reinforcing bar in the reinforced concrete basemat or wall is connected to a mechanical coupler. A similar vertical connection occurs on the vertical edges of panels that interface with the reinforced concrete portion of the shield building wall. In the vertical connection, forces are transferred directly from the hoop bars to the SC faceplate via mechanical couplers. At the junction between the roof and the tension ring of the shield building, a specially designed cap connection is provided. It transfers forces from the reinforcement in the reinforced concrete section into reinforcement couplers and thence into a steel-plated composite section contiguous with the tension ring beam.

The mechanical connections are designed for tension loads of 125 percent of the yield strength of the reinforcing bars in accordance with ACI 349-01. The design of each SC to reinforced concrete connection is presented in Reference 16.3, Section 4.2. Using mechanical connectors ensures the integrity of the reinforced concrete/SC connections under cyclic loading and improves the overall ductility of the connection zone so that the structure behaves in a ductile manner under seismic events.

Benchmarked nonlinear analyses were performed on the shield building anchorages and roof anchorage connections. This is presented in Reference 16.3, Section 10. The benchmarked nonlinear analyses demonstrate significant margin over and above that demonstrated in the linear elastic analyses. Benchmarked Level 2 and 3 analyses were performed to demonstrate the system strength and ductility, both at the global level (Level 2) and at the component level (Level 3). In all cases, the analyses demonstrate large margins and sufficient ductility.

16.10.1.3 Air Inlet Structure and Tension Ring

The air inlet structure is located at the top of the cylindrical wall portion of the shield building. The air inlets serve as the intake for air used as the means for transferring heat as part of the PCS. The air inlet structure is similar in form to the cylindrical wall SC construction, but the overall wall thickness is increased to 1.372 m (4.5 feet)and steel faceplate thicknesses are increased to 25.4 mm (1 inch).

Composite action is provided solely by closely spaced 19-mm-diameter (0.75 inches) tie bars between the faceplates. [ ] shear studs are not used in this instance. The air vents cast-in to the concrete core are formed using 457-mm-diameter (18 inches) carbon steel pipes with [ ] shear connectors on the outer pipe surface. Above the air inlet structure is the region designated as the tension ring that supports the conical roof. The tension ring comprises a SC box girder with 38-mm-thick (1.5 inches) webs and flanges stiffened with internal diaphragms. Composite action between the internal concrete and external steel plating is provided by 19-mm-diameter (0.75 inches) [ ] shear connectors. The contribution of the concrete has been conservatively ignored in deriving the strength of the box girder to ANSI/AISC-N690-1994 (Reference 16.24) code provisions. The tension ring also contains 32 radial beam connections where the radial beams that support the conical roof are connected. These details can be seen in Reference 16.3, Figures 5.1-1 to 5.1-7.

The air inlet structure is sized as a reinforced concrete member equivalent to a cylindrical shell with openings in accordance with ACI 349-01 guidelines assuming conservative section properties for the walls. The air inlet pipes are not credited in the air inlet structure design analyses. Shear studs are welded to the outside surface of the air inlet pipes so that they contribute to composite action and provide additional margin for out-of-plane shear resistance. The design adequacy of the tension ring girder steel plates and the air inlet plates is verified by calculating stresses using detailed finite element models of these components (Reference 16.3, Section 10) at critical sections for the load combinations from the Level 2

analyses member forces and comparing them with ANSI/AISC-N690-1994 (Reference 16.24) allowable stresses. The comparison is presented in Reference 16.3, Sections 5.2.4 and 5.2.5, and shows that significant margins are provided for each component.

16.10.1.4 Shield Building Roof including Compression Ring and Knuckle Region

The roof is a conical shell supporting the PCCWST and air diffuser. Reference 16.3, Section 6.2 presents the detailed methodology for the analysis and design of the shield building roof structure, and the structural steelwork and reinforced concrete details in Figures 6.1.4 to 6.1.6.

16.10.1.5 Passive Containment Cooling System Water Tank

The PCCWST, located above the roof of the shield building, has a stainless-steel liner that provides a leak tight barrier on the inside surfaces of the tank. Its wall liner consists of a plate with stiffeners on the concrete side of the plate. The floor liner is welded to steel plates embedded in the concrete with leak chase channels provided over the liner welds. The liner for the PCCWST is analysed by hand-calculation. The design considers construction loads during concrete placement, loads due to handling and shipping, normal loads including thermal, and the SSE. Buckling of the liner is prevented by anchoring it using the embedded stiffeners and welded studs. The liner is designed as a C-I steel structure.

16.10.2 Analysis and Design Justification for the Reinforced Concrete Construction of the Shield Building

The nuclear island must be analysed as a whole to capture the complex load distributions through the basemat, walls, and slabs of the shield building and auxiliary building. The seismic analyses of nuclear island computer models are discussed in Section 16.8.3. Reference 16.3, Section 6.2, provides information on the design and analysis procedures followed for the RC portions of the cylindrical wall and for the shield building roof.

16.10.3 Analysis and Design Justification of Steel-Concrete Composite Construction for the Shield Building

Reference 16.3 reports that the SC construction justification has been established through extensive testing and international experience. The detailed information in Reference 16.3 demonstrates that SC construction for the shield building can be substantiated conservatively using reinforced concrete code provisions with longitudinal shear transfer between the steel faceplates and concrete core designed in accordance with provisions of ANSI/AISC-N690-1994 (Reference 16.24).

The shield building was analysed using detailed finite element models. Both linear elastic analyses and nonlinear analyses were performed to confirm that the load distribution does not lead to significant cracking and to confirm that the shield building behaves as a monolithic structure. The analyses demonstrated that a margin exists when the shield building is subjected to BDB earthquake loadings. Reference 16.3, Section 3.3 presents nonlinear analyses for the SC modules, which demonstrate that buckling, creep, and shrinkage are not significant effects with regard to the design. Thermal analysis was also performed to quantify the effect of daily and seasonal thermal cycles on the cylindrical wall and the effect of cracking due to thermal gradients.

To provide further assurance about the AP1000 structures, a combination of testing and analysis was performed to confirm the structural adequacy of the design. The confirmatory

research programme comprised seven different types of tests to demonstrate the adequacy of the design approach and to address regulatory concerns on shear strength and ductility provision. The scope of the tests was formulated to confirm the assumed behaviour of the shield building SC construction used in analysis and design as follows:

- Out-of-plane shear without tension to demonstrate that the provisions given in ACI 349-01 for the shear strength of reinforced concrete beams are conservative.
- Out-of-plane shear with tension to demonstrate that axial tension will not significantly affect the ACI strength prediction.
- Cyclic out-of-plane shear to demonstrate ductility.
- Push-out samples on panels to demonstrate the effectiveness of the composite behaviours of the SC structures for both shear connectors and tie bars.
- Weld fatigue tests on tie bars to the steel faceplates to confirm that the fatigue life can meet the anticipated number of stress cycles.
- Cyclic in-plane shear to demonstrate that shear strength of SC can be conservatively estimated using ACI code provisions for reinforced concrete walls as well as ductility requirements.
- Anchorage in the concrete to demonstrate the strength of the reinforced concrete/ SC connection in tension.

The programme was carried out at Purdue University and the tests were fully instrumented to record their behaviour through the loading sequence to destruction so that this could be captured in the nonlinear analyses. The results effectively demonstrate that the ACI 349-01 code provisions for reinforced concrete nuclear structures are conservatively applicable to the SC design of the shield building. The tests results presented in Reference 16.3, Section 7 demonstrate the robust behaviour of the SC structural components in the AP1000 design.

The nuclear island is substantiated using three levels of analysis as identified in Section 16.8. For the shield building SC construction, each level of analyses is verified using two separate approaches (standard and confirmatory). The standard approach uses simpler analytical techniques and design code provision; the confirmatory approach uses benchmarked nonlinear material properties to examine the effects of cracking and local yielding in critically loaded elements to ensure robustness in the design and to confirm that a significant design margin is achieved.

The confirmatory tests at Purdue University are used in the benchmarking of the nonlinear analyses presented in Reference 16.3, Section 8. Examination of the conservatisms associated with the analyses and design assumptions of the shield building (Reference 16.3, Sections 11.1 and 11.2) shows that the design has reserve strength that provides seismic margin above the review-level earthquake. The analyses presented in Reference 16.3, Section 11.3 show that the seismic high confidence of low probability of failure (HCLPF) value is above the review-level earthquake value of 0.5g. The standard seismic margin calculations are based on conservative design loads.

16.10.4 Containment Air Baffle

The containment air baffle is located within the upper annulus of the shield building, providing an airflow path for the PCS as shown in Figure 6-5. The functional requirements are specified in Reference 16.47. The air baffle separates the downward airflow entering at the air inlets from the upward airflow that cools the containment vessel and flows out of the discharge stack. The air baffle is a seismic C-I structure and includes the following sections:

- A wall supported off the shield building roof
- A series of panels attached to the containment vessel cylindrical wall and the knuckle region of the dome
- A flexible seal closing the gap between the wall and the panels fixed to the containment vessel, designed to accommodate the differential movements between the containment vessel and shield building
- Flow guides attached at the bottom of the air baffle to minimize pressure drop

The air baffle is designed to meet the following functional requirements:

- The baffle and its supports are configured to minimize pressure losses as air flows through the system
- The baffle and its supports have a design objective of 60 years
- The baffle and its supports are configured to permit visual inspection and maintenance of the air baffle as well as the containment vessel. Periodic visual inspections are primarily to inspect the condition of the coatings
- The baffle is designed to maintain its function during postulated design basis accidents
- The baffle is designed to maintain its function under specified external events including earthquakes, hurricanes, and tornadoes

The integrity of the steel structure has been demonstrated by applying the criteria presented in ANSI/AISC-N690-1994 (Reference 16.24).

16.11 AUXILIARY BUILDING

The auxiliary building is a C-I structure, forming part of the nuclear island, which houses the Class 1 equipment that is outside the shield building.

The layout of the auxiliary building and its interface with the other buildings of the nuclear island is shown in figures in Reference 16.2. The following are the principal systems and components of the auxiliary building:

- Main control room (MCR)
- Remote shutdown room
- Class 1 dc switchgear
- Class 1 batteries
- Reactor trip switchgear
- Reactor coolant pump trip switchgear

- Main steam and feedwater piping
- MCR heating, ventilating, and air conditioning (HVAC)
- Class 1 switchgear rooms' HVAC
- Spent fuel pool (SFP)
- Fuel transfer canal
- Cask loading and washdown pits
- New fuel storage area
- Cask handling crane
- Fuel handling machine
- CVS makeup pumps
- Normal residual heat removal system (RNS) pumps and heat exchangers
- Liquid radwaste tanks and components
- Spent fuel pool cooling system
- Gaseous radwaste processing system
- Mechanical and electrical containment penetrations

16.11.1 Structural Description

The auxiliary building is a reinforced concrete and structural steel structure. Three floors are above grade and two are located below grade. It is one of three buildings that make up the nuclear island and shares a common basemat with the containment vessel and the shield building.

The auxiliary building is a C-shaped section of the nuclear island that wraps around approximately 50 percent of the circumference of the shield building. As noted in the description of the shield building above, the floor slabs and the structural walls of the auxiliary building are structurally connected to the cylindrical section of the shield building.

Structural modules are used for part of the south side of the auxiliary building using SC construction similar to that used in the construction of the shield building cylindrical wall. Reference 16.38, Figure 4 shows the location of the structural modules. The thickness of the structural wall modules ranges from 762 to 1524 mm (30 to 60 inches) for the key structural walls. The auxiliary building modules also include smaller structural walls that act as labyrinth walls or barrier access walls with thicknesses less than 762mm (30 inches). Local variation in the design of the trusses and spacing of the trusses and shear studs may be required to address internal obstructions and accessibility for fabrication and inspection. The minimum thickness of the faceplates is 12.7 mm (0.5 inch). Portions of the faceplates are thicker than the nominal design thickness to provide strength for localized loads due to attachments and connections. The auxiliary building modules are placed on the nuclear island basemat. A typical connection is shown in Reference 16.4, Figure 3-6. The SC structural modules used in the construction of the auxiliary building and the in-containment structures are termed CA modules. The largest CA module is CA20, which is approximately four storeys high and weighs about 1000 tonnes (2,200,000 pounds) when it is lifted into position before concrete is placed between the steel faceplates.

CA20 is a large portion of the fuel handling area in the radiological controlled portion of the auxiliary building. The fuel handling area provides for transferring new fuel assemblies from the auxiliary building rail car bay to and from the new fuel storage area to the containment building, and for transferring spent fuel assemblies from the containment building to the spent fuel storage pit within the auxiliary building. The spent fuel storage facility is designed to the guidelines of ANS 57.2 (Reference 16.43). The spent fuel storage facility is located

within the seismic C-I auxiliary building fuel handling area. The walls of the SFP are an integral part of the auxiliary building structure.

The SFP provides storage space for the spent fuel. The spent fuel storage racks are designed as seismic C-I equipment. Additionally, the racks are evaluated for uplift loads, fuel assembly drop accidents, and live loads due to lifting.

The fuel handling area provides the means for removing the spent fuel assemblies from the spent fuel storage pit and loading the assemblies into a shipping cask for transfer from the facility.

The fuel handling area is protected from external events such as tornadoes and tornado-produced missiles. Protection is provided for the spent fuel assemblies, the new fuel assemblies, and the associated radioactive systems from external events.

The new fuel storage area is a separate reinforced-concrete pit providing temporary dry storage for the new fuel assemblies.

A cask handling crane travels in the east-west direction. The location and travel of this crane prevents it from carrying loads over the SFP, thus preventing crane loads from falling into the SFP.

The non radiological portion of the auxiliary building contains the MCR, remote shutdown room, and Class 1 electrical and control and instrumentation (C&I) equipment rooms. The ceilings of the MCR and the C&I rooms are designed as finned floor modules. A finned floor consists of a 609.6-mm-thick (24 inches) concrete slab poured over a stiffened steel plate ceiling. The fins are rectangular plates welded perpendicular to the underside of the plate. Shear studs are welded on the upper side of the steel plate so that the steel and concrete act as a composite section. The fins are exposed to the environment of the room and enhance the heat-absorbing capacity of the ceiling. Several shop-fabricated steel panels, placed side by side, are used to construct the stiffened plate ceiling in a modular manner. The stiffened plate is designed to withstand construction loads from wet concrete.

16.11.2 Analysis and Design Justification of Auxiliary Building

The nuclear island must be analysed as a whole to capture the complex load distributions acting on the basemat, walls, and slabs of the shield building and auxiliary building. The seismic analyses of nuclear island computer models are discussed in Section 16.8.3 above. Reinforced concrete and structural steel are justified in design calculations for each structural element to the codes and standards identified in Section 16.5.1 to sustain the loads and effects specified in Sections 16.7 and 16.8. The general approach is described below for each type of structural element.

16.11.2.1 Shear Walls

Shear walls in the auxiliary building vary in size, configuration, aspect ratio, and the amount of reinforcement they contain. The stress levels in the shear walls depend on these parameters and the seismic acceleration level. Exterior shear walls are several stories high and do not have many large openings. Interior shear walls, however, are discontinuous in both vertical and horizontal directions. The in-plane behaviour of these shear walls, including the large openings, is adequately represented in the analytical models for the global seismic response. Where the refinement of these finite element models is insufficient for design of the reinforcement, for example, in walls with a large number of openings, detailed finite element models are used. The shear walls are used as the primary system for resisting lateral loads

such as earthquakes. The auxiliary building shear walls are also evaluated for flexure and shear due to the out-of-plane loads.

The auxiliary building shear walls are designed to withstand the loads discussed in Sections 16.7 and 16.8. Besides dead, live, and other normal operating condition loads, the following loads are considered in the shear wall design:

- Seismic loads
  - The SSE loads for the wall are obtained from the seismic analyses of the auxiliary building and shield building described in Section 16.8.3.
  - Calculations are performed by considering shear wall segments. Segments are rectangles bounded by the floors above and below each segment and perpendicular walls that define the sides of the segment. Appropriate boundary conditions are assumed for the four edges of the segment. The natural frequencies of wall segments are determined using finite element models or text book formulas for the frequency of plate structures. The corresponding spectral acceleration is determined from the applicable response spectrum.
  - Exterior walls, below grade level, are also evaluated for dynamic earth pressure exerted during an SSE for two cases: dynamic earth pressure calculated in accordance with ASCE 4-98 (Reference 16.18) and passive earth pressure.
- Accident pressure load
  - Shear walls of the MSIV rooms are designed for 41 kN/m^2 (6 psi) differential pressure acting in conjunction with the seismic loads. Member forces due to accident pressure and SSE are combined by absolute sum.
  - The MCR wall of the east MSIV compartment is evaluated for the pressure and the jet load due to a postulated main steam line break.
- Tornado load
  - Tornado loads are considered for exterior walls above grade level.

Reference 16.6 includes the design temperatures for thermal gradient and contains the load combinations for which the shear walls are designed, as applicable. The wall sections are designed in accordance with the requirements of ACI 349-01 (Reference 16.15).

16.11.2.2 Composite Structures (Floors and Roof)

The floors consist of a concrete slab on a metal deck, which rests on structural steel floor beams. Several floors in the auxiliary building are designed as one-way reinforced concrete slabs supported continuously on steel beams. Typically, the beams span between two reinforced concrete walls. The beams are designed as composite with formed metal deck spanning perpendicular to the members. Unshored construction is used. For the floors, beams are predominately spaced at about 1.5 to 1.83-m (4.92 to 6 feet) intervals and spans are between 4.6 and 7.6 m (15 and 25 feet). Based on local geometry considerations, the intervals and spans are outside these ranges in a limited number of locations. The spacing between the beams or between beams and walls is as small as 0.91m (3 feet) and as large as 2.44m (8 feet). The span of the beams is as small as 7.6m (25 feet) and as large as 11.7m (38.39 feet). The designs of the beams satisfy the requirements in AISC N690 for composite structures.

The metal deck rests on the top flanges of the structural steel floor beams with the longitudinal axes of the metal deck ribs and floor beams perpendicular to each other. The reinforcement size and spacing are based on loads and spans for this type of floor and are determined at each location based on the requirements in ACI 349-01 and ACI 318-11, Section 12.6. The development of the floor reinforcement in the walls can be either headed reinforcement or standard hooks. The beam size and spacing and beam support designs are based on loads and spans for this type of floor. The beam support designs include beam seats or shear plates connected to the web of the beam. The detail design of the support for the beam, including the portion embedded in the concrete wall, is based on the load and structural system configuration. The designs of these floors are in conformance with AISC N690 and ACI 349. The concrete slab is tied to a structural steel floor beam by shear connectors welded to the top flange of a floor beam. The concrete slab and the floor beams form a composite floor system. For the design loads after hardening of concrete, the transformed section is used to evaluate stresses.

The construction sequence is as follows:

- A section of structural steel floor (comprising a floor beam, metal deck, and shear connectors) is fabricated in the shop, brought to the floor location, and placed in position. In some cases, all the beams and deck are preassembled and placed as a module.

- The metal deck is used as the formwork, and concrete is poured on the metal deck. Until the concrete hardens, the load is carried by the metal deck and the supporting steel floor beams.

- During concreting, no shoring is provided.

The floor design considers the dead, live, construction, extreme environmental, and other applicable loads as identified in the civil structural design criteria (Reference 16.6). The design floor loading includes the equipment attached to the floor. The end conditions for the steel beams are simply supported or continuous as appropriate. The seismic load is obtained using the applicable floor acceleration response spectrum (7-percent damping for the SSE loads).

The load combinations applicable to the design of these floors are shown in Reference 16.6 for steel and reinforced concrete C-I structures. The design of the floor system is performed in two parts:

- Design of steel beams

  – The structural steel floor beams are evaluated to withstand the weight of wet concrete during the placement of concrete. The composite section is designed for the design loads during normal and extreme environmental conditions. Shear connectors are also designed.

- Design of concrete slab

  – The concrete slab and the steel reinforcement of the composite section are evaluated for normal and extreme environmental conditions. The slab concrete and the reinforcement are designed to ACI 349-01 (Reference 16.15).

  – The slab design considers the in-plane and out-of-plane seismic forces. The global in-plane and out-of-plane forces are obtained from the response spectrum analysis of the 3-D finite element model of the auxiliary and shield buildings. The out-of-plane

seismic forces due to the floor local responses are determined by hand calculations using the applicable vertical seismic response spectrum and slab frequency.

16.11.2.3 Reinforced Concrete Slabs

Reinforced concrete floors in the auxiliary building are either 610 or 915 mm (24 or 36 inches) thick. These floors are constructed with reinforced concrete placed on top of 203 to 305-mm-thick (8 to 12 inches) precast concrete panels. The precast concrete panels are installed at the bottom to serve as the formwork and withstand the weight of the wet concrete. The main reinforcement is provided in the cast-in-place concrete. Reinforcement is placed in both the top and bottom layers of the cast-in-place concrete in both directions. For the design of the reinforcement in the cast-in-place floors, post-construction loads are conservatively assumed to be resisted only by the cast-in-place concrete and the reinforcement placed within it. The reinforcement in the cast-in-place portion is fully developed into supporting adjacent walls such that the connection is assumed to be a fixed connection. The development of the floor reinforcement in the walls is achieved using either headed reinforcement or standard hooks.

The precast panels, which are connected to the concrete above by shear reinforcement, satisfy the requirements of ACI 349 Chapter 17. The precast panels and the cast-in-place concrete are made to act together as a composite reinforced concrete slab by roughening the top surface of the precast panel and providing shear ties between the two elements. The detail designs of the supports for the precast panels are based on the loading and design requirements.

The finite element analysis model used for the auxiliary building seismic response assumes a homogenous thickness of concrete for the floor system, and includes floor-to-wall connections that are fixed over the full thickness of the reinforced concrete floor. The detailed design of the floor system includes a gap between the precast panel and the wall and between adjacent precast panels. Although the gap between the precast panels and the wall reduces the thickness of the floor in direct contact with the wall, the design of the floor system satisfies the requirements of ACI 349, including fully developing the floor reinforcement in the wall. The design of the floor system and the connection with the wall provide a fixed connection that transfers forces and moments from the floor to the wall.

Detailed analysis of the floor system connection design details, including the gap between the precast panel and wall, is performed for the floor constructed with precast panels and is consistent with the nuclear island seismic model. The effects of stiffness, reinforcement anchorage, and concrete cracking are considered in the detailed analyses. The detailed analyses demonstrate that these floors have vertical response above 33 Hz and are rigid, which is consistent with the nuclear island seismic model.

16.11.2.4 Concrete Finned Floors

The ceilings of the MCR and C&I room in the auxiliary building are designed as finned-floor modules. A typical floor design is shown in Reference 16.38, Figure 3b. A finned floor consists of a 610–mm-thick (24 inches) concrete slab poured over a stiffened steel plate ceiling. The fins, welded to stiffen the steel plate, are rectangular sections perpendicular to the plate. Shear studs are welded on the other side of the steel plate to allow composite action of the steel and concrete. The fins are exposed to the environment of the room and enhance the heat-absorbing capacity of the ceiling. Several shop-fabricated steel panels, cut to room width and placed side by side perpendicular to the room length, are used to construct the

stiffened-plate ceiling in a modularised fashion. The stiffened plate with fins is designed to withstand construction loads prior to concrete hardening.

The MCR ceiling, comprising a finned floor, is designed for dead, live, and seismic loads.

The finned floor structure is evaluated for the load combinations referred to in Section 16.7.3.

The finned floors are designed as reinforced concrete slabs in accordance with ACI 349-01 (Reference 16.15). The finned floors resist vertical and in-plane forces for both normal and extreme loading conditions. For positive bending, the concrete above the neutral axis carries compressive stresses and the stiffened steel plate resists tension. The steel plate with fin stiffeners serves the function of bottom reinforcement. Negative bending compression is resisted by the stiffened plate and tension in the top reinforcement. For negative bending, the potential for the steel fins to buckle because of compression is checked using ANSI/AISC-N690-1994 (Reference 16.24). In addition, the concrete restrains twisting and therefore lateral buckling of the stiffener. The neutral axis for negative bending is located in the stiffened-plate section and the concrete in tension is assumed to be inactive. Horizontal in-plane forces are resisted by the stiffened plate and the longitudinal reinforcement.

Minimum top reinforcement is provided in the slab in each direction for shrinkage and temperature crack control. In addition, top reinforcement located parallel to the fin stiffeners is used as tension reinforcement in negative bending. The stiffened plate provides crack control capability for the bottom of the slab in the transverse direction.

Composite section properties, based on an all steel-transformed section, as detailed in ANSI/AISC-N690-1994 (Reference 16.24, Section Q1.11), are used to design the following:

- Weld strength between stiffener and steel plate
- Spacing of shear studs for composite action

The stiffened plate alone is designed to resist all construction loads prior to the concrete hardening. The plate is designed against the criteria for bending and shear, specified in ANSI/AISC0-N690-1994 (Reference 16.24, Sections Q1.5.1.4 and Q1.5.1.2). In addition, the weld between the stiffener and the steel plate is designed to satisfy the code requirements. Finned panels have an approximate short span of 4.9 m (16 feet), except for the main control room ceiling finned panel, which has a short span of 11.23 m (37 feet) and requires temporary supports at mid span during construction.

16.11.2.5 Structural Modules

Structural modules are used for some of the structural elements on the south side of the auxiliary building. These structural modules are structural elements built up with welded steel structural shapes and plates. The modules consist of steel faceplates connected by steel vierendeel frames as shown in Reference 16.38. The thicknesses of the steel faceplates are generally 12.7 mm (0.5 inch). In certain locations, the face plates are thickened.

The primary purpose of the frames is to stiffen and hold together the faceplates during handling, erection, and concrete placement. The nominal spacing of the frames is 762 mm (30 inches). Shear studs are welded to the inside faces of the steel faceplates. Faceplates are welded to adjacent faceplates on the same face with full-penetration welds so that the weld is at least as strong as the plate. The structural wall modules are anchored to the concrete base by a mechanical connection that uses reinforcing bars and mechanical connectors. After erection, concrete is placed between the faceplates.

These modules include the SFP, fuel transfer canal, cask loading pit, and cask washdown pit. The structural modules in the auxiliary building are similar to the structural modules for the in-containment structures. Reference 16.38 shows the location of the structural modules in the auxiliary building. The loads and load combinations applicable to the structural modules in the auxiliary building are the same as for the containment internal structures, except that there are no ADS or pressure loads due to pipe breaks.

The design methodology of these modules in the auxiliary building is similar to the design of the in-containment modules presented in Section 16.13.

The design of SC CA modules was a cause of concern for the UK Regulator (see Section 16.20) as the form of construction was not the same as that used for the shield building cylindrical wall. To address this issue, a separate justification was prepared for the SC-constructed CA modules (Reference 16.4).

The concrete floors on steel plates in the CA20 module are designed as reinforced concrete slabs in accordance with ACI 349-01. The steel panels are designed and constructed in accordance with AISC N690. For positive bending, the steel plate is in tension and the steel plate and stiffeners serve as the bottom reinforcement. For negative bending, compression is resisted by the concrete and the stiffened plate and tension by top reinforcement in the concrete. This methodology is described in Reference 16.38, Section 7.2.

16.12 IN-CONTAINMENT CIVIL ENGINEERING STRUCTURES

The design justification of the in-containment structural modules is provided in Reference 16 -4 and is supported by the additional information provided in Reference 16.41. The in-containment structures are part of the nuclear island and are A1 C-I structures. The containment internal structures are those concrete and steel structures inside (not part of) the containment pressure boundary that structurally support the Class 1 components. The containment internal structures include the primary shield wall, reactor cavity, secondary shield walls, IRWST, refuelling cavity walls, operating floor, intermediate floors, various platforms, and the internal structures' basemat. The polar crane girder is considered part of the containment vessel and is addressed in Chapter 20.

Component supports are those steel members designed to transmit loads from the vessels, systems, and components back to the load-carrying elements of the in-containment structures. Component supports are addressed in the ASME jurisdictional boundary and are not considered to be civil engineering structures; therefore, component supports are outside the scope of this chapter. Component failures are addressed through the Structural Integrity program.

16.12.1 Structural Descriptions

The containment internal structures are designed using reinforced concrete and structural steelwork. At the lower elevations, conventional reinforced concrete is used for construction of the basemat, which includes a number of rooms. Permanent steel forms are frequently used in lieu of removable forms based on constructability considerations. These steel form modules (liners) consist of plate reinforced with angle stiffeners and tee sections. The angles and the tee sections are on the concrete side of the plate. Welded studs, or similar embedded steel elements, are attached on the concrete face of the permanent steel form where surface attachments transfer loads into the concrete. Where these surface attachments are C-I, the portion of the steel form module transferring the load into the concrete is classified as C-I.

Walls and floors are generally concrete-filled steel plate structural modules. The walls are supported on the mass concrete containment internal structures basemat with the steel faceplate extending down to the concrete floor on each side of the wall. The steel faceplates of the structural modules provide reinforcement to the concrete. The structural modules are anchored to the base concrete using mechanical connections. Reference 16.38 shows the locations of typical structural modules (Figure 1), the typical structural configuration of the wall modules (Figure 2-5), and a representative floor module (Figure 3a). These structural modules are structural elements built up with welded steel structural shapes and plates. Concrete is used where required for shielding, but reinforcing steel is not normally used.

Walls and floors exposed to water during normal operation or refuelling are constructed using stainless-steel plates.

16.12.1.1 Containment Internal Structures Basemat

The containment internal structures basemat is the reinforced concrete structure filling the bottom head of the containment vessel. It extends from the bottom of the containment vessel head up to the bottom of the structural modules that start between elevations 91.3 m (71'-6") and 100.9 m (103'-0"). The basemat includes rooms as shown in Reference 16.49. The primary shield wall and reactor cavity extend from elevation 91.3 m (71'-6") to 102.2 m (107'-3"). They provide support for the reactor vessel and portions of the secondary shield walls and refuelling cavity walls. The general arrangement drawings in References 16.48 through 16.60, show the location and configuration of the primary shield wall and reactor cavity. The walls of the primary shield, the SG compartments, and the CVS room are structural modules as shown in Reference 16.38, Figure 1. The rest of the basemat is reinforced concrete.

16.12.1.2 Structural Wall Modules

Structural wall modules are used for the primary shield wall around the reactor vessel, the wall between the vertical access and the CVS room, secondary shield walls around the SGs, and pressuriser, for the east side of the IRWST and for the refuelling cavity.

The general arrangement drawings of the nuclear island are shown in References 16.48 through 16.60. Reference 16.38 shows the locations of the structural modules in detail in Figure 1; it provides an isometric view showing some typical arrangements of the structural modules where the steel faceplates provide wall reinforcement in Figures 2 and 6. The structural wall modules are as follows:

- The secondary shield walls are a series of walls that, together with the refuelling cavity wall, enclose the SGs and pressurizer. Each of the two secondary shield wall compartments provides support and houses a SG and reactor coolant loop piping.

- The IRWST extends from approximately elevation 100.9 m (103'-0") to directly below the operating deck. On the west side, along the containment vessel wall, the tank wall consists of a stainless-steel plate stiffened with structural steel sections in the vertical direction and angles in the horizontal direction. Structural steel modules, filled with concrete and forming, in part, the refuelling cavity, SG compartment, and pressuriser compartment walls, compose the east wall.

- The refuelling cavity has two floor elevations: the area around the reactor vessel flange is at elevation 102.2 m (107'-2"), and the lower level is at elevation 99.4 m (98'-1"). The

upper and lower reactor internals storage is at the lower elevation, as is the fuel transfer tube.

- Structural wall modules consist of steel faceplates connected by vierendeel frames. The primary purpose of these frames is to stiffen and hold together the faceplates during handling, erection, and concrete placement. At corner locations, the trusses are replaced with diaphragms. These diaphragms have similar purpose as the trusses and are used to fabricate the modules in the corners. Shear studs are welded to the inside faces of the steel faceplates. Faceplates are welded to adjacent plates with full penetration welds so that the weld is at least as strong as the plate.

The design methodology of the structural wall modules is provided in Reference 16.38, and justification for the design of the structural wall modules is provided in Reference 16.4.

16.12.1.3 Structural Floor Modules

Structural floor modules are used for the operating deck at elevation 110.7 m (135'-3") over the IRWST and for the 102.2 m (107'-2") Maintenance Floor over the rooms in the containment internal structures' basemat. The floors are shown on the general arrangement drawings in References 16.48 through 16.60. The floors consist of steel tee- and wide-flange sections, welded to horizontal steel bottom plates stiffened by transverse stiffeners. After erection, concrete is placed on top of the horizontal plate and around the structural steel section. A portion of the operating floor consists of a concrete slab placed on metal decking supported by structural steel beams. The operating deck is supported by the IRWST walls, refuelling cavity walls, secondary shield walls, and steel columns. Structural details for a representative example of the containment operating deck floor structural module are shown in Reference 16.38, Figure 3a.

16.12.1.4 Internal Steel Framing

The region of the operating floor away from the IRWST consists of a concrete slab placed on metal decking supported by structural steel beams. The maintenance floor mezzanine at elevation 105.6 m (118'-6") consists of steel grating supported by structural steel framing. In addition, a number of steel platforms are located above and below the operating floor. These platforms support either grating floors or equipment such as piping and valves.

16.12.2 Analysis and Design Justification of In-Containment Structures

The loads and load combinations plus the methods of analysis methods generally followed are as presented in Sections 16.7 and 16.8; however, wind loads (W) and tornado loads (Wt) are not applicable to the design of the in-containment internal structures because these structures are protected by both the shield building and the steel containment.

The nuclear island must be seismically analysed as a whole to capture the complex load distributions through the basemat, walls and slabs of the shield building and auxiliary building. The seismic analyses using the nuclear island computer models are discussed in Section 16.8.3. The NI10 model is used to calculate the seismic forces and moments for the in-containment structures.

Section 16.5.1 identifies the codes, standards, and methodologies followed when preparing the design justification for the structures making up the nuclear island, including the in-containment structures. More specific information on how this has been applied is provided in Reference 16.4.

16.13 NUCLEAR ISLAND FOUNDATIONS

16.13.1 Description and Load Paths

The nuclear island structures, consisting of the containment vessel and in-containment structures, shield building, and auxiliary building are founded on a common, cast-in-place, reinforced concrete basemat foundation. The concrete basemat is a C-I structure. The top of the foundation is at elevation 89.8 m (66'-6"). The cellular construction of the auxiliary building serves an important function in stiffening the basemat and distributing the load from the shield building and containment vessel. The cellular construction comprises vertical shear/bearing walls and horizontal floor slabs. The walls carry the vertical loads from the structure to the basemat. Lateral loads are transferred to the walls by the roof and floor slabs. The walls then transmit the loads to the basemat. Reference 16.75 shows a plan of the basemat; References 16.82 through 16.86 show sections through the nuclear island showing the basemat.

Adjoining buildings, such as the radwaste building, turbine building, and annex building are structurally separated from the nuclear island structures by a minimum 50-mm (2 inches) gap at and below the grade. A 101-mm (4 inches) minimum gap is provided above grade. This provides space to prevent interaction between the nuclear island structures and the adjacent structures during a seismic event. Reference 16.97 shows the foundation plan for the nuclear island and the adjoining structures.

For ease of construction, the foundation is built on a mud mat. The mud mat (termed blinding concrete in the UK) is lean, non-structural concrete and rests upon the load-bearing soil. Waterproofing is provided using an appropriate technique as explained in Section 16.9.1.

The ground conditions at a particular site will need to be demonstrated as no more onerous than those considered in the design. The potential exists for ground engineering techniques to be used when undertaking construction specific to a particular site. These are matters to be addressed during site licensing. The Civil/Structural Design Criteria (Reference 16.6) provides information on the criteria used in design of the AP1000 foundation. As required by Chapter 12, site-specific justification will be developed for the AP1000 nuclear island foundation design.

16.13.2 Codes and Standards

The reinforced concrete foundation is designed to ACI 349-01 (Reference 16.15) as is all reinforced concrete in the nuclear island.

16.13.3 Loads and Load Combinations for Integrity and Stability Evaluations

Loads and load combinations are as described in Sections 16.7 and 16.8. The basemat is designed for the upward hydrostatic pressure due to groundwater reduced by the downward deadweight of the basemat.

The containment vessel is a vertical steel cylinder, closed at the top and bottom by hemispherical-shaped steel plates as shown in Figure 16-4. The lower hemisphere is capable of resisting the containment internal pressure without benefit of the nuclear island basemat; however, containment pressure loads affect the nuclear island basemat since the concrete is stiffer than the steel plate forming the lower hemisphere. The containment design pressure is included in the design of the nuclear island basemat as an accident pressure load (Pa), see Section 16.7.5.3.

In addition to evaluating the integrity of the nuclear island foundation to ACI 349-01 requirements (Reference 16.15), the nuclear island is evaluated for stability against sliding and overturning. The loads considered arise from the SSE, winds, and tornadoes. Absence of flotation of the nuclear island basement under floods and high groundwater levels is also verified. The load combinations and minimum required factors of safety against overturning, sliding, and flotation are presented in Section 6.4 of Reference 16.6.

16.13.4 Design and Analysis (Excluding Construction)

The design of the basemat consists primarily of applying the design loads to the structures, calculating shears and moments in the basemat, and determining the required reinforcement. For a site with hard rock below the underside of the basemat, vertical loads are transmitted directly through the basemat into the rock. Horizontal loads arising during an earthquake are distributed to the underside of the basemat, resulting primarily in small membrane forces in the basemat slab.

The analyses of the basemat make use of the NI05 model of the auxiliary building and containment internal structures, which is summarised in Section 16.8.3 above. Interaction of the basemat with the overlying structures and the soil is addressed. Provisions are made in the model for two possible uplifts: the uplift of the containment internal structures from the lower basemat, and the uplift of the basemat from the soil. The 3-D finite element model of the basemat includes the structures above the basemat and their effect on the distribution of loads on the basemat.

The subgrade is modelled with one vertical spring and two horizontal springs at each node of the basemat. The vertical springs act in compression only for the nonlinear analyses. The horizontal springs are active when the vertical spring is closed and inactive when the vertical spring lifts off. The analyses of the basemat account for the range of soil sites specified in Table 16-3. Horizontal bearing reactions on the exterior walls below grade are conservatively neglected.

The nuclear island basemat below the containment vessel, and the containment internal structures basemat above the bottom of the containment vessel, are simulated with solid tetrahedral elements. Nodes on the two basemats are connected with spring elements normal to the theoretical surface of the containment vessel.

Dead loads are applied as inertia loads. Live loads and the SSE loads are applied as concentrated loads at the nodes of the computer model. The SSE loads are applied as equivalent static loads using the assumption that while the maximum response from one direction occurs, the responses from the other two directions are 40 percent of the maximum. Combinations of the three directions of the SSE are evaluated.

Initially, linear analyses are performed for all specified load combinations, assuming that the soil springs can resist tension. Critical load cases are then selected for subsequent nonlinear analyses with basemat liftoff based on the results of the linear cases. The results from the analysis include the forces, shears, and moments in the basemat; the bearing pressures under the basemat; and the area of the basemat that is uplifted. Reinforcing-steel areas are calculated from the member forces for each load combination case.

The required reinforcing steel for the portion of the basemat under the auxiliary building and the shield building is determined by considering the reinforcement envelope for the full nonlinear response of the nuclear island, during the period of seismic shaking, for the most critical load combination cases. Additional reinforcement is provided in the design of the basemat for soil sites so that the basemat can resist loads that are [ ] greater than

the demand calculated by the equivalent static acceleration analyses on uniform soil springs. This increase accommodates potential site-specific lateral variability of the soil, investigated separately in a series of parametric studies.

16.13.5 Analyses of Settlement during Construction

Construction loads have the potential to be significant to the design of the nuclear island basemat, depending on the soil conditions present at a particular site. Settlement evaluations are based on the most onerous soil conditions considered to fall within the scope of the foundation design. Site-specific settlement analyses will be performed at soil sites to provide justification for the nuclear island foundation.

It is anticipated that the basement concrete would be cast as a single placement. The placement would include the first 1.83 m (6 feet) of the thicker basemat below the containment vessel and shield building, but would exclude the central zone directly below the bottom of the containment vessel. Construction would continue with a portion of the shield building foundation and containment internal structure and the walls of the auxiliary building. The critical location for shear and moment in the basemat is around the perimeter of the shield building. Once the shield building and auxiliary building walls are completed to elevation 94.7 m (82'-6"), the load path changes and loads are resisted by the basemat stiffened by the shear walls.

The analyses account for the construction sequence, the associated time-varying load and stiffness of the nuclear island structures, and the resulting settlement time history. To maximise the potential settlement, the analyses consider a 109.7-m-deep (360 feet) soft-soil site. The following two soil profiles are analysed to represent limiting foundation conditions, and address both cohesive and cohesionless soils and combinations thereof:

- A soft-soil site with alternating layers of sand and clay. The assumptions in this profile maximise both the settlement in the early stages of construction and the impact of dewatering.

- A soft-soil site with clay. This assumption maximises the settlement during the later stages of construction and during plant operation.

The analyses focus on the response of the basemat in the early stages of construction when it could be susceptible to differential loading and deformations. As subsequent construction incorporates concrete shear walls associated with the auxiliary building and the shield building, the structural system strengthens significantly, minimising the impact of differential settlement. The displacements, moments, and shear forces induced in the basemat are calculated at various stages in the construction sequence. These member forces are evaluated in accordance with ACI 349-01 (Reference 6.15) using the load factors given in Reference 16.6. Three construction sequences are examined to demonstrate construction flexibility within broad limits:

- A base construction sequence that assumes no unscheduled delays. The site is dewatered and excavated. Concrete for the basemat is placed in a single pour. Concrete for the exterior walls below grade is placed after the basemat is in place. Exterior and interior walls of the auxiliary building are placed in 4.9- to 5.5-m (16 to 18 feet) lifts.

- A delayed shield building case that assumes a delay in the placement of concrete in the shield building while construction continues for the auxiliary building. This bounding case maximises tension stresses on the top of the basemat. The delayed shield building

case assumes that no additional concrete is placed in the shield building after the pedestal for the containment vessel head is constructed. The analysis incorporates construction in the auxiliary building to elevation 105.3 m (117'-6") and filling the CA20 module with concrete to elevation 110.74 m (135'-3"), and thereafter assumes that construction is suspended.

- A delayed auxiliary building case that assumes a delay in the construction of the auxiliary building while concrete placement for the shield building continues. This bounding case maximises tension stresses in the bottom of the basemat. The delayed auxiliary building case assumes that no concrete is placed in the auxiliary building after the basemat is constructed. The analysis incorporates construction in the shield building to elevation 95.123 m (84'-0") and thereafter assumes that construction is suspended.

For the base construction sequence, the largest basemat moments and shears occur at the interface with the shield building before the connections between the auxiliary building and the shield building are credited. Once the shield building and auxiliary building walls are completed to elevation 94.7 m (82'-6"), the load path for successive loads changes and the loads are resisted by the basemat stiffened by the shear walls. Dewatering is discontinued once construction reaches grade, resulting in the rebound of the subsurface.

Of the three construction scenarios analysed, the delayed auxiliary building case results in the largest demand for the bottom reinforcement in the basemat. The delayed shield building results in the largest demand for the top reinforcement in the basemat. The analyses of the three construction sequences demonstrate the following:

- The design of the basemat and superstructure accommodates the construction-induced stresses considering the construction sequence and the effects of the settlement time history.

- The design of the basemat can accommodate delays in the shield building so long as the auxiliary building construction is suspended at elevation 105.2 m (117'-6"). Construction of the auxiliary building can resume once the shield building is advanced to elevation 100 m (100'-0").

- The design of the basemat can accommodate delays in the auxiliary building so long as the shield building construction is suspended at elevation 95.1 m (84'-0"). Construction of the shield building can resume once the auxiliary building is advanced to elevation 100 m (100'-0").

- After the structure is in place and cured to elevation 100 m (100'-0"), the basemat and structure act as an integral 12.0 m (39.5 feet) deep structure; the loading due to construction above this elevation is not expected to cause significant additional flexural demand with respect to the basemat and the shield building concrete below the containment vessel. Accordingly, there is no need for placing constraints on the construction sequence above elevation 100 m (100'-0").

The site conditions considered in the evaluation provide reasonable bounds on construction-induced stresses in the basemat. Accordingly, the basemat design is adequate for practically all soil sites and can tolerate major variations in the construction sequence without causing excessive deformations, moments, and shears due to settlement during the construction period and over the plant life.

The analyses of alternate construction scenarios show that member forces in the basemat are acceptable subject to the limits shown below, imposed for soft-soil sites on the relative level of construction of the buildings. Construction of the plant, when located at a soil site, will satisfy the limits shown below or a site-specific analysis of settlement and member forces will be completed. These limits do not apply to units with a soil profile that satisfies the requirements for soft rock, firm rock, or hard rock.

Prior to completion of both the shield building and auxiliary building at elevation 94.7 m (82'-6"), concrete may not be placed as follows:

- Above elevation 95.1 m (84'-0") for the shield building or containment internal structure.
- Above elevation 105.3 m (117'-6") in the auxiliary building, except in the CA20 structural module, where it may be placed at elevation 110.74 m (135'-3").

Member forces in the basemat considering settlement during construction differ from those obtained from the analyses on uniform elastic soil springs described in Section 16.14.4 above. Although the bearing pressures at the end of construction are similar in the two analyses, the resulting member forces differ because of the progressive changes in structural configuration during construction. Using the results of the analyses described in Section 16.14.4, the design provides sufficient structural strength to resist the specified loads, including bearing reactions on the underside of the basemat. The member forces in these analyses are those due to primary externally applied loads and do not consider secondary stresses and strains locked in during early stages of construction. A confirmatory evaluation was performed to demonstrate that the member forces due to design basis loads, including locked-in forces due to construction settlement, remain within the capacity of the section. The evaluation was performed for critical locations that were selected as locations where the effect of locked-in member forces were judged to be most significant.

The governing scenario is the case with a delay in the auxiliary building construction for the soft-soil site with alternating layers of sand and clay. The delay is postulated to occur just prior to the stage where the auxiliary building walls are constructed. Member forces at the end of construction are calculated considering the effects of settlement during construction. The differences in these member forces from those calculated for dead load in the analyses on soil springs are added as additional dead loads in the critical SSE load combination.

For the five critical sections with the most heavily stressed members, the member forces for the load combination of dead load plus SSE (including the member forces locked-in during various stages of plant construction) lead to stresses that are acceptable with respect to the ACI 349-01 design criteria (Reference 16.15); thus, the strength capacities of the structural members are not exceeded.

16.13.6 Stability Evaluations

16.13.6.1 Bearing Pressure

Bearing pressure demand was calculated using both 2-D and 3-D analyses. Both linear and nonlinear finite element analyses were performed using the 2-D nuclear island model. The maximum bearing pressures calculated include the effects of dead, live, and seismic loads.

The effects of basemat uplift were evaluated using an east-west lumped-mass ANSYS stick model of the nuclear island structures supported on a rigid basemat with nonlinear springs. Since the largest bearing pressure will result from the east-west seismic excitation because of

the smaller width of the basemat in this direction, liftoff was evaluated using an east-west stick model of the nuclear island structures supported on a rigid basemat with nonlinear springs. Finite element time history analyses were performed. Liftoff increases the bearing pressure close to the west edge by 4 to 6 percent, with insignificant effect beneath most of the basemat.

The SASSI soil-structure interaction analyses were performed based on the nuclear island 3-D SASSI model for the HR (hard rock) and the five soil conditions established from the AP1000 2-D SASSI analyses (Reference 16.32, Section 4.4.1.2). The SASSI model of the nuclear island is based on the NI20 finite element model. The bearing pressures from the 3-D SASSI analyses have been obtained by combining the time history results from the north-south, east-west, and vertical earthquakes. The limit on bearing pressure is presented as a site interface parameter in Table 16-3.

16.13.6.2 Sliding, Overturning, and Floatation

The minimum required factors of safety against sliding, overturning, and flotation for the nuclear island structures are given in Section 6.4 of Reference 16.6. The factors of safety for sliding and overturning for the SSE are calculated for each soil case for the base reactions in terms of shear and bending moments about the edges of the auxiliary building and the west side of the shield building at each time step of the seismic time history at a hard rock site. The reactions from the 2-D SASSI model (see Section 16.8.3) are used to obtain seismic response factors between the HR case to the UBSM (upper-bound soft-to-medium soil) case and the SM case (Reference 16.32). These factors are used to adjust the HR time history to reflect the seismic response for the other two potential governing soil cases, UBSM and SM (soft-to-medium soil). The firm rock, soft rock, and soft soil cases have higher factors of safety against sliding and, therefore, are not considered.

Using the 2-D ANSYS model, a nonlinear finite element analysis with sliding friction elements was performed. Sliding was only modelled in the east-west direction. There is no need to consider the north-south direction since the nuclear island deflections, calculated to maintain a factor of safety of 1.1, are largest in the east-west direction. This model was modified by introducing friction elements between the bottom of the basemat and soil media interface. Time history analysis was performed with vertical uplift and sliding allowed. The three cases that have the lowest factor of safety related to sliding were evaluated: HR, UBSM, and SM. The magnitude of the seismic input was increased by 10 percent to maintain the factor of safety against sliding of 1.1. No passive soil resistance is considered. Sliding during the seismic event is therefore negligible and no passive soil resistance is necessary from the backfill (side soil). Hence, it can be concluded that the nuclear island is stable against sliding, and there is no requirement for the backfill material adjacent to the nuclear island basement walls to maintain stability against sliding.

16.13.6.3 Effect of Nuclear Island Basemat Uplift on Seismic Response

The effects of basemat uplift were evaluated using an east-west lumped-mass stick model (see Section 16.13.6.1). Floor response spectra from the SSE time history analyses, which included basemat uplift, were compared with those from analyses that did not include uplift. The comparisons showed that the effect of basemat uplift on the floor response spectra is not significant.

16.14 DESIGN OF STRUCTURES EXTERNAL TO THE NUCLEAR ISLAND

The loads, analysis methods, and design criteria applied for the design of the structures external to the nuclear island are presented in previous sections of this chapter. The design of the structures will meet all the criteria. In particular, the design ensures that no C-II structures will collapse against the nuclear island with consequences that affect nuclear safety. As the safety of the plant is predominantly dictated by the robustness of the nuclear island, it is not necessary for detailed information to be provided on the design of the structures external to the nuclear island.

16.15 MARGINS BEYOND THE DESIGN BASIS

For SSCs required for safe shutdown, the HCLPF magnitudes are equal to or greater than the review-level earthquake, set at 0.5g; thus, it can be concluded that an adequate seismic margin is present for the nuclear island and the Class 1 equipment within it.

Section 16.4 considers extreme wind, extreme snow, hurricanes, and tornadoes to determine whether the design is conservative with regards to potential environments at UK sites.

The shield building is a very robust barrier against winds, tornadoes, and missiles, thus preventing damage to the containment vessel and the in-containment Class 1 safety systems. The external envelope to the auxiliary building, although not as robust as the shield building, is nevertheless more than adequately robust as it has been designed to resist tornado loading. The intensity of tornadoes considered is very conservative in the UK context, indicating large margins with no potential for a step change in response beyond any possible UK tornado. A significant tornado missile considered for the design of the whole of the exterior envelope to the nuclear island is a 1814 kg (4000 lb) car with an impact velocity of 47 m/sec (105 mph) horizontally or 33 m/sec (74 mph) vertically. Thus it can be concluded that significant margins exist with respect to the ability of the nuclear island to withstand extreme wind, extreme snow, tornadoes, and missiles.

Noting that the nuclear island contains the highly reliable Class 1 equipment, the protection of the Class 2 equipment does not need to be so robust for the following reason:

- The hazard-withstand requirements applicable to the remaining Class 2 structures are predominantly driven by the need to ensure that risks are ALARP. Based on the robustness of the nuclear island, it is considered that the approach to the design of the civil engineering structures against extreme wind, extreme snow, tornadoes, and missiles, when considered in its entirety, ensures an adequate margin with respect to nuclear safety.

The absence of site flooding sufficient to lead to an event with nuclear consequences depends on the plant being located at an appropriate elevation, which is a site-specific issue. It is for site-specific safety cases to present the arguments that adequate margins exist with respect to flooding from sources external to the site (i.e., there are no step changes in consequence as a result of slightly lower-frequency events than DBEs).

Should temperatures exceed the design basis limits, there would be some forewarning of such an event and mitigating action would be taken by the operator. The response of the buildings would not change significantly as a result of temperatures moving outside the DBE limits and any building effects would not be significant for the SSCs within the plant.

16.16 RECORDING AND RESPONDING TO EARTHQUAKES

16.16.1 Seismic Instrumentation

The plant seismic instrumentation has no safety function, and therefore, is assigned neither a safety class nor a seismic classification. The instrumentation and associated equipment are used to measure plant response to earthquake motion. Four triaxial acceleration sensor units are connected to a time-history analyser. The time-history analyser recording and playback system is located in a panel in the nuclear island in a room near the main control room. Seismic event data from these sensors are recorded on a solid-state digital recording system at 200 samples per second per data channel.

16.16.2 Post-Earthquake Procedures

Site-specific procedures will be prepared for activities following an earthquake. These procedures will be used to accurately determine both the response spectrum and the cumulative absolute velocity of the recorded earthquake ground motion from the seismic instrumentation system. The procedures and the data from the seismic instrumentation system will provide sufficient information to guide the operator on a timely basis to determine if the level of earthquake ground motion requiring shutdown has been exceeded.

16.17 LIFE CYCLE ENGINEERING SUBSTANTIATION

The plant has a planned 60 years operating life. The capability of the nuclear island civil engineering structures to support and protect the Class 1 SSCs is essential for safety. The engineering and safety arrangements throughout the life cycle of the AP1000 plant are presented in Chapter 7, “Life Cycle Engineering and Safety.” It focuses on specific aspects of the management arrangements associated with the achievement of nuclear safety throughout the design life cycle of the plant considering the design, change control, construction, commissioning, maintenance, ageing, degradation and decommissioning.

Beyond 60 years, it is likely that the nuclear island structures will still need to provide such safety functions until such time as decommissioning has removed all the significant nuclear materials. Replacing the nuclear island civil engineering structures is generally not an option, which can be a possibility when considering internal plant; therefore, the nuclear island structures will need to have a working life well in excess of 60 years, with the exception of some of the water storage structures that may no longer be needed following cessation of power operation.

The nuclear island is constructed from a combination of reinforced concrete, structural steelwork, and SC-constructed elements. A working life of 120 years is achievable in line with normal civil engineering criteria (Reference 16.30, Table NA.2.1). The factors that determine the life of a civil engineering structure and which should be considered to achieve a working life of 120 years are as follows:

- Use of the structure
- Design criteria
- Environmental conditions
- Composition, properties, and performance of the materials and products
- Properties of the soil
- Choice of the structural system
- Shape of members and the structural detailing
- Quality of workmanship and the level of control

- Particular protective measures
- Intended maintenance during the design working life

The nuclear island civil structures are designed and constructed to nuclear-specific codes and standards and will be maintained to a high standard. It is to be expected, therefore, that the life expectancy of the structures will be equivalent to the best that has been achieved for normal construction. Site-specific studies will be undertaken to evaluate whether there are any corrosive effects local to a site and, if found, appropriate protection will be provided. In addition, through-life inspection and testing will be undertaken to ensure that no site-specific or other effects, local to a structure, could cause accelerated ageing.

The nuclear island structures are generally of massive proportions and are not vulnerable to local defects since forces within the structure would redistribute. Where the potential for redistribution may be limited, inspections will be undertaken on a more regular basis.

The tolerability of a reinforced concrete structure to ageing effects depends on the concrete cover, the concrete mix design, and the quality of workmanship. The concrete for construction is specified as having a minimum concrete strength of 27.6 N/mm^2 (4 ksi) (Reference 16.6, Section 7.1) and cover as follows (Reference 16.6, Section 11.2):

Structure	Thickness of Reinforcement Cover
Auxiliary building exterior walls	50 mm (2.0 inch)
Auxiliary building interior walls	38 mm (1.50 inch)
Shield building	50 mm (2.0 inch)
Slabs	25 mm (1.0 inch)

Assuming a 10-mm (0.5 inch) construction tolerance allowance, there will be a minimum reinforcement cover of 38 mm (1.50 inch), which normally provides sufficient protection for an environment containing airborne salts representative of a coastal site. The adequacy of 40-mm protection will depend on the details of the concrete mix design, specified to ACI 349-01 (Reference 16.15), for which more information will be provided during site licensing.

Reference 16.6, Section 7.2 identifies that epoxy-coated reinforcement bars are used when environments are identified as corrosive.

The shield building cylindrical wall is constructed in part using SC construction. The external steel plates will be provided with an external corrosion-resistant coating. This will be inspected, and repaired or renewed as required. The effects of ageing on the SC-constructed structures have been considered in Reference 16.3.

16.18 CONSTRUCTION ASSURANCE

The earlier sections of this chapter explain the justification of the design of the civil engineering structures. The designs must be transformed into real structures that comply with the design intent and are compatible with all the design assumptions. The civil engineering output from the design is typically certified for construction drawings that show the arrangements and sizes of the structures, their components, and the elements forming the components, together with reference to the relevant specifications.

As necessary, this information is translated to construction and fabrication details. Configuration control and quality assurance processes are in place to ensure that the licensed

design configuration is maintained. Specific quality processes track potential changes and deviations during construction. These types of processes provide confidence that the construction-related work is suitable and sufficient, so that the requirements of the safety case for safe operation of the plant are fully achieved relative to the plant structures.

The processes to be followed to provide construction assurance are in part generic to the AP1000 design and depend in part on the country, site, and organisations with responsibility for construction.

16.18.1 Generic Approach to Providing Construction Assurance

The design specifies the requirements that the construction contractor needs to achieve according to US nuclear construction practices:

- The materials, components, and construction methods of the C-I civil engineering structures are specified in accordance with accepted practices and adhere to nuclear-specific codes and standards as appropriate based on the structures safety classification.

- Modular construction is used extensively throughout the plant. Modular construction allows for civil fabrication work to be completed offsite in controlled environments. Construction, examination, and inspection details are specified in accordance with accepted practices and are consistent with nuclear-specific codes and standards as appropriate based on the structures safety classification. The structures supporting the PCCWST within the shield building roof are to be examined before and after first filling of the tank.

- C-II and NNS concrete structures are constructed to the accepted industrial standard embodied in ACI 318-99 (Reference 16.26). C-II and NNS steel structures are constructed to AISC S335 (Reference 16.16). The civil/structural design criteria document (Reference 16.6, Section 7 and Table 9) provides more information on the materials suitable for construction.

The constructability of the AP1000 plant structures using a quality-assured approach is established as part of the design. Westinghouse works closely with its construction partners. Construction, planning, and constructability reviews are performed concurrently with the civil engineering design. Lessons learned from earlier and ongoing construction projects are filtered back into the design, and the construction process will be improved as a result of AP1000 plant construction experience.

SC construction is an example of how the need to provide construction assurance is considered as an integral part of the design process. Construction inspection is conducted to verify the concrete wall thicknesses and the faceplate thicknesses. The location for measurement of the structural wall modules is at the locations of the trusses used to provide the structural framework for the modules. Thicknesses will be measured at appropriate sections including openings and penetrations. Inspections will confirm that each section provides the minimum-required steel and concrete thicknesses. The minimum-required steel and concrete thicknesses represent the minimum values needed to meet the design basis loads. Steel plate thickness provided may exceed the minimum required value for the following reasons:

- Structural margin
- Ease of construction

- Construction loads
- Use of standard thicknesses

The construction and inspection requirements were identified and reviewed early in the design process to ensure that the design was capable of being constructed using a validated approach. Potentially more difficult areas for construction have been identified and mock-ups are built to demonstrate that these areas were capable of being soundly constructed. Following concrete setting, the mock-ups are disassembled for examination for defects by the construction technicians, quality control inspectors, and construction supervisors. This process helps ensure the required construction quality is achieved.

Existing and potential new methods of non-destructive examination (NDE) have been evaluated for their ability to confirm that concrete placed between the permanent steel forms contained neither excessive voids nor other defects that could affect strength. More information is presented in Reference 16.3, Section 9.

16.19 CONCLUSIONS

This chapter summarises the generic design information used to justify that the civil engineering structures will withstand the loads arising from normal operations, internal hazards, external hazards, and internal plant faults. There is clearly a dependency on site-specific information (more so than for equipment housed within the civil engineering structures); however, the approach followed allows for a range of site conditions, providing confidence that the design is suitable and sufficient for a variety of UK sites. The design is based on external hazard data representative of an onerous worldwide site. This leads to structures having robust load-resisting systems well able to withstand the generally more benign UK environments.

The approach to construction is presented in Section 16.18. Demonstrating the achievement of the design intent has some dependency on the site and the organisations with responsibilities for construction. It would be inappropriate for the construction processes to be fully defined during the generic phase because input from all the responsible organisations is needed to deliver a safe and economically constructed AP1000 plant that fully meets the design intent. There are construction processes still to be defined relating to transfer of the design to the UK. Whilst still complying with the codes and standards identified in Section 16.5, choices remain relating to the specification and methods of construction. The construction of AP1000 plants in China clearly demonstrates that the appropriate organisational responsibilities can be defined and delivered so that the design intent is fully achieved.

The design has taken into account the 60 years design life. There will be no erosion of the capability of the civil engineering structures to withstand the loads required by the nuclear safety case. This is subject to appropriate maintenance being undertaken (including examination, inspections, and testing) to confirm that the design assumptions relating to the design life of the plant civil engineering structures remain valid. The details have some dependency on the licensee procedures.

The format of this chapter has been chosen to be consistent with the safety case logic presented in the SAPs (Reference 16.1), specifically addressing those principles applicable to the justification of the plant civil engineering structures. In particular, the process has done the following:

- Explained the categorisation and classification process followed

- Justified the codes, standards, and methods used
- Presented the process for determination of loads and load combinations
- Summarised the justification of the nuclear island structures in some detail because this is where the Class 1 equipment is located, and provided an appropriate level of scrutiny of the remaining structures of less nuclear significance

It is concluded that the design demonstrates that the deterministic justifications of the civil engineering structures are appropriate to their safety function and class; and that the necessary normal and hazard loads will be withstood as required, subject to appropriate investigations and confirmations being provided and relevant to a particular site.

Table 16-1. UK Categorisation and Classification of Civil Engineering Structures

Structure	UK Cat/Class[1]	Seismic Category[2]
• Nuclear Island:		
– Basemat	A1	I
– Containment internal structures	A1	I
– Structural CA wall modules	A1	I
– Structural floor modules	A1	I
– Shield building	A1	I
– Auxiliary building	A1	I
– Foundations	A1	I
• Other structures:		
– Turbine building first bay	A2	II
– Turbine building excluding first bay	C3	NNS
– Diesel generator building	A2	NNS
– Annex building	A2/GNS	II/NNS
– SWS Cooling towers	A2	NNS
– Radwaste building	B3	NNS

Notes:

1. UK categorisation and classification are explained in Chapter 5.
2. Seismic categories are explained in Section 16.3.

Table 16-2. Natural External Hazards – Justification Logic for A2 Structures

Activity	Seismic Category	Requirement for A2 Civil Structures	Reasoning
Loading specification	II	Hazard loading considered to be the same as for C-I structures, i.e., SSE, tornado, extreme wind.	C-II structures are positioned where they could strike and impair the function of a Class 1 SSC. This must not occur for any event under which the Class 1 SSC has been designed to function; therefore, C-II structures must be designed to withstand the same hazard loads as C-I structures.
	NNS	Hazard loading considered in the design as normal practice for industrial structures situated in onerous regions of the world, including seismic regions.	Seismic category NNS structures are located so that their failure could not cause any adverse interaction with a Class 1 system. UK environments are generally more benign than those considered in the design for onerous regions of the world, (see Chapter 12); therefore, hazard loading exceeds UK practice for normal industrial structures. Seismic category NNS structures have hazard-withstand capabilities in between those of C-I structures and normal UK industrial structures.
Structural analysis	II	Use of ASCE 4-98 (Reference 16.18) for seismic analysis, as noted in the civil structural design criteria (Reference 16.6, Table 2), supplemented by information presented in the AP1000 seismic design criteria (Reference 16.7, Section 6). Otherwise, use of normal structural analysis tools is as explained in Reference 16.6, Sections 9 and 10.	Seismic analysis approach is consistent with that adopted for C-I structures. Normal structural analysis tools will provide results of sufficient reliability, provided that appropriate verification and validation procedures are in place.
	NNS	Seismic methods presented in UBC 1997 (Reference 16.17) and use of normal structural analysis tools as explained in Reference 16.6, Sections 9 and 10. See note 1.	Use of simplified methods of seismic analysis, as presented in UBC 1997, is justified for the same reasons noted above against “Loading Specification” for seismic category NNS structures.

Table 16-2. Natural External Hazards – Justification Logic for A2 Structures (cont.)

Activity	Seismic Category	Requirement for A2 Civil Structures	Reasoning
Design/ acceptance criteria	II	Strength of sections determined using ACI 349-01 (Reference 16.15) for reinforced concrete and ANSI/AISC- N690-1994 (Reference 16.24) for structural steelwork (Reference 16.6, Tables 5 and 6).	C-II structures are positioned where they could strike and impair the function of a Class 1 SSC. This must not occur for any event under which the Class 1 SSC has been designed to function. Therefore C-II structures are designed to the same standards as C-I structures.
	NNS	Load cases analysed as presented in Reference 16.6, Tables 7 and 8. Class 2 structures, designated NNS, are designed to ACI 318-99 (Reference 16.26) and AISC S335 (Reference 16.16). These structures will comply with the requirements of UBC 1997 (Reference 16.17). See note 1.	Using non-nuclear specific methods of design is justified for the same reasons noted above against "Loading Specification" for seismic category NNS structures.
Construction	II	The requirements for construction quality assurance during construction are in accordance with ACI 318-99 and AISC S335 (References 16.26 and 16.16).	Provision for using non-nuclear specific controls during construction for C-II structures is justified for the same reasons noted above against "Structural Detailing" applied to C-II structures.
	NNS	As above for C-II.	Provision for using non-nuclear specific controls during construction for NNS structures is justified for the same reasons noted above against "Structural Detailing" applied to C-II structures.

Note: 1) The NNS structures are being redesigned to UK codes; the structural design will use seismic input and design codes to provide margin similar to that provided by the US codes.

Table 16-3. Site Interface Parameters for Civil Design (Excluding Turbine Building) (Reference 16.6, Section 5.2.3 and Table 1)

Parameter	Value	
External building temperatures (excluding nuclear island)	Maximum: Minimum:	38.33°C -23.33°C
Temperatures external to the nuclear island	Maximum: Minimum:	46.11°C dry bulb 30.06°C wet bulb -40 °C
Design Wind speed (1 in 50 year) (3-second gust)		64.82 m/sec
Tornado wind (1 in 1,000,000 year):		
– Design velocity		134.11 m/sec
– Radius of maximum rotational wind from tornado centre		45.7 m
– Atmospheric pressure change		13.8 kN/m^2
– Rate of pressure change		8.3 kN/m^2/sec
• Tornado missiles:		
– 1814-kg automobile (deformable) able to impact the nuclear island at all elevations above grade (Reference 16.13) and other structures at elevations up to 9.1 m above grade.	Horizontal velocity: or Vertical velocity:	47 m/sec 33 m/sec
– A rigid 124.7-kg missile, assumed to be a 203.2-mm diameter armour piercing artillery shell striking the face of a structure at normal incidence.	Horizontal velocity: or Vertical velocity:	47 m/sec 33 m/sec
– A solid steel sphere 25 mm in diameter able to pass through any openings in the protective barriers and assumed to be travelling in the most damaging direction.	Velocity:	47 m/sec 89.41 m/sec
Hurricane wind speed 1 in 10,000 year (3-second gust)		
• Hurricane missiles (injected into the wind at a height of 10 m, unless stated otherwise):		
– 100 mm x 300 mm x 3.65 m long wood plank weighing 90 kg	Velocity:	41.1 m/sec
– 3 m long 75 mm diameter steel pipe weighing 35 kg	Velocity:	21.9 m/sec
– 0.9 m long 25 mm steel rod weighing 3.7 kg	Velocity:	21.9 m/sec
– 3 m long 150 mm diameter steel pipe weighing 130 kg	Velocity:	14.3 m/sec
– 4.5 m long 300 mm steel pipe weighing 337 kg	Velocity:	11.2 m/sec
– 10.7 m long 340 mm diameter telegraph pole weighing 675 kg, injected into the wind at a height of 6 m	Velocity:	11 m/sec
– 2 m x 1.3 m x 5 m car weighing 1814 kg, injected into the wind at a height of 3 m	Velocity:	7.1 m/sec
Standard plant SSE peak ground acceleration		0.3g

Table 16-3. Site Interface Parameters for Civil Design (Excluding Turbine Building) (Reference 16.6, Section 5.2.3 and Table 1) (cont.)

Parameter	Value
Soil parameters:	
– Average allowable static soil-bearing capacity	The allowable bearing capacity, including a factor of safety appropriate for the design load combination, shall be greater than or equal to 426.1 kN/m2 over the footprint of the nuclear island at its excavation depth.
– Maximum allowable dynamic bearing capacity for normal loads plus the SSE	The allowable bearing capacity, including a factor of safety appropriate for the design load combination, shall be greater than or equal to the maximum bearing demand of 1675.8 kN/m2 at the edge of the nuclear island at its excavation depth, or site-specific analyses demonstrate a factor of safety appropriate for normal and SSE loads.
– Minimum soil angle of internal friction	Greater than or equal to 35 degrees below footprint of nuclear island at its excavation depth.
– Shear wave velocity	Greater than or equal to 305 m/sec at the bottom of the foundation, and greater than or equal to 152.5 m/sec at the free surface.
– Liquefaction potential	Negligible
– Lateral variability	Soils supporting the nuclear island should not have extreme variability in subgrade stiffness. (To be demonstrated as shown in Table 4-9 .)
Flood level	Less than plant elevation +100 m
Ground water level	Less than plant elevation +99.39 m
Precipitation:	525.8 mm/hr
– Rain (Probable Maximum Precipitation)	160.0 mm/5 min
– Roof snow/ice 1 in 50 year	3.0 kN/m^2
– Ground snow/ice 1 in 50 year	3.6 kN/m^2

Table 16-4. Building Floor Live Loads
(Reference 16.6, Section 5.2.2)

Building Floor Area(1)	Floor Loading
Containment operating deck	38.3 kN/m^2 (during maintenance and refuelling outages). 9.6 kN/m^2 (during normal operation).
Offices	2.4 kN/m^2
Assembly and locker rooms	4.8 kN/m^2
Laboratories and laundry rooms	4.8 kN/m^2
Stairs and walkways	4.8 kN/m^2 (or a moving concentrated Load of 4.44 kN).
Structural platforms and gratings	4.8 kN/m^2 (However, the grating areas of concrete floors shall be designed for the same live load as the adjacent concrete floor.)
Maintenance & service platforms	(Load shall be calculated for individual locations based on the functional requirements and service equipment).
All other floors (ground floor and elevated floors)	9.6 kN/m^2 (For non-seismic load combinations and for global seismic analysis, this load shall be reduced if the equivalent dead load on the floor is more than 2.4 kN/m^2. The sum of the live load and the equivalent dead load shall be 12 kN/m^2).
In design reconciliation analysis, if actual loads are established to be lower than the above loads, the actual loads may be used for reconciliation. Floor live loads for the design of the operational areas will not be reduced below 4.8 kN/m^2.	
Railroad support structures Truck support structures	Based on American Railway Engineering and Maintenance-of-Way Association manual (Reference 16.36). HS20 loading per American Association of State Highway and Transportation Officials standards (Reference 16.37).

Table 16-5. Roof Loads
(Reference 16.6, Section 5.2.2)

Roof Area	Roof Loading
General	1.43 kN/m^2 or a uniform snow load, whichever is greater.

Table 16-6. Concentrated Loads for the Design of Local Members
(Reference 16.6, Section 5.2.2)

Local Member Type[(1)]	Concentrated Load
Concentrated load on beams and girders, in load combinations that exclude seismic.	22.2 kN to be applied to maximise the induced moment or shear. This load is not carried to the columns. It is not applied in office or access controlled areas (areas where no heavy equipment will be located or transported).
Concentrated load on slabs, to be considered with dead load only.	22.2 kN to be applied to maximise the induced moment or shear. This load is not cumulative and is not carried to the columns. It is not applied in office or access controlled areas (areas where no heavy equipment will be located or transported).

Note:
1. In design reconciliation analysis, if actual loads are established to be lower than the above loads, the actual loads may be used for reconciliation.

Table 16-7. Construction Loads and Temporary Exterior Wall Surcharge
(Reference 16.6, Section 5.2.2)

Local Member Type	Concentrated Load
Applicable exterior subsurface wall	The more critical of either a minimum surcharge outside and adjacent to the subsurface wall of 12 kN/m^2 or a railroad surcharge (the 12 kN/m^2 is a wheel load converted to a lateral equivalent).
Construction live load	Loads produced by cranes, trucks or any type of vehicle when fully loaded, as required for construction.
Steel beams supporting concrete floors	Weight of concrete plus 4.8 kN/m^2 uniform load or 22.2 kN concentrated load, distributed near points of maximum shear and moment. Allowable stresses are permitted to be increased by a third.
Metal decking and precast concrete panels used as formwork concrete floors	Weight of wet concrete plus a uniform live load of 0.96 kN/m^2 or a concentrated load of 0.67 kN.

17 MECHANICAL ENGINEERING

17.1 Introduction

This chapter provides the evidence that the mechanical engineering design of the systems in the AP1000 plant is adequate to meet the safety claims placed upon these systems in other parts of the safety case, both for normal operations and under fault conditions. System Specification Documents (SSDs) are referenced for each relevant mechanical system. The SSD provides additional details and evidence for the safety claims placed upon SSCs. Each SSD identifies the specific design requirements for the system and documents the system design that satisfies the requirements. SSDs do the following:

- Summarises the functions, design criteria, and design data of system
- Describes system layout, instrumentation and control, interfacing systems, and environmental requirements.
- Describes system operations and identifies examination, maintenance, inspection, and testing (EMIT) guidelines.
- Listing of the pertinent Piping and Instrumentation Diagrams for the system.
- Lists supporting references

The mechanical systems largely provide safety functions to prevent fuel damage and the consequent release of radioactivity. Analysis of these systems has therefore been carried out to review their requirements against three primary safety functions: reactivity control, heat transfer/residual heat removal, and containment. The intention of the justification against these safety functions is to demonstrate how the risks have been reduced to a level that can be considered as low as reasonably practicable (ALARP).

The mechanical systems, subsystems, and components and their operation are described in Chapter 6. Consequently, Chapters 6 and 17 are interrelated and complement each other. In addition, Appendix 15A contains the various component safety categorisation and classification.

Generic component failure data parameters for the SSCs discussed in Chapter 17 are shown in Table 10-34 and Table 10-35. The component failure data is used as an input to the AP1000 plant Probabilistic Safety Assessment (PSA) discussed in Chapter 10.

Justification against the reactivity control primary safety function considers the way in that the mechanical design of plant systems can influence control of the nuclear fission chain reaction in the reactor core.

Justification against the heat transfer/residual heat removal primary safety function considers the way in that the mechanical design of plant systems influences the management of heat from its production in the fuel assemblies to its dispersal in the ultimate heat sink.

Justification against the containment primary safety function examines how the mechanical design of plant systems ensures that the containment boundary provided by the fuel cladding is protected. It also examines how the containment provided by the reactor coolant system (RCS), and the associated systems linked to it, are protected. Finally, it reviews how the containment provided by the containment vessel is protected.

The report against each of the relevant mechanical systems is structured:

- Discussion of its role in normal and abnormal operation and identification of the primary safety functions to that the system contributes; and discussion of how the system contributes to the relevant primary safety functions.

- Description of the relevant system's structures and components that contribute to providing the system function.

- Classification and categorisation of these components and identification of what they must do to meet any safety requirements..

- Justification of requirements.

It is noted that for components that provide a Category A, Class 1 structural pressure boundary function and which do not have any other Class 1 or 2 safety function and no claim is made, a specific description has not been included in the discussion below. These components however are included in the safety categorisation and classification listing provided in Appendix 15A. Examples include components such as a closed vent or drain valve in the RCS pressure boundary, check valves that prevent backflow and which have no safety function to open, and the RCS pressuriser heaters.

Note the components within this chapter designed to the ASME Boiler and Pressure Code Section III are Division 1. The value following "Section III" (if specified) indicates the ASME BPVC Class.

17.2 Scope of Mechanical Systems

The scope of mechanical systems has been selected by examination of fault studies work and can be grouped as those that interface directly with reactor control or are directly connected to the RCS function as part of the engineered safety features

The mechanical equipment and systems are grouped by their functions:

- Function as part of the RCS and the reactor itself

- Are associated with the provision of feedwater to, and the acceptance of steam from, the steam generators (SGs)

- Collectively make up the passive core cooling system (PXS)

- Provide and help to maintain the integrity of the reactor containment

- Are associated with the movement of new and irradiated fuel

- Are associated with the handling of heavy loads over the reactor and RCS and also around the spent fuel pool (SFP)

- Are associated with the safe storage of irradiated fuel

- Are other mechanical systems that support other systems in the provision of their safety roles

17.3 REACTOR COOLANT AND ASSOCIATED SYSTEMS

17.3.1 Reactor Coolant Pumps (RCS-MP-01A/B, RCS-MP-02A/B)

17.3.1.1 Role

A detailed description of the reactor coolant pumps (RCPs) is given in Section 6.4. See Reference 17.1 for more detail on the Reactor Coolant System.

The pumps draw RCS primary coolant from the SG (RCS-MB-01/02) cold side channel head and pump it, via the RCS cold leg pipework, into the reactor vessel where the water is heated. The water then flows, via the RCS hot leg pipework, into the SGs where the water is cooled and returns to the RCP suction. The continued operation of the RCPs is required to permit removal of fission and decay heat from the reactor core when the plant is at power. If they fail during power operation, then the capacity for heat removal is reduced and there are consequent demands on the protection system to shut the reactor down. The pumps are not a part of a formal safety system, but their continued operation is required to permit removal of fission heat from the core when the reactor is at power. Whilst the normal operation of the pumps is not part of a safety function, there is a requirement for them to continue to provide circulation during coastdown following a loss of their ac electrical power supplies that is consistent with the time required for reactor trip. The RCPs also form a portion of the RCS natural circulation flow path if they lose power supplies. This feature contributes to the heat transfer/residual heat removal primary safety function.

The pumps are also structurally a part of the RCS and therefore, in terms of structural integrity, they have a role in providing RCS primary circuit integrity. This contributes to the containment primary safety function. Three concerns are associated with structural integrity:

- The RCS pressure boundary remains intact to ensure that RCS water inventory is maintained.

- The consequences of impact of any debris created through the failure of pump internals does not lead either to direct damage to fuel or to fuel damage due to overheating caused by impaired coolant flows.

- The disintegration of the pump flywheel does not cause consequential damage to the RCS pressure boundary or cause missiles which jeopardise the containment vessel boundary function.

There are four RCPs. Each one consists of a removable pump assembly that includes the rotating assembly, motor stator, and casing. Through the use of a sealless, wet-wound motor, there is no need for a seal assembly associated with the pump unit. It also means that the pump unit is lubricated by primary coolant, thus removing the requirement for a lubricating oil system. There is, however, a motor cooler that is required to operate whenever the RCP is running. This cooler enables the pump motor and bearings to operate at a temperature that is consistent with their design. The rotating assembly includes a flywheel to ensure that an appropriate pump coastdown characteristic is provided. A thermal barrier assembly is provided to remove heat generated by the flywheel and enable the flywheel to operate at a low and uniform temperature.

Cooling to the RCP motor coolers and the thermal barrier is provided by the component cooling water system (CCS) and this system therefore supports the RCPs in normal operation. It does not support structural integrity and the associated safety requirements.

The RCPs do not support other systems in their safety functions.

17.3.1.2 System Components and Equipment Contributing to Safety Function

The pump impeller, flywheel, motor electrical rotor, and shaft are linked together solidly and form an integral rotating assembly. The flywheel casing/thermal barrier and the motor casing are all bolted to the pump casing and form an integral RCS pressure boundary. The following components contribute to the RCPs performing their safety function:

- **Pump unit** – One pump unit is associated with each RCP. Each one is a single-stage centrifugal pump designed to produce an approximate head of 111 m (365 ft) at the the approximate design flow rate of 17,900 m^3/hr (78,750 gpm). The pump casing is manufactured from a ferritic forging with an austenitic cladding of the wetted surface and is designed for approximately 17.2 MPa (2,500 psia) and 343°C (650°F). The unit is mounted vertically onto the bottom of the SG channel head and all bearings are lubricated by the RCS primary coolant. There is no separate lubrication system. A requirement that the pumps can be shut down on demand is achieved through isolation of the electrical supply and is not therefore a feature of the pump itself.

- **Flywheel/thermal barrier assembly** – A single flywheel/thermal barrier assembly is associated with each RCP. The flywheel is formed from a single stainless-steel forging with axially aligned holes into that tungsten cylinders are fitted. The tungsten cylinders provide flywheel mass whilst the stainless-steel forging acts as the structural component. The thermal barrier is supplied with a cooling flow from the CCS and serves to cool the water that circulates from the pump casing into the motor assembly to ensure that the flywheel energy does not heat up the pump motor. The thermal barrier is an integral part of the forged martensitic stainless-steel pressure casing. The safety requirements are that the components forming part of the RCS pressure boundary will maintain their structural integrity, the flywheel assembly will also maintain its structural integrity, and the flywheel assembly will provide enough rotational inertia to provide the required coastdown characteristics for the entire pump, motor rotor, shaft, and flywheel assembly.

- **Motor unit** – A single motor is associated with each RCP. The motor is a squirrel-cage, induction-type fed from a variable-frequency drive to allow the pump speed to be changed as required during warm-up and cooldown of the RCS. When the RCS is at elevated temperature and during power operation, the RCP motors operate at 6900 V and 60 Hz. The motor has a “wet-wound” stator that contains the individually insulated windings so that the motor is cooled directly by RCS primary coolant flowing over the motor windings. The principal safety requirement, as with the pump unit, is the maintenance of the RCS pressure boundary. The requirement that the motor can be shut down on demand is achieved through isolation of the electrical supply and is not therefore a feature of the motor itself.

- **Motor Cooling System** - The flow of RCS primary coolant around the motor internals provides the cooling of the motor, and this circulation is achieved through the use of an auxiliary impeller on the shaft. This flow then passes through a separate heat exchanger (HX) that allows waste heat to be transferred to the CCS. The CCS also removes heat from the thermal barrier to cool the RCS water entering the pump flywheel assembly to maintain a low and uniform flywheel temperature and to minimise the temperature of the water entering the motor. These cooling functions are essential to support operation of the RCPs, but not in supporting RCP structural integrity or the coastdown capability. The flywheel and motor cooling system therefore supports a Category C safety function and is not considered further.

17.3.1.3 Claims on Components and Equipment

Pump Unit

The RCP pump unit is an integral part of the RCS pressure boundary. Maintaining the integrity of the RCS pressure boundary is a Category A safety function. RCP integrity is fundamental to preventing RCS leakage and hence the RCP structure must be considered Class 1 as discussed in Chapter 5.

Flywheel/Thermal Barrier Assembly

The thermal barrier assembly is an integral part of the RCS pressure boundary. Maintaining the integrity of the RCS pressure boundary is a Category A safety function. Thermal barrier integrity is fundamental to preventing RCS leakage and so the RCP structure must be considered Class 1. See Appendix 15A.

The role of maintaining sufficient RCS flow while the reactor trip function reduces core power following a loss of electrical power is also a Category A safety function. The RCP coastdown characteristics are essential to maintain sufficient departure from nucleate boiling (DNB) ratio to avoid fuel cladding damage and, as the flywheel is instrumental in providing this, it must also be considered Class 1 in this respect. See Appendix 15A.

The integrity of the flywheel assembly prevents the generation of hazards leading to the consequential damage to other plant components that could impact the heat transfer/residual heat removal primary safety function. This safety function is again Category A and the integrity justification is the primary means of demonstrating safety, so these components are also Class 1. See Appendix 15A.

The flywheel/thermal barrier assembly requirement is that they prevent the generation of hazards leading to the consequential damage to other plant components that could impact the heat transfer/residual heat removal primary safety function .

Motor Unit

The RCP motor unit includes a motor casing, which is an integral part of the RCS pressure boundary. Maintaining the integrity of the RCS pressure boundary is a Category A safety function. Motor casing integrity is fundamental to preventing RCS leakage and so the RCP structure must be considered Class 1. See Appendix 15A.

The integrity of the motor casing also prevents the generation of hazards leading to the consequential damage to other plant components that could impact heat transfer/residual heat removal primary safety function. This safety function is again Category A and the integrity justification is the primary means of demonstrating safety, so these components are also Class 1. See Appendix 15A.

The requirement of the RCP motor units is, therefore, that they will not fail in such a way that threatens RCS pressure boundary integrity or generates debris that might affect other RCS components or fuel assemblies.

17.3.1.4 Justification of Claims on Components and Equipment

Pump Unit

The pressure boundary of pump unit is described above. The selected material is considered stronger and more straightforward in terms of in-service inspection procedures than alternative cast austenitic materials. The pressure boundary integrity of the pump unit is justified in Appendix 20F.

The RCP pump unit incorporates a number of features to help guarantee highly reliable operation:

- Lubrication is by RCS fluid so there is no dependency on a separate lubricating oil system.
- There is no shaft seal because the rotating elements of the pump unit are entirely contained within the pressure boundary.
- The damped natural frequency of the rotating assembly exceeds 120 percent of normal operating speed or is sufficiently damped to prevent adverse effects on the rotating assembly, to ensure smooth operation and minimise induced vibration.
- Mounting the pump unit directly in the SG channel head eliminates the crossover loop piping eliminating the need for a pump support structure, eliminating stresses due to thermal growth, as well as reducing the number of welds in the RCS loop.

The pump units are continuously in service during periods of reactor operation. As such, they are continuously monitored, and thus indications of temperature, vibration, speed, RCS flow, etc., would indicate if degradation had occurred. In addition to this, there is an ongoing in-service inspection programme to meet the standards of American Socoety of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code, Section XI.

Flywheel/Thermal Barrier Assembly

The thermal barrier and associated pressure casing are manufactured from forged martensitic stainless steel to ensure compatibility with the reactor coolant fluid that passes through them. The tungsten cylinders fitted in the flywheel have stainless-steel end caps welded in position to ensure that they are isolated from the reactor coolant. The pressure boundary integrity of the thermal barrier assembly is covered further in Appendix 20F.

Integrity of the flywheel itself is a particular safety concern and a number of design features are included to reduce risk as follows:

- The flywheel has no central bore and is equipped with a Hirth radial-face toothed-serration connection to couple it to both the pump impeller and the motor rotor. These arrangements eliminate any shrink-fit to attach the flywheel to the shaft, and hence any of the associated high stresses in the bore.
- The design enables the flywheel to have journal bearings on either side. This robust arrangement will aid the running stability of the motor.
- In the unlikely event of flywheel failure, the analysis of the thermal barrier indicates that the pressure boundary function would still be maintained.

- The flywheel is situated in the thermal barrier that ensures that the flywheel is kept at a relatively constant temperature. This helps to minimise any stresses in the flywheel that might otherwise develop as a result of temperature gradients in the material.

- The pump flywheel has a design speed of 125 percent of the motor operating speed. This provides a generous design margin, that, along with the extensive testing and inspection during fabrication, provides confidence that integrity will be maintained during operation.

Motor Unit

As a part of the reactor coolant pressure boundary, the motor unit shell is also designed to ASME Boiler and Pressure Vessel Code, Section III- Division 1 (Reference 17.4). The motor unit casing is manufactured from forged martensitic stainless steel to ensure compatibility with the reactor coolant fluid that passes through them. In the unlikely event that rotating electrical elements of the motor should fail, analysis shows that any fragments will be contained without loss of the pressure boundary function performed by the motor casing. See Appendix 20F for justification of the motor unit pressure boundary. The RCP motor unit incorporates a number of features to help guarantee highly reliable operation:

- The windings are insulated by a specially developed cross-linked polyethylene insulation system. The insulation has a high resistance against environmental strain cracking and is stable at elevated temperatures. This property provides a built-in safety factor in case of a temperature fluctuation occurring during a transient of the cooling system.

- The use of wet windings ensures that more even cooling of the motor is provided; this helps to avoid hot spots that can lead to more rapid degradation of the insulation.

- With vertical mounting and impeller on top, the motors are "self-venting" and automatically vent any entrained gas into the pump casing. This minimises the potential for the motor to be operated with inadequate cooling of the windings.

- Because the motors are driven through variable-frequency drives, the speed can be controlled to ensure that the current drawn by the motor remains within limits and that consequent heatup of the motor components can also be controlled.

The motor units are continuously in service during periods of reactor operation. As such, they are continuously monitored, and thus indications of temperature, vibration, and speed will indicate if degradation has occurred.

17.3.2 Reactor Coolant System Pressure Relief

17.3.2.1 Role

The RCS and associated pressure-relief capability is described in detail in Section 6.4. See Reference 17.1 for more detail on the Reactor Coolant System.

In normal operation and during all fault conditions, it is vital to maintain the integrity of the RCS. The RCS pressure relief components ensure this and therefore provide a major input to the core heat removal/heat transfer primary safety function, and the containment primary safety function. Under normal operating conditions, the pressuriser sprays, with flow controlled by the pressuriser spray control valves (RCS-PL-V110A/B), are used to control RCS over-pressure. If the spray valves should stick open, there is a risk that the consequent

depressurisation could be a threat to continued plant operation, so the pressuriser spray block valves (RCS-PL-V111A/B) are fitted to protect against this fault. Under extreme conditions, the pressuriser sprays may not be able to adequately control system over-pressure, and under these circumstances, the pressuriser safety relief valves (RCS-PL-V005A/B) are available to protect RCS integrity. A subsystem of the RCS is the automatic depressurization system (ADS). The ADS acts in conjunction with the PXS to mitigate the consequences of loss-of-coolant accidents (LOCAs). The safety-related ADS function is to automatically depressurize the RCS so that the PXS can adequately cool the core during small-break LOCAs. Even though the ADS are RCS components they are dicussed in the PXS section below.

The pressuriser spray valves are air operated and therefore supported by the instrument air system. The pressuriser spray block valves are motor-driven and therefore supported by the main ac power system. The pressuriser safety valves themselves do not require any separate motive force for operation and so are not supported by other systems.

The pressure relief components of the RCS do not support other systems.

17.3.2.2 System Components and Equipment Contributing to Safety Function

The reactor coolant pressure relief system is effectively a part of the RCS itself. The integrity of the pipework itself, along with the pressuriser vessel, is discussed in the section on structural integrity (Chapter 20). The following components contribute to the ability of the RCS pressure relief system to perform its safety function:

- **Pressuriser Safety Valves (RCS-PL-V005A/B)** – These are 150-mm DN (6-inch), spring-loaded, self-actuated safety relief valves with back-pressure compensation. Each one is set to open at 17.13 MPa and is sized to ensure that the full insurge to the pressuriser can be accommodated should there be a complete loss of steam flow to the turbine, with coincident loss of feedwater at 102 percent of reactor rated power. The valves do not require separate actuation, but opening at the setpoint pressure is a safety requirement.

- **Pressuriser Spray Valves (RCS-PL-V110A/B)** – These are 100-mm DN (4-inch), air-operated ball valves set up to fail closed on loss of air supply. The valves are controlled by the plant control system (PLS) and do not have a specific protection actuation signal.

- **Pressuriser Spray Block Valves (RCS-PL-V111A/B)** – These are 100-mm DN (4-inch), motor-operated gate valves and are manually actuated through the PLS if the operator deems that the pressuriser spray valves are not operating correctly on demand.

17.3.2.3 Claims on Components and Equipment

Pressuriser Safety Valves (RCS-PL-V005A/B)

The pressuriser safety valves provide the principal Class 1 protection against RCS overpressure which could result from the expansion of primary coolant that takes place due to the temperature rise following load rejection transients. Maintenance of the RCS pressure boundary is considered a Category A safety function. See Appendix 15A. Whilst the pressuriser pressure control system would provide the first response to high RCS pressure, the primary safety requirement rests with the pressuriser safety valves. This is a Category A safety fuction and designed to Class 1.

There are two pressuriser safety valves mounted in parallel. Both valves are required to function under the most limiting transient conditions. They are also required to close when the RCS pressure falls below their setpoint.

These valves are subject to two requirements. The first is that they will open on demand when RCS pressure exceeds a specific setpoint.. The second requirement is that having opened and relieved the overpressure transient, the valve reseats at the correct pressure. If this does not happen, then the initial overpressure transient becomes a RCS leak or LOCA depending on the leak rate.

Pressuriser Spray Valves (RCS-PL-110A/B)

The pressuriser spray valves control the flow of spray water to provide their role in the normal pressuriser pressure control function (the other part of the normal pressure control function is provided by the pressuriser heaters, that serve to maintain and increase RCS pressure). The spray valves offer the first response to, but not the primary Class 1 protection against, any overpressure transient. Control of RCS pressure and maintenance of the RCS pressure boundary is a Category A safety function, and as such their pressure boundary is Class 1. See Appendix 15A.

There are two spray valves, each one deriving flow from separate RCS cold legs. They perform the full-pressure control function and maintain pressure within normal operating limits except under the most limiting transient conditions.

The normal operation requirement for these valves is that they will modulate correctly in response to the control signals from the pressuriser pressure control system.

Pressuriser Spray Block Valves (RCS-PL-V111A/B)

The pressuriser spray block valves provide an extra level of protection against the depressurisation transient that would result from a stuck-open pressuriser spray valve. This could lead to a loss of primary coolant and RCS fluid subcooling and so be a potential challenge to core cooling. This is a Category A safety function. The pressuriser spray block valves are providing a defence in depth function and so they are Class 2. Additionally it serves as a RCS pressure boundary which is a Category A safety function and is a Class 1 component. See Appendix 15A.

The requirement for these valves is that they will close on demand to isolate the pressuriser sprays. This demand will only be provided by operator action: there is no automatic system demand.

17.3.2.4 Justification of Requirements on Components and Equipment

Pressuriser Safety Valves (RCS-PL-V005A/B)

The pressuriser safety valves are of the spring-loaded, self-actuated type and operation depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The total pressuriser safety valve capacity is required to be sufficient to limit the RCS pressure during the maximum surge rate into the pressuriser during an overpressure transient. The maximum surge rate into the pressuriser for this transient occurs before the valve setpoint is reached and the main steam safety valves are opened; therefore, the relief capacity

specified for the pressuriser safety valves is greater than that required to limit the peak RCS pressure to 110 percent of the design pressure for the transient being analysed. Additional conservatism is included in this sizing procedure by maintaining reactor power at its initial value during the entire transient as described in Reference 17.6, Section 3.

The valves are manufactured from stainless steel to provide compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III, Division 1. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The Code, with its supporting testing and examination, provides the foundations for performance claims made on the pressuriser safety valves.

The valves are very similar to those already in service that are providing the same function on currently operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a low probability of failure to open. This is better than the value assumed in the PSA and indicates that the claims against these valves are conservative. In addition, both valves are equipped with positive position indication so that operations staff can determine their true position.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, Division 1, the valves are designed and installed to seismic Category I (C-I) standards (Reference Table 15A-1). The combination of the ASME Boiler and Pressure Vessel Code, Section III and other design and manufacture codes with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the pressuriser safety relief valves are based on the programmes associated with ASME Boiler and Pressure Vessel Code, Section III qualification. The testing requires every valve to be tested as installed, or bench-tested, every 5 years; and to have its position-indication equipment inspected every 2 years.

Pressuriser Spray Valves (RCS-PL-110A/B)

The pressuriser spray valves are air operated with the actuators designed to close the valve in the event of a loss of air supply (i.e., “fail closed”). This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

A failure mechanism of particular concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure; however, the valves proposed are very similar in like service in many operating power stations, and this extensive operational experience provides confidence in their high reliability. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III-1, the valves are designed and installed to seismic Category I (C-I) standards and are qualified for operation in a harsh environment (Reference Table 15A-1). The ASME Boiler and Pressure Vessel Code and other codes for design and manufacture will minimise the probability of these failure mechanisms occurring. Two valves are provided in parallel. In the event of a failure of one of these valves to open, the other pressuriser spray valve is capable of providing spray flow sufficient to maintain pressure within normal operating limits except in the case of a large load rejection transient.

If the failure results in a spray valve being stuck open, the pressuriser spray block valves can be closed to mitigate the impact of this event.

The pressuriser spray valves, by the nature of their function, are always demonstrating correct operation when RCS pressure is maintained within normal control limits.

Pressuriser Spray Block Valves (RCS-PL-111A/B)

The two pressuriser spray block valves are both motor operated, which means they will inherently fail "as is" and this is not fail-safe with respect to the pressuriser spray isolation function. However, given that spurious actuation of this function when not required could give rise to safety concerns, because of the involvement of the system in RCS pressure control, this arrangement is judged appropriate.

The valves are manufactured from stainless steel to provide compatibility with the RCS fluid that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1. The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. However, these valves are very similar to those in like service in many operating power stations, and the extensive operational experience gives confidence of high reliability. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are designed and installed to seismic C-I standards (Reference Table 15A-1). The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture will minimise the probability of these failure mechanisms occurring.

17.3.3 Control Rod Drive Mechanism (RXS-MY-Y01)

17.3.3.1 Role

A full description of the control rod drive mechanisms (CRDMs) is given in Section 6.3. Further design details of this system and its constituent components are delineated in Reference 17.37

The CRDMs contribute to the reactivity control primary safety function. There are two groups of control rods:

- **Rod control cluster assemblies (RCCAs)** − Shutdown and power control assemblies that are effectively "black" to neutrons.
- **Gray rod cluster assemblies** − Assemblies used for load follow that are "gray" to neutrons.

In each case, the contribution to reactivity control is made through the movement of the absorber rods of an RCCA or gray rod cluster assembly into and out of the reactor core by its CRDM.

The CRDM housings are part of the primary reactor coolant pressure boundary. The pressure housing therefore also contributes to providing the containment primary safety function by maintaining the integrity of the RCS pressure boundary.

The integrity of the CRDM pressure housing also contributes to the reactivity control primary safety function in that failure of the pressure housing could lead to ejection of a control rod from the core, or could challenge alignment that could prevent a control rod from falling into the core on demand.

The overriding safety requirement of the CRDMs is to be able to release the control rod drive rods on demand and drop the RCCAs into the core within a required time.

The CRDMs, once de-energised, are not supported by other systems in achieving their safety function, nor do they support other systems in achieving their safety function.

17.3.3.2 System Components and Equipment Contributing to Safety Function

The following components contribute to the CRDM performing its safety function:

- **CRDM pressure housing** – There are 69 individual CRDMs, each with its own associated pressure housing. This component does have a significant safety requirement in contributing to maintenance of RCS integrity.

- **Latch assembly** – Each CRDM has a dedicated latch assembly inside its pressure housing. Each latch assembly has two different latches that work in sequence to move the RCCA or gray rod. The stationary latch is required to hold the CRDM shaft in position whilst its actuating magnet is energised and release the CRDM shaft to fall when de-energised. The stationary latch performs a grip or release role only. The moveable latch is engaged when the RCCA or gray rod assembly is stepped into or out of the reactor core. The engaged movable latch combined with its requirement to be magnetically raised or lowered, raises or lowers the RCCA or gray rod through individual steps.

  The safety function of the stationary latches is achieved by their relaxing automatically to the "release" position when power is cut from their associated control magnets. This happens on receipt of a reactor trip signal for all rods and on receipt of certain load rejection signals for selections of rods.

  The safety function of the movable latches is achieved by their relaxing automatically to the "release" position when power is removed from their associated control magnets. This is the case when the RCCA or gray rod cluster assembly is not being stepped; on receipt of a reactor trip signal for all rods; and for selections of rods on receipt of certain load rejection signals.

- **Magnets** – Whilst the CRDM magnets and associated flux rings have a key role in the operation of the CRDM, no movement is required and so, from a mechanical perspective, no further analysis is required. The magnets are de-energised to their safe (reactor trip) state by isolation of the electrical supply and therefore this is not a feature of the magnet itself.

- **CRDM drive shafts** – The CRDM drive shafts provide the link that ensures that the individual RCCAs move in the required way. They are, however, basically passive components with all active control of movement remaining with the latch mechanisms; no further analysis is required.

17.3.3.3 Claims on Components and Equipment

Pressure Housing

Maintenance of the RCS pressure boundary is a Category A safety function. The pressure housings are considered to be Class 1. See Appendix 15A.

The individual pressure housings are each mounted separately on the reactor vessel head, and each one effectively has a separate requirement with respect to structural integrity that it will not fail catastrophically.

Latch Assembly

The latch assembly controls the movement of the control rods either through the mechanism for individual "steps" or by releasing the control rod drive shaft so that the rods can fall into the reactor core by gravity. This movement of control rods is used to control reactivity, that is a Category A safety function. Given that control rod movement is the principal method of controlling reactivity and that the latch assembly is integral to control movement control, it is considered to be Class 1. See Appendix 15A.

Each set of latches is within its own CRDM pressure housing and can therefore be considered independent with respect to performance.

17.3.3.4 Justification of Claims on Components and Equipment

Pressure Housing

The design of the internally mounted, magnetically actuated latch assembly means that no components pass through the pressure housing and, therefore, that there are no seals, etc. Demonstration of the integrity of this arrangement is inherently more straightforward. It also justifies why integrity need only be a structural issue, there being no seals, etc.

Latch Assembly

The latch assembly, through detailed design and orientation of installation, will always sit in the released position when the magnets are not energised. Energising of the associated magnets is required to grip the CRDM drive rod, raise, lower, or hold it in place through individual steps. De-energisation of the magnets, associated with the action of gravity, will ensure that the latches release the CRDM drive rod. This arrangement ensures that the safety function, to release the rods so that they drop into the core, requires no motive power and is inherently safe.

The latch assembly is a proprietary design and so no specific design standards apply. The design is, however, very similar to that used on previous generations of Westinghouse pressurised water reactors (PWR) and so service experience from these can give an accurate picture of the expected reliability. Analysis of this service experience suggests a low probability of an RCCA failing to drop into the core on demand because of mechanical faults with the CRDM.

On this basis, even with a very conservative claim on individual rod reliability, the scenario with two or more RCCAs failing to insert for reasons of mechanical failure is not considered credible. This is reflected in the reactivity faults presented in Chapter 9.

The only credible failure would therefore be in the case of some form of common mode failure. Although examination of the latch mechanism has indicated that there is no credible inherent common mode failure mechanism that could simultaneously affect the operation of all RCCAs for anticipated transient without trip (ATWT) evaluations of frequent faults presented in Chapter 9, a common mode failure of all RCCAs to insert is conservatively assumed.

An extensive test programme has also been carried out to demonstrate the number of cycles that an individual CRDM unit can be expected to complete without failure. This is discussed further in Reference 17.37.

As the latches wear, there is increased incidence of "missed steps" when the CRDM is instructed to move the control rod by a step and either the rod withdrawal does not take place or the rod insertion is by more than one step. The resulting misalignment will be picked up as a part of the routine operational surveillance programmes. This is discussed further in Reference 17.37.

17.3.4 Chemical and Volume Control System

17.3.4.1 Role

A detailed description of the chemical and volume control system (CVS) is given in Section 6.4.

The CVS contributes to the provision of three primary safety functions: reactivity control, containment, and RCS water inventory required for removal of heat from the core. In normal operation, the CVS passes a portion of the reactor coolant through a filtration and purification process (Chapter 21). This is carried out at full RCS pressure by the chemical control subsystem with the RCP head providing the differential pressure to drive fluid through the system. This element of the system makes no specific operational contribution to safety; however, through the makeup subsystem, the CVS can provide a makeup and letdown function for inventory control. Also, there is the ability for this makeup to be of variable boron concentration.

Isolation of the makeup on high pressuriser level and of the letdown on low pressuriser level contributes to the maintenance of the integrity of the RCS and adequate coolant inventory respectively. Consequently, this contributes to the heat transfer/residual heat removal primary safety function.

The ability to provide makeup water of variable boron concentration is part of normal operations and would not normally be a contribution to the primary safety function of reactivity control. The prevention of inadvertent undetected RCS dilution, that could occur immediately after a reactor trip if a dilution was in progress at the time or at other times when the reactor is shutdown, is a contribution to this safety function by the makeup subsystem.

The makeup subsystem supplies makeup to the RCS through the containment boundary; the system isolation valves at this point support the integrity of containment and thus contribute to the containment primary safety function.

The operation of the CVS makeup pumps taking suction from the boric acid tank is clearly available to help mitigate the impact of a very small LOCA, since this would reduce the demands on the automated safety injection systems. There is no requirement specifically made for the CVS makeup pumps; however, they do provide a defence in depth function for maintaining RCS inventory and core reactivity control. The CVS is supported by the essential electrical supplies in the provision of its safety functions. Except for infrequent EMIT activities (e.g., providing borated makeup to PXS tanks), the CVS does not support other systems in provision of their safety functions.

Further design details of this system and its constituent components are delineated in Reference 17.3.

17.3.4.2 System Components and Equipment Contributing to Safety Function

The pipework systems associated with the CVS that are designed and constructed to ASME standards are: the sections directly connected to the RCS are ASME Boiler and Pressure Vessel Code, Section III-1; the sections associated with containment isolation are ASME Boiler and Pressure Vessel Code, Section III, and certain other in-containment pipework is ASME Boiler and Pressure Vessel Code, Section III. The remaining parts of the system are constructed either to ASME Boiler and Pressure Vessel Code, Section VIII (Reference 17.9) or the ANSI/ASME Section B31.1 Power Piping Code (Reference 17.10). The following components contribute to the CVS performing its safety functions:

- **Demineralised Water System Isolation valves (CVS-PL-V136A/B)** – These are 75-mm DN (3-inch), air-operated butterfly valves that fail closed on loss of air supply. They close on receipt of a boron dilution block signal from the protection and safety monitoring system (PMS), shutting off the supply of demineralised water and so terminating any dilution of the RCS that is in progress, as a backup to the closure of CVS-PL-V090 and CVS-PL-V091 as discussed below.

- **Makeup Pump Suction Header Three-way Blend Valve (CVS-PL-V115)** – This is a 100-mm DN (4-inch), three-way, air-operated plug valve. It is normally set so that it can modulate to control the blend of boric acid and demineralised water to the CVS makeup pump suction, but on loss of the air supply, it fails to the full borate position. On receipt of a boron dilution block signal, the valve is signalled by the PLS, but from a signal originating in the PMS, to move to the full borate position so that the blend supplied is to the full boric acid concentration. This is intended to ensure that if an RCS makeup operation is in progress, the makeup will switch from whatever boron concentration was originally desired to makeup at maximum boron concentration only. This is a defence in depth function to the demineralised water supply isolation valves. Therefore, there are no safety claims on this valve.

- **RCS Purification Stop Valves (CVS-PL-V001, -V002, and -V003)** – These are two 75–mm DN (3-inch), motor-operated gate valves and a 75-mm DN (3-inch), motor-operated globe valve respectively. All valves are required to close on demand from the PMS by a purification line isolation signal or manual initiation of the CVS isolation signal. This is intended to isolate a potential source of leaks and also isolate planned system letdown operations in the event of an apparent reduction in RCS inventory.

- **Makeup Line Containment Isolation Valves (CVS-PL-V090 and CVS-PL-V091)** – These are 75-mm DN (3-inch), motor-operated gate valves. They are required to close on demand from a CVS isolation signal generated in the PMS. This is a safety requirement. They are also containment isolation valves (CIVs) and are required to isolate the CVS makeup line through the containment boundary on receipt of a containment isolation signal.

- **Letdown Containment Isolation Valves (CVS-PL-V045 and V047)–** These are 75-mm DN (3-inch), air-operated globe valves. They are required to close on demand from a CVS isolation signal generated in the PMS; therefore this is a safety requirement. They are also containment isolation valves (CIVs) and are required to isolate the CVS letdown line through the containment boundary on receipt of a containment isolation signal.

- **Zinc Injection Containment Isolation Valve (CVS-PL-V092 and V094)** – This is a 25-mm DN (1-inch), air-operated globe valve. It is required to close on demand from a CVS isolation signal on an RCS pressuriser Low-1 level signal generated in the PMS. This actuation occurs only to prevent an accumulation of zinc acetate in the piping and therefore, this is not a safety requirement. It is also a CIV and is required to isolate the zinc injection line through the containment boundary on receipt of a containment isolation signal.

- **Hydrogen Injection Containment Isolation Valve (CVS-PL-219) –** This is a 12-mm (0.5-inch) nominal-bore, air-operated globe valve. It is required to close on demand from a CVS isolation signal on an RCS pressuriser Low-1 level signal generated in the PMS. This actuation occurs to prevent an accumulation of H_2 in the piping should this signal be generated prior to a containment isolation signal and therefore, this is a Class 1 safety requirement. It is also a CIV and is required to isolate the H_2 addition line through the containment boundary on receipt of a containment isolation signal.

17.3.4.3 Claims on Components and Equipment

Demineralised Water System Isolation Valves (CVS-PL-V136A/B)

The demineralised water supply makeup isolation valves prevent the inadvertent dilution of the RCS and thus protect against inadvertent criticality. Control of core reactivity is considered to be a Category A safety function. Given that the control rods are normally fully inserted when the reactor is shut down, prevention of inadvertent dilution becomes the primary method of maintaining the shutdown condition. As such, these valves are considered to be Class 1. See Appendix 15A.

The requirement against these valves is that they will close on demand. There are two valves in series, so either one closing successfully will achieve the safety function.

Makeup Pump Suction Header Three-way Blend Valve (CVS-PL-V115)

Failure of this valve will result in boration of the primary coolant and a reduction in plant power generation. This is not the primary means of boration of the RCS but spurious failure could interrupt power operations. The valve provides a Category C function and is Class 3. See Appendix 15A.

RCS Purification Stop Valves (CVS-PL-V001, -V002, and -V003)

These valves provide an element of control of RCS inventory in response to loss of inventory faults. Control of RCS inventory is instrumental in providing adequate heat removal and so this is a Category A function. These valves are a primary means of maintaining adequate inventory by isolating the CVS purification loop so they are Class 1. See Appendix 15A.

The requirement against these valves is that they will close on demand. There are two gate valves and one globe valve in series: any one of the three successfully closing will achieve the safety function.

Makeup Line Containment Isolation Valves (CVS-PL-V090 and CVS-PL-V091)

These valves protect RCS integrity and, under certain circumstances, SG integrity, by preventing overfilling. This is protecting against the release of radioactive material and so is a Category A safety function. In this role, they are Class 1. See Appendix 15A.

These valves also prevent the inadvertent dilution of the RCS and thus protect against inadvertent criticality. Control of core reactivity is considered to be a Category A safety function. Given that the control rods are normally fully inserted when the reactor is shut down, prevention of inadvertent dilution becomes the primary method of maintaining the shutdown condition.

These valves also provide containment isolation to protect the integrity of the containment pressure boundary and prevent the release radioactivity. This isolation also is credited as a means to terminate potential boron dilutions in Chapter 9. These are Category A safety functions. These valves are a primary means of performing these functions and are therefore Class 1. See Appendix 15A.

The requirement against these valves is that they will close on demand. There are two valves in series, so either one successfully closing will achieve the safety function.

See Table 10-34 for generic component failure data parameters.

Letdown Containment Isolation Valves (CVS-PL-V045 and V047)

These valves protect RCS integrity isolating the letdown of RCS fluid on pressuriser low level or following receipt of a safeguards actuation signal. This is a Category A function. These valves also provide containment isolation to protect the integrity of the containment pressure boundary and prevent the release of radioactivity, which are Category A safety functions. These valves are a primary means of performing these functions and are therefore Class 1. See Appendix 15A.

The requirement against these valves is that they will close on demand. There are two valves in series, so either one successfully closing will achieve the safety function.

Zinc Injection Containment Isolation Valves (CVS-PL-V092 and V094)

These valves protect RCS integrity isolating the zinc addition flow path to the RCS fluid on pressuriser low level or following receipt of a safeguards actuation signal. This is a Category A function. This valve also provides containment isolation to protect the integrity of the containment pressure boundary and prevent the release of radioactivity. These are also Category A safety functions. This valve is a primary means of performing these functions and is therefore Class 1. See Appendix 15A.

The requirement against these valves is that they will close on demand. There are two valves in series, so either one successfully closing will achieve the safety function.

See Table 10-34 for generic component failure data parameters.

Hydrogen Injection Containment Isolation Valve (CVS-PL-219)

This valve protects RCS integrity isolating the H_2 addition flow path to the RCS fluid on pressuriser low level or following receipt of a safeguards actuation signal. This is a Category A function. This valve also provides containment isolation to protect the integrity of the containment pressure boundary and prevent the release of radioactivity. These are also Category A safety functions. This valve is a primary means of performing these functions and is therefore Class 1. See Appendix 15A.

The requirement against this valve is that it will close on demand. There is another valve in series which is a check valve CIV (CVS-PL-V217) (see Section 17.6.2 below), so either one successfully closing will achieve the safety function.

17.3.4.4 Justification of Claims on Components and Equipment

Demineralised Water Supply Makeup Isolation Valves (CVS-PL-V136A/B)

The demineralised water supply makeup isolation valves are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with the demineralised water that passes through them and to prevent potential for valve corrosion products from being injected into the RCS. They are designed to the ASME Boiler and Pressure Vessel Code, Section III-3 design code. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the demineralised water supply makeup isolation valves.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards (see Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of two valves in series provides redundancy and hence further reduces the probability of failure.

The maintenance and testing arrangements for the demineralised water supply makeup isolation valves are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with the ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

In addition to this, the valve will be seen to operate correctly every time the RCS makeup system is initiated, so this will provide numerous other opportunities to identify operational problems.

Makeup Pump Suction Header Three-way Blend Valve (CVS-PL-V115)

Failure of this valve will result in boration of the primary coolant and a reduction in plant power generation. This is not the primary means of boration of the RCS but spurious failure could interrupt power operations. This valves are designed in accordance with ASME B16.34.

Although there is no formal surveillance testing of the valve, routine maintenance and testing of the valve will be performed according to the manufacturer's recommendations and testing will be carried out to verify that performance has been maintained.

RCS Purification Stop Valves (CVS-PL-V001, -V002, and -V003)

The three purification stop valves are motor operated, which means they will fail "as is". Clearly, this is not fail-safe with respect to the letdown isolation function, but given that spurious actuation of this function when not required could give rise to safety concerns, and given the relationship between RCS pressure and letdown, it is judged as appropriate.

All three valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. Two of the valves, are designed to ASME Boiler and Pressure Vessel Code, Section III-1; the third is designed to the ASME Boiler and Pressure Vessel Code, Section III-3 design code. The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I, and are qualified for operation in a harsh environment (see Table 15A-1). The provision of three valves in series further reduces the probability of failure. The fact that two of the valves are of different design (gate valves) from the third (globe valve) provides diversity and further confidence that common mode failure issues have been minimised.

The valves are very similar to those already in like service in many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a low probability of failure to close indicating that the claim being made is conservative. The maintenance and testing arrangements for the purification stop valves are based on the ASME Boiler and Pressure Vessel Code, programmes that are appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed once during each refuelling outage.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

Makeup Line Containment Isolation Valves (CVS-PL-V90 and CVS-PL-V091)

The two makeup discharge header CIVs are both motor operated, which means they will inherently fail "as is". Clearly, this is not fail-safe with respect to the containment isolation function itself, but given that spurious actuation of this function when not required could give rise to other safety concerns and because of the involvement of the system in RCS makeup, this arrangement is judged as appropriate. In addition, these motor operated valves are powered by 1E batteries which provides for a balance of high reliability to close in the vent of containment isolation with high reliability to be open when makeup is needed.

Both valves are manufactured from stainless steel to provide compatibility with the borated water that passes through them. They are designed to ASME Code, Section III-2. The code, with its supporting testing and examination provides the foundations for performance claims made on the makeup discharge header CIVs.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a low probability of failure to close indicating that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards, and the inside CIV is also qualified for operation in a harsh environment (see Table 15A-1). The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of two valves in series further reduces the probability of failure to achieve the safety function.

The maintenance and testing arrangements for the makeup discharge header CIVs are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with the ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed in line with the CIV leak test programme, the requirements for that are outlined in Reference 17.11.

Letdown Containment Isolation Valves (CVS-PL-V045 and V047)

The letdown line containment isolation valves are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with the demineralised water that passes through them. They are designed to the ASME Boiler and Pressure Vessel Code, Section III-2 The code, with its supporting testing and examination provides the foundations for performance claims made on the demineralised water supply makeup isolation valves.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards (see Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III, and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of two valves in series provides redundancy and hence further reduces the probability of failure.

The maintenance and testing arrangements for the demineralised water supply makeup isolation valves are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with the ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

In addition to this, the valve will be seen to operate correctly every time the RCS boration or dilution requires that letdown be initiated, so this will provide numerous other opportunities to identify operational problems.

Zinc Injection Containment Isolation Valve (CVS-PL-V092 and V094)

The zinc addition containment isolation valve is air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valve is manufactured from stainless steel to ensure that no corrosion of the valve occurs since it contains zinc at elevated pressure. It is designed to the ASME Boiler and Pressure Vessel Code, Section III-2. The code, with its supporting testing and examination, provides the foundations for performance claims made on the zinc addition isolation valve.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valve is also designed and installed to seismic C-I standards (see Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III, and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

Hydrogen Injection Containment Isolation Valve (CVS-PL-V219)

The H_2 addition containment isolation valve is air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valve is manufactured from stainless steel to ensure that no corrosion of the valve occurs since it contains H_2 at elevated pressure. It is designed to the ASME Boiler and Pressure Vessel Code, Section III-2. The code, with its supporting testing and examination, provides the foundations for performance claims made on the zinc addition isolation valve.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valve is also designed and installed to seismic C-I standards (see Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III, and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. There is another valve in series which is a CIV check valve (see Section 17.6.2 below). The provision of two valves in series provides redundancy and hence further reduces the probability of failure.

The maintenance and testing arrangements for the H_2 addition isolation valve are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with the ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

In addition to this, the valve will be seen to operate correctly every time the H_2 addition function is started or stopped, so this will provide numerous other opportunities to identify operational problems.

17.4 STEAM AND FEEDWATER SYSTEMS

17.4.1 Steam Generator and Main Steam Supply Systems

17.4.1.1 Role

A detailed description of the steam generator system (SGS) and main steam system (MSS) is given in Section 6.5.

The SGS consists of the feed water piping, steam generators, steam piping, valves, and related appurtenances that are located within the nuclear island (NI). The MSS exists to transfer the steam produced in the SGs from the NI boundary (Auxiliary Building wall into the First Bay) to the main turbine generator and thus the SGS and MSS have a power generation Category C function. This Category C function includes the functions to remove core decay heat during hot standby and during the initial phase of plant cooldown making use of the feedwater system (FWS) and the MSS steam bypass valves and the main condenser. The remaining discussions below apply to the SGS only.

The SGS supports the core reactivity control, core heat removal, and the containment primary safety functions. If there is a steam line break or other significant secondary-side depressurisation, the consequences are a rapid fall in temperature of the primary coolant with consequent impact on reactivity and potential impact on primary circuit integrity. In addition, significant overpressure of the SGs could result in a challenge to RCS integrity. The SGS also acts to remove core decay heat following design basis events making use of the SG secondary side water inventory and the SG safety valves. These are Category A functions and since the SGS provides a primary means of performing these functions, its systems, structures, or components (SSCs) are Class 1. Following a postulated break in a main steam line located within the containment, the SGS main steam isolation valves are automatically closed to prevent the blowdown of both SGs into the containment. For a steamline break outside containment, closure of both main steam isolation valves would isolate the break and limit the steam release to the turbine building. Following a SG tube rupture where contaminated primary coolant leaks to the secondary side, the SGS main steam isolation valves also contribute to the containment primary safety function by preventing the movement of contamination into the turbine building main steam pipework and potentially offsite.

The SGS isolation valves are adjacent to the containment boundary and are required to be CIVs and along with the SGS pressure boundary contribute to the containment safety function.

The SGS also provides protection against secondary-side overpressure and consequent support to RCS integrity that contributes to both the residual heat removal/heat transfer and the containment safety functions, through the provision of pressure relief valves.

The SGS is supported in providing its Category A safety functions by the essential electrical system. The main steam isolation valve (MSIV) actuators are qualified to operate throughout the normal and abnormal temperature range, including in case of loss of ac power and loss of heating, ventilation, and air conditioning (HVAC). The annex/auxiliary building non-radioactive HVAC system (VXS) does not support the SGS in the provision of its Category A safety functions and therefore carries the same classification as the MSS in the provision of its Category C safety function.

SGS also contributes to the reactivity control primary safety function and the containment primary safety function. This is achieved through the provision of main feedwater isolation valves (MFIVs) backed up by the main feedwater control valves (MFCVs), and in certain circumstances by the main feedwater check valves.

The reactivity control primary safety function is met by isolating the main feedwater line to prevent feedwater from being supplied to the SGs if they appear to be overfilling or if the heat removal is excessive. This prevents excessive temperature changes to the reactor coolant and consequent effects on reactivity.

The containment primary safety function is met by isolating the main feedwater line in the event of an SG tube leak to limit the amount of mass injected during an SG tube rupture (SGTR) to prevent SG overfill. The main feedwater line is also isolated to prevent the escape of high-energy fluid in the event of breaks in either feedwater or main steam lines not associated with SG tube leaks.

The MFIVs are also CIVs and contribute to the containment safety function.

The SGS is supported in providing its safety function by the essential electrical system, but it does not support other systems in their safety functions.

The SGS does not support other systems in their safety functions.

Further design details of this system and its constituent components are delineated in Reference 17.5 and Reference 17.8.

17.4.1.2 System Components and Equipment Contributing to Safety Function

The pipework systems associated with the SGS are designed and constructed to ASME Boiler and Pressure Vessel Code, Section III-2 (Reference 17.4). The pipework systems associated with the MSS are designed and constructed to ANSI/ASME B31.1 Power Piping Code standards (Reference 17.10).

The following components contribute to the main steam line performing its Class 1 safety functions:

- **Main Steam Line Isolation Valves (SGS-PL-V040A/B)** – These are 950-mm DN (38-inch), power-operated, quick-acting, bidirectional, wedge gate valves. The valve actuator consists of a piston and cylinder with a compressed nitrogen energy storage system. The valve is opened by driving hydraulic fluid into the cylinder so that the piston moves to compress the nitrogen “spring”. The hydraulic fluid is locked in the system at high pressure to keep the valve open. Two redundant pairs of solenoid valves

operate to control the flow of hydraulic fluid to move the valve. The valve has three modes of operation: slow close, fast close, and open. All solenoids remain de-energised for the "open" mode, with the hydraulic pump operating to pump fluid into the actuator cylinder to compress the nitrogen spring. For the "slow close" mode, both solenoids in either pair must energise. For the "fast close" mode, a specific solenoid valve in either pair must energise. The arrangement of the solenoids is designed to provide a fail "as is" capability on loss of all electrical supplies. The "fast close" mode is initiated on receipt of a main steam line isolation signal from the PMS to isolate their respective SGs from the effects of secondary-side depressurisation. This requirement to quickly isolate the main steam line is therefore a safety requirement. The MSIVs are also CIVs and are required to isolate on demand from a PMS containment isolation signal.

- **MSIV Bypass Isolation Valves (SGS-PL-V240A/B)** – These are 75-mm DN (3-inch), modulating air-operated globe valves. The valves fail closed on loss of air and redundant solenoid valves are actuated on receipt of a main steam line isolation signal from the PMS to dump air and close the valves. As with the MSIVs, this is to complete the isolation of the respective SG from the effects of secondary-side depressurisation, and is therefore a safety requirement. The MSIV bypass valves are also CIVs and are required to isolate on demand from a PMS containment isolation signal.

- **Main Steam Safety Valves (SGS-PL-V030A/B, -V031A/B, -V032A/B, -V033A/B, -V034A/B, and -V035A/B)** – These are 200-mm DN (8-inch), spring-loaded safety relief valves. Each valve must have a rated capacity of approximetly 623,240 kg/hr (1.374×10^6 lb/hr) at a pressure of approximetly 8.8 MPa (1274 psia). As spring-loaded safety valves, they do not require any external signals or motive power to initiate a lift, but they are required to lift at a set steam pressure and be capable of passing design flow at 110 percent of system design pressure to protect MSS integrity. This is therefore a safety requirement. Once excess steam pressure has been relieved, the valves are required to close because a stuck-open valve will have similar consequences to a steam system leak and will result in an RCS cool down. The re-isolation is therefore also a safety requirement.

- **PowerOperated Relief Valves (PORV) (SGS-PL-V233A/B)** – These are 300-mm DN (12-inch), air-actuated globe valves. The valve responds to signals from four separate pressure tappings on the associated steam line. The setpoint is variable and can be selected remotely from the main control room (MCR). In the event of a loss of air supply, the valves fail closed. In terms of system overpressure protection, the PORVs do not have a statutory role because full protection is provided by the main steam safety valves. The PORVs are used to provide a controlled steaming route to atmosphere and serve as the initial relief path to minimise the numbers of lifts of the main steam safety valves and consequent risk of failure to correctly reseat. As a result, the requirement to open is not a safety requirement; however, a stuck-open PORV will result in an RCS cool down, and the requirement to close in response to an SG relief isolation signal from the PMS is a Class 1 safety requirement.

- **PORV Block Valves (SGS-PL-V027A/B)** – These are 150-mm DN (6-inch), motor-operated gate valves. The valves serve to protect against the impact of a stuck-open PORV. Given that the PORV pressure relief capability is not classified as part of the formal pressure relief arrangements, it is acceptable to include additional isolation valves in the line. The valves are required to close on receipt of an SG relief isolation signal from the PMS and this is a Class 1 safety requirement.

- **SG Blowdown Isolation Valves (SGS-PL-V074A/B, -V075A/B) –** The blowdown isolation valves contribute to the SGS performing its safety function. They are 100-mm DN (4-inch), air-operated globe valves that fail closed on loss of air supply. They are required to close on receipt of an SG blowdown isolation signal from the PMS. This is intended to shut off the SG blowdown flow and stop further drain down of the associated SG. It will also terminate any associated contribution to an increased heat removal event and provide containment isolation.

- **Main Feed Water Isolation Valves (SGS-PL-V057A/B)** – These 500-mm (20-inch) nominal-bore, bidirectional, wedge-type gate valves are composed of a valve body welded into the system pipeline and provided with a hydraulic/pneumatic actuator. The valve actuator is supported by the yoke that is attached to the top of the body and consists of a piston and cylinder with a compressed nitrogen energy storage system. The valve is opened by driving hydraulic fluid into the cylinder so that the piston moves to compress the nitrogen that acts as a spring. The hydraulic fluid is maintained locked in the system at high pressure to maintain the valve open. Two redundant pairs of solenoid valves operate to control the flow of hydraulic fluid to move the valve. The valve has three modes of operation: slow close, fast close and open. All solenoids remain de-energised for open, with the hydraulic pump operating to pump fluid into the actuator cylinder to compress the nitrogen spring. For slow close, both solenoids in one of the two pair must energise. For fast close, the hydraulic dump solenoid valve in either pair must energise via signals from the PMS. The arrangement of the solenoids is designed to provide a fail "as is" capability on loss of all electrical supplies. The valves are required to fast close on receipt of a main feedwater line isolation signal, to isolate their respective SGs from the effects of overfeeding. They are also required to fast close to prevent the overfilling of an SG following a tube rupture to accomplish their containment isolation function. The ability to fast close is therefore a safety requirement.

- **Main Feedwater Control Valves (SGS-PL-V250A/B)** – These air-operated 500-mm (20-inch) nominal-bore globe valves are designed to fail closed on loss of air. The valve modulates to control feedwater flow to maintain a proper SG level. The air used for valve modulation passes through a solenoid-operated dump valve that is normally energised but is de-energised by the PMS main feedwater line isolation signal. This dumps the air pressure and causes the valve to run fully closed. The valve is a tight shutoff design that can provide isolation as well as modulating control. Whilst the primary role of the valve is to control feedwater flows during normal operation, it is required to provide a backup to the main feedwater line isolation valves, to terminate feedwater flow on demand, and to isolate the containment. This secondary role is a safety requirement.

- **Main Feedwater Check Valves (SGS-PL-V058A/B)** – These 500-mm (20-inch) nominal-bore, control closure, lift check valves are simple, passive devices that require no control action to operate. This valve provides some defence in depth for reverse flow feedwater isolation; no specific performance claims are made on its ability to isolate reverse flow in the safety case. There is a requirement; however, against its ability to close over a timescale slow enough to limit hydrodynamic shock loads on associated piping and nozzles.

- **Startup Feedwater Control Valves (SFCV) (SGS-PL-V255A/B)** – These 150-mm (6-inch) nominal-bore, air-operated, modulating control globe valves fail closed on loss of air supply. They are designed to ensure tight shutoff when closed to allow them to provide isolation as well as control startup feedwater over the required flow range. The SFCV actuator is equipped with an auxiliary air accumulator so that if normal

instrument air supply is lost, the valve can continue to modulate for a time. The control air is supplied through a solenoid-operated dump valve that has to be energised to provide the air supply. The Class 1 safety requirement of the valves is to contribute to the isolation of flow on receipt of a startup feedwater isolation signal from the PMS.

- **Statrtup Feedwater Isolation Valves (SFIV) (SGS-PL-V067A/B)** – These 150-mm (6-inch) nominal-bore, motor-operated, gate valves are designed to fail "as is". Their Class 1 safety requirement is to isolate startup feedwater flow on receipt of a startup feedwater isolation or containment isolation signal from the PMS.

- **Startup Feedwater Check Valve (SGS-PL-V256A/B)** – This 150-mm (6-inch) nominal-bore, nozzle-type check valve is located downstream of the SFIV. It is a simple passive device that is held open by flow and closed by differential pressure of the flowing medium: it requires no other power or actuation. The Class 1 safety role is to provide redundancy for Class 1 containment isolation.

17.4.1.3 Safety Requirements Identified against Components and Equipment

Main Steam Line Isolation Valves (SGS-PL-V040A/B)

The MSIVs protect against excessive containment pressurisation and RCS cooldown due to secondary-side steam leakage with the resulting challenges to containment integrity, and core reactivity and RCS integrity. In the event of an SGTR, these valves close to prevent the release of primary fluid and are also containment isolation valves. These are all Category A safety functions. The MSIVs are the principal means of providing this protection and, as such, are Class 1. See Appendix 15A.

There is a single MSIV on the steam line from each SG (two in total) and the requirement against each is that they will close on demand. In order to prevent the blowdown of both SGs following a postulated steam line break inside containment, either MSIV has to close to meet the safety function.

MSIV Bypass Isolation Valves (SGS-PL-V240A/B)

The MSIV bypass valves also provide protection against excessive RCS cooldown due to secondary-side steam leakage with the resulting challenges to core reactivity and RCS integrity. In the event of an SGTR, these valves close, if they are open, to prevent the release of primary fluid and are also containment isolation valves. They are therefore supporting a Category A safety function. These bypass valves are positioned in parallel with the MSIVs and they are normally closed during power operation. They are opened during plant heatup when the MSIVs are closed and they must close to achieve the safety function. This makes them Class 1. See Appendix 15A. In order to prevent the blowdown of both SGs following a postulated steam line break inside containment, either bypass valve has to close to meet the safety function.

Main Steam Safety Valves (SGS-PL-V030A/B, -V031A/B, -V032A/B, -V033A/B, -V034A/B, and -V035A/B)

The main steam safety valves protect against SG overpressure and consequent challenges to RCS integrity. This is a Category A safety function. Reseating following a lift to prevent uncontrolled cooldown is a requirement also associated with RCS integrity as well as core reactivity, and again makes the valves Category A. As the main steam safety valves are the primary method of providing this function, they are Class 1. See Appendix 15A.

Six safety valves are associated with the main steam line from each SG. They are set to a series of staggered lift points so that they open sequentially as steam pressure rises. The requirement against each valve, therefore, is that it will open at the correct set pressure and then reseat when the pressure falls appropriately. The capacity of the 12 main steam safety valves is claimed to provide sufficient capacity to prevent the SGS pressure from exceeding 110 percent of the design value.

Power Operated Relief Valves (PORV) (SGS-PL-V233A/B)

The main steam PORVs do not have a formal safety function for limiting main steam line pressure although they will still operate. They do have a safety function to close on demand to prevent cooldown due to secondary-side depressurisation. This is a Category A safety function. Although the primary requirement for isolation of the relief path is with the PORV block valve, closure of the PORV itself is required to ensure that the function remains available even in the event of a single failure. As a result, the PORVs are Class 1. See Appendix 15A.

One PORV is associated with each SG. It is arranged in series with its associated block valve so that either closing will achieve the safety function. The safety claim, therefore, is that the PORV will close on demand.

PORV Block Valves (SGS-PL-V027A/B)

The main steam system PORV block valves exist to protect against a stuck-open PORV. As this is protecting against the cooldown due to secondary-side depressurisation, these valves are again Category A. As they are the principal equipment to provide this on the PORV line, they are Class 1. See Appendix 15A.

One block valve is associated with each PORV, arranged in series as described above. The safety requirement is that the block valve will close on demand.

SG Blowdown Isolation Valves (SGS-PL-V074A/B, -V075A/B)

The blowdown isolation valves help to prevent uncontrolled cooldown and the consequent potential impact on reactivity. Control of reactivity is a Category A safety function. The normal protection for this function is provided by flow restrictions in the blowdown lines, and these restrictions are located downstream in the turbine building. Therefore, the blowdown isolation valves have a backup, or defence in depth, role in the event of a failure upstream of the flow restriction and downstream of the isolation valves. See Appendix 15A.

The blowdown isolation valves also close to preserve SG water inventory. This is to assist in maintaining a heat sink and is also considered a Category A safety function. Because the blowdown isolation valves are the only means of providing the maintenance of heat sink safety function, they are Class 1. See Appendix 15A.

The blowdown isolation valves also serve to preserve containment integrity. Containment integrity is a Category A safety function. Because the blowdown isolation valves are a primary means of providing the containment integrity safety function, they are Class 1. See Appendix 15A.

Thus the SG blowdown valves are Class 1. The requirement against these valves is that they will close on demand. There are two valves in series, so either one closing successfully will achieve the safety function for that SG. Clearly, to achieve the safety function in total, at least one valve in each SG blowdown line must close successfully.

Main Feed Water Isolation Valves (SGS-PL-V057A/B)

The MFIVs are designed to prevent inadvertent temperature changes of the reactor coolant and consequent reactivity concerns as a result of excess feedwater flow. Reactivity control is a Category A safety function. The MFIVs provide a primary means of supporting this safety function and are therefore deemed Class 1. See Appendix 15A.

The MFIVs are CIVs. Containment isolation is a Category A safety function and because the MFIVs are the primary isolation valves for the feedwater system penetrations, they are also Class 1 in this role. See Appendix 15A.

Two MFIVs are provided, one in the main feedwater line to SG A and one in the main feedwater line to SG B. The requirement against each is that they close on demand. Both valves have to close to ensure that the safety function is met in all circumstances. To limit the mass and energy addition to containment in the event of steam or feedwater line breaks inside containment, there is a requirement that the MFIV be capable of isolation in fast close mode within 5 seconds.

The design of the valve and its associated actuator is very similar to valves used for similar functions in existing in-service PWRs.

Main Feedwater Control Valves (SGS-PL-V250A/B)

The MFCVs, in addition to their normal role of controlling feedwater flow, are designed to provide defence in depth to the MFIVs in preventing inadvertent temperature changes of the reactor coolant and consequent reactivity concerns as a result of excess feedwater flow. Reactivity control is a Category A safety function. The MFCVs, in conjunction with the MFIVs, provide the primary means of supporting this safety function and are therefore deemed Class 1. See Appendix 15A.

Two MFCVs are provided: one each in the main feedwater lines to SGs A and B. The requirement against each is that they close on demand. Both valves have to close to ensure that the safety function is met in all circumstances.

The design of the valve and its associated actuator is very similar to valves used similar functions in existing in-service PWRs.

Main Feedwater Check Valves (SGS-PL-V058A/B)

As stated previously, there is no safety requirement against the ability of the main feedwater check valves to change state, but their ability to do so in a way that is not detrimental to the structural integrity of the feedwater system pipework is an implicit requirement. Longer-term protection of feedwater system pipework would be commensurate with protection against internal hazards from major pipework leaks and so can be considered a Category A safety function. The main feedwater check valve closure times are fundamental to preventing hydrodynamic shocks and so the valves are considered to be Class 1. See Appendix 15A. The bodies of the main feedwater check valves effectively form a part of the containment penetration. Providing containment integrity is a Category A safety function and, given that they form a part of the penetration, they are considered Class 1 in this respect.

Two main feedwater check valves are provided, one each in the main feedwater lines to SGs A and B. The requirement against each is that they close over such a timescale that the hydrodynamic shock generated will be within the design limits for the

main feedwater system. It is therefore required that the main feedwater check valves close in >1 but <2 seconds.

Startup Feedwater Flow Control Valve (SGS-PL-V255A/B)

The SFCVs, in addition to their normal role of controlling feedwater flow, are designed to support the SFIVs in providing containment isolation in addition to preventing inadvertent temperature changes of the reactor coolant and the consequent impact on reactivity as a result of excess feedwater flow. Reactivity control and containment isolation are Category A safety functions. The SFCVs, with the SFIVs, provide the principal means of supporting these safety functions and are therefore deemed Class 1. See Appendix 15A.

Two SFCVs are provided, one each in the startup feedwater lines to SG A and SG B. The requirement against each is that they will close on demand. Both valves have to close to ensure that the safety function is met in all circumstances.

Startup Feedwater Isolation Valve (SGS-PL-V067A/B)

The SFIV is designed to prevent inadvertent temperature changes of the reactor coolant and consequent impact on reactivity as a result of excess feedwater flow. Reactivity control is a Category A safety function. The SFIVs provide the primary means of supporting this safety function and are therefore deemed Class 1. They are also CIVs. Containment isolation is also a Category A safety function. The SFIVs provide the primary means of supporting this safety function and are therefore also deemed to be Class 1 in this role. See Appendix 15A.

Two SFIVs are provided, one each in the startup feedwater lines to SG A and SG B. The requirement against each is that they will close on demand. Both valves have to close to ensure that the safety function is met in all circumstances.

Startup Feedwater Check Valve (SGS-PL-V256A/B)

This valve provides defence in depth against cooldown transients associated with failure of the startup feedwater pipework upstream of the SFCVs. Protection against cooldown transients and the consequent impact on reactivity control is a Category A safety function. The SFCVs support the feedwater isolation and containment isolation functions and are therefore Class 1. See Appendix 15A.

There are two valves, one on the startup feedwater line to each SG. Both are required to close to satisfy the safety function. The requirement is that they will close when they see reverse flow in the startup feedwater lines.

17.4.1.4 Justification of Claims on Components and Equipment

Main Steam Line Isolation Valves (SGS-PL-V040A/B)

The MSIV valve actuator requires that the hydraulic pressure must be held in place to keep the valve open, which means that any leakage or failure of the hydraulic system will result in the valve closing by virtue of the energy stored in the “gas spring”. The system of solenoid valves used to control operation of the hydraulic system is described above. Clearly, this is not fail-safe with respect to the main steam line isolation function; however, given that spurious actuation of this function when not required could, in itself, give rise to safety concerns through the sudden loss of heat sink when at power, it is judged as appropriate.

Both valves are manufactured from alloy steel to ensure compatibility with steam at the conditions at that it passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2 that has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III-2, the valves are also designed and installed to seismic C-I standards, and are qualified for operation in a harsh environment. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. Both solenoids in either pair must energise for the slow close function, but the requirement that only a single solenoid need energise for the fast close and the fact that redundancy is provided, gives extra confidence in the reliability of achieving the required safety function.

The maintenance and testing arrangements for the MSIVs are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- A full stroke operability test is performed every 2 years when the plant is at cold shutdown. This is required to demonstrate that the valve closure time is less than 5 seconds. Even though a test every three months might be specified for this type of service, exercising the valve with the unit at power is deemed to present an unacceptable risk to normal operation and hence, under the ASME Boiler and Pressure Vessel Code, Section III rules, can be varied.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

- Given that they are CIVs, leakage testing is performed as part of the containment integrated leak rate test (ILRT). This test will be performed in line with the CIV leak test programme.

- The actuator nitrogen pressure is monitored to ensure that the valve remains operable in accordance with technical specifications (Tech Specs).

MSIV Bypass Isolation Valves (SGS-PL-V240A/B)

The MSIV bypass valves are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from alloy steel to provide compatibility with steam at the conditions at that it passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a value to remain closed for an air-operated valve. This is comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards and are qualified for operation in a harsh environment. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the MSIV bypass valves are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- A full stroke operability test is performed every 3 months with the reactor at power.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- Given that they are CIVs, leakage testing is performed as part of the containment ILRT. This test will be performed in line with the CIV leak test programme.

Main Steam Safety Valves (SGS-PL-V030A/B, -V031A/B, -V032A/B, -V033A/B, -V034A/B, and -V035A/B)

The main steam safety valves are of the spring-loaded, self-actuated type; operation depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from carbon steel as they do not normally see a flow of steam and are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of six relief valves with staggered lifting pressure also helps to minimise the impact of any one valve failing to open on demand or, having opened correctly, subsequently failing to reseat.

The maintenance and testing arrangements for the main steam safety valves are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- Each valve should be tested as installed, or bench-tested, every 5 years.
- Given the multiple valves present on each steam line, the ASME Boiler and Pressure Vessel Code standard requires that in fulfilling the above requirement, 20 percent of the valves will be tested, either installed or on the bench, every 2 years.

Power Operated Relief Valves (PORV) (SGS-PL-V233A/B)

The main steam PORVs are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from alloy steel to ensure compatibility with the steam at the conditions at that it passes through them. Unlike the main steam safety valves, they are expected to pass flow under off-normal operations when providing RCS cooling by steam generation but with the turbine condensers unavailable. They are designed to ASME Boiler and Pressure Vessel Code, Section III.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) are comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards and are qualified for operation in a harsh environment. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the MSIV bypass valves are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- A full stroke operability test is performed every 3 months with the reactor at power.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

PORV Block Valves (SGS-PL-V027A/B)

The PORV block valves are motor operated, which means that inherently they will fail “as is”. Clearly, this is not fail-safe with respect to the function of isolating a stuck-open PORV, but a spurious actuation of this function could inhibit the operation of a correctly operating PORV. In this case, there might be resulting safety concerns with the incorrect isolation of a heat removal path, so the requirement to fail “as is” is judged as appropriate.

The valves are manufactured from alloy steel to ensure compatibility with steam at the conditions they will see. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I standards and are qualified for operation in a harsh environment. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the MSS PORV block valves are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- Given that they are CIVs, leakage testing is carried out as part of the containment ILRT. This test will be performed in line with the CIV leak test programme.

SG Blowdown Isolation Valves (SGS-PL-V074A/B, -V075A/B)

The blowdown isolation valves are air operated with the actuators designed to transfer closed in the event of a loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from alloy steel to ensure compatibility with the SG secondary-side water that passes through them. They are designed to either the ASME Boiler and Pressure Vessel Code, Section III-2 or Section III-3.

The design of the air-operated globe valve is very similar to those valves used for similar functions in PWR reactors already operating. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure comparable to the claim being made.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valve is also designed and installed to seismic C-I standards and is qualified for operation in a harsh environment. The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of this occurring. The provision of two valves in series further reduces the probability of failure to provide the safety function.

The maintenance and testing arrangements for the blowdown isolation valves is based on the ASME Boiler and Pressure Vessel Code programmes appropriate for this type of valve as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with the ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- Given that they are CIVs, leakage testing is carried out as part of the containment ILRT. This test will be performed in line with the CIV leak test programme.

Main Feedwater Isolation Valves (SGS-PL-V057A/B)

The MFIV is held open by a hydraulic actuator and closes using compressed nitrogen stored within the actuator. Any failure or leakage of the hydraulic system will result in the nitrogen pressure closing the valve. The design action of the solenoid valves that control the hydraulic system provides a fail "as is" feature on loss of all electrical supplies. This is not intrinsically fail-safe with respect to main feedwater line isolation; however, spurious closing of the MFIV could cause loss of heat removal capability and other transient effects, so this arrangement is judged to be appropriate.

The MFIV is manufactured from alloy steel to ensure compatibility with the feedwater that passes through it. By design, its trims and seats are constructed of materials to allow the valve to close within 5 seconds against a major feedwater pipe rupture. The bidirectional wedge design is used to ensure that the valve effectively seals in both directions. Because the failure mechanism of concern would involve the valve jamming or sticking, it is designed to the ASME Boiler and Pressure Vessel Code, Section III design code, Class 2, and seismic C-I; and is qualified for harsh environment. Components designed and built to this code have accumulated a vast body of experience in similar applications. This code, with its supporting testing and examination, provides the foundation for performance claims made on these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) provide a probability of failure to close for a hydraulically operated valve of this type.

The maintenance and testing arrangements for the MFIVs are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- A full stroke operability test is performed every 2 years when the plant is at cold shutdown. This is required to demonstrate that the valve closure time is less than 5 seconds. Even though a test every 3 months might be specified for this type of service, exercising the valve with the unit at power is deemed an unacceptable risk to normal operation; therefore, under the ASME Boiler and Pressure Vessel Code, rules, the frequency can be varied.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed in line with the CIV leak test programme (Reference 17.11).

Monitoring of the actuator nitrogen pressure is performed to ensure that the valve remains operable in accordance with Tech Specs.

Main Feedwater Control Valves (SGS-PL-V250A/B)

The MFCVs are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The MFCVs are manufactured from alloy steel to ensure compatibility with the feedwater that passes through them. By design, their trims and seats are constructed of materials to allow them to close within 5 seconds against a major pipe rupture upstream or downstream. Because the failure mechanism of concern would involve the valves jamming or sticking, they are designed to ASME Boiler and Pressure Vessel Code, Section III-3 and seismic C-I, and are qualified for a harsh environment. Components designed and built to this code have accumulated a vast body of experience in similar applications. This code, with its supporting

testing and examinations, provides the foundation for performance claims made on these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) provide a probability of failure to close for an air-operated valve of this type.

The maintenance and testing arrangements for the MFCVs are based on the programmes associated with ASME Boiler and Pressure Vessel Code qualification. The testing is:

- A full stroke operability test is performed every 2 years when the plant is at cold shutdown. This is required to demonstrate that the valve closure time is less than 5 seconds. Even though a test every 3 months might be specified for this type of service, exercising the valve with the unit at power is deemed an unacceptable risk to normal operation; therefore, under the ASME Boiler and Pressure Vessel Code, the frequency can be varied.

- Visual confirmation of valve operation during the stroke testing is carried out every 2 years.

Main Feedwater Check Valves (SGS-PL-V058A/B)

The operation of the main feedwater check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-2 that has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the accumulator check valves.

The valves are very similar to those already in like service on many operating power stations. This provides a good level of confidence that the valve performance will remain consistent.

Startup Feedwater Control Valves (SGS-PL-V255A/B)

These valves are air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe. The presence of an auxiliary air accumulator to provide a “ride-through” capability against temporary interruption of the air supplies supports reliability during normal operation.

The valves are manufactured from carbon steel and are designed to ASME Boiler and Pressure Vessel Code, Section III.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a value that is comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment. The maintenance and testing arrangements for the SFCVs are based on the programmes associated with ASME Boiler and Pressure Vessel Code, qualification. The testing is:

- A full stroke operability test is performed every 3 months with the reactor at power.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

Startup Feedwater Isolation Valves (SGS-PL-V067A/B)

These valves are motor operated with the actuators designed to fail "as is" in the event of a loss of power supply. This is not an inherently safe mechanism but the complications associated with ensuring that an air-operated system is protected from spurious failure (for example, the SFCVs) were felt to make for a less reliable solution than a straightforward motor-operated valve.

The valves are manufactured from mild steel and are designed to ASME Boiler and Pressure Vessel Code, Section III-2. The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that this is comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment. The maintenance and testing arrangements for the SFIVs is based on the programmes associated with ASME Boiler and Pressure Vessel Code, qualification. The testing is:

- A full stroke operability test is performed every 3 months with the reactor at power.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

Startup Feedwater Check Valves (SGS-PL-V256A/B)

The operation of these check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability. The nozzle-type check valve is able to close very rapidly and was selected to minimise the potential for water hammer if there is a flow reversal in the pipework.

The valve is manufactured from mild steel and is designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valve is very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from the valve proposed for the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that this is conservative with respect to the value being claimed.

17.4.2 Steam Generator Blowdown System

17.4.2.1 Role

A detailed description of the steam generator blowdown system (BDS) is given in Section 6.5.

The BDS sole safety function is preventing the release of radioactive waste material from onsite radioactive waste systems. As dicussed in section 17.1 components that have no other safety function other than a pressure boundary are not discussed in this chapter. As delineated in Table 15A BDS valves achieve the aforementioned function but are not discussed here. Further design details of this system and its constituent components are delineated in Reference 17.18.

17.4.3 Turbine Bypass and Other MSS and Main Turbine System (MTS) Valves

17.4.3.1 Role

A detailed description of the turbine bypass function is given in Section 6.5.

The role of the turbine bypass is to provide an alternative route to handle steam generated when the main turbine is unable to accept it. There are six turbine bypass valves, two exhausting into each turbine condenser pass. These valves allow the station to handle up to 100 percent electrical load rejection and maintain primary and secondary circuit conditions so that demands on the main steam safety valves and pressuriser safety valves are eliminated. This means that the turbine bypass system is effectively providing a defence in depth function even though it is the preferred system to manage these transients.

The system does, however, contribute to the reactivity control and heat transfer/residual heat removal primary safety functions. Incorrect operation of the turbine bypass system when, for example, a bypass valve is opened, will result in increased heat removal and a cooldown transient. To combat this, the turbine bypass valves have a function to isolate on demand. Whilst the main steam isolation valves are the principal means of providing this function, under certain circumstances, isolating the turbine bypass valves is also claimed as defence in depth.

Similarly, there are other valves in the MSS and MTS where isolation is required to provide backup protection against increased heat removal due to excess steam demand events or to limit steam backflow into containment following a postulated steam line break inside containment. These locations are the auxiliary steam supply isolation valves, the steam supply isolation valves to the second stage of the moisture separator reheaters (MSR), and the high pressure turbine stop and control valves. These valves are required to isolate their respective steam paths to meet their defence in depth function.

All the above valves are supported by the PMS and PLS in achieving their safety functions. These valves support the SGS as their safety functions.

Further design details of this system and its constituent components are delineated in Reference 17.20 and Reference 17.8.

17.4.3.2 System Components and Equipment Contributing to Safety Function

The pipework and valve design of the turbine bypass system is to ASME Standard, B31.1. The following components contribute to the turbine bypass system and other steam supplies performing their safety function:

- **Turbine Bypass Control Valves (MSS-PL-V001, -V002, -V003, -V004, -V005, -V006)** – These are 400-mm DN (16-inch), air-operated angle globe valves. The actuators are designed to fail closed on the loss of air supplies. They are required to close on receipt of a main steam line isolation signal from the PMS. This stops any steam flow through the bypass line and terminates the contribution to RCS cooldown; therefore, the isolation of the steam path on demand is a safety requirement.

- **MSR 2nd Stage Reheat Supply Steam Isolation Valves (MSS-PL-V015A/B)** – These are 250-mm DN (10-inch), air-operated globe valves. The actuators are designed to fail closed on loss of air supply. They are required to close on receipt of a main steam line isolation signal that stops any steam flow into the reheater and terminates the contribution to RCS cooldown. This is a safety requirement. They are also required to close on receipt of a main steam line isolation signal to stop any steam flow from the reheater back into the containment in order to limit the mass and energy contribution to the containment atmosphere following a steam line break inside the containment. This is a safety requirement.

- **Auxiliary Steam Supply Header Isolation Valve (MSS-PL-V020)** – This is a 400-mm (16-inch) nominal-bore, air-operated globe valve. The actuator is designed to fail closed on the loss of air supplies. The valve is required to close on receipt of a main steam line isolation signal to prevent any flow into the auxiliary steam systems and terminate the contribution to RCS cooldown. This is a safety requirement.

- **High Pressure Turbine stop valves (MTS-PL-V001A/B and V003A/B) and Control Valves (MTS-PL-V002A/B, and V004A/B)** – The high pressure turbine stop valves and control valves are 700 mm DN (28-inch) valves with electro-hydraulic actuators that can function to quickly shut off steam flow to the turbine under emergency conditions, and control the main steam flow from the steam generator to match electrical power output demand, respectively. Furthermore, the control valves help control heat transfer of the steam generator. The main stop valves are located in the main steam piping directly ahead of the control valves with the outlet of each main stop valve welded directly to the inlet of a separate control valve casing. The valves are required to close on receipt of a main steam line isolation signal to prevent any flow into the high pressure turbine and terminate the contribution to RCS cooldown. As a result, this is a safety requirement. The valves are also required to close on receipt of a main steam line isolation signal to prevent any back flow from the high pressure turbine and MSR into the containment following a steam line break inside containment. This is also a safety requirement.

17.4.3.3 Claims on Components and Equipment

Turbine Bypass Control Valves (MSS-PL-V001, -V002, -V003, -V004, -V005, -V006)

The turbine bypass control valves, when closed, enable the isolation of secondary-side steam flows and so help to prevent cooldown of the RCS. The most immediate concern with

cooldown is the control of reactivity. Control of reactivity is a Category A safety function. The turbine bypass control valves are not the primary means of providing this function as this rests with the main steam isolation valves. The turbine bypass control valves therefore perform a Category C safety function and are Class 3 (Ref. 17.21). See Appendix 15A.

The requirement against these valves is that they will close on demand. Each steam flow path into its associated condenser pass has a single control valve. As a result, all six valves must close to fulfil the safety function.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a value to remain closed for an air-operated valve. This is comparable to the value being claimed.

MSR 2nd Stage Reheat Supply Steam Isolation Valves (MSS-PL-V015A/B)

The MSR second-stage reheat steam isolation valves, when closed, enable the isolation of secondary-side steam flows and thus help to prevent cooldown of the RCS. The most immediate concern with cooldown is the control of reactivity that is a Category A safety function. The MSR second-stage reheat steam isolation valves are not the primary means of providing this function as this rests with the main steam isolation valves. The MSR second-stage reheat steam isolation valves therefore perform a Category C safety function and are Class 3 (Reference 17.21). See Appendix 15A.

The requirement against these valves is that they will close on demand. Two MSRs are associated with the turbine generator and a single isolation valve is associated with the second-stage reheat on each MSR. This means that both second-stage reheat steam isolation valves must close to fulfil the safety function.

Auxiliary Steam Supply Header Isolation Valve (MSS-PL-V020)

The auxiliary steam supply header isolation valve, when closed, enables the isolation of secondary-side steam flows and thus helps to prevent cooldown of the RCS. The most immediate concern with cooldown is the control of reactivity that is a Category A safety function. The auxiliary steam supply header isolation valve is not the primary means of providing this function as this rests with the main steam isolation valves. The auxiliary steam supply header isolation valve therefore performs a Category C safety function and is Class 3 (Reference 17.21). See Appendix 15A.

There is one isolation valve associated with auxiliary steam supply and the safety requirement is that the valve will close on demand.

High Pressure Turbine Stop Valves (MTS-PL-V001A/B and V003A/B) and Control Valves (MTS-PL-V002A/B, and V004A/B)

The high pressure turbine stop valves and control valves, when closed, enable the isolation of secondary-side steam flows and so help to prevent cooldown of the RCS or back flow into the containment following a steam line break inside containment. The concern with cooldown is the control of reactivity. Control of reactivity is a Category A safety function. The concern with back flow is containment integrity which is also a Category A safety function. The high pressure turbine stop valves and control valves are not the primary means of providing this function as this rests with the main steam isolation valves. The high pressure turbine stop and

control valves therefore perform a Category C safety function and are Class 3 (Reference 17.21). See Appendix 15A.

The requirement against these valves is that they will close on demand. Each of the four steam flow paths into the high pressure turbine has a single stop valve and control valve in series. All eight valves receive a signal to close when the PMS generates a main steam isolation signal. As a result, either of the stop and control valves in each pair in each of the high pressure turbine steam inlet paths must close to fulfil the safety function.

17.4.3.4 Justification of Claims on Components and Equipment

Turbine Bypass Control Valves (MSS-PL-V001, -V002, -V003, -V004, -V005, -V006)

The turbine bypass control valves are designed to fail closed on loss of air supply. This function is provided by springs within the actuator and, because it does not depend on any external actuation, it is an inherently safe approach.

The air supply to each turbine bypass control valve is provided through three solenoid-operated valves, each of that has to remain energised for the air supply to be maintained and the valve open. Two of these solenoid valves are de-energised to close by signals from the PMS. Either solenoid valve opening will dump the air supply pressure and cause the associated turbine bypass control valve to close. Clearly, this arrangement also means that any failure in the electrical supplies to the solenoid valves will also result in loss of air supply and closure of the associated turbine bypass control valve.

The valves are designed to ASME Section B16.34. The maintenance and testing arrangements for the turbine bypass control valves are based on the programmes that demonstrate both the ability of the valves to stroke through their full operating range and to meet the maximum closure time assumed in the response to faults. The testing is:

- A stroke test to confirm that each valve closure time is within a 5-second limit is performed with the unit at normal operating temperature and pressure but before return to power, after each refuelling outage.

- A full stroke test of each valve is performed during each cold shutdown to confirm that the valve is moving correctly within its position limits.

MSR 2nd Stage Reheat Supply Steam Isolation Valves (MSS-PL-V015A/B)

The MSR second-stage reheat steam isolation valves are designed to fail closed on loss of air supply. This function is provided by springs within the actuator and, because it does not depend on any external actuation, is an inherently safe design.

The air supply to each MSR second-stage reheat steam isolation valve is provided through a solenoid-operated valve that has to remain energised for the air supply to be maintained and the valve open. The solenoid valve is de-energised to close by signals from the PMS. This will dump the air supply pressure and cause the MSR second-stage reheat steam isolation valve to close. Clearly, this arrangement also means that any failure in the electrical supplies to the solenoid valves will also result in loss of air supply and closure of the associated MSR second-stage reheat steam isolation valve.

The valves are designed to ASME Section B16.34. The maintenance and testing arrangements for the MSR second-stage reheat steam isolation valves are based on the programmes that demonstrate both the ability of the valves to stroke through their full

operating range and to meet the maximum closure time assumed in the response to faults. The testing is:

- A stroke test to confirm that each valve closure time is within a 5-second limit is performed with the unit at normal operating temperature and pressure but before return to power, after each refuelling outage.

- A full stroke test of each valve is performed during each cold shutdown to confirm that the valve is moving correctly within its position limits.

Auxiliary Steam Supply Header Isolation Valve (MSS-PL-V020)

The auxiliary steam supply header isolation valve is designed to fail closed on loss of air supply. This function is provided by springs within the actuator and, because it does not depend on any external actuation, is an inherently safe design.

The air supply to the auxiliary steam supply header isolation valve is provided through a solenoid-operated valve that has to remain energised for the air supply to be maintained and the auxiliary steam supply header isolation valve open. The solenoid valve is de-energised to close by signals from the PMS. This will dump the air supply pressure and cause the auxiliary steam supply header isolation valve to close. Clearly, this arrangement also means that any failure in the electrical supplies to the solenoid valve will also result in loss of air supply and closure of the associated auxiliary steam supply header isolation valve.

The valves are designed to ASME Section B16.34 (Reference 17.19).

The auxiliary steam supply header isolation valve performs a defence in depth function.

High Pressure Turbine Stop Valves (MTS-PL-V001A/B and V003A/B) and Control Valves (MTS-PL-V002A/B, and V004A/B)

The valve actuator for the high pressure turbine stop and control valves requires that the hydraulic pressure must be held in place to keep the valve open. Each of the eight valves has two, fail open solenoid valves, one of which is required to open for the valve to close. Each of these solenoid valves is controlled by two pilot valves which both have to be de-energised for the solenoid valve to open. Once, either of the two solenoid valves opens, the steam flow in the valves causes the valve to quickly close. This system of solenoid valves used to control operation of the hydraulic system provides a fail close feature for loss of all electrical supplies.

The valves are manufactured from alloy steel to ensure compatibility at the conditions at which steam passes through them. They are specially designed and manufactured valves that do not fall under any industry standard; however, they are tested to ASME Power Piping Code B31.1 test pressures.

The valves are very similar to those already in service for the same function on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. The rigorous design and manufacture requirements for these valves, the normal operation of the valves during plant operation, together with the test regime described below will minimise the probability of these failure mechanisms occurring. The requirement that only a single solenoid need

de-energise for the fast close and the fact that redundancy is provided, gives extra confidence in the reliability of achieving the required safety function.

The maintenance and testing arrangements for these valves are based on manufacturer's recommendations including:

- Visual confirmation of valve operation during the stroke testing is performed.
- The electro-hydraulic actuators and supporting equipment are monitored during valve operation to ensure proper operation.

17.4.4 Main Feedwater System

17.4.4.1 Role

A detailed description of the main feedwater system is given in Section 6.5.

In normal operation, the role of the main feedwater system is primarily associated with normal power operation and is required to deliver water at the correct flow rate, pressure, temperature, and chemical composition to each SG.

Further design details of this system and its constituent components are delineated in Reference 17.23.

17.4.4.2 System Components and Equipment Contributing to Safety Function

The main feedwater system comprises two parallel main feedwater lines, designated A and B. Each main feedwater line from the deaerator up to the turbine building wall is designed and constructed to the Power Piping Code B31.1. From the turbine building wall but excluding the MFIV (SGS-PL-V057A/B), the lines are constructed to ASME Boiler and Pressure Vessel Code, Section III-3 in the auxiliary building. Each main feedwater line from the MFIV (SGS-PL-V057A/B) to the SG is constructed to ASME Boiler and Pressure Vessel Code, Section III Class 2.

As dicussed in section 17.1 components that have no other safety function other than a pressure boundary are not discussed in this chapter. As delineated in Table 15A Main Feedwater components are Category C and Class 3.

17.4.5 Startup Feedwater Portion of the Feedwater System

17.4.5.1 Role

A detailed description of the startup feed water portion of the FWS is given in Section 6.5.

In normal operation, the startup feedwater system (SFW) is required to provide and control the flow of feed water to each of the two SGs during low-load operation. It performs the same role when the SGs are steaming with the reactor shut down and the main feedwater system unavailable. The SFW can draw water from either a connection with the main feedwater system or via its own dedicated supply from the condensate storage tanks (CST).

The SFW contributes to the reactivity control, heat transfer/residual heat removal, and containment primary safety functions.

The SFW provides a defence in depth (Class 2) function to support heat transfer/residual heat removal primary safety function by providing feedwater from the CST so the SGs can be used for decay heat removal post reactor trip. This flow is fed to the SGs via the SFIVs and SFCVs.

The SFW is supported by the on-site ac electrical power system (ECS) with standby power provided by the onsite standby power system (ZOS), if needed. The SFW supports the SG system.

Further design details of this system and its constituent components are delineated in Reference 17.23 and Reference 17.24.

17.4.5.2 System Components and Equipment Contributing to Safety Function

The SFW pipework between the startup feedwater isolation valves and the SGs is designed and constructed to the requirements of ASME Boiler and Pressure Vessel Code, Section III-2 and seismic C-I. The section in the auxiliary building is designed and constructed to the requirements of ASME Boiler and Pressure Vessel Code, Section III-3 and seismic C-I. The portion of the SFW in the turbine building is designed and constructed to section B31.1 of the power piping code. The following components contribute to the SFW fulfilling its safety requirements:

- **Condensate storage tank (DWS-MT-02)** – This is a vertical, stainless-steel, cylindrical tank with a capacity greater than that required for its safety function. Level and temperature instrumentation are provided and the tank level is maintained by the makeup valve. Freeze protection is supplied by immersion-type electric heaters. The location of the tank and the arrangements for the off take of condensate ensure that an adequate net positive suction head is provided for the startup feedwater pumps. The safety requirement is that the tank be a reliable source of water for the startup feedwater pumps.

- **Startup Feedwater Pumps (FWS-MP-03A/B)** – These are multistage centrifugal pumps designed to Hydraulic Institute standards. They are driven by an ac induction motor. The pump lubrication subsystems are self-contained and do not require external cooling. The startup feedwater pumps are tripped on high SG-level by signals from the PMS. The safety requirement is to provide feedwater for low and no power operations at appropriate pressure and flow.

- **Startup Feedwater Flow Venturi (FWS-FE-015A/B)** – This is fitted to the pump discharge pipework and is designed so that, at high flow conditions, flow will cavitate in the venturi. This results in the flow choking in the throat and is used to limit flow to prevent pump runout at low pressures. The safety requirement is to limit flow at low discharge pressure.

- **Startup Feedwater Pump Automatic Recirculation Check Valves (FWS-PL-V012A/B)** – These are 100-mm DN (4-inch) combination check and bypass valves (Automatic Ricurculation Valves (ARC)). The valves incorporate a spring-loaded check valve in the SFW pump discharge flow path and a bypass flow control device. Mini-flow recirculation is controlled by the bypass flow control device and the valve also functions as a check valve to prevent reverse flow through the pump when it is not operating and the pump discharge valve has not yet closed. This valve requires no external power and modulates flow through the recirculation path based on pressure-sensing capability. If forward flow to the system drops below approximately 47.7 m^3/hr (210 gpm), the

control valve automatically modulates open to maintain the total pump flow (forward flow plus recirculation flow) at this value. Most of the pressure breakdown of the recirculated flow is accomplished internally in the control valve. The safety requirement is to ensure that minimum flow requirements for the pump are met.

- **Main Feedwater Pump to Startup Feedwater Header Crossflow Valve (FWS-PL-V097)** – This 200-mm DN (8-inch), air-operated globe valve fails closed on loss of air supply. Its normal role is to open to allow the main feedwater pumps to supply the startup feedwater header at low power operation. The valve is normally closed during full-power operation and provides positive isolation of main feedwater to avoid potential thermal stratification effects in the startup feedwater piping. The valve is closed by the PLS on receipt of a main feedwater isolation signal. The safety requirement is to isolate the SFW from main feedwater on demand.

- **Main feedwater to Startup Feedwater Header Check Valve (FWS-PL-V096)** – This 250-mm (10-inch) nominal-bore swing check valve ensures that during operation of the startup feedwater pumps, they cannot inadvertently discharge back into the main feedwater system. The safety requirement is to prevent flow from the SFW into the main feedwater system.

17.4.5.3 Claims on Components and Equipment

Condensate Storage Tank (DWS-MT-02)

The CST provides the source of water to enable the SFW to provide feedwater to the SGs to remove decay heat. Removal of decay heat is a Category A safety function. The use of startup feedwater and SGs for decay heat removal is a defence in depth function, the passive residual heat removal (PRHR) system being the primary method. As such, the CST is Class 2. See Appendix 15A.

The requirement is that the CST capacity is sufficient to maintain steam generator cooling for at least 24 hours following a loss of normal ac power. The CST capacity is also sufficient to cool the RCS to safe shutdown conditions such that the RNS can be put into service. This includes 8 hours for the RCS to be borated and 6 hours to cool the RCS from hot standby to RNS initiation temperature. The single tank provides the supply to both startup feedwater pumps.

Startup Feedwater Pumps (FWS-MP-03A/B)

The startup feedwater pumps provide the motive force to get water from the CSTs to the SGs to remove decay heat. Removal of decay heat is a Category A safety function. The startup feedwater pumps are considered Class 2. See Appendix 15A.

Two pumps are arranged in parallel, and each can supply the required flow to provide the full system duty. They are required to start on demand and continue to run as required.

Startup Feedwater Flow Venturi (FWS-FE-015A/B)

The venturi is designed to cavitate at a flow near but less than the pump runout point; the choked flow in the throat of the venturi under such conditions prevents further flow increase. Thus, the venturi prevents the startup feedwater pump from running beyond its designed maximum flow rate. This device provides essential protection to the startup feedwater pump that supports a Category A safety function. The pump is Class 2, so the venturi must also be Class 2. See Appendix 15A.

The requirement is that the venturi will limit pump flow to a safe level.

Startup Feedwater Pump Automatic Recirculation Check Valves (FWS-PL-V012A/B)

These valves are provided to recirculate flow automatically from each pump discharge back to the CST to ensure a minimum flow through the pump when no flow is supplied forward to the SG. The pumps are supporting a Category A safety function and are Class 2 equipment, so the startup feedwater pump automatic recirculation valves must also be Class 2. See Appendix 15A.

Two valves are provided, one for each pump. Each valve can only support the pump with that it is associated. These valves are required to open on demand.

Main Feedwater Pump to Startup Feedwater Header Crossflow Valve (FWS-PL-V097)

This is required to close when startup feedwater is needed to fulfil the segregated safety function of decay heat removal in lieu of main feedwater. Decay heat removal is a Category A safety function and the startup feedwater system provides defence in depth and is Class 2. This valve supports the startup feedwater system and is therefore also Class 2. See Appendix 15A.

This valve is required to close on demand.

Main Feedwater to Startup Feedwater Header Check Valve (FWS-PL-V096)

This valve is required to close when startup feedwater is supplied for decay heat removal. Decay heat removal is a Category A safety function, and startup feedwater provides defence in depth and is Class 2. This valve supports the startup feedwater and is therefore also Class 2. See Appendix 15A.

This valve is required to close on demand.

17.4.5.4 Justification of Claims on Components and Equipment

Condensate Storage Tank (DWS-MT-02)

The CST contains at least sufficient capacity to meet cooling needs to achieve cold shutdown following a loss of main feedwater.

The CST is fabricated in stainless steel to ensure compatibility with the stored condensate and is vented, to prevent pressurisation. The tank is constructed to API-650 Code standards (Table 15A-1). The design is very similar to that of tanks like on currently operating PWRs and other nuclear power stations. This gives considerable confidence that the tank will be able to perform as expected.

Data collected from in-service plants (Reference 17.7, Table 5-1) indicate that the probability of a minor leak in an unpressurised tank is conservative relative to the value being claimed.

Startup Feedwater Pumps (FWS-MP-03A/B)

The startup feedwater pumps are similar to the pumps performing this duty on currently operating PWRs. As a result, the information from the operation of these in-service pumps offers a high degree of confidence about the reliability to be expected from the pumps

proposed for the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate that the claims being made are in line with operational experience.

Potential failure mechanisms of overloading, overheating, and lubrication failure are overcome by providing a venturi flow-limiting device, mini-flow flow capability, and cooling directly from the flowing medium.

Although there is no formal surveillance testing of the startup feedwater pumps, they can be tested using the mini-flow facility to verify performance. Routine maintenance and testing of the SFW pumps will be performed according to the manufacturer's recommendations and testing will be carried out to verify that performance has been maintained.

Startup Feedwater Flow Venturi (FWS-FE-015A/B)

A venturi is a passive device with proven performance. The suitability of the detailed design of this device will be established early during commissioning tests. It needs minimal maintenance and testing and, because it has no moving parts, is inherently able to perform its safety function.

Startup Feedwater Pump Automatic Recirculation Check Valves (FWS-PL-V012A/B)

The operation of the startup feedwater pump automatic recirculation check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are designed and manufactured to the ASME Standard B16.34. The valves are similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence in the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim is conservative.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. Compliance with ASME Standard B16.34, along with the testing, should minimise the probability of these failure mechanisms being present.

Main Feedwater Pump to Startup Feedwater Header Crossflow Valve (FWS-PL-V097)

This valve is air operated with the actuators designed to fail closed in the event of a loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valve is designed and manufactured to ASME Standard B16.34 The valves are similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim is in line with operational experience.

Main Feedwater to Startup Feedwater Header Check Valve (FWS-PL-V096)

The operation of this check valve depends only upon the pressure difference across it and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valve is designed and manufactured to ASME B16.34 that is well established for power station plants. The valve is similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim is conservative.

17.5 Passive Core Cooling System and Associated Systems

17.5.1 Accumulators

17.5.1.1 Role

A detailed description of the PXS accumulators (PXS-MT-01A/B) is contained in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.25.

The accumulators contribute to the provision of two primary safety functions: reactivity control and heat transfer/residual heat removal. It supports the heat transfer and residual heat removal safety function by providing large quantities of water to ensure that the reactor core is reflooded as quickly as possible following a LOCA. The reactivity control function is supported through this water being borated to cold shutdown levels.

The plant design provides for two independent accumulator tanks, each with its own line connecting to a direct vessel injection line to deliver coolant directly into the reactor vessel. These tanks are partially filled with borated water and contain pressurised nitrogen that acts as the motive force for injecting the water. A single accumulator is claimed to provide sufficient water to mitigate all but the largest LOCAs without core damage. For the largest LOCA, both accumulators are credited to discharge to limit core damage.

At power, the accumulators are maintained between minimum and maximum levels of borated water, between minimum and maximum pressure levels, and between minimum and maximum boron concentrations. Each injection line contains two check valves arranged in series and both must open to permit the injection of water. The accumulator check valves are held closed by the greater pressure under normal operating conditions in the RCS. All that is required for the system to operate is for the check valves to open when the differential pressure across them is reversed as the RCS depressurises. There is also a normally open motor-operated isolation valve in the injection line to allow the accumulator to be isolated when the reactor is shut down and the RCS is depressurised.

To ensure that accumulator pressure is maintained at all times, an accumulator nitrogen makeup isolation valve allows pressure to be increased, and a vent valve vents surplus nitrogen to containment and thus reduces accumulator pressure. To ensure that the volume of water in the accumulator can be controlled, system makeup and drain valves are also incorporated into the design.

The Category A safety function of the accumulators requires no supporting systems and they are Class 1 components. Their actuation requires only opening of check valves, which is discussed in Section 17.5.1.3.

The accumulator system does not support any other systems in their safety functions.

17.5.1.2 System Components and Equipment Contributing to Safety Function

The accumulator vessels themselves are discussed within the structural integrity section (Chapter 20). The associated pipework is designed to ASME Boiler and Pressure Vessel Code, Section III standards. The following components contribute to the accumulator system performing its safety function:

- **Accumulator Discharge Check Valves (PXS-PL-V028A/B and -V029A/B)** – These 200-mm DN (8-inch) swing check valves are required to remain closed when the RCS pressure is higher than the accumulator pressure and to open when the differential pressure across them is reversed. Being straightforward check valves, there is no requirement for any actuation signal, but the requirement to open when the differential pressure is reversed is a safety function.

- **Accumulator Discharge Isolation Valves (PXS-PL-V027A/B)** – These 200-mm DN (8-inch), motor-operated gate valves are required to close to enable controlled RCS pressure reduction to take place without accumulator injection, but are maintained open when the reactor is at power. The valves are not required to move as part of the accumulators achieving their safety function, but they must be open. The valve position will be checked during routine 12-hourly operational surveillances; whilst in this condition, the power supplies to the actuator will be isolated to prevent inadvertent operation. To support the achievement of the accumulator safety function, these administrative arrangements are backed up by the initiation of an open signal to these valves, from the PLS, whenever a safeguards actuation signal is generated. It is felt that these arrangements are sufficiently robust that further analysis is not required.

- **Accumulator Nitrogen Makeup/Vent Isolation Valves (PXS-PL-V021A/B)** – These 25-mm (1-inch) nominal-bore, solenoid-operated globe valves are set up to fail closed. The makeup isolation valve gives the ability to add nitrogen and increase accumulator pressure. The vent valve permits release of nitrogen to the containment atmosphere, and hence a reduction in accumulator pressure, to maintain its nominal set pressure. These operations will be performed in response to routine 12-hourly operational surveillance checks and the valves are not required to change state for the accumulator to perform its safety function.

- **Accumulator Fill/Drain Isolation Valves (PXS-PL-V232A/B)** – These 25-mm (1-inch) nominal-bore, air-operated globe valves are set up to fail closed. They provide the facility to fill or drain the accumulator to correct the level as required. These operations will be performed in response to routine 12-hourly operational surveillance checks and the valves are not required to change state for the accumulator to perform its safety function. Further analysis is therefore not required.

17.5.1.3 Claims on Components and Equipment

Accumulator Check Valves (PXS-PL-V028A/B and -V029A/B)

The accumulator system is provided to help mitigate the consequences of a LOCA. Maintenance of coolant inventory is a Category A safety function. See Appendix 15A. The check valves themselves are fundamental to the operation of the accumulators and failure to operate on demand would compromise the performance of the accumulator. The accumulators are a primary means of meeting the maintenance of RCS inventory is a Category A safety function, and therefore the check valves are Class 1 components. See Appendix 15A.

Both check valves on each accumulator are required to open for the accumulator to perform its safety function, because either one sticking closed would block the injection flow.

Whilst achievement of safety injection through the correct opening of the accumulator check valves is clearly the principal safety requirement, there is an implicit requirement that under normal operation, the accumulator check valves operate with minimal leakage from the RCS back into the accumulator itself. But unless this happens because of a gross failure, that is not considered credible, the changes in accumulator level that result from the leakage will be observed during the 12-hourly routine operational surveillance checks. Any in-leakage would also be detected by the resultant increase in accumulator pressure. The design ensures that in-leakage will result in a high nitrogen cover gas pressure alarm prior to exceeding the maximum permissible water level.

Accumulator Isolation Valves (PXS-PL-V027A/B)

The accumulator system is provided to help mitigate the consequences of a LOCA. Maintenance of coolant inventory is a Category A safety function. See Appendix 15A. The isolation valves themselves are fundamental to the operation of the accumulators and failure to operate on demand or spurious closure would compromise the performance of the accumulator. The accumulators are a primary means of meeting the maintenance of RCS inventory is a Category A safety function, and therefore the isolation valves are Class 1 components. See Appendix 15A.

The valves are not required to move as part of the accumulators achieving their safety function, but they must be open. The valve position will be checked during routine 12-hourly operational surveillances; whilst in this condition, the power supplies to the actuator will be isolated to prevent inadvertent operation.

Accumulator Nitrogen Makeup/Vent Isolation Valves (PXS-PL-V021A/B)

The accumulator system is provided to help mitigate the consequences of a LOCA. Maintenance of coolant inventory is a Category A safety function. See Appendix 15A. The isolation provided by the valves themselves are fundamental to the operation of the accumulators and the valves are not required to change state for the accumulator to perform its safety function. The accumulators are a primary means of maintaining the RCS inventory is a Category A safety function, and therefore the isolation valves are Class 1 components. See Appendix 15A.

The valves are not required to move as part of the accumulators achieving their safety function, but they must be closed. The valve position will be checked during routine 12-hourly operational surveillances; whilst in this condition.

Accumulator Fill/Drain Isolation Valves (PXS-PL-V232A/B)

The accumulator system is provided to help mitigate the consequences of a LOCA. Maintenance of coolant inventory is a Category A safety function. See Appendix 15A. The isolation provided by the valves themselves are fundamental to the operation of the accumulators and the valves are not required to change state for the accumulator to perform its safety function. The accumulators are a primary means of meeting the maintenance of RCS inventory is a Category A safety function, and therefore the isolation valves are Class 1 components. See Appendix 15A.

17.5.1.4 Justification of Claims on Components and Equipment

Accumulator Check Valves (PXS-PL-V028A/B and -V029A/B)

The operation of the accumulator check valves offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure to open is an order of magnitude better than the value assumed in the PSA and indicates that the claims against these valves are conservative.

The operating mechanism for the valve is very simple and, aside from gross mechanical failure, some form of "sticking" might be considered the principal mechanism for valve failure. There are four reasons for believing this risk to be low, as listed below:

- Given that the valves are not normally called upon to operate, the moving parts do not experience significant wear.

- The materials of design have been specifically chosen to maximise compatibility with the RCS fluid, thus minimising the risk of chemical corrosion interfering with valve operation.

- The valves sit in a region where the RCS fluid is stagnant, this being true even under accident conditions until safety injection from the accumulators begins. As such, they will normally see constant temperatures, and temperatures can only change significantly once the valves have opened and therefore completed their safety function.

- Even if some small amount of "sticking" were to occur in the valve mechanism, the differential pressure across the valve that is generated during fault conditions is substantial. The force available to open the valve is directly proportional to differential pressure and will, therefore, be more than adequate.

The first three of the four reasons above help justify why the accumulator check valves are very unlikely to stick. The same reasoning also provides support for the implicit requirement that back-leakage through the accumulator check valves will be minimal. In addition, the presence of two valves in series provides a significant enhancement to the claim.

Testing of the accumulator check valves is precluded when the reactor is at power and, as a result, routine testing is all carried out during shutdowns. Two types of tests are proposed:

- A flow test of the accumulator performed with the RCS and accumulators at predetermined pressures and injection initiated by opening the motor-operated isolation valve. This should result in a full stroke of the check valve and, through the measurement of achieved flow rate tests, the degree of opening can be determined. Because of the disturbance to RCS operation, this test can only be performed when the

RCS is depressurised during refuelling (Mode 6) every 2 years. This test demonstrates ongoing capability to meet the full safety requirement.

- A partial-flow test makes use of test connections around the check valves and injection of small quantities for fluid to confirm that the valve does, in fact, begin to open at the correct pressure. During this test, it will not be possible to see significant check valve movement, so it cannot confirm full freedom of operation, but it does allow confirmation that the valve is not stuck on its seat. Because of the much smaller quantities of fluid involved, this test can be performed with the RCS intact in Mode 5. It is suggested that this test be performed approximately every 2 years.

Accumulator Isolation Valves (PXS-PL-V027A/B)

The low probability of spurious closure valves offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of spurious closure value assumed in the PSA and indicates that the claims against these valves are conservative.

Accumulator Nitrogen Makeup/Vent Isolation Valves (PXS-PL-V021A/B)

The low probability of spurious actuation offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of spurious actuation value assumed in the PSA and indicates that the claims against these valves are conservative.

Accumulator Fill/Drain Isolation Valves (PXS-PL-V232A/B)

The low probability of spurious actuation offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for

in-service plants (Reference 17.7, Table 5.1) indicate a probability of spurious actuation value assumed in the PSA and indicates that the claims against these valves are conservative.

17.5.2 Core Makeup Tanks

17.5.2.1 Role

A detailed description of the core makeup tanks (CMTs) is given in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.25.

The PXS CMTs have three primary safety functions: reactivity control, heat transfer/residual heat removal, and actuation of the ADS valves. They support the heat transfer/residual heat removal safety function by providing large quantities of coolant to maintain the reactor coolant inventory/reflood to the core following a LOCA. The reactivity control safety function is supported by the borated water in the CMTs. The positioning of the CMTs in relation to the rest of the primary circuit also allows for natural circulation to feed the contents of the CMTs into the primary circuit. This can take place with the RCS pressure at any value and thus provides the capability to borate the RCS and consequently reduce reactivity. Sensing a reduction in the CMT level provides information used to actuate the ADS valves.

The plant design makes provision for two independent CMTs, each connected to one of the two sets of direct vessel injection pipework to deliver coolant directly to the reactor vessel. The CMTs can operate in two different modes, depending on the RCS conditions. If the cold legs are filled with water, CMTs operate in a water recirculation mode with the driving force based on the density difference between the hot reactor coolant in the CMT balance line and the colder water in the CMT. The pressure balance line is well insulated and routed continuously upward from the top of the cold leg to a high point close to the top of the CMT. This arrangement ensures that the water in the line will remain hot, that aids natural circulation injection of the CMT water. This mode of operation can be relied upon to circulate the borated CMT water into the RCS and reduce reactivity.

If the cold legs become voided, as they do during LOCAs, the CMTs will operate in a steam-displacement injection or steam drain down mode. In this mode, the driving force is generated by the density difference between steam from the cold legs and water in the CMTs.

Each CMT is designed to work in tandem with the associated accumulator connected to the same direct vessel injection line. For small-break LOCAs, the CMTs are the initial source of safety injection, whilst for large-break LOCAs, they supplement safety injection when the accumulators have discharged. The CMTs are sized to ensure that the full safety function can be performed even if one of the direct vessel injection lines is the postulated break.

The positions of the CMT connections to the RCS mean that if the RCPs are running, the pressure difference is such that the CMT recirculation will be impeded if the discharge isolation valves are opened. The RCPs, therefore, are shut down to enable the CMT to function correctly.

At power, the CMTs remain filled with cool water in that a minimum boron concentration is maintained. Each CMT injection line contains two check valves in series. A portion of each injection line has parallel paths, each with a normally closed air-operated isolation valve to prevent reverse flow back into the CMT. For the system to operate one of the two air-operated isolation valves must open and the check valves must allow flow.

The CMTs are not supported by other safety systems in performing their safety function.

The CMTs do not support any other systems in the provision of their safety functions.

17.5.2.2 System Components and Equipment Contributing to Safety Function

The CMT vessels themselves are discussed in the structural integrity section (Chapter 20). The associated pipework and systems are constructed to ASME Boiler and Pressure Vessel Code, Section III-1. The following components contribute to the CMTs performing their safety function:

- **CMT Discharge Isolation Valves (PXS-PL-V014A/B and -V015A/B)** – These are 200-mm DN (8-inch), air-operated globe valves. The valves fail open on loss of air supply and are signalled to open on receipt of a safeguards signal. Each valve has its own solenoid-operated air valve that is driven from the PMS and de-energises to dump the air supply and open the valve. There is also a separate single solenoid-operated air valve, driven from the diverse actuation system (DAS) that is required to energise to dump the air supply and provides an alternate method to open all CMT outlet isolation valves. The CMT outlet isolation valve safety requirement is to enable the CMTs to inject to the RCS.

- **CMT Discharge Check Valves (PXS-PL-V016A/B and -V017A/B)** – These are 200-mm DN (8-inch), inline nozzle check valves. They are required to be normally open and remain open to facilitate injection from the CMT unless there is a reverse flow. This could happen when the accumulators are discharging into a depressurised RCS. Under these circumstances, the safety requirement is for the valve to isolate the line back to the CMT.

- **CMT Inlet Isolation Valve (PXS-PL-V002A/B)** – These are 200-mm DN (8-inch), motor-operated gate valves. They are required to be open for their respective CMTs to perform their safety function. With the reactor at power, they are left in their open position with the actuator power supplies isolated. This condition is then checked on a 12-hourly basis as part of the routine operational surveillances. They do, however, also receive a confirmatory open signal from the PMS. Further analysis is therefore not required.

- **CMT Fill Header Isolation Valves (PXS-PL-V230A/B)** – These are 25-mm DN (1-inch), air-operated globe valves set up to fail closed. They provide the facility to add and remove CMT fluid to ensure that the correct boron concentration is maintained. These operations will be performed in response to routine operational surveillance checks on boron concentration that are performed every 7 days. The valves are not required to change state for the CMT to perform its safety function. Further analysis is therefore not required.

17.5.2.3 Claims on Components and Equipment

CMT Discharge Isolation Valves (PXS-PL-V014A/B and -V015A/B)

The CMT outlet isolation valves open to provide makeup to the RCS in the event of a LOCA and control of core radioactivity. Maintenance of RCS inventory and control of reactivity is a Category A safety function. The CMTs are a primary method of maintaining RCS inventory under fault conditions and as such, these valves are Class 1. See Appendix 15A.

There are two CMT outlet isolation valves arranged in parallel for each CMT. At least one of the two valves is required to open to ensure that the safety function is performed.

CMT Discharge Check Valves (PXS-PL-V016A/B and -V017A/B)

The CMT discharge check valves are provided to ensure that during the injection phase from the accumulators, all fluid is discharged through the direct vessel injection piping and none can find a route through the CMTs. This safety function is associated with maintenance of RCS inventory and control of core reactivity is a Category A safety function. These valves are the primary means of ensuring that injection from the accumulators is properly injected and therefore maintaining RCS inventory. As such, the CMT discharge check valves are Class 1. See Appendix 15A.

There are two CMT discharge check valves in series for each CMT, either one of the two closing will achieve the safety function.

The probability of having the check valves closed and not detected is essentially the same as the probability of the check valves failing to remain open on demand.

Whilst the prevention of incorrect routing of accumulator safety injection flow is the primary safety requirement, there is an implicit requirement that the valves remain open and do not impede any safety injection flow from the CMTs into the RCS when this is required.

CMT Inlet Isolation Valve (PXS-PL-V002A/B)

They are required to be open for their respective CMTs to perform their safety function. With the reactor at power, they are left in their open. This safety function is associated with maintenance of RCS inventory and control of core reactivity is a Category A safety function. As such, the CMT discharge check valves are Class 1. See Appendix 15A.

CMT Fill Header Isolation Valves (PXS-PL-V230A/B)

They are required to be closed for their respective CMTs to perform their safety function. With the reactor at power, they are left in the closed. This safety function is associated with maintaining the integrity of the integrity of RCS which is a Category A safety function. As such, the CMT discharge check valves are Class 1. See Appendix 15A.

17.5.2.4 Justification of Claims on Components and Equipment

CMT Discharge Isolation Valves (PXS-PL-V014A/B and -V015A/B)

The CMT outlet isolation valves are air operated with the actuators designed to fail open in the event of loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of a failure to open that is comparable to the value being claimed.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment.

The maintenance and testing arrangements for the CMT outlet isolation valves are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- A system flow test is performed every 10 years and will confirm valve operating performance.

CMT Discharge Check Valves (PXS-PL-V016A/B and -V017A/B)

The operation of the CMT discharge check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The design of this valve has seen some, although not extensive, previous service in nuclear applications. As a result of the limited operating experience in nuclear applications, there is little service data to support the PSA claims. There are, however, a number of reasons to support the claim that they will be highly reliable in service:

- The valve design exhibits a very low pressure drop, and so offers minimum impediment to the establishment of flow from the CMT through natural circulation.
- The valve provides a very rapid response to closure with reverse flow. This minimises the reverse flow velocities seen and consequent water hammer when the valve closes.
- The valve is easy to design so that it sits in the fully open position when there is no flow. This means that there is no requirement for it to open during small LOCAs when the CMT makeup provides the first stage of safety injection.
- In normal operation, there is no flow through the valve and so there will be no wear of moving parts.
- Because there is no flow, the fluid sitting in the valve does not change and so there is no credible opportunity for boric acid to precipitate out and accumulate. This minimises the risk of seizure.
- Any movement of the valves takes place with the valve still containing fluid at ambient containment conditions. The valve only sees large changes in temperature when it has

moved to its fully open position and flow has been established. At this point, the safety requirement is that it remains open so any seizure would not be a safety issue.

Full-stroke checks of the CMT discharge check valves are precluded when the reactor is at power because significant flow is required to force the valves to the closed position, and it is felt that this might generate unacceptable transients. The testing is therefore treated as an exemption to the normal ASME Boiler and Pressure Vessel Code rules. The testing is:

- Verification, from the valve position indication, that the valve is open will be performed quarterly.

- Full valve exercising will be performed during refuelling outages when the RCS boron concentration is much closer to that of the CMTs, and also when the Tech Specs do not require the CMTs to be operable.

- A system flow test is performed every 10 years and will confirm valve operating performance.

CMT Inlet Isolation Valve (PXS-PL-V002A/B)

The low probability of spurious closure valves offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of spurious closure value assumed in the PSA and indicates that the claims against these valves are conservative.

CMT Fill Header Isolation Valves (PXS-PL-V230A/B)

The low probability of spurious closure valves offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of spurious opening value assumed in the PSA and indicates that the claims against these valves are conservative.

17.5.3 Automatic Depressurisation System

17.5.3.1 Role

A detailed description of the automatic depressurisation system (ADS), which is part of the RCS, is given in Section 6.4. Further design details of this system and its constituent components are delineated in Reference 17.1.

The ADS, in addition to its RCS pressure boundary function, contributes to the provision of the heat transfer/residual heat removal primary safety function by providing the means to carry out a controlled depressurisation of the RCS to allow the passive core cooling system to function and deliver the required quantities of water to refill the reactor vessel.

The plant design makes provision for four stages of depressurisation. The stages of the ADS operate sequentially to depressurise the RCS so that safety injection takes place as required by the plant design. Specifically, the reactor coolant system will depressurize to the pressure at which the accumulators begin to deliver core cooling flow, and eventually the reactor coolant system is depressurised to the in-containment refuelling water storage tank (IRWST) pressure. Each ADS Stage 1, 2, and 3 has two sets of depressurisation valves. ADS Stage 1 valves open when an ADS signal is generated on CMT low level. ADS Stage 2 and 3 valves are given the signal to open in line with a timed sequence following the initiation of the ADS signal (ADS stage 1 opening). ADS Stages 1, 2, and 3 discharge through spargers to the IRWST. ADS Stage 4 has four depressurisation valves which open sequentially with Stages 1, 2, 3 or on a CMT low-low level signal. The ADS Stage 4 piping connects directly to each RCS hot leg and discharges directly into their respective loop compartment.

The ADS is supported by the essential electrical system in performing its safety function.

The ADS does not support any other systems in performing their safety functions.

17.5.3.2 System Components and Equipment Contributing to Safety Function

The following components contribute to the ADS performing its safety function:

- **ADS Stage 1 Control Valves (RCS-PL-V001A/B)** – These are 100-mm (4-inch) nominal-bore, slow–opening, motor-operated globe valves. The valves fail “as is” upon loss of power supplies and are signalled to open by the stage 1 ADS signal. The auto-initiation of this function is derived from the PMS using CMT level transmitters. Manual actuation is available via both the PMS and DAS. The stage 1 valves are connected to the pressuriser via isolation valves and discharge via a sparger to the IRWST. The valves are closed during normal operation. The safety requirement is for them to open to provide a flow path on demand.

- **ADS Stage 2 Control Valves (RCS-PL-V002A/B)** – These are 200-mm DN (8-inch), slow-opening, motor-operated globe valves. The valves fail “as is” upon loss of power supplies and are signalled to open by the stage 1 ADS signal following a time delay. The auto-initiation of this function is derived from the PMS. Manual actuation is available via both the PMS and DAS. The stage 2 valves are connected to the pressuriser via isolation valves and discharge via a sparger to the IRWST. The valves are closed during normal operation. The safety requirement is for them to open to provide a flow path on demand.

- **ADS Stage 3 Control Valves (RCS-PL-V003A/B)** – These are 200-mm DN (8-inch), slow-opening, motor-operated globe valves. The valves fail "as is" upon loss of power supplies and are signalled to open by the stage 1 ADS signal following a further time delay beyond stage 2. The auto-initiation of this function is derived from the PMS. Manual actuation is available via both the PMS and DAS. The stage 3 valves are connected to the pressuriser via isolation valves and discharge via a sparger to the IRWST. The valves are closed during normal operation. The safety requirement is for them to open to provide a flow path on demand.

- **ADS Stage 4 Control Valves (RCS-PL-V004A/B/C/D)** – These are 350-mm DN (14-inch), squib-type valves. The valves are opened by actuating a propellant charge that requires an electrical firing signal and once opened, there is no mechanism for closure. The valves can therefore be considered to fail "as is" in either open or closed positions. The firing signal is generated from the stage 4-ADS signal. The auto-initiation of this function is derived from the PMS. Manual actuation is available via both the PMS and DAS. The stage 4 valves are connected to the RCS hot leg via normally open isolation valves and discharge directly into the containment loop compartments. The safety requirement is for them to open to provide a flow path on demand.

- **ADS Stage 1 Isolation Valves (RCS-PL-V011A/B)** – These are 100-mm DN (4-inch) nominal-bore, motor-operated, flex wedge gate valves. The valves fail "as is" upon loss of power supplies and are signalled to open by the PMS prior to the opening of the stage 1 ADS control valves. The valves are closed during normal operation. The safety requirement is for them to provide reliable isolation but also open to provide a flow path on demand.

- **ADS Stages 2 and 3 Isolation Valves (RCS-PL-V012A/B and -V013A/B)** – These are 200-mm DN (8-inch) , motor-operated, flex wedge gate valves. The valves fail "as is" upon loss of power supplies and are signalled to open by the PMS prior to the opening of their respective ADS control valves. The valves are closed during normal operation. The safety requirement is for them to provide reliable isolation but also open to provide a flow path on demand.

- **ADS Stage 4 Isolation Valves (RCS-PL-V014A/B/C/D)** – These are 350-mm DN (14-inch), motor-operated, wedge gate valves. The valves fail "as is" upon loss of power supplies and are open during normal operation. The safety requirement is for them to be open so that a flow path is provided when ADS 4 is demanded.

17.5.3.3 Claims on Components and Equipment

ADS Stage 1 Control Valves (RCS-PL-V001A/B)

The ADS stage 1 control valves provide the initial depressurisation capability in response to a loss of coolant from the RCS which results in a decrease in CMT level to the ADS actuation setpoint. This RCS pressure reduction is in preparation for the opening of the larger ADS stages 2, 3, and 4 valves, all of which serve to enable continued injection by gravity from the CMTs, accumulators and the IRWST. Maintenance of RCS inventory is a Category A safety function. The valves are a principal means of achieving the function and are therefore Class 1. See Appendix 15A. There are two parallel sets of two series ADS stage 1 valves. Following a LOCA, they are claimed to receive their open signal at a set time after a CMT low-level setpoint is reached. During this period, controlled by a programmed time delay, the stage 1 isolation valves are expected to reach their full open position. The ADS stage 1

control valves are expected to open against the full differential pressure from the RCS to the IRWST.

The ADS stage 1 valves are also designed to provide the operator with the facility to manually depressurise the RCS in response to events such as SGTR where the natural depressurisation rate of the RCS is small, but the leak rate from the RCS to the faulted SG secondary side can be terminated by reducing the RCS pressure. The ADS stage 1 control valves are therefore claimed to have a throttling duty in addition to traversing to fully open in response to the automatic ADS signal. If the operator takes no action following an SGTR, the PXS will be actuated and the operation of the CMTs and PRHR HX will result in a decrease in RCS pressure and the RCS pressure will equalise with the SG pressure. This automatically will terminate the RCS to SG break flow without actuation of the ADS stage 1 valve.

ADS Stage 2 Control Valves (RCS-PL-V002A/B)

The ADS stage 2 control valves provide the second stage of blowdown to support RCS depressurisation. As with the stage 1 valves, this is in support of maintenance of RCS inventory and hence is in support of a Category A safety function. The stage 2 valves are also, as part of the depressurisation sequence, a primary contributor to this function and are therefore Class 1. See Appendix 15A.

There are two parallel sets of ADS stage 2 valves. They receive their open signal a set time after the stage 1 control valves receive their open signal that is longer than the time to open stage 1 valves. These ADS stage 2 control valves are sequenced to open after their associated ADS isolation valves reach their full open position and are expected to do so against the full differential pressure from the RCS to the IRWST.

ADS Stage 3 Control Valves (RCS-PL-V003A/B)

The ADS stage 3 control valves provide the third stage of blowdown to support RCS depressurisation. As with the stage 1 and 2 valves, this is in support of maintenance of RCS inventory and hence is in support of a Category A safety function. The stage 3 valves are also, as part of the depressurisation sequence, a primary contributor to this function and are therefore Class 1. See Appendix 15A.

There are two parallel sets of ADS stage 3 valves. They receive their open signal at a set time after the stage 2 control valves actuate.

ADS Stage 4 Control Valves (RCS-PL-V004A/B/C/D)

The ADS stage 4 control valves provide the final stage of RCS depressurisation. As with the other ADS valves, this is in support of maintenance of RCS inventory and hence is in support of a Category A safety function. The stage 4 valves are also, as part of the depressurisation sequence, a primary contributor to this function and are therefore Class 1. See Appendix 15A.

There are four ADS stage 4 control valves arranged in parallel with two attached to each hot leg. Three stage 4 valves opening will provide the safety function, as discussed in the Squib Valve Safety Case (Reference 17.36). They receive their open signals in a staggered sequence. One stage 4 control valve connected to each hot leg receives its open signal upon the later of the following conditions: a) a set time after the stage 3 control valves receive their open signal, or b) signal receipt from the CMT lowest-level setpoint (CMT level at approximately 20 percent). The second set of stage 4 control valves receives its open signal at a set time after the first set. The valves are claimed to reduce the RCS pressure to allow

gravity injection from the IRWST to take place and subsequently containment recirculation to be established.

As discussed in the Squib Valve Summary Report (Reference 17.2), the AP1000 design includes squib valves because of their high reliability and suitability to a function where there is a one-time need for the valve to actuate. This reputation is supported by the use of squib valves in many designs where the valve cannot fail to perform its function. Examples of these designs include boiling water reactor safety systems, weapons systems, and space systems. The squib valve design is simple and there are few ways for the valve to fail to actuate. This type of design contrasts with the designs of air-operated or motor-operated valves, which have more moving parts that can fail and prevent the valve from actuating.

The advanced light water reactor (ALWR) Utility Requirements Document (URD) indicates a low failure probability (failure to operate) for squib valves. This failure rate does not indicate a valve design with extremely high reliability, as would be expected. This may be because the basis for the URD value is a small population of valves and extrapolation from older, less relevant data.

Section 17.5.3.4 provides the additional details on the design and function of the ADS stage 4 squib valves. Chapter 6 provides discussion on the RCS which contains the ADS valves and references the system specification documents. Table 8A-2 presents faults that credit ADS stage 4 actuation for mitigation of the initiating events; associated fault analyses are referenced, with all design basis analyses presented in Chapter 9. The plant PSA (Chapter 10) includes consideration of the valves to actuation upon demand, as well as the consequences associated with spurious operation. The valve resilience to applicable internal hazards is discussed in Chapter 11. Additional detail on the interfacing C&I systems (PMS and DAS) is provided in Chapter 19, with the spurious operation blocker devise being discussed in Section 19.4.1.2.13. The electrical systems that provide power for actuation are discussed in Chapter 18.

ADS Stage 1, 2, and 3 Isolation Valves (RCS-PL-V011A/B, -V012A/B -V013A/B)

The upstream valve in each ADS path is designated as an ADS isolation valve. The functional requirements for these valves specify each to be leak tight to prevent operational and safety complications arising from an RCS pressure boundary leak. Each ADS stage 1, 2, and 3 isolation valve opens ahead of its corresponding control valve to support RCS depressurisation. As with the other ADS valves, support of the maintenance of RCS inventory is a Category A function. The isolation valves have a primary role in this and hence are Class 1. See Appendix 15A.

Following ADS stage 1, 2, and 3 system-level actuation, these normally closed isolation valves are sequenced to reach their full open position prior to their corresponding control valves receiving their open signals. The failure of an isolation valve to open yields the same results as a failure of its corresponding control valve to open. Although the valves are designed to open against differential pressures up to the maximum RCS operating pressure at blowdown conditions, their design-basis safety requirement is to open with no flow and high differential pressure. When the ADS is then demanded to operate, these valves are required to open and this forms an additional safety claim.

ADS Stage 4 Isolation Valves (RCS-PL-V014A/B/C/D)

Given the high confidence in the leak tightness of the squib valves used on ADS stage 4, it is not necessary to have the stage 4 isolation valves normally closed as is required for the other stages of ADS. Because of this, the stage 4 isolation valves are normally open and are not

required to change state at any time during the ADS sequence. The valves exist to provide an isolation facility to permit maintenance of the ADS stage 4 valves and also can be used to terminate stage 4 ADS operation at the commencement of recovery operations. There is therefore no safety requirement against these valves themselves except to serve as a RCS pressure boundary; however, because the stage 4 isolation valves are situated in the stage 4 ADS blowdown path, there is a requirement that the valves can be confirmed open, so there is a safety requirement against their position indication. As with the other ADS valves, support of the maintenance of RCS inventory is a Category A function. The isolation valves have a primary role in this and hence are Class 1. See Appendix 15A.

17.5.3.4 Claims on Components and Equipment

ADS Stage 1, 2 and 3 Control Valves (RCS-PL-V001A/B, -V002A/V, -V003A/B)

The ADS stage 1, 2, and 3 control valves are all motor operated globe valves, which means they will inherently fail “as is”. To understand why this is appropriate, it is instructive to consider the implications of other failure modes.

If the valves were designed to fail open, then if this happened during normal operation, it would constitute initiation of a substantial LOCA and therefore would not be appropriate. If this happened during the phase of a blowdown sequence when the valves were controlling, it would increase the blowdown rate sharply and potentially invalidate the assumptions used to justify maintenance of adequate coverage of the core; consequently, this would not be appropriate. If the valves failed open following completion of the blowdown sequence, they effectively would fail “as is”.

If the valves were designed to fail closed, then if this happened during normal operation, they would effectively fail “as is”. If this happened during the phase of a blowdown sequence when the valves were controlling, it would decrease the blowdown rate sharply and hence could delay either the introduction or the rate of safety injection that would not be appropriate. If the valves failed closed following completion of the blowdown sequence, it might complicate the plant recovery procedures or lead to stage 4 ADS initiation, even though the plant operators had stabilised the plant after stage 3. This would also be inappropriate.

In addition, the ADS isolation valves can be used to close the flowpath in the event of an ADS control valve failing “as is” in an open condition. On the basis of these arguments, the selection of valves that fail “as is” is considered appropriate.

Globe valves are used for the stage 1, 2, 3 control function because they are better suited to handle the high flow / differential pressure conditions that occur during ADS flow initiation. They are also better suited to handle the gradual flow initiation requirement.

The stage 1, 2, 3 isolation valves use gate valve bodies because they are better suited to providing leak tight service that the globe valve used for the control function.

Both the isolation and control valves on all three stages of ADS are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1. The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of a failure to open that is comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment (17.1, Table 2.1.2-1).

The requirement of these valves is not to provide the primary isolation from the RCS under normal operating conditions, but to provide the controlled blowdown under fault scenarios. This control function is felt to be met best through the use of globe valves. There are two limiting failures with respect to the ADS. The limiting valve failure is for one ADS stage 4 control valve (V004A, B, C, or D) to fail to open. The limiting electrical failure would cause pairs of stage 1 and 3 control and isolation valves to fail to open (while the other pairs of stage 1 and 3 valves functioned as designed). Safety analyses show the depressurisation function to be met given either failure (Table 9.0-11).

The maintenance and testing arrangements for the ADS stage 1, 2, and 3 valves comply with ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Exercise full stroke at cold shutdown frequency. These tests are not intended to be conducted at power due to risk of inadvertent ADS operation. They are intended to be performed during shutdown conditions with no flow and no differential pressure across the valve. These ADS valves are tested during cold shutdowns when the RCS pressure is reduced to atmospheric pressure so that mispositioning of a single valve during this in-service testing (IST) will not cause a LOCA. Testing these valves at every cold shutdown is consistent with the AP1000 PSA.

- Operability testing will be performed with the reactor shut down. Each valve will be tested through its full range. Because the RCS is depressurised when this is performed, there is no significant flow and no differential pressure. The test frequency is the longer of every three refuelling cycles or 5 years, until sufficient data exist to determine if a longer test frequency is appropriate. The maximum test interval will be once every 10 years provided there is sufficient experience to justify this longer interval.

- Local observation of valve position will be performed during stroke tests at a 2-year frequency to confirm that the remote position indication is operating correctly.

ADS Stage 4 Control Valves (RCS-PL-V004A/B/C/D)

The ADS stage 4 control valves are all squib-type valves, which means they will inherently fail “as is”. Clearly, this is not fail-safe with respect to the automatic depressurisation function, but given that spurious actuation of this function when not required could, in itself, create a substantial transient, effectively a large-break LOCA, it is judged appropriate.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The design of squib valves is such that the firing of a propellant charge is used to build gas pressure above a piston. At a prescribed pressure, a tension bolt fractures, releasing the piston; the piston travels down and impacts the end of the shear cap, shearing off the end. There is a very high level of confidence that the propellant charge and the subsequent actions will happen successfully and the valve will open correctly. The arguments and evidence that the squib valves are designed adequately to reliably perform their necessary safety fuction are provided in the Squib Valve Safety Case (Reference 17.36). The valve reliability depends

heavily on the firing reliability of the propellant charge. This reliability is enhanced by providing each stage 4 squib valve with two PMS igniters actuated from separate Class 1 Divisions. Each squib valve also has a DAS igniter. Actuation of any one of these three igniters will open the valve. As a consequence, the squib valve is believed to be highly reliable. Valve reliability is discussed further in the squib valve summary report (Reference 17.2).

The presence of four valves gives redundancy and, with the design being significantly different from the valves used in ADS stages 1, 2, and 3, provides diversity within the ADS.

The maintenance and testing arrangements for the ADS stage 4 valves comply with ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing (Reference 17.2) is:

- Given that correct firing of the propellant charges is the primary concern for squib valve reliability, 20 percent of the charges installed on the plant will be replaced and fired every 2 years. These tests will be performed in a test fixture away from the valve, and the positions they occupied in valves on the plant will be taken by replacement charges.

ADS Stage 1, 2, and 3 Isolation Valves (RCS-PL-V011A/B, -V012A/B -V013A/B)

All isolation valves on ADS stages 1, 2, and 3 are motor operated, which means they will inherently fail “as is”. Clearly, this is not fail-safe with respect to the blowdown isolation function, but given that spurious actuation of this function when not required could, in itself, give rise to safety concerns, effectively a significant LOCA, failure “as is” is judged appropriate.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of a failure to open that is comparable to the value being claimed.

The failure mechanism of concern would involve the valves sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment.

The requirement of these valves is to provide the primary isolation from the RCS under normal operating conditions, not to provide the controlled blowdown under fault scenarios. This isolation function is considered to be met best through the use of gate valves. Each stage of ADS has redundant valves and there is also redundancy between stages. When considering the ADS valves in series with the associated isolation valves, no single failure would prevent the isolation of the ADS stages nor the minimum required flowpaths. The limiting electrical failure would cause pairs of stage 1 and 3 control and isolation valves to fail to open (while the other pairs of stage 1 and 3 valves functioned as designed). Safety analyses show the depressurisation function to be met given either failure (Chapter 9).

The maintenance and testing arrangements for the ADS stage 1, 2, and 3 isolation valves comply with the ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Exercise full stroke at cold shutdown frequency. These tests may be conducted at power but are intended to be performed with no flow and no differential pressure across the valve. These ADS valves are tested during cold shutdowns when the RCS pressure is reduced to atmospheric pressure so that mispositioning of a single valve during this IST will not cause a LOCA. Testing these valves at every cold shutdown is consistent with the AP1000 design PSA.

- Operability testing will be performed with the reactor shut down, and each valve will be tested through its full range. Because the RCS is depressurised when this is performed, there is no significant flow and no differential pressure. The test frequency is the longer of every three refuelling cycles or 5 years until sufficient data exist to determine if a longer test frequency is appropriate. The maximum test interval is once every 10 years provided there is sufficient experience to justify this longer interval.

- Local observation of valve position will be performed during stroke tests at a two-year frequency to confirm that the remote position indication is operating correctly.

ADS Stage 4 Isolation Valves (RCS-PL-V014A/B/C/D)

All four isolation valves on ADS stages 4 are motor operated, which means they will inherently fail "as is". Given that the valves are normally open and have no safety requirement on any change of state, this arrangement is inherently safe.

As indicated above, it is the position indication equipment on this valve that carries the safety requirement. The testing performed on the valve is important for the demonstration of the correct operation of this equipment.

The maintenance and testing arrangements for the ADS stage 4 isolation valves comply with the ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Local observation of valve position will be performed during stroke tests to confirm that the remote position indication is operating correctly.

- A check will be made every 12 hours, as a part of routine operational Tech Spec surveillances, to ensure that the valves are open.

17.5.4 In-Containment Refuelling Water Storage Tank

17.5.4.1 Role

A detailed description of the IRWST (PXS-MT-03) is given in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.25.

In normal operation, the PXS IRWST provides borated water to flood up the refuelling cavity when the reactor vessel head is removed for refuelling. During faults, however, it contributes to the heat transfer/residual heat removal and reactivity control primary safety functions.

The contribution of the IRWST to the heat transfer/residual heat removal primary safety function is summarised below:

- Forms the initial heat sink when the PRHR system is actuated. The PRHR HX is situated in the IRWST and transfers heat from the RCS by natural circulation.

- Is the final source of water for injection into the RCS when the RCS has been almost fully depressurised. The IRWST injection isolation valves allow the flow of water from the IRWST into the direct vessel injection lines of the reactor vessel.

- Is the major source of water used to flood the containment and provide the long term source of core cooling through natural circulation into the reactor vessel.

- Accepts steam released from ADS stages 1, 2, and 3 and condenses it with the aid of the depressurisation spargers pipework inside the tank.

- Is the source of water for the defence in depth safety function performed by the normal residual heat removal system (RNS) pumps for low-pressure safety injection.

- Collects water condensed on the inside of the containment shell by operation of the passive containment cooling system (PCS) and the PXS gutter for use as PXS low pressure safety injection.

The IRWST consists of the tank itself, vents to ensure that the tank pressure remains in equilibrium with the containment atmosphere, over flow paths to prevent overfilling the tank, the ADS spargers and lines, and screens that filter out debris during the final stage of safety injection.

The IRWST components are entirely passive in nature and are not supported by other systems.

The IRWST provides support to the PRHR HX and the ADS; and for the RNS when performing its defence in depth safety injection function.

17.5.4.2 System Components and Equipment Contributing to Safety Function

The IRWST is constructed as part of the in-containment structures (Section 6.6). The following components contribute to it fulfilling its safety function:

- **Storage Tank (PXS-MT-03)** – This large, stainless-steel-lined, concrete and steel tank in containment is required to contain borated water. The tank is vented to the containment atmosphere and so there are no pressure retention claims on it. It is constructed as a part of the in-containment structure at a level sufficiently elevated above the RCS to ensure that it can drain by gravity to provide the final stage of safety injection. The safety requirement is to provide the assumed heat sink capability and the assumed safety injection capability.

- **IRWST Vents** – These are an arrangement of vents installed in the roof of the storage tank around its periphery. There are several types of vents that prevent the tank from becoming pressurised from either internal or external pressurisation sources. They provide a sufficient combined release area. They are normally closed to prevent debris from falling into the tank and also to contain water vapour and radioactive gases during normal operation (Section 6.6). The vents are opened by the generation of a slight

positive pressure inside the tank with respect to the containment atmosphere. There are also vents that are opened by the generation of slight positive pressure in containment with respect to the IRWST. The safety requirement is to ensure that significant over pressure or negative pressure compared to the containment pressure does not develop in the IRWST that exceeds the IRWST design pressure.

- **IRWST Overflows –** These are an arrangement of openings at the top of the IRWST vertical wall adjacent to the refuelling cavity. The openings have hinged covers which are opened by the generation of a slight positive pressure inside the tank. These overflows operate to prevent overfilling of the IRWST and ensure that sufficient space is maintained above the IRWST water level. The overflows can also act as additional vent area to prevent IRWST overpressure.

- **Spargers (PXS-MW-01A/B)** – These are two, four-armed, cruciform-type, stainless-steel spargers with outlet holes (Section 6.6). They sit in the IRWST. The spargers receive steam and water discharged through the first three stages of automatic depressurisation and distribute the ADS discharge into the IRWST water. The spargers enable the ADS steam to be condensed to minimise any immediate effects of ADS on the containment environment. The safety requirement is that the ADS discharge does not result in large hydro-dynamic loading on the IRWST structure

- **Screens (PXS-MY-Y01A/B/C)** – These pocket-type screens use a perforated sheet as the filter medium. They are situated at the base of the tank and ensure that injection from the IRWST into the RCS can take place without the accumulation of debris in the reactor vessel, since such debris may inhibit core cooling.

- **IRWST Injection Squib Valves (PXS-PL-V123A/B and -V125A/B)** – These are 200-mm DN (8-inch), squib-type valves. They effectively fail "as is" on loss of control supplies and are signalled to open on receipt of a stage 4 ADS signal from the PMS. The safety requirement is that the valves will enable direct injection from the IRWST into the RCS, as discussed in the Squib Valve Safety Case (Reference 17.36). These squib valves are similar to the containment recirculation isolation valves discussed in Section 17.5.5.2. However, there are a number of design features that create diversity between the two sets of valves as described in Reference 17.2.

  Section 17.5.4.3 provides the additional details on the design and function of the IRWST injection squib valves. Chapter 6 provides discussion on the PXS which contains the IRWST injection valves and references the system specification documents. Table 8A-2 presents faults that credit IRWST injection actuation for mitigation of the initiating events; associated fault analyses are referenced, with all design basis analyses presented in Chapter 9. The plant PSA (Chapter 10) includes consideration of the valves to actuation upon demand, as well as the consequences associated with spurious operation. The valve resilience to applicable internal hazards is discussed in Chapter 11. Additional detail on the interfacing C&I systems (PMS and DAS) is provided in Chapter 19, with the spurious operation blocker devise being discussed in Section 19.4.1.2.13. The electrical systems which provide power for actuation are discussed in Chapter 18.

- **IRWST Injection Line Isolation Valves (PXS-PL-V121A/B)** – These are 200-mm DN (8-inch), motor-operated gate valves. They are designed to fail "as is" on loss of electrical supplies. They are normally open and are only required to be closed to allow maintenance on the IRWST injection isolation valves. The valves are not required to move as part of the IRWST achieving its safety function, but they must be open. The valve position will be checked during routine 12-hourly operation surveillances and

whilst in this condition, the power supplies will be isolated to prevent inadvertent operation. To support the achievement of the IRWST safety function, these administrative arrangements are backed up by the initiation of an open signal from the PLS when a safeguards actuation signal is generated. It is felt that these arrangements are sufficiently robust so that further analysis is not required.

- **IRWST Injection Line Check Valves (PXS-PL-V122A/B and -V124A/B)** – These are 200-mm (8-inch) nominal-bore, swing-check valves. These valves exist to prevent reverse flow if the IRWST opens during a LOCA sequence with the RCS pressure slightly above the IRWST pressure or in the event of an inadvertent actuation of the associated IRWST injection isolation valve. Their safety function is to open on demand to enable direct injection from the IRWST into the RCS.

17.5.4.3 Claims on Components and Equipment

Storage Tank (PXS-MT-03)

The IRWST provides the source of water to enable the final stage of safety injection to take place (prior to containment recirculation injection), provides the heat sink for the PRHR, and quenches the ADS discharge flow. Maintenance of RCS coolant inventory and removal of decay heat are both Category A safety functions. The IRWST storage tank is integral to the PXS designed as the principal methods of providing this safety function and therefore is Class 1. See Appendix 15A.

The requirement is that the tank will provide sufficient water to complete containment sump floodup to a high enough level to initiate containment recirculation flow.

IRWST Vents and Overflows

The vents and overflows on the IRWST ensure that its integrity is not compromised through inadvertent internal or external pressurisation. This supports the maintenance of equipment performing a Category A safety function and so is also in itself a Category A safety function. The vents and overflows are the principal means of ensuring that the internal and external design pressures of the IRWST with respect to the containment atmosphere cannot be exceeded, and therefore are Class 1. See Appendix 15A.

The requirement is that the vents will open when the IRWST pressure begins to deviate from the containment pressure.

Spargers (PXS-MW-01A/B)

The spargers in the IRWST ensure that steam from the ADS is condensed and that the ADS discharge does not result in excessive loads on the IRWST structure. Maintenance of RCS inventory is a Category A safety function. The spargers support the primary method of achieving this by depressurising the RCS sufficiently to enable the PXS to provide safety injection flow into the RCS and therefore are Class 1. See Appendix 15A.

There are two spargers in the IRWST (Section 6.6). The requirement is that each sparger will accommodate steam and water flow from its associated set of ADS stage 1, 2, and 3 valves and distribute it within the IRWST without producing excessive dynamic loads on the IRWST.

Screens (PXS-MY-Y01A/B/C)

The screens ensure that injection from the IRWST into the RCS can take place without the accumulation of debris in the reactor vessel, since such debris may inhibit core cooling. Maintenance of heat removal from the core is a Category A safety function and because the screens are the primary means of ensuring that debris does not block core cooling flow, they are Class 1. See Appendix 15A.

There are three screens available and the requirement is that they will allow adequate flow for gravity injection even when half-blocked.

IRWST Injection Squib Valves (PXS-PL-V123A/B and -V125A/B)

The IRWST injection line isolation valves open to initiate gravity injection from the IRWST into the RCS. Maintenance of RCS inventory is a Category A safety function and as these valves are the primary means of enabling the gravity injection flow, they are Class 1. See Appendix 15A.

There are two injection routes available and each route has two parallel IRWST injection isolation valves. For each injection route, either of the IRWST injection isolation valves operating will establish the full safety function, provided that the associated isolation line check valve has opened. The requirement is therefore that one IRWST injection valve will open, as discussed in the Squib Valve Safety Case (Reference 17.36).

IRWST Injection Line Isolation Valves (PXS-PL-V121A/B)

They are designed to fail “as is” on loss of electrical supplies. They are normally open and are only required to be closed to allow maintenance on the IRWST injection isolation valves. The valves are not required to move as part of the IRWST achieving its safety function, but they must be open. They are Category A, Class 1. See Appendix 15A.

IRWST Injection Line Check Valves (PXS-PL-V122A/B and -V124A/B)

The check valve is required to open to enable the gravity injection from the IRWST to the RCS to take place. Maintenance of RCS inventory is a Category A safety function and as these valves are the primary means of enabling the gravity injection flow, they are Class 1. See Appendix 15A.

There are two injection routes available and each route has two parallel IRWST injection line check valves. For each injection route, either of the IRWST injection line check valves operating will establish the full safety function, provided that the associated injection isolation valve has opened. The requirement is therefore that one IRWST injection line check valve will open.

17.5.4.4 Justification of Claims on Components and Equipment

Storage Tank (PXS-MT-03)

The IRWST provides a large quantity of water in containment and is available as a heat sink to quench steam in the initial stages of RCS depressurisation and for injection by gravity into the RCS. It is entirely passive in nature and requires no pumps or mechanical fluid circulation devices to operate. This confers a high degree of inherent safety.

The tank is manufactured from concrete and carbon steel and lined with stainless steel to ensure maximum compatibility with the borated water it contains. It is designed as a seismic C-I structure with sufficient structural strength for expected pressure differentials to the containment pressure.

Other than its location, the storage tank is very similar to tanks used in currently operating PWRs. As a result, the information from the performance of these in-service tanks offers a high degree of confidence about the reliability to be expected from the tank design as applied to the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate that the probability for a major or minor leak in an unpressurised tank is conservative relative to the value being claimed.

It should also be noted that even in the event of a leak; the contents of the IRWST would drain into the containment sumps and so would still be available for long-term RCS cooling duty.

IRWST Vents and Overflows

The vent and overflow designs are based around a simple flap arrangement that will inherently lift when the tank internal pressure begins to rise and will close again under the influence of gravity. Similarly, some of the vents are designed to also open inward when the containment pressure begins to rise and will close again under the influence of gravity. These movements are entirely passive in nature and offer a high degree of inherent safety.

The principal failure mechanism is likely to be disruption of the vent area due to excessive loads, etc., during operation. The vents are constructed to a manufacturer's standard and are seismic C-I. A comprehensive finite element model has been analysed to ensure that there are adequate design margins.

Spargers (PXS-MW-01A/B)

The spargers are situated in the IRWST and are consequently always covered with water. This inherently ensures that the spargers will be able to fulfil their function with high reliability.

The sparger design has benefited from experience gained from suppression pool design for boiling water reactors and full sized, full flow prototype testing. This has resulted in the spargers arm and arm hole arrangement that results in acceptable hydrodynamic effects and loads during ADS discharge into the IRWST. The spargers are constructed to ASME Boiler and Pressure Vessel Code, Section III-3 and are seismic C-I. They are manufactured from stainless steel to ensure compatibility with the borated water in the IRWST.

Screens (PXS-MY-Y01A/B/C)

The screens are passive devices that offer an inherently high reliability for filtration. In addition, the following design features are intended to minimise the risk of the screens blocking:

- Three screens are provided and cross-connected so that flow leaving either IRWST injection line pulls flow through all three screens.

- The screens are mounted vertically to minimise the risk of particle accumulation on them.

- The design features of the IRWST precludes debris from entering it.

- There is a large margin between the minimum required surface area and the actual surface area provided.

- The screen area is large enough that the expected debris loading found in the IRWST will only cause a minor differential pressure across the screen surface.

- The screens are arranged such that the lowest screening surface is above the floor of the IRWST. This design feature prevents high-density debris from being swept across the floor and into the screen face.

The screens are manufactured from stainless steel to ensure maximum compatibility with RCS coolant. A number of tests have been done to better understand the performance of the screens, and these are discussed further in Reference 17.12. The above design improvements give confidence that the reliability will be as good as, or better than, experience on operating power stations. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate the probability of filter blockage used in analyses is conservative.

IRWST Injection Squib Valves (PXS-PL-V123A/B and -V125A/B)

The IRWST injection isolation valves are squib-type valves which means they will inherently fail “as is”. Clearly, this is not fail-safe with respect to the IRWST injection function but these valves have demonstrated high reliability. Given the importance of their actuation, it is judged appropriate.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The design of squib valves is such that the firing of a propellant charge is used to drive a piston onto the valve shear cap. The shear cap, that is designed to accommodate normal service loads, is broken off by the piston. The piston comes to rest with an opening aligned with the flow path to allow full flow through the valve. Provided that the propellant charge fires correctly, there is a very high level of confidence that the subsequent actions will happen successfully and the valve will open correctly. Consequently, the valve reliability depends almost entirely on the firing reliability of the squib. This issue is discussed further in the squib valve summary report (Reference 17.2).

The maintenance and testing arrangements for the IRWST injection isolation valves comply with ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- The inservice testing of the squib valves requires that 20 percent of the charges installed on the plant will be removed from the squib valves, placed in test fixtures and actuated every 2 years. These tests will be performed in a test fixture away from the valve, and the positions they occupied in valves on the plant will be taken by replacement charges.

IRWST Injection Line Isolation Valves (PXS-PL-V121A/B)

They are designed to fail "as is" on loss of electrical supplies. They are normally open and are only required to be closed to allow maintenance on the IRWST injection isolation valves. The valves are not required to move as part of the IRWST achieving its safety function, but they must be open.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure to open an order of magnitude better than the value assumed in the PSA and indicates that the claims against these valves are conservative.

The operating mechanism for the valve is very simple and, aside from gross mechanical failure, some form of failure to open might be considered the principal mechanism for valve failure. There are two particular reasons for believing this risk to be low and they are:

- Under normal operating conditions, the valves sit without differential pressure across them in a relatively clean fluid environment. This, along with the specified seat materials, is judged to reduce the probability of seizure due to corrosion or self-welding to a very low level.

- The valves only see flow for very limited periods during testing. As a result, they are not subject to degradation due to the vibration resulting from fluid flow of impact loads caused by sudden flow reversal and seating.

The maintenance and testing arrangements for the IRWST injection line check valves are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Visual confirmation of valve position indication operation during the stroke testing is performed every 2 years.

IRWST Injection Line Check Valves (PXS-PL-V122A/B and -V124A/B)

The operation of the IRWST injection line check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure to open an order of magnitude better than the value assumed in the PSA and indicates that the claims against these valves are conservative.

The operating mechanism for the valve is very simple and, aside from gross mechanical failure, some form of failure to open might be considered the principal mechanism for valve failure. There are two particular reasons for believing this risk to be low and they are:

- Under normal operating conditions, the valves sit without differential pressure across them in a relatively clean fluid environment. This, along with the specified seat materials, is judged to reduce the probability of seizure due to corrosion or self-welding to a very low level.

- The valves only see flow for very limited periods during testing. As a result, they are not subject to degradation due to the vibration resulting from fluid flow of impact loads caused by sudden flow reversal and seating.

The maintenance and testing arrangements for the IRWST injection line check valves are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Stroke testing of Class 1 check valves would ideally be performed quarterly. However exercising the valve with the unit at power is deemed to present unacceptable risk to normal operation. Therefore, a full stroke operability test is performed every 2 years as allowed by the ASME Boiler and Pressure Vessel Code in such circumstances.

- Visual confirmation of valve position indication operation during the stroke testing is performed every 2 years.

- A determination of the initial opening differential pressure will be performed every 2 years.

17.5.5 Containment Recirculation Function

17.5.5.1 Role

A detailed description of the PXS containment recirculation function is given in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.25.

Containment recirculation does not play a part in normal operations but is key to maintaining the heat transfer/residual heat removal primary safety function during long term recovery from faults. Containment recirculation functions in two ways:

- If the RCS remains intact, then decay heat is transferred to the IRWST by the PRHR HX. The IRWST water temperature rises and ultimately begins to boil. The steam produced escapes through the IRWST vents and condenses on the inner surface of the containment. Under these circumstances, passive containment cooling, gutters, and downspouts ensure that the condensate on the inner surface of the containment building is returned to the IRWST to maintain its inventory and consequent cooling capability. Note that in the long-term (greater than 14 days) the fact that the return rate back into the IRWST is not 100% can lead to uncover of enough of the PRHR HX that the RCS temperature will rise and ADS valves would have to be actuated transitioning the RCS into a passive feed and bleed cooling mode.

- If the RCS has been breached, the IRWST contents are injected into the RCS. When the IRWST water level reaches its low-low level, the containment recirculation paths to the

direct vessel injection lines are opened. In this situation a steam / water mixture is vented from the RCS breach and the ADS lines. The steam rises into the containment and condenses on the inner surface of the containment. This condensate is returned to the IRWST through a series of gutters. From the IRWST, the condensate is returned to the RCS through the IRWST injection lines. The water vented from the RCS falls down into the containment and is recirculated through containment recirculation screens into the IRWST injection lines and the RCS.

The containment recirculation system functions through the provision of valves that control the drainage path of condensate from the containment inner wall, and by the opening of the recirculation flowpaths from the containment recirculation screen intakes. These recirculation screens are arranged in parallel and filter out debris from the containment floodup water. Water that passes through the screens is available for recirculation through any of the recirculation routes.

Containment recirculation is supported in providing its safety functions by the essential electrical system and also implicitly by the IRWST and its debris screens.

The PXS containment recirculation does not support any other systems in providing their safety functions.

17.5.5.2 System Components and Equipment Contributing to Safety Function

The following components contribute to containment recirculation performing its safety function:

- **IRWST Gutter Drain Isolation Valves (PXS-PL-V130A/B)** – These are 50-mm DN (2-inch), air-operated ball valves that fail closed on loss of air supply. The valves are normally open and are closed on receipt of a PRHR HX actuation signal from either the PMS or the DAS. This isolates the drain line to the containment radwaste sump and diverts the water collected by the IRWST gutter into the IRWST. The safety requirement is to ensure that injection from the IRWST into the RCS can take place without the accumulation of debris in the reactor vessel, since such debris may inhibit core cooling.

- **Containment Recirculation Screens (PXS-MY-Y02A/B)** – These pocket-type screens use a perforated sheet as the filter medium. There are two sets of screens which are situated in the East loop compartment (Loop 2) adjacent to the reactor vessel biological shield wall and ensure that particles are prevented from entering the RCS. The safety requirement is to prevent debris from entering the RCS through the recirculation lines.

- **Containment Recirculation Isolation Valves (PXS-PL-V118A/B & PXS-PL-V120A/B)** – These are 200-mm DN (8-inch), squib-type valves. They effectively fail "as is" on a loss of control supplies and are signalled to open by an open containment recirculation valves signal by the PMS. Opening the valves establishes a gravity injection route from the flooded containment into the RCS and hence a long-term stable heat removal path post-accident. The requirement to establish a flow path is therefore a safety requirement, as discussed in the Squib Valve Safety Case (Reference 17.36). These squib valves are similar to the IRWST injection isolation valves discussed in Section 17.5.4.3. However, there are a number of design features that create diversity between the two sets of valves as described in Reference 17.2.

  Sections 17.5.5.3 and 17.5.5.4 provide additional details on the design and function of the containment recirculation squib valves. Chapter 6 provides discussion on the PXS

which contains the containment recirculation valves and references the system specification documents. Table 8A-2 presents faults that credit containment recirculation actuation for mitigation of the initiating events; associated fault analyses are referenced, with all design basis analyses presented in Chapter 9. The plant PSA (Chapter 10) includes consideration of the valves to actuation upon demand, as well as the consequences associated with spurious operation. The valve resilience to applicable internal hazards is discussed in Chapter 11. Additional detail on the interfacing C&I systems (PMS and DAS) is provided in Chapter 19, with the ADS blocker devise being discussed in Section 19.4.1.2.13. The electrical systems that provide power for actuation are discussed in Chapter 18.

- **Containment Recirculation Isolation Valves (PXS-PL-V117A/B)** – These are 200-mm (8-inch) nominal-bore, motor-operated gate valves that fail "as is" on loss of supplies. These normally open valves are not required to move in order for containment recirculation to achieve its safety function because they are already in their proper position. The valve position will be checked during routine 12-hourly operation surveillances and whilst in this condition the power supplies will be isolated to prevent inadvertent operation. To support the achievement of the containment recirculation safety function, these administrative arrangements are backed up by the initiation of an open signal from the PMS when an open containment recirculation valves signal is generated. It is considered that these arrangements are sufficiently robust that further analysis is not required.

- **Containment Recirculation Check Valves (PXS-PL-V119A/B)** – These are 200-mm DN (8-inch), swing check valves. These valves exist to prevent reverse flow in the event of an inadvertent actuation of the associated containment recirculation isolation valve. Their safety function is to open on demand to enable direct injection from the containment sumps into the RCS.

17.5.5.3 Claims on Components and Equipment

IRWST Gutter Drain Isolation Valves (PXS-PL-V130A/B)

The normal IRWST gutter drain lines are isolated to ensure that condensate from the containment walls is returned to the IRWST to maintain its water inventory and decay heat removal capability via the PRHR HX. Removal of decay heat is a Category A safety function. These valves are the primary means of diverting the containment drainage into the IRWST and are therefore Class 1. See Appendix 15A.

There are two valves in series and either one closing will fulfil the required safety function.

Recirculation Screens (PXS-MY-Y02A/B)

The recirculation screens ensure that recirculation flow from the flooded containment into the RCS can take place without the accumulation of debris in the reactor vessel, since such debris may inhibit core cooling. Maintenance of heat removal from the core is a Category A safety function and because the screens are the primary means of ensuring that debris does not block core cooling flow, they are Class 1. See Appendix 15A.

There are two screens available and the requirement is that they will allow adequate flow for gravity recirculation even when they have captured a conservative amount of debris.

Containment Recirculation Isolation Valves (PXS-PL-V118A/B & PXS-PL-V120A/B)

The containment recirculation isolation valves open to initiate gravity injection from the flooded containment into the RCS. Maintenance of RCS inventory is a Category A safety function and as these valves are the primary means of enabling the gravity injection flow, they are considered to be Class 1. See Appendix 15A.

There are two recirculation routes available and each has two parallel lines containing containment recirculation isolation valves. For sufficient recirculation flow, either of the containment recirculation isolation valves in either operating recirculation route will establish the full safety function, provided that the associated isolation valve in series has opened, as discussed in the Squib Valve Safety Case (Reference 17.36). The reliability for operation of the valves is given in the Squib Valve Summary Report (Reference 17.2).

Containment Recirculation Check Valves (PXS-PL-V119A/B)

The check valve is required to open to enable the gravity injection from the flooded containment to the RCS to take place. Maintenance of RCS inventory is a Category A safety function and as these valves are the primary means of enabling the gravity injection flow, they are considered to be Class 1. See Appendix 15A.

There are two recirculation injection routes available and each has two parallel lines with one line containing a containment recirculation line check valve. For each route, either of the two containment recirculation check valves operating will establish the full safety function, provided that their associated injection isolation valve has opened. It is noted that either of the two other parallel lines that do not contain check valves will also establish the full safety function, provided that their associated injection isolation valve has opened.

17.5.5.4 Claims on Components and Equipment

IRWST Gutter Drain Isolation Valves (PXS-PL-V130A/B)

The IRWST gutter drain isolation valves are air operated with the actuators designed to fail closed in the event of loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) are comparable to the value being claimed.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment (Table 15A-1).

The maintenance and testing arrangements for the IRWST gutter drain isolation valves are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

Recirculation Screens (PXS-MY-Y02A/B)

The recirculation screens are passive devices that offer an inherently high reliability for filtration. In addition, the following design features are intended to minimise the risk of the screens blocking:

- The screens are mounted vertically to minimise the risk of particle accumulation on them.

- The design of the containment structures, coatings, and piping insulation minimises the amount of debris that can be created by a postulated fault, as well as the amount of debris which can travel to the screens by providing low flow velocity (large flow areas) approaching the screens to allow high density debris to settle out.

- There is a large margin between the minimum required surface area and the actual surface area provided.

- The screen area is large enough that the expected debris loading found in the containment will only cause a minor differential pressure across the screen surface.

- The screens are arranged such that the lowest screening surface is above the floor of the containment. This design feature prevents high-density debris from being swept across the floor and into the screen face.

The screens are manufactured from stainless steel to ensure maximum compatibility with RCS coolant. A number of tests have been done to better understand the performance of the screens, and these are discussed further in Reference 17.12. The above design improvements give confidence that the reliability will be as good as or better than experience on operating power stations. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of filter blockage so that the claim is conservative.

Containment Recirculation Isolation Valves (PXS-PL-V118A/B & PXS-PL-V120A/B)

The containment recirculation isolation valves are squib-type valves which means they will inherently fail “as is”. Clearly, this is not fail-safe with respect to the containment recirculation function, but given that the high actuation reliability of these valves, it is judged appropriate.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The design of squib valves is such that the firing of a propellant charge is used to drive a piston onto the valve shear cap. The shear cap, that is designed to accommodate normal service loads, is broken off by the piston. The piston comes to rest with an opening aligned with the flow path to allow full flow through the valve. There is a very high level of confidence that the propellant charge and the subsequent actions will happen successfully and

that the valve will open correctly. The arguments and evidence that the squib valves are design adequately to reliably perform their necessary safety function are provided in the Squib Valve Safety Case (Reference 17.36). The valve reliability depends heavily on the firing reliability of the propellant. This issue is discussed further in the squib valve summary report (Reference 17.2).

The maintenance and testing arrangements for the IRWST injection isolation valves comply with ASME Boiler and Pressure Vessel Code and are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Twenty percent of the charges installed on the plant will be fired every 2 years. These tests will be performed in a test fixture away from the valve and the positions they occupied in valves on the plant will be taken by replacement charges.

Containment Recirculation Check Valves (PXS-PL-V119A/B)

The operation of the containment check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the RCS chemistry conditions and are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure to open that is an order of magnitude better than the value assumed in the PSA and indicates that the claims against these valves are conservative.

The operating mechanism for the valve is very simple and, aside from gross mechanical failure, some form of failure to open might be considered the principal mechanism for valve failure. There are two particular reasons for believing this risk to be low:

- Under normal operating conditions, the valves sit without differential pressure across them in a relatively clean fluid environment. This, and the specified seat materials, is judged to reduce the risk of seizure due to corrosion or self-welding to a very low level.

- The valves only see flow for very limited periods during testing. As a result, they are not subject to degradation due to vibration resulting from fluid flow of impact loads caused by sudden flow reversal and seating.

The maintenance and testing arrangements for the containment recirculation check valves are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed every 2 years in accordance with ASME Boiler and Pressure Vessel Code. Even though a test every three months might be specified for this type of service, exercising the valve with the unit at power is deemed to present an unacceptable risk to normal operation and hence, under the ASME Boiler and Pressure Vessel Code rules, can be varied.

- Visual confirmation of valve position indication operation during the stroke testing is performed every 2 years.

- A check of the initial opening differential pressure will be performed every 2 years.

17.5.6 Passive Residual Heat Removal

17.5.6.1 Role

A detailed description of the PRHR HX and associated piping and valves is given in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.25.

The PRHR HX is located within the PXS IRWST and is submerged in the IRWST water which serves as the heat sink for heat transferred from the RCS via the heat exchanger tube surfaces. The PRHR HX has no function during normal operation but serves as the primary Class 1 decay heat removal path during fault conditions with the RCS intact, when the normal heat removal path via the SGs is unavailable. As such, it contributes to the heat transfer/residual heat removal primary safety function.

The system is purely passive in operation with loop pipes and associated valves connecting the PRHR HX inlet to the RCS hot leg and outlet to the RCS cold leg by means of the SG channel head.

The PRHR is supported in the provision of its safety function by the IRWST and the essential electrical system.

The PRHR does not support any other systems in the provision of their safety functions.

17.5.6.2 System Components and Equipment Contributing to Safety Function

All the PRHR pipework, along with the HX (PXS-ME-01) itself, is constructed to ASME Boiler and Pressure Vessel Code, Section III, Class 1 and is also seismic C-I.

- **PRHR HX (PXS-ME-01)** – This comprises Inconel™ 690 tubes arranged in a single-pass, horizontal "C" arrangement. The remaining HX components are manufactured from stainless-steel-lined carbon steel and/or stainless steel. The design limiting heat removal requirement is met with approximately 5-percent tube plugging. The heat transfer duty is a safety requirement.

- **PRHR HX Inlet Isolation Valve (PXS-PL-V101)** – This is a 350-mm DN (14-inch), motor-operated gate valve designed to fail "as is" on loss of electrical supplies. It is normally open and is only required to be closed to allow IST of the outlet valves and for shutdown maintenance on the PRHR HX. The valve is not required to move as part of the PRHR achieving its safety function since it is normally open. The valve position will be checked during routine 12-hourly operation surveillances and whilst in this condition, the power supplies will be isolated to prevent inadvertent operation. To support the PRHR safety function, these administrative arrangements are backed up by the initiation of an open signal from the PMS when a PRHR actuation signal is generated. It is felt that these arrangements are sufficiently robust that further analysis is not required.

- **PRHR HX Control Valves (PXS-PL-V108A/B)** – These are 350-mm DN (14-inch) air-operated ball valves that fail open on loss of air supplies. The valve is normally

closed and is signalled to open on receipt of a PRHR actuation signal from either the PMS or the DAS to separate air control solenoids. The valve opening sets up the natural circulation flow path from the RCS through the PRHR and enables passive cooling of the RCS. The establishment of this flow path is a safety requirement.

17.5.6.3 Claims on Components and Equipment

PRHR Heat Exchanger (PXS-ME-01)

The PRHR HX is the primary post-fault means of removing RCS decay heat with the RCS intact. Decay heat removal is a Category A safety function. The PRHR is deemed to be Class 1.

There is a single HX and it must operate correctly for the system to perform its safety function. The requirement is that the HX will provide adequate heat transfer capability to accommodate RCS decay heat generation and thus cool the RCS.

PRHR HX Inlet Isolation Valve (PXS-PL-V101)

PRHR HX inlet isolation valve must be open to allow decay heat removal from the RCS but is in the open position during operation. Decay heat removal is a Category A safety function. The valves are Class 1. See Appendix 15A.

PRHR Heat Exchanger Control Valves (PXS-PL-V108A/B)

The PRHR HX control valves open to allow decay heat removal from the RCS. Decay heat removal is a Category A safety function. The valves are Class 1. See Appendix 15A.

There are two PRHR HX control valves arranged in parallel. At least one of them is required to open to ensure that the safety function is performed. The requirement is therefore that at least one of the PRHR HX control valves will open.

17.5.6.4 Justification of Requirements on Components and Equipment

PRHR Heat Exchanger (PXS-ME-01)

The PRHR HX is a passive component. Given that it is mounted in the IRWST beneath the water level, and provided that hot fluid is able to circulate through the tubes, heat transfer is inherently going to take place.

The HX is manufactured to ensure maximum compatibility with the RCS coolant and IRWST contents. It is built to ASME Boiler and Pressure Vessel Code, Section III-1.

A number of design features support the reliability claimed for the PRHR HX:

- The tubes are constructed from Inconel 690, a material selected because of its resistance to stress-corrosion cracking. It has been well proven as an SG tube material in current PWRs.

- The use of stainless-steel-lined channel heads is similar to the cladded carbon steel design utilised in the RCS major components, including the reactor vessel and vessel head.

- The PRHR is maintained pressurised during normal operations so that it can be placed into service without water hammer.

- The connections onto the RCS are placed to ensure a strong initial natural circulation driving head.

- The inlet line is sloped up to the HX to ensure that internal convection will maintain it in a hot condition. The inlet pipework is also lagged, again to maintain the inlet to outlet temperature difference and enhance the establishment of natural circulation.

- With the RCPs operating, the PRHR HX operates with the flow in the same direction as when only natural circulation exists. This precludes disruption of the thermal driving head on transfer from forced to natural circulation in the RCS.

The tubes are not designed to be replaced and hence the design has an approximately 5-percent tube-plugging margin to adequate surface area after tube plugging following in-service detection of tube corrosion or cracking or leakage.

Although the PRHR HX is a new concept with the AP1000 design, the principle of tubed HXs is well established in PWRs and other nuclear power stations. As such, the reliability experienced by operating stations can contribute to establishing confidence in the expected PRHR reliability. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate the probability of a tube leak in an HX is comparable to the value being claimed.

The maintenance and testing arrangement for the PRHR HX are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for similar equipment as used on existing nuclear power stations. The testing is:

- A system test is performed every 10 years to confirm PRHR heat transfer capability.

- The PRHR closure heads will be accessible for cladding and tube inspection during every refuelling outage, and there will be external access to the tube bank when the IRWST is drained.

PRHR HX Inlet Isolation Valve (PXS-PL-V101)

Must be open to allow decay heat removal from the RCS but is in the open position during operation.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

PRHR Heat Exchanger Control Valves (PXS-PL-V108A/B)

The PRHR HX control valves are air operated with the actuators designed to fail open in the event of loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are similar to those already in service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of a failure to open is comparable to the value being claimed.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I and are qualified for operation in a harsh environment (Table 15A-1).

The maintenance and testing arrangements for the PRHR HX control valves are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is carried out quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- A system test is performed every 10 years to confirm PRHR heat transfer capability. This will also confirm valve operating performance.

17.5.7 Normal Residual Heat Removal System

17.5.7.1 Role

A detailed description of the RNS is given in Section 6.4. Further design details of this system and its constituent components are delineated in Reference 17.26.

The RNS contributes to the primary containment isolation safety function and may contribute to the heat transfer/residual heat removal defence in depth safety functions. During normal shut down operation, it supports the heat transfer/residual heat removal through the removal of decay heat generated in the core when the RCS temperatures are below the level where effective heat removal is possible through steaming the SGs. It also provides the motive force to circulate RCS fluid through the CVS system when the RCPs are shut down.

The RNS contributes to heat transfer/residual heat removal through the following Class 2 defence in depth functions:

- The RNS can provide cooling for the IRWST during operation of the PRHR heat exchanger. The system is manually aligned and can be used to prevent the IRWST boiling.
- Following an accident which has resulted in actuation of all stages of ADS, the RNS can be aligned to provide injection flow from inside the containment to the reactor vessel and provide core decay heat removal instead of making use of the PXS containment recirculation capability.
- The RNS can also provide post-accident low pressure make-up taking water either from the IRWST or from the cask loading pit following actuation of ADS stages 1, 2, and 3. This is intended to provide the facility for the plant to be stabilised before the PXS core makeup tanks drain down to their ADS stage 4 actuation level setpoint. Either train of the

RNS can also be used to cool the spent fuel pool during normal plant operation provided it is not being used for core decay heat removal.

The RNS piping connections from and to the RCS pass through the containment boundary and have containment isolation valves for the containment isolation safety function. This feature supports the containment primary safety function.

After an accident which has included fourth stage ADS, long term makeup may be required from outside of containment. The flow path for this long-term (2-4 weeks following the event) supply of water is administratively controlled and water addition is supplied through either of the two RNS heat exchanger channel head drain connections.

The RNS system consists of two separate and independent trains of mechanical equipment. The RNS shares a common connection to one of the RCS hot legs. After this connection the line is split into two separate RNS lines with separate pipe lines, valves, pumps and HX. Each RNS suction line also has a separate connection from the IRWST and suction relief valves. Single connections are provided to and from the CVS purification demineralisers and filter. Each suction line contains inside and outside containment isolation valves and is routed to its corresponding RNS pump suction. Downstream of each outside containment RNS suction isolation valve, each RNS pump suction line has a connection from the spent fuel pool and from the cask wash down pit. Each RNS pump discharges through its own heat exchanger (cooled by the CCS), and each heat exchanger has its own flow control valves and bypass line to control the RCS cooldown rate. Each pump/heat exchanger discharge line has a piping connection to the spent fuel pool; a separate containment penetration with outer and inner containment isolation valves; and connections inside containment to the IRWST and to the CVS purification demineralisers and filter. Each then feeds into its corresponding PXS direct vessel injection line which connects to the reactor vessel downcomer.

The RNS is supported by the ECS and under certain circumstances by the ZOS. Heat removal from the RNS HXs and pump seal cooling is supported by the CCS. Each RNS pump room is equipped with a central chilled water system (VWS) cooler and the operation of the VWS air cooled chiller subsystem is required to support longer-term operation of the pumps (more than 24 hours). Clearly, for low-pressure RCS makeup, the RNS is supported by the IRWST and/or the cask loading pit.

The RNS supports the SFS in providing their safety function when the full core is placed in the SFP or when there is a failure in the SFS. The RNS also provides a defence in depth function to support PXS low pressure safety injection, long-term recirculation function, and shutdown decay heat removal function.

17.5.7.2 System Components and Equipment Contributing to Safety Function

The pressure boundary of the RNS (pipework, pump casing, valves, and HX) outside of containment are designed to ASME Boiler and Pressure Vessel Code, Section III-3. They are capable of accepting full reactor system pressure without bursting, although there may be some plastic deformation. The sections of RNS pipework inside of containment are designed for full RCS design pressure. The RCS pressure isolation portion of the RNS is designed to ASME Boiler and Pressure Vessel Code, Section III-1; the containment isolation portion of the RNS is designed to ASME Boiler and Pressure Vessel Code, Section III-2; and the rest of the RNS piping inside containment is designed to ASME Boiler and Pressure Vessel Code, Section III-3. The whole system is designed to seismic C-I (Table 15A-1).

- **RNS Pumps (RNS-MP-01A/B)** – These are single-stage, vertical, in-line, bottom-suction, centrifugal pumps constructed of stainless steel. They are directly coupled to an ac induction motor. The pumps develop sufficient shutoff head. The pumps are protected by mini-flow pipework from the HX discharge to the pump suction. They have mechanical seals on the drive shaft and these are cooled by the CCS. The pumps are operated solely by manual operator control and there are no automatic signals to initiate operation. The specific safety requirement of the RNS pumps is to provide the required RNS design flow from the RCS, through the RNS, and back to the reactor vessel.

- **RNS HXs (RNS-ME-01A/B) –** These are vertically mounted shell-and-U-tube design HXs with the RCS fluid to be cooled circulating through the tubes and CCS fluid circulating through the shell. The shell is manufactured from carbon steel and the tubes from stainless steel. The HXs are sized to allow the design plant cooldown profile to be achieved in conjunction with the RNS pump design flow rate. The safety requirement of the RNS HXs is to provide adequate heat transfer to remove core decay heat and cool down the RCS during normal shutdown and accident conditions.

- **RNS Hot Leg Suction Isolation - Inner Valves (RNS-PL-V001A/B)** – These are 250-mm DN (10-inch), motor-operated gate valves located inside containment. They fail "as is" on loss of power. The valves are opened manually to initiate RCS cooling by the RNS system, albeit with permissive interlocks based on RCS pressure and IRWST suction valve position, and are signalled closed by the PMS on receipt of an RNS isolation signal. The safety requirement of the valves is to open on demand to allow use of the RNS system in its defence in depth function, and also to isolate the RNS suction lines on demand from an RNS isolation signal.

- **RNS Hot Leg Suction Isolation Valves (RNS-PL-V002A/B)** – These are 250-mm DN (10-inch), motor-operated gate valves. They fail "as is" on loss of power. The valves are opened manually to initiate RCS cooling by the RNS system, albeit with permissive interlocks based on RCS pressure and IRWST suction valve position, and are signalled closed by the PMS on receipt of a manual RNS isolation signal or a RNS containment isolation signal. The safety requirement of the valves is to open on demand to allow use of the RNS system in its defence in depth function, and also to isolate the RNS suction lines on demand from an RNS or containment isolation signal.

- **RNS return from CVS CIVs (RNS-PL-V061A/B) –** These are 75-mm DN (3-inch), air-operated globe valves located inside containment. They fail closed on loss of air supply, and one is normally opened only when the RNS is in service to return flow from the CVS demineralisers and filters to the RNS, with the flow to the CVS provided from an RNS discharge. This flow path contributes to enabling the RNS to pump RCS fluid through the CVS when the RCPs are shut down. Because of where they are connected to the RNS suction pipework, the valves are CIVs and are closed by the PMS on receipt of a containment isolation signal. The safety requirement of the valves is to isolate the RNS containment penetration on demand.

- **RNS Hot Leg Suction Pressure Relief Valves (RNS-PL-V021A/B)** – These are 75-mm DN (3-inch) safety relief valves located inside containment, with one relief valve connected to each RNS train. The valves provide overpressure protection to the RNS at all times and also provide low-temperature overpressure protection to the RCS when either RNS train is in service. This size has been chosen so that the pressure in the RCS and RNS can be kept below the lower value of the RNS design pressure and the low-temperature limit for the reactor vessel, based on ASME Boiler and Pressure Vessel

Code, Section III, Appendix G. The valves do not require separate actuation but opening at the setpoint pressure is a safety requirement.

- **RNS Suction Header CIVs (RNS-PL-V022A/B)** – These are 250-mm DN (10-inch), motor-operated gate valves located inside containment. They fail "as is" on loss of power and are only opened when it is required to put the RNS into service. They are CIVs and are signalled closed on receipt of a containment isolation signal from the PMS. They also close on receipt of a manual RNS isolation signal from the PMS. The safety requirement of the valves is to open on demand to allow use of the RNS system in its defence in depth function and also to isolate the RNS containment penetration on demand.

- **RNS Discharge CIVs (RNS-PL-V011A/B)** – These are 150-mm DN (6-inch), motor-operated gate valves located outside containment. They fail "as is" on loss of power and are only opened when it is required to put the RNS into service. They are CIVs and are signalled closed by the PMS on receipt of an RNS containment isolation signal. The safety requirement of the valve is to open on demand to allow use of the RNS system in its defence in depth function and also to isolate the RNS containment penetration on demand.

- **RNS HX Outlet Flow Control Valves (RNS-PL-V006A/B)** – These are 150-mm DN (6-inch), air-operated globe valves that fail open on loss of air. They are positioned from the MCR to control RCS cooldown rates but are normally set to the fully open position at other times to ensure maximum cooling should the RNS be used for one of its defence in depth functions.

- **RNS HX Bypass Flow Control Valves (RNS-PL-V008A/B)** – These are 100-mm DN (4-inch), air-operated globe valves that fail closed on loss of air. They are positioned from the MCR to control RCS cooldown flow rates (control is integral to the HX flow control valves) but are normally positioned to the fully closed position at other times to ensure maximum cooling should the RNS be used for one of its defence in depth functions.

- **RNS Suction from IRWST CIVs (RNS-PL-V023A/B)** – These are 250-mm DN (10-inch) nominal-bore, motor-operated gate valves located inside containment. They fail "as is" on loss of power and are only opened when it is required to use the RNS to inject IRWST water, or to initiate IRWST cooling, as part of the RNS defence in depth functions. They are also CIVs and are signalled closed by the PMS on receipt of an RNS containment isolation signal. The safety requirement of the valves is to enable flow from the IRWST on demand when IRWST water is required, and to isolate the IRWST to RNS suction line on demand for normal RNS operation or for containment isolation.

- **RNS Discharge to IRWST Isolation Valves (RNS-PL-V024A/B)** – These are 150-mm DN (6-inch), motor-operated gate valves located inside containment. They fail "as is" on loss of power and are only opened to use the RNS to cool the IRWST as part of its defence in depth function. This is done manually and there is no automatic actuation of these valves. The safety requirement is to enable flow from the RNS pump suction to the IRWST on demand.

- **RNS Pump Suction to Cask Loading Pit Isolation Valves (RNS-PL-V055A/B)** – These are 200-mm DN (8-inch), motor-operated gate valves. They fail "as is" on loss of power and are only opened to use the RNS to provide low-pressure injection from the cask loading pit as part of the RNS defence in depth function. This is done manually and

there is no automatic actuation of these valves. The safety requirement is to enable flow from the cask load pit on demand.

- **RNS Discharge CIV - IRC (RNS-PL-V013A/B)** – These are 150-mm DN (6-inch) swing check valves. They are required to remain open to provide heat transfer and residual heat removal but are also required to isolate on reverse flow and serve as CIVs. Both functions are safety requirements.

- **RNS Discharge RCS Pressure Boundary Stop Check Valves (RNS-PL-V015A/B)** – These are 150-mm DN (6-inch) stop check valves. They are required to open for the RNS to be placed into service and serve as the RCS pressure boundary under normal operating conditions. The safety requirement is to maintain the RCS pressure boundary at all times when they are subject to a reverse pressure difference, and to open when this pressure difference is removed to enable the RNS to be put into service.

- **RNS Discharge RCS Pressure Boundary Check Valves (RNS-PL-V017A/B)** – These are 150-mm DN (6-inch) swing check valves. They are required to open for the RNS to be placed into service and serve as the RCS pressure boundary under normal operating conditions. The safety requirement is to maintain the RCS pressure boundary at all times when they are subject to a reverse pressure difference, and to open when this pressure difference is removed to enable the RNS to be put into service.

17.5.7.3 Claims on Components and Equipment

RNS Pumps (RNS-MP-01A/B)

The RNS pumps provide the motive force to either circulate water through the RNS or to inject water from the IRWST/cask loading pit into the RCS. These flows provide a heat transport capability for the removal of decay heat. Removal of decay heat is a Category A safety function. The RNS pump motor and rotating parts are Class 2. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary with a consequent function to contain radioactive material. Maintaining the reactor coolant pressure boundary is a Category A safety function and the RNS component pressure boundaries are Class 1 in this respect. See Appendix 15A.

There are two RNS pumps; both of them are required to be available to provide the full cooling. However, the loss of one RNS pump does not preclude the ability to cool down, but results in longer cooldown times. The requirement on the pumps is that they will start on demand and continue to run reliably as required.

RNS HXs (RNS-ME-01A/B)

The RNS HXs provide the capability to transfer heat to the CCS. Removal of decay heat is a Category A safety function. The RNS HX shells are Class 2. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary with a consequent function to contain radioactive material. Maintaining the reactor coolant pressure boundary is a Category A safety function and the RNS HX channel heads and tubes are Class 1 in this respect. See Appendix 15A.

There are two RNS HXs, both of that are required to provide the full shutdown cooling duty. However, the loss of one RNS heat exchanger does not preclude the ability to cool down the RCS, but results in longer cooldown times. The requirement on the heat exchangers is that they will provide adequate heat transfer and that they will not impair the operation of the

RNS, or will not themselves be unavailable, through leakage.

Hot Leg Suction Isolation Inner – Valves (RNS-PL-V001A/B)

The RCS hot leg to RNS suction inner isolation valves provide isolation for the lower design pressure portion of the RNS from the RCS. They are required to enable flow into the RNS and therefore are enabling the transfer of decay heat. Removal of decay heat is a Category A safety function. The hot leg suction inner isolation valves are considered Class 2. See Appendix 15A. They are also part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the hot leg suction inner isolation valves are Class 1 in this respect. See, Appendix 15A.

There is one valve arranged in series with the hot leg suction outer isolation valve, discussed below, on each RNS train. Closing either the hot leg suction inner isolation valve or the hot leg suction outer isolation valve will isolate the suction line; the second valve provides thus redundancy. The requirement on the valves therefore is that they will close on demand.

RNS Hot Leg Suction Outer Isolation Valves (RNS-PL-V002A/B)

The RCS hot leg to RNS suction outer isolation valves provide isolation for the RNS from the RCS. They are required to enable flow into the RNS system and therefore are enabling the transfer of decay heat. Removal of decay heat is a Category A safety function. The hot leg suction isolation valves are considered Class 2. The valves also perform a containment isolation function and containment is also a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the hot leg suction outer isolation valves are Class 1 in this respect. See Appendix 15A.

There is one valve arranged in series with the hot leg suction inner isolation valve, discussed above, on each RNS train. Closing either the hot leg suction inner isolation valve or the hot leg suction outer isolation valve will isolate the suction line; the second valve provides redundancy. The requirement on the valves therefore is that they will close on demand.

RNS Return from CVS Containment Isolation Valves (RNS-PL-V061A/B)

The RNS return from CVS CIVs perform a containment isolation function and containment is a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, they effectively become a part of the RCS pressure boundary with a consequent function to contain radioactive material. Containment of radioactive material is a Category A safety function, these valves are Class 1 in this respect also. See Appendix 15A.

The requirement on the valves is that they will close on demand to meet their contribution to isolation of their associated containment penetrations.

RNS Hot Leg Suction Pressure Relief Valves (RNS-PL-V021A/B)

Each RNS hot leg suction pressure relief valve provides cold overpressure protection to the RCS and also provides overpressurisation protection to the RNS, whilst the RNS is in service. Protection of the RCS pressure boundary is a Category A safety function, these valves are deemed to be Class 1. See Appendix 15A.

The requirement on the valves is that they will open on demand when their set pressure is exceeded.

RNS Suction Header Containment Isolation Valves (RNS-PL-V022A/B)

Each RNS suction line CIV is required to open to enable flow into its corresponding RNS train and therefore is enabling the transfer of decay heat. Removal of decay heat is a Category A safety function. These valves are Class 2. The valves also perform a containment isolation function and containment is also a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the pump suction outside containment isolation valves are Class 1 in this respect. See Appendix 15A.

Each valve is on a separate containment penetration and the requirement is that they will open on demand to meet the RNS heat transfer and residual heat removal requirements and will close on demand to meet the containment isolation requirements.

RNS Discharge Containment Isolation Valves (RNS-PL-V011A/B)

The RNS discharge CIVs enable flow through the RNS and back to the RCS, and therefore are enabling the transfer of decay heat. Removal of decay heat is a Category A safety function and the pump discharge header isolation valves are Class 2. The valves also perform a containment isolation function and containment is also a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintaining the reactor coolant pressure boundary is a Category A safety function. Therefore, the CIVs are Class 1 in this respect. See Appendix 15A. These valves are also required to open to provide a long-term supply for makeup to containment inventory. Since this function is not needed until at least 2 to 4 weeks after an accident, it is classified as a Category B safety function and the valves are Class 2 for this function.

Each valve is on a separate containment penetration and the requirement is that they will open on demand to meet the RNS heat transfer, residual heat removal and low pressure requirements and will close on demand to meet the containment isolation requirements.

RNS Heat Exchanger Outlet Flow Control Valves (RNS-PL-V006A/B)

These valves provide part of the temperature control arrangements for the RNS under normal shutdown operations. Because the valves sit in the main RNS HX flow paths, it is important that they can be operated to enable cooling and consequent decay heat removal from the fluid passing through the RNS. Removal of decay heat is a Category A safety function and the valves are Class 2 for this function. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor cooling pressure is a Category A safety function and the valves are Class 1 in this respect. See Appendix 15A. These valves are also required to open to provide a long-term supply for makeup to containment inventory. Since this function is not needed until at least 72 hours after an accident, it is classified as a Category B safety function and the valves are Class 2 for this function.

Each HX has its own flow control valve and each one will fulfil the temperature control function for its HX. The requirement is that the valve will open on demand to enable full cooling flow.

RNS Heat Exchanger Bypass Flow Control Valves (RNS-PL-V008A/B)

These valves provide part of the temperature control arrangements for the RNS under normal shutdown operations. Because the valves are in a bypass to the main RNS HX flow path, it is important that they can be operated to enable cooling and consequent decay heat removal from the fluid passing through the RNS. Removal of decay heat is a Category A safety function and the valves are Class 2 for this function. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the valves are Class 1 in this respect.

Each HX has its bypass flow control valve and each one will fulfil the temperature control function for that HX. The requirement is that the valve will close on demand to enable full cooling flow.

RNS Suction from IRWST CIVs (RNS-PL-V023A/B)

The IRWST to RNS suction isolation valves provide an isolation facility for the IRWST from the RNS. They are required to open to enable flow from the IRWST into the RNS and therefore are enabling the transfer of decay heat and providing a source for low-pressure injection to the RCS to maintain RCS inventory. Both of these are Category A safety functions and the valves are considered Class 2. These valves also perform a containment isolation function and containment is also a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function the valves are Class 1 in this respect. See Appendix 15A.

Each valve is on a separate containment penetration and the requirement is that they will open on demand to meet the RNS low-pressure injection and IRWST decay heat removal requirements, and will close on demand to meet the containment isolation requirements.

RNS Discharge to IRWST Isolation Valves (RNS-PL-V024A/B)

The RNS discharge to IRWST isolation valves provide an isolation facility for the IRWST from the RNS. They are required to enable flow back to the IRWST from the RNS and therefore are enabling the transfer of decay heat. Removal of decay heat is a Category A safety function and the valves are considered Class 2 for this function. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the valves are Class 1 in this respect. See Appendix 15A.

There are two isolation valves, one associated with each RNS train; the requirement is that either one will open on demand in conjunction with its corresponding IRWST suction isolation valve, to meet the RNS IRWST decay heat removal requirements.

RNS Pump Suction from Cask Loading Pit Isolation Valves (RNS-PL-V055A/B)

The cask loading pit to RNS suction isolation valves provide an isolation facility for the cask loading pit from the RNS. They are required to enable a supply of borated water to be taken from the cask loading pit to the RNS and therefore are a source of low-pressure makeup to the RCS. Maintaining reactor coolant inventory is a Category A safety function and the valves are considered Class 2 for this function. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the

reactor coolant pressure boundary is a Category A safety function and the valves are Class 1 in this respect.

There are two isolation valves, one associated with each RNS train; the requirement is that either one will open on demand to meet the RNS low-pressure injection requirements.

RNS Discharge Check CIV – IRC (RNS-PL-V013A/B)

The RNS discharge line check valves are required to open to enable the RNS to perform its decay heat removal and low-pressure injection, both of that are Category A functions and these valves are Class 2 for these functions. These valves also perform a containment isolation function and containment is also a Category A safety function. These valves are classified in this function as Class 1. See Appendix 15A. When the RNS is in service, it effectively becomes a part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and the valves are Class 1 in this respect. These valves are also required to open to provide a long-term supply for makeup to containment inventory. Since this function is needed no sooner than 72 hours after an accident, it is classified as a Category B safety function and the valves are Class 2 for this function.

Each valve is on a separate containment penetration and the requirement is that they close on reverse pressure with a consequent function to contain radioactive material. Containment of radioactive material is a Category A safety function and they are Class 1 in this respect. See Appendix 15A.

RNS Discharge RCS Pressure Boundary Stop Check Valves (RNS-PL-V015A/B)

The discharge RCS pressure boundary stop check valves are required to open to enable the RNS to perform its decay heat removal and low-pressure injection. These are Category A functions and these valves are Class 2 for these functions. When the RNS is out of service, these valves are the isolation point between the RNS and RCS and as a result, they are part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and these valves are Class 1 in this respect. See Appendix 15A. These valves are also required to open to provide a long-term supply for makeup to containment inventory. Since this function is not needed until at least 72 hours after an accident, it is classified as a Category B safety function and the valves are Class 2 for this function.

RNS Discharge RCS Pressure Boundary Check Valves (RNS-PL-V017A/B)

The discharge RCS pressure boundary check valves are required to open to enable the RNS to perform its decay heat removal and low-pressure injection, both of which are Category A functions. The valves are Class 2 for these functions. When the RNS is out of service, these valves are the isolation point between the RNS and RCS and as a result, they are part of the RCS pressure boundary. Maintenance of the reactor coolant pressure boundary is a Category A safety function and these valves are Class 1 in this respect. These valves are also required to open to provide a long-term supply for makeup to containment inventory. Since this function is not needed until at least 72 hours after an accident, it is classified as a Category B safety function and the valves are Class 2 for this function.

17.5.7.4 Justification of Claims on Components and Equipment

Normal Residual Heat Removal System Pumps (RNS-MP-01A/B)

The pressure boundary of the RNS pumps are designed to ASME Boiler and Pressure Vessel Code, Section III-3 and the RNS pump motors are designed to commercial standards. Therefore, these pumps are very similar to the design of pumps performing this duty on currently operating PWRs. As a result, the information from the operation of these in-service pumps offers a high degree of confidence about the reliability to be expected from the pumps proposed for the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate that the probability of failure to start is low.

The generic design of these pumps should provide high reliability. The design specification requires that manufacturers identify any specific design features that will provide support in this area. Two specific design features that have been identified that aid the achievement of high reliability in operation:

- In order to limit leakage in the unlikely event of an inter-system loss of coolant accident (IS-LOCA), the pump design includes a "disaster bushing" that is fitted adjacent to, and just outside of, the mechanical seal. The bushing provides a close fit between the pump shaft and the bearing housing and will limit any leakage in the event of mechanical seal failure. This ability is maintained even with RNS pressures in excess of normal design.

- The pumps are designed to run with 3-percent air ingestion with the pump suction without loss of performance. The pumps are also designed to accommodate 5-percent air entrainment at the pump suction but with potentially some degradation of performance.

Given the importance of the RNS pumps to the defence in depth safety functions, it is expected that routine full-flow testing will be performed with the pumps aligned to draw from and discharge to the IRWST. This testing will be carried out quarterly in accordance with the surveillance requirements for investment protection short-term availability control. The pumps will also be subject to routine overhaul and maintenance in line with the manufacturer's recommendations.

RNS Heat Exchangers (RNS-ME-01A/B)

The HXs are manufactured with stainless-steel tubes to maximise compatibility with the RCS fluid. They are designed to ASME Boiler and Pressure Vessel Code, Section III on the tube side and Section VIII, Division 1 (Reference 17.9) on the shell side. The tubes are expanded onto the tube sheet over its full depth and seal-welded in addition. This is intended to minimise the chance of leakage from the RNS side into the CCS.

The HX design is very similar to that used for this role on currently operating PWRs and as such the service experience on existing power stations is a good guide to the expected performance in the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate a low probability of HX fouling leading to blockage. This indicates that the claims being made are in line with operational experience.

Routine maintenance and testing of the RNS HXs will be performed according to the manufacturer's recommendations; this will include routine changeover of the HXs allocated to duty and standby roles. No specific surveillance test requirements are identified.

Hot Leg Suction Isolation – Inner Valves (RNS-PL-V001A/B)

The RCS hot leg to RNS suction inner isolation valves are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain RCS pressure boundary integrity.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1. This code has been specifically developed to qualify pressure-retaining components in safety-significant nuclear power applications. The code, with its supporting testing and examination, provides the foundations for performance claims made on the hot leg suction inner isolation valves.

The valves are very similar to those already in like service on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a low probability of failure to open or close. This indicates that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I; this inside CIV is also qualified for operation in a harsh environment (Table 15A-1). The combination of the ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of two valves in parallel further reduces the probability of failure associated with opening the valves to initiate the RNS. The presence of the hot leg suction outer isolation valves in series with these valves further reduces the probability of failure associated with isolation of the system on demand.

The maintenance and testing arrangements for the hot leg suction inner isolation valves are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Pressure isolation leak testing of these valves is performed on these valves every 2 years. This test will be performed during normal power operation. The maximum leakage requirement for pressure isolation is included in the surveillance requirements for Tech Spec 3.4.15.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

- As CIVs, these are tested in accordance with the Reference 17.11 to verify seat leakage.

Hot Leg Suction Outer Isolation Valves (RNS-PL-V002A/B)

The RCS hot leg to RNS suction outer isolation valves are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain RCS pressure boundary integrity.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the hot leg suction outer isolation valves.

The valves are very similar to those already on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from the valves proposed for the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a low probability of failure to open or close. This indicates that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I (Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III, and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. The provision of two valves in parallel further reduces the probability of failure associated with opening the valves to initiate the RNS. The presence of the hot leg suction inner isolation valves in series with these valves further reduces the probability of failure associated with isolation of the system on demand.

The maintenance and testing arrangements for the hot leg suction outer isolation valves are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The proposed testing is as follows:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Pressure isolation leak testing of these valves is performed on these valves every 2 years. This test will be performed during normal power operation. The maximum leakage requirement for pressure isolation is included in the surveillance requirements for Tech Spec 3.4.15.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

As CIVs, these are tested in accordance with the Reference 17.11 to verify seat leakage.

RNS Return from CVS Containment Isolation Valves (RNS-PL-V061A/B)

The RNS returns from the CVS CIVs are air operated. They fail closed on a loss of motive air supply and hence will inherently move closed and thus fail-safe.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with the testing and examination that supports it, provides the foundations for performance claims made on the RNS return from CVS CIV.

The valves are very similar to those already in service to provide similar functions on currently operating PWRs. As a result the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from the valve proposed for the AP1000 design. The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME III, the valves are also designed and installed to seismic C-I (Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the return from CVS CIV is based around the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

- As CIVs, these are tested in accordance with the “Primary Containment Leakage Rate Test Program” specified in 10 CFR 50, Appendix J (Reference 17.11) to verify seat leakage.

RNS Hot Leg Suction Pressure Relief Valves (RNS-PL-V021A/B)

The RNS hot leg suction pressure relief valves are of the spring-loaded, self-actuated type and operation depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

Each RNS suction line relief valve provides low-temperature overpressure protection for the RCS. Each valve is sized to limit the pressure of the RCS below the minimum pressure limit for the limiting design-basis low-temperature overpressure transients, so that protection is provided even if only one RNS train is in service. The following two limiting transients were identified as the design basis:

- **Mass injection** – Two CVS makeup pumps delivering at the RNS relief valve set pressure at the limiting conditions of circuit temperature.

- **Heat input** – Startup of an RCP with a 27.8°C (50°F) temperature difference between the RCS and the SG secondary side at the limiting conditions of circuit temperature.

The ASME Code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The Code, with its supporting testing and examination, provides the foundations for performance claims made on the RNS hot leg suction pressure relief valves.

The valves are very similar to those already in service to provide the same function. The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III-2, the valves are also designed and installed to seismic C-I (Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring. This is reflective in the low temperature over pressure protection (LTOP) operability for the AP1000 design at 135°C (275°F) rather than a higher temperature (177°C [350°F]) typical to existing PWRs.

The maintenance and testing arrangements for the RNS hot leg suction pressure relief valves are based on the programmes associated with ASME Boiler and Pressure Vessel Code, Section III qualification. The proposed testing is as follows:

- Every valve should be tested as installed, or bench-tested, every 5 years.

- As CIVs, these are tested to verify seat leakage.

RNS Suction Header Containment Isolation Valves (RNS-PL-V022A/B)

The RNS suction header isolation valves are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain isolation of the containment penetration.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the RNS suction header CIVs.

The valves are very similar to those already in service to provide the same function. The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and

installed to seismic C-I (Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the pump suction header isolation valve are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The proposed testing is as follows:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

- As CIVs, these are tested in accordance with the "Primary Containment Leakage Rate Test Program" specified in 10 CFR 50, Appendix J (Reference 17.11) to verify seat leakage.

RNS Discharge Containment Isolation Valves (RNS-PL-V011A/B)

The RNS discharge CIVs are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain isolation of the containment penetration.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the RNS discharge CIV.

The valves are very similar to those already in like service on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate low probability of failure to open or close. This indicates that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I (Table 15A-1). The combination of ASME Boiler and Pressure Vessel Code, Section III and other codes for design and manufacture with the test regime described below will minimise the probability of these failure mechanisms occurring.

The maintenance and testing arrangements for the pump discharge header isolation valve are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

- As CIVs, these are tested in accordance with the "Primary Containment Leakage Rate Test Program" specified in 10 CFR 50, Appendix J (Reference 17.11) to verify seat leakage.

RNS Heat Exchanger Outlet Flow Control Valves (RNS-PL-V006A/B)

The RNS HX flow control valves are air operated and fail open on loss of air. This ensures that they fail to the position providing maximum cooling and so is inherently safe.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3. This code has been specifically developed to qualify pressure-retaining components in safety-significant applications on nuclear power stations. The code, with its supporting testing and examination, provides the foundations for performance claims made on the RNS HX flow control valves.

Whilst routine maintenance and inspection of the RNS HX flow control valves will be performed according to the manufacturer's recommendations, no specific surveillance test requirements are specified.

RNS Heat Exchanger Bypass Flow Control Valves (RNS-PL-V008A/B)

The RNS HX bypass flow control valves are air operated and fail closed on loss of air. This ensures that they fail to the position that provides maximum cooling and so is inherently safe.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

Routine maintenance and inspection of the RNS HX bypass flow control valves will be performed according to the manufacturer's recommendations, no specific surveillance test requirements are specified.

RNS Suction from IRWST Containment Isolation Valves (RNS-PL-V023A/B)

The IRWST suction isolation valves are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service cooling the

IRWST, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain IRWST isolation and containment isolation.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The valves are very similar to those already in like service on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I (Table 15A-1).

Although the generic design of these valves should provide high reliability, the design specification requires that manufacturers identify any specific design features that will provide support in this area.

The maintenance and testing arrangements for the IRWST suction isolation valves are based on the ASME programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Remote position indication of these valves is observed locally during valve exercising to verify proper operation of the position indication. This position indication test is performed every 2 years.

- Full stroke exercise testing of these valves is performed during cold shutdown conditions. Opening during normal power operation may result in damage to equipment or initiation of a reactor trip. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation of the testing interval and these valves will be exercised only when the RNS is aligned to remove core decay heat.

- Operability testing of these valves is performed every 10 years as part of the normal valve in-service testing programme.

- As CIVs, these are tested in accordance with the Reference 17.11 to verify seat leakage.

RNS Discharge to IRWST Isolation Valves (RNS-PL-V024A/B)

The IRWST discharge isolation valves are motor operated, which means they will fail “as is” on loss of power. This is judged appropriate because if the RNS is in service cooling the IRWST, it is required that the valves fail open to maintain cooling; if the RNS is shut down, it is required that the valves fail closed to maintain IRWST isolation.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence

about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I (Table 15A-1).

Routine maintenance and inspection of the IRWST discharge isolation valves will be performed according to the manufacturer's recommendations, no specific surveillance test requirements are specified.

RNS Pump Suction from Cask Loading Pit Isolation Valves (RNS-PL-V055A/B)

The cask loading pit suction isolation valves are motor operated, which means they will fail "as is" on loss of power. This is judged appropriate because if the RNS is in service injecting water from the cask loading pit, it is required that the valves fail open to maintain cooling. If the RNS is shut down, it is required that the valves fail closed to maintain cask loading pit isolation.

The valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service on currently operating PWRs. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate that the claim being made is conservative.

The failure mechanism of concern would involve the valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I (Table 15A-1).

Routine maintenance and inspection of the cask loading pit suction isolation valves will be performed according to the manufacturer's recommendations, no specific surveillance test requirements are specified.

RNS Discharge Check Valves CIV – IRC (RNS-PL-V013A/B)

The operation of the discharge check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a value that is an order of magnitude better than the value assumed in the PSA.

The maintenance and testing arrangements for the discharge check valve are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- To exercise these valves closed requires draining of the associated piping and performing a backflow leakage test. This testing would impose undue personnel radiation exposure and place the RNS in an undesirable operational configuration. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation and these valves will be fully stroke-tested during refuelling shutdowns.

- As CIVs, these are tested in accordance with the "Primary Containment Leakage Rate Test Program" specified in 10 CFR 50, Appendix J (Reference 17.11), to verify seat leakage.

RNS Discharge RCS Pressure Boundary Stop Check Valves (RNS-PL-V015A/B)

The operation of the RNS discharge RCS pressure boundary stop check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) do not differentiate between stop check valves and swing check valves, but for check valves indicate values that are an order of magnitude better than the values assumed in the PSA.

The maintenance and testing arrangements for the discharge RCS pressure boundary stop check valve are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- The maximum leakage requirement for pressure isolation is included in the surveillance requirements for Tech Spec 3.4.15.

RNS Discharge RCS Pressure Boundary Check Valves (RNS-PL-V017A/B)

The operation of the RNS discharge RCS pressure boundary check valves depends only upon the pressure difference across them and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valves are manufactured from stainless steel to ensure compatibility with the borated RCS fluid that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-1.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate values that are an order of magnitude better than the values assumed in the PSA and indicate that the claims against these valves are conservative.

The maintenance and testing arrangements for the discharge RCS pressure boundary check valve are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- To exercise these valves closed requires draining of the associated piping and performing a backflow leakage test. This testing would impose undue personnel radiation exposure and place the RNS in an undesirable operational configuration. As a result, the ASME Boiler and Pressure Vessel Code rules allow a relaxation and these valves will be fully stroke-tested during refuelling shutdowns.

- Pressure isolation leak testing of these valves is performed on these valves every 2 years. The maximum leakage requirement for pressure isolation is included in the surveillance requirements for Tech Spec 3.4.15.

17.6 Containment

17.6.1 Passive Containment Cooling

17.6.1.1 Role

A detailed description of the passive containment cooling system (PCS) is given in Section 6.6. Further design details of this system and its constituent components are delineated in Reference 17.27.

The PCS is designed to limit and reduce containment pressure following a containment pressurisation event and provide the ultimate heat sink for long-term RCS decay heat removal following accidents. The system supports the heat transfer/residual heat removal primary safety function.

For intact RCS faults where the IRWST boils or where a LOCA or steam line break releases steam directly into containment, the steam circulates by natural convection and condenses on the inside surface of the containment shell which is being cooled by the operation of the PCS. Heat is transferred through the containment vessel by conduction and is dispersed to the atmosphere outside by convection. To enhance the external heat transfer process, water is released from the passive containment cooling water storage tank (PCCWST), which contains sufficient water for 72 hours (three days) of operation. This water flows over the external surface of the containment, is heated, and through evaporation provides a high heat transfer rate. The resulting humid air is swept into the atmosphere by the natural circulation.

The passive containment cooling ancillary water storage tank (PCCAWST) exists as an additional, dedicated, on-site source of make-up water to the containment shell or to the PCS PCCWST and hence allow the system to operate beyond the 72 hours for which the PCCWST is sized. The PCCAWST provides enough water for the plant between 72 hours and 7 days. If the PCCAWST is not available or after 7 days condenser cooling water from the river or sea (or other onsite source) can be used to provide PCS makeup.

The PCS is supported by the essential electrical system in the provision of its safety function.

The PCS supports the PXS decay heat removal function by transferring core decay heat to the environment, and condensing steam on the inside containment shell which is returned to the IRWST. The PCS also supports spent fuel cooling since the PCS PCCWST water can be used for makeup to the SF pool when the decay heat of the fuel inside containment is less than or equal to a set amount and no ac electrical power is available. The PCS also provides a

seismically qualified source of water for the fire protection system (FPS) for use on fires in safety Category A, Class 1 equipment in the non-radiological portion of the auxiliary building. This water source is contained in the PCCWST and is a limited quantity to preclude the possibility of the FPS water flooding and disabling the Class 1 SSCs in this portion of the auxiliary building.

17.6.1.2 System Components and Equipment Contributing to Safety Function

The containment vessel itself is a large pressure vessel and is discussed further in the structural integrity section of this PCSR (Chapter 20). The following PCS components contribute to it fulfilling its safety function:

- **PCCWST (PCS-MT-01)** – This is a stainless-steel-lined concrete tank. It is supported by the top of the shield building above the containment vessel and is intended to provide the source of water, by gravity flow, for passive evaporative cooling of the containment vessel outer surface for at least 72 hours. This is a safety requirement.

- **Recirculation Heater (PCS-MB-01)** – This is a 100-kW electrical heater provided in the PCCWST recirculation path. The heater assembly is constructed from stainless steel and the heater element sheaths from Inconel. The safety requirement is to transfer heat to the PCCWST water to ensure that it does not freeze. The heater is required to maintain the water in the PCCWST in a suitable condition to meet its safety requirement but the heater itself is not required to be available for the PCCWST to operate. Further analysis is therefore not required.

- **PCS Recirculation Pumps (PCS-MP-01A/B)** – These are electrically driven centrifugal constructed from stainless steel. They recirculate the water in the PCCWST to ensure that it is maintained in a homogeneous condition (chemistry and temperature). They can also be used as one way to pump water up to the PCCWST to allow it to maintain cooling duty beyond the 72 hours provided for by the tank storage capacity. The safety requirement of the pumps is to provide this capability to maintain PCS cooling duty beyond 72 hours. The recirculation pump is not required to be available for the PCCWST to operate. If it is unavailable after 72 hours, offsite diesel powered pumps can be used in its stead. Further analysis is therefore not required.

- **Water Distribution Bucket and Weir (PCS-MT-03, MT-04)** – The bucket is stainless-steel. There are 16 equally spaced slots around the circumference of the vessel. The bucket is positioned above the centre of the top of the containment dome to ensure that the PCS water flow is evenly distributed into eight radial sectors at the centre of the dome. The PCS includes two water distribution weirs which include a selection of divider plates and dams secured to the top of the containment dome below the bucket. These are arranged to spread the water flow relatively evenly so that it passes down over the containment outer surface in a thin film. This is a safety requirement as it maximises the heat transfer through evaporation.

- **PCCAWST (PCS-MT-05)** – This is a cylindrical carbon steel tank that is situated at ground level and its contents can be pumped to the PCCWST by the recirculation pumps. The safety requirement for the tank is to provide makeup to extend the operation of the PCS beyond 72 hours. Note that site water (river / sea) can be used for this function if this tank is not available.

- **PCCWST Outlet Air-Operated Isolation Valves (PCS-PL-V001A/B)** – These are 150-mm DN (6-inch), air-operated butterfly valves that fail open on loss of air supplies.

The valves are normally closed and open on receipt of a PMS containment cooling actuation signal. There is also a separate, single solenoid-operated air valve, driven from the DAS that can be energised to dump the air supply and provides an alternate method to open these valves. The safety requirement is to enable the water contained in the PCCWST to be discharged onto the outside surface of the containment vessel.

- **PCCWST outlet motor-operated isolation valve (PCS-PL-V001C)** – This is a 150-mm DN (6-inch), motor-operated gate valve that fails "as is" on loss of power. The valve is normally closed and opens on receipt of a containment cooling actuation signal from either the PMS or the DAS. The safety requirement is to enable the water contained in the PCCWST to be discharged onto the outside surface of the containment vessel.

- **PCCWST outlet motor-operated line isolation valves (PCS-PL-V002A/B/C)** – These are 150-mm DN (6-inch), motor-operated gate valves that fail "as is" on loss of electrical power. The valves are required to be open for their respective PCCWST isolation valves to perform their safety function. With the reactor at power, they are left in their open position with the actuator power supplies isolated. They do, however, also receive a confirmatory open signal from the PMS. Further analysis is therefore not required.

17.6.1.3 Claims on Components and Equipment

Passive Containment Cooling Water Storage Tank (PCS-MT-01)

The PCCWST provides the source of water to enable passive cooling of the containment and is instrumental in establishing a heat sink for decay heat removal. Decay heat removal is a Category A safety function and the tank is Class 1. See Appendix 15A.

The requirement is that the tank will provide enough water to ensure that sufficient evaporative cooling from the external surface of the containment vessel is maintained for at least 72 hours.

Recirculation Heater (PCS-MB-01)

The heater reduces the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident by precluding freezing of the PCCAWST tank after 72 hours following an accident. This a category B function and the heater is Class 2.

PCS Recirculation Pumps (PCS-MP-01A/B)

The pumps provide means to supply water to Containment and/or the Spent Fuel Pool after 72 hours following an accident. Maintenance of a Category A safety function beyond 72 hours is a Category B safety function and the pumps are Class 2. See Appendix 15A.

Water Distribution Bucket and Weir (PCS-MT-03, MT-04)

The water distribution bucket and weirs ensure that water from the PCCWST is correctly distributed on the surface of the containment vessel to ensure that adequate cooling by evaporation is available for removal of decay heat. Decay heat removal is a Category A safety function and the water distribution bucket and weirs are Class 1. See Appendix 15A.

Passive Containment Cooling Ancillary Water Storage Tank (PCS-MT-05)

The PCCAWST provides the source of water to enable passive cooling of the containment, for decay heat removal, to be provided beyond 72 hours. Maintenance of a Category A safety function beyond 72 hours is a Category B safety function and the PCCAWST is Class 2. See Appendix 15A.

PCCWST Outlet Air-Operated Isolation Valves (PCS-PL-V001A/B)

The PCCWST outlet air-operated, fail-open, isolation valves open to initiate flow from the PCCWST over the outside surface of containment to establish cooling and decay heat removal. Decay heat removal is a Category A safety function. These valves are Class 1. See Appendix 15A.

There are three isolated flow paths from the PCCWST that supply water to the distribution bucket from a common PCCWST outlet discharge header. As such, any one of the three PCCWST outlet isolation valves (these two air operated valves or the diverse motor operated isolation valve, discussed below) opening will satisfy the safety function, provided its associated line isolation valve is also open.

PCCWST Outlet Motor-Operated Isolation Valve (PCS-PL-V001C)

The PCCWST outlet motor-operated isolation valve opens to initiate flow from the PCCWST over the outside surface of containment to establish cooling and decay heat removal. Decay heat removal is a Category A safety function. This valve is Class 1. See Appendix 15A.

There are three isolated flow paths from the PCCWST that supply water to the distribution bucket from a common PCCWST outlet discharge header. As such, any one of the PCCWST outlet isolation valves opening (this motor-operated valve or the diverse air-operated valves, discussed above) will satisfy the safety function, provided its associated line isolation valve is also open.

PCCWST outlet motor-operated line isolation valves (PCS-PL-V002A/B/C)

With the reactor at power, they are left in their open position with the actuator power supplies isolated. They must maintain their position to allow flow to initiate flow from the PCCWST over the outside surface of containment to establish cooling and decay heat removal. Decay heat removal is a Category A safety function. This valve is Class 1. See Appendix 15A.

There are three isolated flow paths from the PCCWST that supply water to the distribution bucket from a common PCCWST outlet discharge header. As such, any one of the PCCWST outlet isolation valves opening (this motor-operated valve or the diverse air-operated valves, discussed above) will satisfy the safety function, provided its associated line isolation valve is also open.

17.6.1.4 Justification of Claims on Components and Equipment

Passive Containment Cooling Water Storage Tank (PCS-MT-01)

The PCCWST provides a large quantity of water above the containment vessel that can be released to flow by gravity and provide evaporative heat transfer to the ultimate heat sink. It is entirely passive in nature and requires no pumps or mechanical fluid circulation devices to operate. This confers a high degree of inherent safety.

The tank is manufactured from concrete and is lined with stainless steel. It is built to American Concrete Institute (ACI) standards.

The tank has four connections to the outlet pipework arranged at different levels within the tank. All the outlet pipes have separate screens that protect the pipe from being blocked by debris. When recirculated, the water in the tank is very slowly circulated which will result in foreign objects settling in the tank. When activated for containment cooling, the outlet flow from the tank only results in very slow water velocity in and at the bottom of this large tank Settled debris will not be swept to even the lowest of the four outlets. This lowest outlet is elevated above the bottom of the tank to prevent debris from directly flowing into the outlet. Therefore, loss of water flow due to blockage within the PCCWST is considered to be highly unlikely. In the unlikely event that the lower screen becomes plugged, it is estimated that the PCS water will be supplied from the higher level pipes at a lower flow rate for at least 40 hours even with a completely blocked lower screen.

The maintenance and testing programme is fulfilled through the Tech Spec surveillance requirements:

- The PCCWST stored water volume and stored water temperature will be verified every 7 days.

- The capability of the tank to meet water supply requirements will be demonstrated as part of the surveillance testing programme every 10 years.

PCS Recirculation Pumps (PCS-MP-01A/B)

These are industry standard pumps constructed to Hydraulic Standards Institute with a long history of reliability. These components included in the design reliability assurance programme (D-RAP) program (see Chapter 5). which provides confidence that availability is designed into the plant and that availability is maintained throughout plant life. The PCS Reciculation Pumps are intended to provide water to support the PCS in the period beyond 72 hours from its initiation. This timescale is considered to provide adequate time to address issues associated with operation of the pumps and therefore no specific justification is required to support this requirement.

Water Distribution Bucket and Weirs (PCS-MT-03, MT-04)

The water distribution bucket and weirs are passive fixtures above and on the top of the containment vessel. Their function is based entirely on the inherent physical properties of water and water flow and therefore there is a very high confidence that they will function as designed.

The PCS water distribution weirs are used to ensure effective wetting of the dome and vertical sides of the containment shell. The weirs are of limited height and would, in a relatively short time (minutes), be flooded and overflow; therefore, they cannot completely block water flow. The weirs are sectored such that partial blockage of one weir will only affect at most 1/16 of the shell. The nature of the system, and thus sensitivity to shell coverage, is not significant; hence, loss of heat transfer capacity due to a reduction in wetted area as a result of water blockage of the weir is considered to be highly unlikely. The maintenance and testing programme is fulfilled through the Tech Spec surveillance requirements:

- The capability of the water bucket and weirs to meet water supply requirements will be demonstrated as part of the surveillance testing programme every 10 years.

Passive Containment Cooling Ancillary Water Storage Tank (PCS-MT-05)

The PCCAWST is intended to provide water to support the PCS in the period beyond 72 hours from its initiation. This timescale is considered to provide adequate time to address issues associated with operation of the PCCAWST and therefore no specific justification is required to support this requirement.

17.6.1.5 Passive Containment Cooling Water Storage Tank Outlet Air-Operated Isolation Valves (PCS-PL-V001A/B)

The PCCWST outlet air-operated isolation valves are designed to fail open in the event of loss of air supply. This is an inherently safe mechanism, meaning that only in the event of a valve sticking will there be a failure to a condition other than safe.

The valves are manufactured from stainless steel to ensure compatibility with PCCWST water that is in contact with them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valves are very similar to those already in like service in many operating power stations. As a result the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of a failure to open is comparable to the value being claimed.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valves are also designed and installed to seismic C-I.

The maintenance and testing arrangements for the PCCWST outlet air-operated isolation valves are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- A system flow test is performed every 10 years and this will confirm valve operating performance.

PCCWST Outlet Motor-Operated Isolation Valve (PCS-PL-V001C)

The PCCWST outlet motor-operated isolation valve is designed to offer a diversity of actuation to its air operated counterparts. It is a gate valve as opposed to butterfly valves to offer diversity of valve design also. This serves to maximise the reliability such that the PCCWST water supply function can be provided.

The valve is manufactured from stainless steel to ensure compatibility with PCCWST water that is in contact with them. It is designed to ASME Boiler and Pressure Vessel Code, Section III-3.

The valve is very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from the valve proposed for the AP1000 design. Data collected from in-service plants (Reference 17.7, Table 5.1) indicate a probability of failure to open is comparable to the value being claimed.

The failure mechanism of concern would involve a valve sticking or jamming. This could be a result of wear, corrosion, or maintenance-induced failure. In addition to being designed to ASME Boiler and Pressure Vessel Code, Section III, the valve is also designed and installed to seismic C-I.

The maintenance and testing arrangements for the PCCWST outlet motor-operated isolation valve are based on the programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is performed every 2 years.
- A system flow test is performed every 10 years and this will confirm valve operating performance.

17.6.2 Containment Isolation

17.6.2.1 Role

A detailed description of the containment isolation system is given in Section 6.7. Further design details of this system and its constituent components are delineated in Reference 17.28.

The provision of a containment structure is key to supporting the primary safety function of containment. The structural integrity issues surrounding the containment vessel are covered in Chapter 20, but the provision of containment isolation facilities for the individual process lines that pass through the containment boundary are discussed here and elsewhere in this PCSR.

Most fluid system penetrations through the containment boundary are equipped with a CIV inside the containment itself, and a CIV situated external to the containment. In some cases, there is a single valve and the pipework itself represents the containment boundary (e.g., the SG and main steam lines). Where pipework branches are adjacent to the penetration, there may be more than one line that requires isolation to achieve the safety function. As a result, on some systems there may be more than one inside CIV or outside CIV. Isolation of the flow path at either the inside or outside location(s), along with integrity of the fluid system pipework, will ensure that the individual contribution to the containment safety function of that penetration is ensured.

For the systems that provide other safety functions and are addressed elsewhere in Chapters 17 and 23, the safety requirement of the CIVs and justification of this requirement are discussed in the individual system sections.

This section addresses the remaining valves where there are CIVs that have a safety function but the rest of the system does not.

The containment isolation system is supported by the essential electrical system in achieving its safety function.

The containment isolation system does not support other systems in the achievement of their safety functions.

17.6.2.2 System Components and Equipment Contributing to Safety Function

The isolation of containment is established with provision of internal and external isolation valves for fluid systems, or by the fitting of an access hatch for personnel and equipment entry points.

The isolation valves are all sized to match the system pipework associated with the containment penetration; the valve type is selected to match the fluid, and conditions under which isolation is required, for each system. A full list of containment penetrations and associated isolation valves is given in Table 15A-1.

17.6.2.3 Claims on Components and Equipment

Isolation Valves

All CIVs are required to close to isolate the respective penetrations and contribute to the establishment of containment integrity. Preventing the release of radioactive material from the containment is a Category A safety function. See Appendix 15A. In all cases, the CIVs are Class 1. See Appendix 15A.

Each penetration has inner and outer isolation valves and closing either valve will achieve the safety function (if there is branched pipework, then all of the valves providing either the inner or the outer isolation must close). The requirement is therefore that for each penetration, at least one valve, or set of valves, must close.

Access Hatches (CNS-MY-Y01, Y02, Y03, Y04)

The access hatches provide the containment boundary for the passage of equipment, maintenance and personnel. Preventing the release of radioactive material from the containment is a Category A safety function. See Appendix 15A. In all cases, the containment access hatches are Class 1. See Appendix 15A.

The two equipment and maintenance hatches will remain in place at all times during power operation and the requirement is that they will have been fitted, following use, in such a way to provide adequate leak tightness. The two personnel hatches are each comprised of two interlocked doors. These hatches may be used during power operation but at least one of the two doors is always closed in order to provide adequate leak tightness.

17.6.2.4 Justification of Claims on Components and Equipment

Isolation Valves

The air-operated CIVs fail closed and so will fail safe. This is justified for systems when inadvertent isolation due to actuator faults can be tolerated. The motor-operated valves will fail “as is” and therefore not in a position that is necessarily safe in respect to containment isolation. This is justified for systems where inadvertent operation due to actuator faults would, in itself, give rise to safety concerns associated with the system involved.

The valves are all designed to ASME Boiler and Pressure Vessel Code, Section III-2. They are also designed to seismic C-I requirements.

The valves are very similar to those already in like service on many operating power stations. As a result, the information from testing these in-service valves offers a high degree of confidence about the reliability to be expected from these valves. Data collected for in-service plants (Reference 17.7, Table 5.1) are comparable to the values being claimed.

Testing of containment isolation equipment is performed in accordance with Reference 17.11:

- A local leak rate test (LLRT) of an individual penetration where test connections are used to pressurise the individual penetration and confirm that leakage remains within acceptable limits.
- An ILRT where the whole containment building is pressurised to confirm that leakage remains within acceptable limits.

The frequency of these tests is governed by Tech Specs.

Access Hatches (CNS-MY-Y01, Y02, Y03, Y04)

The access hatch penetrations are all designed to ASME Boiler and Pressure Vessel Code, Section III, NE (MC). They are also designed to seismic C-I requirements.

Testing of containment isolation equipment is performed in accordance with Reference 17.11:

- LLRT of an individual penetration where test connections are used to pressurise the individual penetration and confirm that leakage remains within acceptable limits.
- ILRT where the whole containment building is pressurised to confirm that leakage remains within acceptable limits.

The frequency of these tests is governed by Tech Specs.

17.7 Light Load Handling Systems

17.7.1 Refuelling Machine (FHS-FH-01)

17.7.1.1 Role

A detailed description of the refuelling machine is given in Section 6.12. Further design details of the Fuel Handling System (FHS) and its constituent components are delineated in Reference 17.29.

The refuelling machine is required to move new and spent nuclear fuel between the reactor vessel and the fuel transfer system in containment. The system contributes to the containment primary safety function by ensuring that all movement of fuel is carried out with minimum risk of damaging fuel cladding directly, or in such a way that damage could become apparent during either further handling or irradiation. In this way, the opportunity for release of radioactive material is minimised.

The refuelling machine is also designed so that, when handling irradiated fuel assemblies during operation, there will always be an adequate depth of water to maintain adequate shielding of staff on the refuelling machine gantry.

The main hazard to containment integrity, and hence to maintenance of the primary safety function, comes from either dropping fuel assemblies or driving them into obstacles through incorrect operation of the handling equipment. The protection from these hazards comes from appropriate design of the handling equipment itself and the provision of appropriate interlocks to control fuel handling movements. The provision of interlocks is through a mixture of electrical and mechanical means.

The refuelling machine is not supported by other systems in the provision of its safety functions. It does not support other systems in the provision of their safety functions.

17.7.1.2 System Components and Equipment Contributing to Safety Function

The refuelling machine is designed in accordance with the guidelines of the American Nuclear Society (ANS) (Reference 17.13). This specifies a number of necessary design features and the following subsystems are critical in ensuring that the system can support its safety function:

- **Mast hoist** – The mast hoist has numerous redundent features complient with Reference 17.14, such as with wire ropes and redundant braking systems designed to hold loads up to 150 percent of the rated load. The safety requirement of the mast hoist is to minimise the risk of fuel assembly damage, and consequently the challenge to fuel cladding integrity, through being dropped.

- **Mast** – The mast itself has two parts: the inner mast and outer mast that together form a telescopic assembly to hold a fuel assembly during transport around the refuelling cavity in containment. Guide bars in the outer mast are designed to restrain a fuel assembly at each corner of the fuel. This effectively “sheaths” the fuel during transit from the reactor to the fuel transfer mechanism. The safety requirement is therefore to protect fuel from any impact during traversing operations. The design of the inner mast provides an attachment point for the gripper assembly. This is also a safety requirement.

- **Gripper** – The gripper engages the mast hoist mechanism onto the top of the fuel assembly. The gripper is designed to “float” so that misalignment with the fuel assembly can be accommodated to allow the four engagement fingers to correctly latch onto the fuel assembly. The design is such that once the weight of the fuel assembly is being born by the gripper; it holds the gripper in the “latched” position and prevents release of the fuel assembly. The safety requirement of the gripper is to minimise the risk of fuel assembly damage, and consequently the challenge to fuel cladding integrity, through it being dropped.

- **Bridge and trolley** – The bridge and trolley provide the capability to move the mast around the refuelling cavity in the containment building. They are designed in accordance with applicable portions of Crane Manufacturers Association of America specification 70 for class A service. The design provides numerous interlocks to prevent traversal into inappropriate areas, and the machine is designed with appropriate restraints to ensure that it remains in position in the event of a seismic disturbance. The safety requirement of the bridge and trolley is to ensure that fuel movements are confined to areas of the refuelling cavity where there is no risk of damage to the fuel assembly by impact.

- **Monorail hoist** – The monorail hoist is used to support the control rod drive shaft unlatching tool and various other long-handle tools. The safety requirement is to ensure that fuel in the reactor vessel is not damaged as a result of this tool being dropped. However, all of the tools are sufficiently light that, even if dropped, it could not cause damage to fuel. There is therefore no further analysis of the monorail hoist.

17.7.1.3 Claims on Components and Equipment

Mast Hoist

The mast hoist is required to ensure that there is no damage to a lifted fuel assembly from being dropped. Protecting against damage to the integrity of spent fuel, and consequent release of radioactive material, is a Category A safety function and the hoist is Class 2. See Appendix 15A.

The requirement against the mast hoist is that any single failure of the redundant components in the hoist equipment train will result in the fuel assembly being held in position.

Mast

The mast itself is required to ensure that there is no damage to a fuel assembly in the fully raised position through side impact as it is being moved around the refuelling cavity. Protecting against damage to the integrity of spent fuel, and consequent release of radioactive material, is a Category A safety function and the mast is considered Class 2. See Appendix 15A.

The mast is also required to ensure that an adequate depth of water to provide adequate shielding is maintained above any irradiated fuel assembly being transported. Minimisation of occupational radiation exposure is a Category C safety function and the mast is considered Class 3 in this respect.

Gripper

The gripper is required to ensure that there is no damage to a lifted fuel assembly by preventing it from being dropped. Protecting against damage to the integrity of spent fuel, and the consequent release of radioactive material, is a Category A safety function and the gripper is Class 2. See Appendix 15A.

The requirement against the gripper is that it will not release a fuel assembly in any position other than when the fuel assembly is correctly lowered into the reactor core, the fuel transfer mechanism, or the in-containment fuel storage rack.

Bridge and Trolley

The bridge and trolley are required to maintain good alignment of the mast during raising and lowering, and also to ensure that the fuel is moved in a controlled fashion within permissible areas, all to minimise the risk of fuel damage including during a seismic event. Protection against damage to the integrity of spent fuel is a Category A safety function and the bridge and trolley are Class 2. See Appendix 15A.

17.7.1.4 Justification of Claims on Components and Equipment

Mast Hoist

Whilst there is no "inherently safe" way to design lifting equipment, the provision of multiple load paths along with substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The mast hoist is designed with the following principal provisions to achieve a high level of hoist integrity:

- The minimum design load is approximately 120 percent of the maximum expected working load.
- The hoist has twin redundant brakes, one mechanically actuated and one electrically actuated, either of which can restrain 150 percent of the rated design load.
- Twin wire ropes are used to support the inner mast, either of that is capable of carrying the full load of the inner mast and an associated fuel assembly.
- The design loads on the wire ropes do not exceed 0.2 times the average breaking strength.
- The attachment to the inner mast is through a load-equalising device to ensure that each wire rope always takes an equal share of the load.
- The wire ropes are manufactured from stainless steel to provide corrosion resistance against the high-humidity containment atmosphere and potential contact with boric acid solution.

The design is very similar to that used in currently operating PWRs and there have been no failures of mast system hoists resulting in dropped fuel as discussed further in Appendix 17A. This provides support to the reliability claims.

The maintenance and testing arrangements for the mast hoist are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- At the beginning of each refuelling outage and prior to the handling of irradiated fuel, the mast hoist will be tested to 125 percent of the design rated load.
- Prior to each refuelling outage, there will be an inspection for loose parts and foreign objects.
- Prior to each outage, checks will be carried out to demonstrate full functionality of the mast hoist.

Mast

The mast provides a physical container around the fuel assembly being moved. This is not dependent on any control or actuation systems and does not require any power supplies. As a result, it provides an inherently safe arrangement for the prevention of damage to the fuel during movement.

The mast is manufactured from stainless steel to ensure compatibility with the borated water environment in which it operates. It is also designed as seismic Category II (C-II). The principal provisions in the design for achieving a high level of fuel protection are:

- The guide bars in the outer mast are adjustable to ensure that they can be set up with fine tolerance to the grid straps on the fuel. This allows the fuel to be held tightly and securely within the mast.

- The mast provides physical restraint stops to prevent irradiated fuel from being raised to a point where an inadequate depth of water for shielding remains above it.

- Control interlocks are associated with the mast to ensure that full movement of the refuelling machine bridge and trolley cannot take place unless a fuel assembly is correctly stowed in the mast.

The design is very similar to that used in currently operating PWRs and from a review of NUREG 1774, 30 crane events involving fuel assembly drops or damage were identified during a 34+ year period in the US fleet. None of these events resulted in fuel cladding damage or any release of radioactivity, and only one was associated with the failure of a hoist. This provides support to the reliability claims.

The maintenance and testing arrangements for the mast are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to each refuelling outage, there will be an inspection for loose parts and foreign objects.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the mast assembly.

Gripper

Whilst there is no “inherently safe” way to design lifting equipment, the provision of multiple load paths along with substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The gripper is manufactured from stainless steel to ensure compatibility with the borated water environment in that it operates. It is also designed as seismic C-II. The principal provisions in the design for achieving a high level of lifting integrity are:

- The gripper design has four “fingers” that grip the fuel assembly being lifted. The design ensures that any two of these will adequately support the weight of the fuel assembly.

- The gripper head is designed to float so that it can move to align correctly when engaging a fuel assembly.

- The design of the gripper assembly is such that once a fuel assembly has been latched into position any load on the latches from lifting operations will tend to cause the latch mechanism to engage further. This feature is not dependent on external actuation or the provision of separate power supplies and so inherently supports the requirement of secure lifting.

- The gripper assembly is designed so that the refuelling machine cannot raise a fuel assembly unless the gripper is fully engaged.

The design is very similar to that used in currently operating PWRs. This provides support to the reliability claims.

The maintenance and testing arrangements for the gripper are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- At the beginning of each refuelling outage and prior to the handling of irradiated fuel, the gripper will be tested to 125 percent of the design rated load.

- Prior to each refuelling outage, there will be an inspection for loose parts and checks of the limit switches and limit switch actuators.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the gripper.

Bridge and Trolley

The bridge and trolley run on machined rails with one rail used by guide rollers to control lateral movement as well as for support. This design ensures that movement can be limited to known areas without use of separate protection equipment, and is an inherently safe approach.

The bridge and trolley are constructed from a coated carbon steel to provide protection against the atmospheric environment in the containment building. They are also designed as seismic C-II. The principal provisions to ensure that fuel cannot be damaged during handling operations, especially through contact with fittings in the refuelling cavity, are:

- Positive stops are provided on the trolley rails to prevent the mast from contacting the wall of the refuelling cavity. Energy-absorbing devices are provided to handle impact with the trolley moving at maximum traverse speed.

- Positive stops are provided on the bridge rails to prevent the mast from contacting the wall of the refuelling cavity. Energy-absorbing devices are provided to handle impact with the bridge moving at maximum traverse speed.

- The bridge propulsion motors are designed so that an integral brake is engaged when power is not being supplied to move the bridge.

- The trolley propulsion motors are designed so that an integral brake is engaged when power is not being supplied to move the trolley.

- The speeds of the bridge and trolley have been set such that inertia loads on fuel assemblies during handling operations do not exceed allowable limits.

- Hold-down devices are provided on both the trolley rails and the bridge rails to prevent the bridge or trolley from leaving the rails in the event of a seismic occurrence.

The design is very similar to that used in currently operating PWRs and from a review of NUREG 1774, 30 crane events involving fuel assembly drops or damage were identified during a 34+ year period in the US fleet. None of these events resulted in fuel cladding

damage or any release of radioactivity, and only one was associated with the failure of a hoist. This provides support to the reliability claims.

The maintenance and testing arrangements for the bridge and trolley are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to each refuelling outage, there will be an inspection for loose parts, an inspection of exposed gears, and checks of the limit switches and limit switch actuators.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the bridge and trolley.

17.7.2 Fuel Handling Machine (FHS-FH-02)

17.7.2.1 Role

A detailed description of the fuel handling machine is given in Section 6.12. Further design details of the FHS and its constituent components are delineated in Reference 17.29.

The fuel handling machine is required to move new and irradiated nuclear fuel within the spent fuel pool and from the spent fuel storage racks in the auxiliary building fuel handling area to the fuel transfer system outside containment. The system contributes to the containment primary safety function by ensuring that all movement of fuel is carried out with minimum risk of damaging fuel cladding directly, or in such a way that damage could become apparent during further handling or irradiation. In this way, the opportunity for release of radioactive material is minimised.

The fuel handling machine is also designed to limit the lift height so that during operation, when handling irradiated fuel assemblies, there will always be an adequate depth of water to maintain adequate shielding of staff on the fuel handling machine gantry.

The main hazard to containment integrity, and hence to maintenance of the primary safety function, comes from either dropping fuel assemblies or driving them into obstacles through incorrect operation of the handling equipment. The protection from these hazards comes from appropriate design of the handling equipment itself and the provision of appropriate interlocks to control fuel handling movements. Interlocks are provided through a mixture of electrical and mechanical means.

The fuel handling machine is not supported by other systems in the provision of its safety functions. It does not support any other systems in the provision of their safety functions.

17.7.2.2 System Components and Equipment Contributing to Safety Function

The fuel handling machine is designed in accordance with the guidelines in Reference 17.13. This specifies a number of necessary design features, the following are critical in ensuring that the system can support its safety function:

- **New Fuel Handing Area Hoist** – This hoist has twin wire ropes and redundant braking systems designed to hold loads in excess of its rated value. The safety requirement of the hoist is to minimise the risk of damage to spent fuel assemblies in the fuel storage racks from the impact of dropped loads. It is also required to ensure that new fuel cannot be

subject to any impact damage that might result in fuel failure during further handling post-irradiation.

- **Spent Fuel Pool Area Hoist** – This hoist also has twin wire ropes and redundant braking systems designed to hold loads in excess of the rated value.. The safety requirement of the hoist is to minimise the risk of damage to spent fuel assemblies from their being dropped during fuel handling operations.

- **Bridge and hoist trolley(s)** – The bridge and hoist trolley(s) provide the facility to move items attached to either the New Fuel Handing Area Hoist or Spent Fuel Pool Area hoists around the fuel handling facility in the auxiliary building. The design provides numerous interlocks to prevent traversal into inappropriate areas and the machine is designed with appropriate restraints to ensure that it remains in position in the event of a seismic disturbance. The safety requirement of the bridge and hoist trolley(s) is to ensure that fuel movements are confined to areas of the refuelling cavity where there is no risk of damage to the fuel assembly from impact.

- **Fuel assembly handling tools** – The fuel assembly handling tools are suspended from the fuel handling machine hoists with an appropriate choice of tool made for each operation. Each tool contains a latching mechanism to connect to the top nozzle box of a fuel assembly. The design is such that once the weight of the fuel assembly is being borne by the mechanism, it holds it in the "latched" position and prevents release of the fuel assembly or a control component. The safety requirement of the handling tools is to minimise the risk of fuel assembly damage, either directly through being dropped, or consequently as a result of dropping on the spent fuel storage racks.

17.7.2.3 Claims on Components and Equipment

New Fuel Handling Area Hoist

This hoist is required to ensure that no loads can be dropped onto the spent fuel storage racks with the consequential risk of damage to the spent fuel and potential release of radioactive material. Protection against damage to the integrity of spent fuel is a Category A safety function and the hoist is Class 2. See Appendix 15A.

This hoist has dual redundant components such that either of the respective components can perform the full duty. Where redundancy is not available, as on the hoist hook, a double design safety factor is employed. The requirement against the New Fuel Handling Area hoist is that any credible single failure in the hoist equipment train will result in the fuel assembly being held in position.

Spent Fuel Pool Area Hoist

The Spent Fuel Pool Area hoist is required to ensure that spent fuel assemblies cannot be dropped whilst they are being handled, leading to either damage to the dropped assembly or consequential damage to fuel in the spent fuel storage racks. Protection against damage to the integrity of spent fuel is a Category A safety function and the hoist is Class 2. See Appendix 15A.

The Spent Fuel Pool Area hoist has some dual redundant components such that there is a measure of redundancy in performing the lifting duty. The requirement against the Spent Fuel Pool Area hoist is that the risk of dropping a fuel assembly is very low and that the results of any drop do not lead to a significant risk of release of radioactive material.

Bridge and Hoist Trolley(s)

The bridge and hoist trolley(s) are required to ensure that the hoists and loads that they may be supporting are moved in a controlled fashion within the permissible area to minimise the risk of damage. Protection against damage to the integrity of spent fuel is a Category A safety function and the bridge and hoist trolley(s) are Class 2. See Appendix 15A.

Fuel Assembly Handling Tools (FHS-FH-52)

The fuel handling tools are required to ensure that there is no damage to a lifted fuel assembly from being dropped. Protecting against damage to the integrity of spent fuel, and consequent release of radioactive material, is a Category A safety function and the spent fuel handling hoist tool is Class 2. The new fuel handling tool is Class 2. See Appendix 15A. New fuel cannot be transported over the spent fuel racks using the fuel handling machine hoist and the new fuel handling tool. This is controlled by interlock.

The requirement against the fuel assembly handling tools is that they will not release a fuel assembly in any position other than when the fuel assembly is correctly lowered into the fuel racks, the fuel transfer mechanism, or the spent fuel storage flask.

17.7.2.4 Justification of Claims on Components and Equipment

New Fuel Handling Area Hoist

Whilst there is no "inherently safe" way to design lifting equipment, the provision of multiple load paths and substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The New Fuel Handling Area hoist is designed against NUREG-0554 (Reference 17.14). It is also designed as seismic C-II. The principal provisions to achieve a high level of hoist integrity are:

- The hoist has a mechanical ratchet and pawl brake and two independent electric brakes. Either one is capable of handling 150 percent of rated load.
- The braking arrangements are such that they are automatically set whenever drive power is removed from the hoist motor.
- There are dual lifting cables, each capable of taking the full rated load.
- The hoist ropes are stainless steel to provide compatibility with the expected atmosphere in the fuel handling area.
- The design load on the hoist ropes does not exceed 0.2 times the average breaking load.

The design is very similar to that used in PWRs already operating, and there have been no failures of hoists of this design resulting in dropped fuel. This provides support to the reliability claims.

The maintenance and testing arrangements for the New Fuel Handing Area hoist are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to dispatch from their manufacturers, the New Fuel Handing Area hoist will be tested to 125 percent of the design rated load.

- Prior to each refuelling outage, there will be an inspection for loose parts, an inspection of hoist cables, and checks of the limit switches and limit switch actuators.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the New Fuel Handing Area hoist.

Spent Fuel Pool Area Proof Hoist

Whilst there is no "inherently safe" way to design lifting equipment, the provision of multiple load paths and substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The Spent Fuel Pool hoist, whilst not designed formally against NUREG-0554 (Reference 17.14), however incorporates a number of features from this standard. It is also designed as seismic C-II. The principal provisions to achieve a high level of hoist integrity are:

- The hoist has a mechanical brake and an independent electric brake. Either one is capable of handling 150 percent of rated load.

- The braking arrangements are such that they are automatically set whenever drive power is removed from the hoist motor.

- There are dual lifting cables, each capable of taking the full rated load.

- The hoist ropes are stainless steel to provide compatibility with the expected atmosphere in the fuel handling area.

- The design load on the hoist ropes does not exceed 0.2 times the average breaking load.

The design is very similar to that used in PWRs already operating.

The maintenance and testing arrangements for the Spent Fuel Pool Area hoist are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to dispatch from their manufacturers, the Spent Fuel Pool Area hoist will be tested to 125 percent of the design rated load.

- Prior to each refuelling outage, there will be an inspection for loose parts, an inspection of hoist cables, and checks to the limit switches and limit switch actuators.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the Spent Fuel Pool Area hoist.

Bridge and Hoist Trolley(s)

The bridge runs on machined rails with one rail being used by guide rollers to control lateral movement as well as for support. This design ensures that movement can be limited to known areas without use of separate protection equipment and is an inherently safe approach. Mounted on the bridge is a superstructure that includes two monorail trolley-hoists. These two trolley-hoists share the same monorail.

The bridge and trolley are constructed from a coated carbon steel to provide protection against the atmospheric environment over the spent fuel storage pond. They are also designed as seismic C-II. The principal provisions to ensure that fuel cannot be damaged during handling operations, especially through contact with fittings in the fuel pools, are:

- Positive stops are provided on the trolley monorail to prevent the trolley-hoist from disengaging the monorail. Energy-absorbing devices are provided to handle impact with the trolley moving at maximum traverse speed.

- Positive stops are provided on the bridge rails to prevent the bridge from rail disengagement. Energy-absorbing devices are provided to cater for impact with the bridge moving at maximum traverse speed.

- The bridge propulsion motors are designed so that an integral brake is engaged when power is not being supplied to move the bridge.

- The trolley propulsion motors are designed so that an integral brake is engaged when power is not being supplied to move the trolley.

- The speed of the bridge and trolley have been set such that inertia loads on fuel assemblies during handling operations do not exceed allowable limits.

- Hold-down devices are provided on the bridge rails to prevent the bridge or trolley from leaving the rails in the event of a seismic occurrence. The monorail I-beam provides the necessary hold-down capability to prevent the hoist-trolleys from disengaging during a seismic event.

The design is very similar to that used in PWRs already operating and from a review of NUREG 1774, 30 crane events involving fuel assembly drops or damage were identified during a 34+ year period in the US fleet. None of these events resulted in fuel cladding damage or any release of radioactivity, and only one was associated with the failure of a hoist. This provides support to the reliability claims.

The maintenance and testing arrangements for the bridge and hoist trolley(s) are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to each refuelling outage, there will be an inspection for loose parts, an inspection of exposed gears, and checks to the limit switches and limit switch actuators.

- Prior to each outage, checks will be carried out to demonstrate full functionality of the bridge and trolley.

Fuel Assembly Handling Tools

The fuel assembly handling tools are manufactured from stainless steel to ensure compatibility with the borated water in the spent fuel pool. The principal provisions to ensure that they only release fuel assemblies in the correct location are:

- The handling tool latch assembly has four “fingers” that grip the fuel assembly being lifted. The design ensures that any two of these fingers will adequately support the weight of the fuel assembly.

- The design of the latch assembly is such that once a fuel assembly has been latched into position any load on the latches from lifting operations will tend to cause the latch mechanism to engage further. This feature is not dependent on external actuation of the provision of separate power supplies and so inherently supports the requirements of secure lifting.

- The actuating handle of the fuel handling tools has a positive means of locking the actuating shaft to preclude inadvertent release of a fuel assembly.

The design is very similar to that used in PWRs already operating and from a review of NUREG 1774, 30 crane events involving fuel assembly drops or damage were identified during a 34+ year period in the US fleet. None of these events resulted in fuel cladding damage or any release of radioactivity, and only one was associated with the failure of a hoist. This provides support to the reliability claims.

The maintenance and testing arrangements for the fuel handling tools are based on both the statutory inspections required for lifting equipment and those aimed at ensuring reliable operation. The testing is:

- Prior to dispatch from their manufacturers, the fuel handling tools will be tested to 125 percent of the design rated load.

- Prior to each use, there will be an inspection for nicks, burrs, or other physical damage.

- Prior to each use, checks will be carried out to demonstrate full functionality of the fuel handling tools.

17.7.3 Fuel Transfer System (FHS-FH-05)

17.7.3.1 Role

Further design details of the Fuel Handling System (FHS) and its constituent components are delineated in Reference 17.29 and Section 6.12.

The fuel transfer system is required to move new and irradiated fuel between the refuelling pool inside containment and the spent fuel pool in the auxiliary building fuel handling area. The system contributes to the containment primary safety function by ensuring that all movement of fuel is carried out with minimum risk of damaging fuel cladding directly, or in such a way that damage could become apparent during either further handling or irradiation. In this way, the opportunity for release of radioactive material is minimised.

The fuel transfer system is also designed so that during operation, when handling irradiated fuel assemblies, there will always be an adequate depth of water to maintain adequate shielding of staff involved with the operation of the system.

The fuel transfer system contains the equipment that allows fuel assemblies to be turned from the vertical orientation, for handling by the refuelling machine and the fuel handling machine, to the horizontal orientation, for passing through the fuel transfer tube and vice versa.

The main risk to cladding integrity, therefore, comes from the potential for snags between the fuel assembly being transferred and the fixed parts of the transfer mechanism. The particular concern in this area is operation of the up-ender mechanism when a fuel assembly has not been fully released from either the refuelling machine or the fuel handling machine.

Protection from this issue is provided by the design of the equipment itself and also the provision of appropriate interlocks to control the fuel handling movements. The interlocks provided are a mixture of electrical and mechanical systems. There is also a requirement for the transfer system to move fuel without subjecting it to unacceptable physical shocks that could give rise to fuel assembly damage.

The fuel transfer system is not supported by other systems in the provision of its safety functions. It does not support any other systems in the provision of their safety functions.

17.7.3.2 System Components and Equipment Contributing to Safety Function

The fuel transfer system is designed in accordance with the guidelines of an ANS standard, Reference 17.13. This specifies a number of necessary design features, the following features are critical in ensuring that the system can support its safety function:

- **Fuel Container** – This is a stainless-steel container designed to fully enclose the fuel assembly on all sides except for the top. It is intended to provide adequate support for the fuel assembly under transfer and prevent any in-transit damage by positively locating the assembly within the container. The prevention of physical damage is a safety requirement. The container has openings in its sides so that there is a sufficient circulation of water by natural convection to provide adequate heat removal. Adequate cooling is also provided to prevent any localised damage to fuel assemblies and is therefore a safety requirement.

- **Containment Building Up-Ender** – The up-ender mechanism provides the means for change of orientation of the fuel container between horizontal and vertical. It is manufactured from stainless steel with all bearing surfaces self-lubricated by the water in that the mechanism is immersed. The mechanism is designed to ensure that the limits at extremes of travel, to both the horizontal and vertical positions are provided with necessary protection to limit shocks to the fuel assembly being transferred. The controls of the up-ender are interlocked to ensure that the mechanism cannot attempt to move from vertical to horizontal if a fuel assembly is not fully inserted. The safety requirement is prevention of damage from impact shocks during movement or from movement when the fuel is not correctly stowed.

- **Auxiliary Building Fuel Handling Area Up-Ender** – The design is identical to the containment building up-ender.

- **Fuel Transfer Car** – This wheeled vehicle, manufactured from stainless steel, provides support to the fuel container through the latter's pivot and runs on a track between the containment up-ender and the auxiliary building fuel handling area up-ender. The car is driven by a traverse drive system mounted on the operating floor above the water level in the auxiliary building fuel transfer canal. The car runs on a track, also manufactured from stainless steel, bolted to the transfer tube. The safety requirement is to prevent damage either from impact shocks or snagging of the fuel assembly.

17.7.3.3 Claims on Components and Equipment

Fuel Container

The fuel container is required to ensure that there is no damage to a fuel assembly from snagging, or shocks, as it is moved from the containment building to the fuel handling area of

the auxiliary building. Protecting against damage to the integrity of spent fuel, and consequent release of radioactive material, is a Category A safety function and fuel container is Class 2. See Appendix 15A. The fuel container is also required to ensure that an irradiated fuel assembly is adequately cooled whilst in transit. Again, this is protection against damage to the integrity of spent fuel and is consequently a Category A safety function and the container is Class 2. See Appendix 15A.

Containment Building Up-Ender

The containment building up-ender is required to ensure that there is no damage to a fuel assembly from snagging, or shock loading, as its orientation is changed from horizontal to vertical (or vice versa). It shall not allow rotation between horizontal and vertical positions until the fuel assembly is seated and the hoist on the respective machine is clear of the up-ender. There is also a requirement that during translation, the fuel will not be damaged as a result of shock loads from violent movements. Protecting against damage to the integrity of spent fuel is a Category A safety function and the containment building up-ender is Class 2. See Appendix 15A.

Auxiliary Building Fuel Handling Area Up-Ender

The requirements are identical to those on the containment building up-ender.

Fuel Transfer Car

The fuel transfer car is required to ensure that there is no damage to a fuel assembly from shock loading as it traverses through the fuel transfer tube. The requirement is that it shall not generate shock loads that might damage a fuel assembly during transfer from the auxiliary building to the containment building (or vice versa). The protection of spent fuel assembly integrity is a Category A safety function and the fuel transfer trolley is Class 1. See Appendix 15A.

17.7.3.4 Justification of Claims on Components and Equipment

Fuel Container

The fuel container provides a physical container around the fuel assembly being moved. This is not dependent on any control or actuation systems and does not require any power supplies. As a result, it provides an inherently safe arrangement for the prevention of damage to the fuel during movement. The arrangements made for cooling of an irradiated fuel assembly in transit depend only on natural convection of the water inside and around the fuel transfer mechanism. Again, this is an inherently safe arrangement.

The fuel container is manufactured from stainless steel to ensure compatibility with the borated water environment in that it operates. The principal provisions in the design for achieving a high level of fuel protection are:

- The fuel container encloses the fuel assembly on all sides except the top.
- The inside dimensions of the fuel container, along with associated tolerances, finish, and lead-in configuration, are all selected to ensure good matching with fuel assemblies.
- The openings in the sides of the fuel container allow sufficient flow of water to ensure that boiling of the water around the fuel rods is precluded.

- The fuel container provides support for the fuel assembly at all fuel assembly grid locations.

- There is a nominal clearance between the fuel container and the inside of the fuel transfer tube that is adequate to minimise the risk of snagging.

The design is very similar to that used in currently operating PWRs and, as discussed in Appendix 17A, there have been no occurrences of damaged fuel due to failure of the fuel container to give adequate protection, or adequate cooling, to fuel being transported. This provides support to the reliability claims.

The maintenance and testing arrangement for the fuel container is based on ensuring reliable operation. The testing is:

- At the beginning of each outage, prior to the handling of fuel assemblies, visual inspection of the fuel container to ensure that it is free from damage, loose components, and foreign objects.

- Prior to each outage, checks to demonstrate full functionality of the fuel container.

Containment Building Up-Ender

The containment up-ender is manufactured from stainless steel to ensure compatibility with the borated water environment in that it operates. The principal provisions in the design for achieving a high level of fuel protection are:

- The up-ender mechanism is designed to tilt the fuel container and hold it hard against stops to locate it in the correct vertical alignment to allow fuel assemblies to be inserted and withdrawn.

- The up-ender tilt mechanism is sized so that tilting can only occur when the fuel container is properly located at the end of travel through the transfer canal.

The design is very similar to that used in currently operating PWRs and, as discussed in Appendix 17A, there have been no occurrences of damaged fuel due to failure of the up-ender mechanism. This provides support to the reliability claims.

The maintenance and testing arrangements for the containment up-ender are based on ensuring reliable operation. The testing is:

- At the beginning of each outage and prior to the handling of fuel assemblies, visual inspection of the up-ender to ensure that it is free from damage, loose components, and foreign objects.

- Visual inspection of limit switches and limit switch actuators for damage.

- Prior to each outage, checks to demonstrate full functionality of the up-ender.

Auxiliary Building Fuel Handling Area Up-Ender

The justification is identical to that of the containment building up-ender.

Fuel Transfer Car

The fuel transfer car runs on rails and is equipped with guide rollers to control lateral movement as well as for support. This design ensures that movement can be limited to the rail guide path and is an inherently safe approach.

The fuel transfer car is constructed from stainless steel to provide protection against the borated water in the fuel transfer tube. The principal provisions to ensure that fuel cannot be damaged during handling operations are:

- Wheels are mounted on the transfer car on either side of the loaded centre of gravity to promote stability. The wheels are spaced to ensure that gaps in the track, that are adjacent to each up-ender, can be negotiated.
- The transfer car is restrained from leaving the track for the full length of travel.
- The transfer car is mechanically locked to the tracks to prevent traverse once the up-ender moves to the vertical position.
- Positive stops are provided on the system rails to prevent the car from overrunning.
- The traverse drive mechanism is cut off at loads that minimise the risk of shock loadings due to failures in the drive mechanism components.
- The drive propulsion motor is designed so that an integral brake is engaged when power is not being supplied to move the car.
- The design load on the wire rope used in the transfer mechanism drive is less than 0.2 times the average breaking strength of the wire.

The design is very similar to that used in PWRs already operating and, as discussed in Appendix 17A, there have been no occurrences of damaged fuel due to failure of the fuel transfer car mechanism. This provides support to the reliability claims.

The maintenance and testing arrangements for the fuel transfer car are based on ensuring reliable operation. The testing is:

- At the beginning of each outage, prior to the handling of fuel assemblies, visual inspection of the fuel transfer car to ensure it is free from damage, loose components, and foreign objects.
- Visual inspection of limit switches and limit switch actuators.
- Prior to each outage, checks to demonstrate full functionality of the fuel container.

17.8 Heavy Load Handling Systems

17.8.1 Polar Crane (MHS-MH-01)

17.8.1.1 Role

A detailed description of the polar crane is given in Section 11.8. Further design details of this system and its constituent components are delineated in Reference 17.30.

The polar crane is required to move an assortment of heavy assemblies around the containment building, such as the integrated head package, reactor internals, and RCP components. The system contributes to the primary safety function of containment by ensuring that all the movements are carried out in such a way that there is minimum risk of impact damage to nuclear fuel directly and also to any equipment that is part of the systems responsible for other primary safety functions.

The main hazards presented by the polar crane, and hence to maintenance of the primary safety function, are from either heavy loads being dropped or collision with other plant items. The protection from these hazards comes from appropriate design of the handling equipment itself and the provision of appropriate control of lifting movements.

The polar crane is not supported by other systems in the provision of its safety functions. The polar crane does not support any other systems in the provision of their safety functions.

17.8.1.2 System Components and Equipment Contributing to Safety Function

The polar crane is designed to NUREG-0554 (Reference 17.14) supplemented by ASME NOG-1-1998 (Reference 17.15). This specifies a number of necessary design features, the following subsystems are critical in ensuring that the system can support its safety function:

- **Main hoist** – This hoist is designed with twin wire ropes and redundant braking systems designed to hold loads in excess of the rated value. The design is seismic C-I. The safety requirement of the hoist is to prevent uncontrolled lowering of a critical load.

- **Auxiliary hoist** – This hoist is designed with twin wire ropes and redundant braking systems designed to hold loads in excess of the rated value. The design is seismic C-I. The safety requirement of the hoist is to prevent uncontrolled lowering of a critical load.

- **Bridge**– The bridge is designed for a nominal capacity based on the potential application to SG replacement. The design is seismic C-I, but only up to a reduced lifting capacity based upon standard outage lifts. The bridge and trolley are also required to withstand the pressure and temperature transients associated with conditions inside containment following a LOCA. The safety requirement is to ensure that neither the bridge and trolley nor the supported hoists can collapse and cause damage to equipment inside the containment building.

17.8.1.3 Claims on Components and Equipment

Main Hoist

The main hoist is required to ensure that the heavy loads it lifts around the containment building cannot be subject to an uncontrolled lowering and cause consequential damage to either fuel in the reactor vessel or to other plant SSCs. Protecting the integrity of spent fuel is a Category A safety function. Protection against hazards that might affect the operation of other plant supporting a Category A function is also a Category A safety function. The main hoist is Class 1. See Appendix 15A.

The main hoist is a design that has dual redundant respective components such that each can perform the full safety duty. The hook does not have dual redundancy but is designed with a double factor of safety. The requirement against the main hoist is that any single failure in the hoist equipment train will result in the lifted load being held steady.

Auxiliary Hoist

The auxiliary hoist is required to ensure that the loads it lifts around the containment building cannot be subject to an uncontrolled lowering and cause consequential damage to either fuel in the reactor vessel or to other plant SSCs. Protecting the integrity of spent fuel is a Category A safety function. Protection against hazards that might affect the operation of other plant supporting a Category A function is also a Category A safety function. The auxiliary hoist is Class 1. See Appendix 15A.

The auxiliary hoist is of a design that has dual redundant respective components such that each can perform the full safety duty. The hook does not have dual redundancy but is designed with a double factor of safety. The requirement against the auxiliary hoist is that any single failure in the hoist equipment train will result in the lifted load being held steady.

Bridge and Trolley

The bridge and trolley are required to ensure that the hoists they support, and therefore any loads they may be carrying, do not fall onto either the reactor vessel or onto any other associated plant SSCs. This is effectively protecting against a hazard that might affect other plant SSCs from performing a Category A safety function and hence is also a Category A safety function. The bridge and trolley are Class 1. See Appendix 15A.

The requirement against the bridge and trolley is that they will correctly track along their rails and will maintain structural integrity, even through the pressure and temperature transients associated with a LOCA.

17.8.1.4 Justification of Claims on Components and Equipment

Main Hoist

There is no “inherently safe” way to design lifting equipment, the provision of multiple load paths and substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The main hoist is designed to the provisions as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15). The principal features for achieving high integrity are:

- There are redundant components in all elements of the lifting path except the hook.
- There are redundant braking systems, as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15).
- The equaliser assembly ensures that load is always shared equally between the two wire ropes, and if one wire rope fails the load is transferred to the remaining wire rope with minimal movement of the load.
- The load bearing hooks are designed with a double design safety factor.
- The assembly is designed to seismic C-I for critical lifts up to a defined load.

The design is very similar to the polar crane main hoists used in currently operating PWRs. There have been no failures to date with any of them that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the main hoist is based on UK statutory inspection arrangements and ASME B30.2, as discussed in Reference 17.16.

Auxiliary Hoist

There is no "inherently safe" way to design lifting equipment, the provision of multiple load paths and substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The auxiliary hoist is designed to the provisions as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15). The principal features for achieving high integrity are:

- There are redundant components in all elements of the lifting path except the hook.
- There are redundant braking systems, as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15).
- The equaliser assembly ensures that load is always shared equally between the two wire ropes; if one wire rope fails, the load is transferred to the remaining wire rope with minimal movement of the load.
- The load bearing hooks are designed with a double design safety factor.
- The assembly is designed to seismic C-I for critical lifts up to a defined load.

The design is very similar to the polar crane auxiliary hoists used in currently operating PWRs. There have been no failures to date with any of these that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the auxiliary hoist are based around UK statutory inspection arrangements and ASME B30.2 (Reference 17.16).

Bridge and Trolley

The bridge is designed for working loads associated with SG replacement. These are far in excess of the loads seen during normal refuelling activities. As such, with the exception of seismic protection, there is a further very large factor of safety on top of those normally included in the design.

Specific design features incorporated to give confidence of high integrity are:

- Positive stops are provided on the trolley rails to prevent the trolley running off the bridge. In addition to this, the physical location of the polar crane within the containment structure ensures that the trolley cannot run off the bridge.
- The assembly is designed to seismic C-I.

- The design has provisions to ensure that in the event of a LOCA or main steam line break inside containment, the consequent disruption cannot lead to either the bridge or trolley being displaced from their installed positions. All enclosed box sections of the bridge/trolley structure are vented to allow pressure equalisation during containment pressurisations. The structural and mechanical integrity of the crane will not be compromised at 216°C (420°F). The calculated crane expansion versus containment expansion during a DBA has been assessed and there is sufficient clearance between the wheels and the rail to allow for the difference. This is clearly protection of the crane structure only, and a significant programme of examination and testing would be required before the crane could actually be used following this type of event.

- Prior to heavy lifts, lifting plans will be prepared to identify safe load paths.

The design is very similar to the polar crane bridge and trolley design used in currently operating PWRs. There have been no failures to date with any of these that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the bridge and trolley are based around UK statutory inspection arrangements and ASME B30.2 (Reference 17.16).

17.8.2 Cask Handling Crane (MHS-MH-02)

17.8.2.1 Role

Further design details of this system and its constituent components are delineated in Reference 17.31 and Section 6.12

The cask handling crane is required to move spent fuel casks, and cask lids around the fuel handling area of the auxiliary building. The system contributes to the containment primary safety function by ensuring that all the movements are carried out in such a way that there is minimum risk of impact damage either to the fuel stored in the fuel storage pool or to any equipment that is part of the systems responsible for other primary safety functions.

The main hazards presented by the cask handling crane, and hence to maintenance of the primary safety function, are either from heavy loads being dropped, or by collision with other plant items. The protection from these hazards comes from appropriate design of the handling equipment itself and the provision of appropriate control of lifting movements.

The cask handling crane is not supported by other systems in the provision of its safety functions.

The cask handling crane does not support any other systems in the provision of their safety functions.

17.8.2.2 System Components and Equipment Contributing to Safety Function

The cask handling crane is designed to NUREG-0554 (Reference 17.14) supplemented by ASME NOG-1-1998 (Reference 17.15). This specifies a number of necessary design features, the following subsystems are critical in ensuring that the system can support its safety function:

- **Main Hoist** – This is a design with twin wire ropes and redundant braking systems designed to hold loads in excess of the rated value. The design is seismic C-I. The safety requirement of the hoist is to prevent uncontrolled lowering of a load.

- **Auxiliary Hoist** – This is a design with twin wire ropes and redundant braking systems designed to hold loads in excess of the rated value. The design is seismic C-I. The safety requirement of the hoist is to prevent uncontrolled lowering of a load.

- **Bridge and Trolley** – These are designed to match the nominal rating of the main hoist. The design is seismic C-I. The safety requirement is to ensure that neither the bridge nor trolley, nor the supported hoists, can collapse and cause damage to SSCs or the fuel assemblies in the SFP.

17.8.2.3 Claims on Components and Equipment

Main Hoist

The main hoist is required to ensure that the spent fuel casks and cask lids that it lifts around the auxiliary building fuel handling area cannot be subject to an uncontrolled lowering and cause consequential damage to SSCs or the spent fuel stored in the SFPs. Protection of the integrity of spent fuel is a Category A safety function. The main hoist is Class 1. See Appendix 15A.

Auxiliary Hoist

The auxiliary hoist is required to ensure that the loads it lifts around the auxiliary building fuel handling area cannot be subject to an uncontrolled lowering and cause consequential damage to SSCs or the spent fuel stored in the SFPs. Protection of the integrity of spent fuel is a Category A safety function. The auxiliary hoist is Class 1. See Appendix 15A.

Bridge and Trolley

The bridge and trolley are required to ensure that the hoists they support, and therefore any loads that may be being carried cannot be dropped and cause consequential damage to SSCs or the spent fuel stored in the SFPs. Protection of the integrity of spent fuel is a Category A safety function. The bridge and trolley are Class 1. See Appendix 15A.

The requirement against the bridge and trolley is that they will correctly track along their rails and will maintain structural integrity.

17.8.2.4 Justification of Claims on Components and Equipment

Main Hoist

Whilst there is no “inherently safe” way to design lifting equipment, the provision of multiple load paths along with the provision of substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The main hoist is designed to the provisions as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15). The principal features for achieving high integrity are:

- There are redundant components in all elements of the lifting path with the exception of the hook.
- There are redundant braking systems, as specified in Reference 17.15.
- The equaliser assembly ensures that load is always shared equally between the two wire ropes; if one wire rope fails, the load is transferred to the remaining wire rope with minimal movement of the load.
- The load bearing hook is designed with a double design safety factor.
- The assembly is designed to seismic C-I.

The design is very similar to the cask handling crane main hoists used in currently operating PWRs. There have been no failures to date with any of them that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the main hoist are based on UK statutory inspection arrangements and ASME B30.2 (Reference 17.16).

Auxiliary Hoist

Whilst there is no "inherently safe" way to design lifting equipment, the provision of multiple load paths and substantial factors of safety is generally accepted as the best solution to minimise the risk of dropped loads.

The auxiliary hoist is designed to the provisions as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15). The principal features for achieving high integrity are:

- There are redundant components in all elements of the lifting path with the exception of the hook.
- There are redundant braking systems, as specified in ASME NOG-1-1998 and NUREG 0554 (Reference 17.14 and 17.15).
- The equaliser assembly ensures that load is always shared equally between the two ropes; if one rope fails, the load is transferred to the remaining rope with minimal movement of the load.
- The load bearing hook is designed with a double design safety factor.
- The assembly is designed to seismic C-I.

The design is very similar to the cask handling crane auxiliary hoists used in currently operating PWRs. There have been no failures to date with any of them that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the auxiliary hoist are based on UK statutory inspection arrangements and ASME B30.2 (Reference 17.16).

Bridge and Trolley

Specific design features incorporated to give confidence of high integrity are the following:

- Positive stops are provided on the trolley rails to prevent the trolley from running off the bridge. In addition, the location of the crane within the auxiliary building structure also physically prevents the trolley from running off the bridge.
- Positive stops are provided on the bridge rails to prevent the bridge from running off the support rails.
- The assembly is designed to seismic C-I.
- The crane rails do not extend over the SFP, so it is not physically possible to lift loads over it.

The design is very similar to the cask handling crane bridge and trolley design used in currently operating PWRs. There have been no failures to date with any of them that have resulted in a dropped load. This provides support to the reliability claims.

Maintenance and testing for the bridge and trolley are based on UK statutory inspection arrangements and ASME B30.2 (Reference 17.16).

17.9 Fuel Storage

17.9.1 Spent Fuel Pool Cooling

17.9.1.1 Role

A detailed description of the SFS is given in Section 6.12.4. Further design details of this system and its constituent components are delineated in Reference 17.32.

The SFS contributes to the heat transfer/residual heat removal primary safety function and also the containment primary safety function. It supports the heat transfer/residual heat removal primary safety function through the removal of decay heat generated in the irradiated fuel assemblies stored in the SFP. It supports containment through purification of the pool water to remove any entrained contamination that could ultimately give rise to an airborne hazard. It also supports this primary safety function through the purification of water in the refuelling cavity during refuelling operations.

The SFS consists of two trains of mechanical equipment. Each train includes one SFP pump, one SFP HX, one SFP demineraliser, and one SFP filter. The two trains of equipment have separate suction and discharge connections to the SFP. In addition to the contribution to primary safety functions described above, the SFS also has the capability to provide cleanup and purification to the IRWST, and to control the transfer of water from the IRWST to the refuelling cavity and back. The system is designed so that one train can perform this duty whilst the other continues to provide SFP cooling.

The connections to the IRWST and the refuelling cavity clearly go through the containment boundary and valves are provided for the containment isolation safety function. This feature provides support to the containment primary safety function.

The SFS is supported by the CCS and also by the ECS and the ZOS.

Whilst the SFS supports the operation of other systems, it does not support them in performing any safety functions.

17.9.1.2 System Components and Equipment Contributing to Safety Function

- The pipework of the SFS is designed to ASME Power Piping Code, B31.1 (Reference 17.10) and ASME Boiler and Pressure Vessel Code, Section III-2 (Reference 17.4) where associated with CIVs.

- **Spent Fuel Cooling Pumps (SFS-MP-01A/B)** – These are single-stage, horizontally mounted centrifugal pumps manufactured from stainless steel and driven directly by an ac induction motor. The pumps are designed to supply the required flow and pressure. One pump is normally running and the safety requirement is to have at least one pump continue running to provide adequate flow to meet SFP cooling requirements.

- **Spent Fuel Pool Heat Exchangers (SFS-ME-01A/B)** – These are plate-type HXs, that consist of multiple thin plates mounted in a frame. SFS water is circulated on one side of the multiple thin plates, while CCS water circulates on the opposite side of them. The HX plates and piping connections are manufactured from stainless steel. The safety requirement of the SFS HXs is to provide adequate heat transfer to ensure that the SFP temperature remains stable for the full range of design conditions. See Appendix 17E.

- **Skimmers (SFS-PY-S03A/B, -PY-S04A/B)** – Skimmer assemblies are provided for the SFP and on the refuelling cavity. The skimmers float freely about the surface of either pool and have a flexible hose leading from the skimmer bottom outlet to a hose adapter. The adapter connects to the skimmer piping quick-connect fitting at the SFP or refuelling cavity wall. The operation of the SFS pump(s) draws water into the skimmer(s). The skimmers are designed to collect debris that may be on the water surface. The skimmer function is not a safety requirement and will not be discussed further.

- **Filters (SFS-MV-02A/B)** – These are sized to collect particulates and resin fines passed by the demineraliser and suspended solids. Process flow is side entry and bottom discharge. The vessel top is a flat head with a flange and gasket hinged with a quick-release closure to allow easy filter cartridge replacement and handling. The assembly is constructed of austenitic stainless steel and uses disposable filter cartridges that can be compacted for waste storage. The safety requirement is to remove particulate contamination from pool water to prevent release to atmosphere.

- **Demineralisers (SFS-MV-01A/B)** – These are constructed from stainless steel and are sized to be charged with a mixture of hydrogen-type cation resin and hydroxyl-type anion resin to remove fission and corrosion products. The demineralisers are sized to accept purification flow from the cooling train. This flow is designed to provide two water volume changes of the SFP within 24 hours. The safety requirement for the demineralisers is to remove dissolved contamination from the pool water to prevent potential release to atmosphere.

- **SFS Suction Line CIVs (SFS-PL-V034 and -V035)** –These are 150-mm DN (6-inch), motor-operated butterfly valves designed to fail “as is” on loss of electrical supplies. Both valves are required to close on receipt of a containment isolation signal from the PMS to support the containment integrity function, or on a SFP low-water-level signal from the PMS to protect the stored spent fuel. The safety requirement is to isolate the containment penetration.

- **SFS Discharge Line CIV (SFS-PL-V038)** – This is a 100-mm DN (4-inch), motor-operated butterfly valve designed to fail "as is" on loss of electrical supplies. The valve is required to close on receipt of a containment isolation signal from the PMS to support the containment integrity function, or on a SFP low water-level signal from the PMS to protect the stored spent fuel. The safety requirement is to isolate the containment penetration.

- **Discharge CIV (SFS-PL-V037)** – This is a 100-mm DN (4-inch) swing check valve. The valve is required to close on reverse flow. This prevents reverse flow in the SFS transfer lines and also contributes to the containment integrity function. The safety requirement is to isolate the penetration.

17.9.1.3 Claims on Components and Equipment

Spent Fuel Pool Cooling Pumps (SFS-MP-01A/B)

The SFS pumps provide the motive force to circulate water from the SFP through the HXs and purification system. Removal of decay heat is a Category A safety function. The SFS pumps are Class 2. See Appendix 15A.

Purification prevents release of radioactive material that accumulates in the SFP and is a Category B safety function. The SFS pumps are Class 2. See Appendix 15A.

Two SFS pumps are provided, either of which can provide sufficient flow to ensure the provision of adequate cooling and also to meet the purification requirements. The requirement on the pumps is that they will continue to run reliably as required.

Spent Fuel Pool Heat Exchangers (SFS-ME-01A/B)

The SFS HXs provide the facility for heat transfer into the CCS and consequent control of spent fuel pool water temperature. Removal of decay heat is a Category A safety function. The SFS HXs are Class 2. See Appendix 15A.

There are two component SFS HXs, either of which can provide the full cooling duty during normal plant operation. The requirement on the HXs is that they will provide adequate heat transfer, they will not impair the operation of the SFS, and they will not be unavailable because of leakage.

Skimmers (SFS-PY-S03A/B, -PY-S04A/B)

The skimmers serve to remove particulate contamination from the SFP water. Purification removes radioactive material from the water in the SFP, refuelling cavity, and IRWST, and this is a Category C safety function. The skimmers are Class 3.

Four skimmers are provided, two for the SFP and two for the Refueling Cavity. The requirement on them is that they will capture appropriate particulate and fission products.

Filters (SFS-MV-02A/B)

The SFS filters serve to remove particulate contamination from the SFP water. Purification removes radioactive material from the water in the SFP, refuelling cavity, and IRWST, and this is a Category C safety function. The SFS filters are Class 3. See Appendix 15A.

Two filters are provided, one on each SFS train. Either filter is able to carry out the full design duty. The requirement on them is that they will capture appropriate particulate material.

Demineralisers (SFS-MV-01A/B)

The SFS demineralisers serve to remove dissolved ionic contamination (both radioisotopes and other ionic materials) from the SFP water. Purification limits the radioactivity of the water in the SFP, refuelling cavity, and IRWST, and this is a Category C safety function. The SFS demineralisers are Class 3. See Appendix 15A.

Two demineraliser units are provided, one on each SFS train. Either demineraliser is able to carry out the full design duty. The requirement on them is that they will maintain dissolved solid concentrations below the required limits.

SFS Suction Line CIVs – (SFS-PL-V034 and -V035)

The CIVs serve to support containment integrity and prevention of the release of radioactive material. This is a Category A safety function and they are considered Class 1. See Appendix 15A.

There are two valves and one of them has to function to secure containment isolation. The requirement is that they will close on demand.

SFS Discharge Line Containment Isolation Valve (SFS-PL-V038)

The CIV serves to support containment integrity and prevention of the release of radioactive material. This is a Category A safety function and the valve is considered Class 1. See Appendix 15A.

The valve is partnered with the check valve in isolation of the penetration. The requirement is that this valve will close on demand.

SFS Discharge Line Containment Isolation Check Valve (SFS-PL-V037)

The CIV serves to support containment integrity and prevention of the release of radioactive material. This is a Category A safety function and the valve is considered Class 1. See Appendix 15A.

The valve is partnered with the motor-operated valve in isolation of the penetration. The requirement is that this valve will close on demand.

17.9.1.4 Justification of Claims on Components and Equipment

Spent Fuel Pool Cooling System Pumps (SFS-MP-01A/B)

The pumps are designed to Hydraulic Institute standards and are very similar to the design of like pumps on currently operating PWRs. As a result, the successful operation of these pumps in service offers a high degree of confidence in the reliability to be expected from these pumps.

Routine maintenance and testing of the SFS pumps will be performed according to the manufacturer's recommendations and will include routine changeover of the pumps allocated

to duty and standby roles. No specific surveillance test requirements are identified since these pumps are normally in operation.

Spent Fuel Pool Cooling Heat Exchangers (SFS-ME-01A/B)

The HXs are manufactured with stainless-steel plates to ensure maximum compatibility with the CCS fluid and the service water system (SWS) fluid that passes through. The HXs are manufactured to ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 (Reference 17.9).

The use of plate HX for this type of application is very well established. The use of this type of heat exchanger gives the ability to easily change the number of plates installed and consequently allow variations to be made in heat exchange area, to optimise the performance of the coolers to the system needs. The plate heat exchangers are substantially smaller than conventional shell and tube heat exchangers since they operate in a true counter-current flow arrangement and use turbulent flow to increase the U-value of the heat exchanger.

Routine maintenance and testing of the SFS HXs will be performed according to the manufacturer's recommendations and will include routine changeover of the HXs allocated to duty and standby roles. No specific surveillance test requirements are identified since these heat exchangers are normally in operation.

Filters (SFS-MV-02A/B)

The filter vessel is constructed from stainless steel to provide compatibility with the SFP water. The vessel is constructed to ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 (Reference 17.9). The design is very similar to like filters on currently operating PWRs and other nuclear power stations. This gives considerable confidence that the filter will be able to perform as expected.

Routine maintenance and inspection of the filter vessel will be performed according to the manufacturer's recommendations. No specific surveillance test requirements are identified since these filters are normally in operation.

The filter element will be replaced periodically unless differential pressure indications suggest that a change is required more frequently.

Demineralisers (SFS-MV-01A/B)

The demineraliser vessels are constructed from stainless steel to provide compatibility with the SFP water. The vessels are constructed to ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 (Reference 17.9). The design is very similar to like demineralisers on currently operating PWRs and other nuclear power stations. This gives considerable confidence that the filter will be able to perform as expected.

Routine maintenance and inspection of the demineraliser vessel will be performed according to the manufacturer's recommendations. No specific surveillance test requirements are identified since these demineralisers are normally in operation.

The demineraliser resin will be replaced periodically unless chemical monitoring suggests that a change is required more frequently.

SFS Suction Line Containment Isolation Valves (SFS-PL-V034 and -V035)

The CIVs are both motor operated, which means they will inherently fail "as is," and clearly, this is not fail-safe with respect to the containment isolation function itself. Given that spurious actuation of this function when not required could, in itself, give rise to safety concerns, this arrangement is judged appropriate.

Both valves are manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the SFS CIVs are based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is carried out quarterly in accordance with ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is carried out every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

SFS Discharge Line Containment Isolation Valve (SFS-PL-V038)

The CIV is motor operated, which means it will inherently fail "as is," and clearly, this is not fail-safe with respect to the containment isolation function itself. Given that spurious actuation of this function when not required could, in itself, give rise to safety concerns, this arrangement is judged appropriate.

The valve is manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through it. It is designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the SFS CIVs is based on the ASME Boiler and Pressure Vessel Code programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is carried out quarterly in accordance with ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is carried out every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

SFS Discharge Line Containment Isolation Valve (SFS-PL-V037)

This CIV is a check valve and operation depends only upon the pressure difference across it, and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valve is manufactured from stainless steel to ensure compatibility with the reactor coolant water that passes through it. It is designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the SFS CIVs is based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is carried out quarterly in accordance with ASME Boiler and Pressure Vessel Code.
- Visual confirmation of valve operation during the stroke testing is carried out every 2 years.
- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

17.10 Other Supporting Systems

17.10.1 Component Cooling Water System (CCS)

17.10.1.1 Role

A detailed description of the CCS is given in Section 6.11. Further design details of this system and its constituent components are delineated in Reference 17.33.

Whilst the system does not provide a direct contribution to the primary safety functions of reactivity control or heat transfer/residual heat removal in itself, it does support a number of the systems used as defence in depth to contribute to these primary safety functions. The system provides this support through two roles:

- **Role a** − A heat transport mechanism for the transfer of decay heat away from systems directly responsible for cooling the reactor core or spent fuel stored in the SFP.
- **Role b** − A heat transport mechanism for the transfer of heat, such as that from motors, etc., generated within equipment in the supported system.

The system is made up of two CCS pumps, arranged in parallel, either of which can provide 100 percent of the flow requirement during normal plant power operation. Both are required to be in service to achieve target RCS cooldown times in preparation for refuelling, but the availability of a single pump only increases the cooldown time. Each pump has an associated HX that is also able to provide 100-percent heat duty for normal power operation. It is, however, also possible to align either pump with either HX to facilitate maintenance activities.

The rest of the system is the interconnected pipework that links the pumps and HXs to the individual system heat loads. This pipework is arranged so that one or two operating CCS pumps and HXs can cool all the heat loads. However, the CCS can be segregated into two redundant trains, with each pump and HX train cooling one of two trains of defence in depth components; namely, an RNS HX and pump seal, an SFS HX, and a CVS makeup pump mini-flow HX. When segregated, the remaining non-defence in depth heat loads can be isolated or cooled by either CCS train but without full redundancy.

The CCS provides cooling to equipment in containment and therefore has CIVs as part of its system. These valves support the primary safety function of containment.

The CCS provides support to enable the following systems to perform their safety functions:

- RNS (Roles a and b)
- SFS (Role a)
- CVS (Role b)

The CCS also supports the following systems in normal operation but is required to provide isolation of specific equipment as part of the primary safety function of containment:

- RCP high-pressure motor cooler (Role b)
- RCP flywheel jacket cooler (Role b)
- CVS letdown heat exchanger

The CCS also provides cooling to other systems but in these cases does not support any of them in providing primary safety functions, either as the principal system or as defence in depth.

The CCS is supported by the SWS, a portion of the turbine building ventilation system (VTS), the ECS, and the ZOS if needed.

17.10.1.2 System Components and Equipment Contributing to Safety Function

Most of the CCS system pipework is designed and constructed to ASME B31.1 standards with the exception of the CIVs, containment penetrations, and associated pipework. These are designed and constructed to ASME Boiler and Pressure Vessel Code, Section III-2. A small section of the containment supply and return lines just inside the innermost containment isolation valve is designated Class 1. This section of the line contains the relief valves provided to protect the containment isolation valves from excess pressure buildup while being closed automatically to isolate a Reactor Coolant Pump external heat exchanger tube leak. The following components contribute to the CCS performing its safety functions:

- **Component Cooling Water Pumps (CCS-MP-01A/B)** – These pumps are single-stage, horizontal, centrifugal pumps manufactured from carbon steel and driven directly by an ac induction motor. One of the pumps is normally running and the safety requirement is to continue running to provide adequate CCS fluid to meet design cooling requirements.

- **CCS Heat Exchangers (CCS-ME-01A/B)** – These are plate-type, counterflow HXs that transfer heat from the CCS to the SWS. The HXs are each sized to transfer the full heat load on the CCS during normal operation with 10-percent oversurfacing to handle surface fouling during operation. Component cooling water and service water circulate through the alternating channels formed by contiguous plates in the CCS HXs. Component cooling water is maintained at a higher pressure than the service water to

prevent leakage of the service water into the CCS. The HX plates are constructed of austenitic stainless steel for plants with fresh water recirculating cooling-tower SWS. The closure heads are constructed of carbon steel. The safety requirement of the CCS HXs is to provide adequate heat transfer and maintain acceptable CCS temperatures through the full range of design heat loads.

- **CCS Surge Tanks (CCS-MT-01A/B)** – The surge tanks are constructed from carbon steel and have a capacity sufficient to accommodate shrink or swell within the CCS liquid volume due to operational variations in bulk average temperature and to enhance the period of time for operator response in the event of leakage into, or out of, the system. The surge tanks are maintained at atmospheric pressure via a vent line. The safety requirement of the tank is to ensure that the CCS remains primed and, through its facility to accept shrink or swell, to maintain the CCS inventory and pump suction pressure. Two surge tanks are provided in the event that the CCS subsystems are segregated. Normally, only one CCS surge is operated.

- **CCS CIV Relief Valve (CCS-PL-V220) –** A relief valve is provided to prevent overpressurisation of the return component cooling water line containment penetration. This relief valve prevents overpressurisation that might be caused by thermal expansion of the fluid between the containment isolation valves following an event causing containment isolation. This relief valve is located inside the containment.

- **CCS CIVs (CCS-PL-V200, -V207, -V208)** – These are 250-mm DN (10-inch), motor-operated butterfly valves that fail "as is" on loss of supplies. The valves are required to close on receipt of a safeguard signal from the PMS. This is required to provide isolation of the CCS containment penetrations and is a safety requirement. These valves are also required to close on receipt of a reactor coolant pump bearing water high temperature pump trip signal. This is required to provide automatic isolation of the CCS containment supply and return lines in the event of a reactor coolant pump external heat exchanger tube break at power, to prevent leakage of reactor coolant activity outside containment and radioactive release through the CCS surge tank vent into the turbine building.

- **CCS CIV Check Valve (CCS-PL-V201)** – This is a 250-mm DN (10-inch) swing check valve. The valve is required to close on reverse flow. This prevents reverse flow in the CCS inlet line to containment and also contributes to containment integrity. The safety requirement is to isolate the flow of water.

17.10.1.3 Claims on Components and Equipment

Component Cooling Water Pumps (CCS-MP-01A/B)

The component cooling water pumps provide the motive force to circulate water around the system. This flow provides the heat transfer capability to support transfer of decay heat from the reactor core via the RNS, and the SFP via its cooling system. Removal of decay heat is a Category A safety function mini-flow heat exchanger and the CCS pumps are Class 2. See Appendix 15A.

Two CCS pumps are provided, either of which can provide sufficient CCS flow to ensure the provision of adequate cooling. The requirement on the pumps is that they will continue to run reliably as required.

CCS Heat Exchangers (CCS-ME-01A/B)

The component cooling water HXs provide the facility for heat transfer to the SWS and consequent control of temperature. This supports the transfer of decay heat from the RNS and the SFS. Removal of decay heat is a Category A safety function and the CCS HXs support are Class 2. See Appendix 15A.

There are two CCS HXs, either of which can provide the full cooling duty. The requirement on the HXs is that they will provide adequate heat transfer, will not impair the operation of the CCS, and will not be unavailable because of leakage.

CCS Surge Tanks (CCS-MT-01A/B)

The CCS surge tanks provide the facility to accommodate shrink and swell of the CCS fluid due to bulk temperature changes. They also allow the total CCS inventory to be monitored. This allows the CCS to support the transfer of decay heat from the RNS and the SFS. Removal of decay heat is a Category A safety function and the CCS surge tanks are Class 2. See Appendix 15A.

CCS CIV Relief Valve (CCS-PL-V220)

A relief valve is provided to prevent overpressurisation of the return component cooling water line containment penetration. The valve serves to support containment integrity and the prevention of the release of radioactive material. This is a Category A safety function. The valves are considered Class 1. See Appendix 15A.

CCS CIVs (CCS-PL-V200, -V207, -V208)

The CIVs serve to support containment integrity and the prevention of the release of radioactive material. This is a Category A safety function. The valves are considered Class 1. See Appendix 15A.

These valves are also required to close on receipt of a reactor coolant pump bearing water high temperature pump trip signal. This is required to provide automatic isolation of the CCS containment supply and return lines in the event of a reactor coolant pump external heat exchanger tube break at power, to prevent leakage of reactor coolant activity outside containment and radioactive release through the CCS surge tank vent in the turbine building. Prevention of release of radioactive material through the RCS pressure boundary is a Category A safety function. The primary protection against these is through the integrity of the RCP high pressure motor coolers.

Two valves are partnered in isolation of the penetration and the requirement is that at least one of them will close on demand. A third motor-operated valve is partnered with the check valve in isolation of the penetration. The requirement is that this valve will close on demand.

CCS CIV Check Valve (CCS-PL-V201)

The CIV serves to support containment integrity and the prevention of the release of radioactive material. This is a Category A safety function and the valve is considered Class 1. See Appendix 15A.

The valve is partnered with a motor-operated valve in isolation of the penetration. The requirement is that this valve will close on demand.

17.10.1.4 Justification of Claims on Components and Equipment

Component Cooling Water Pumps (CCS-MP-01A/B)

The component cooling water pumps are designed to Hydraulic Institute standards and are very similar to the design of like pumps on currently operating PWRs. As a result, the information from the operation of these in-service pumps offers a high degree of confidence about the reliability to be expected from these pumps. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate the probability of failure to start, the probability of failure within the first hour of operation and the probability of failure to continue operation. This indicates that the claims being made are in line with operational experience.

Given that with the unit at power, at least one of the CCS pumps will be running, the claims applicable to the starting conditions for the majority of fault sequences are considered conservative.

Routine maintenance and testing of the CCS pumps will be performed according to the manufacturer's recommendations and will include routine changeover of the pumps allocated to duty and standby roles. No specific surveillance test requirements are identified.

CCS Heat Exchangers (CCS-ME-01A/B)

The use of HXs for this type of application is very well established. The use of this type of heat exchanger gives the ability to easily change the number of plates installed and consequently allow variations to be made in cooler flow velocity, and heat exchange area, to optimise the performance of the coolers to the system needs. The plate heat exchangers are substantially smaller than conventional shell and tube heat exchangers since they operate in a true counter-current flow arrangement and use turbulent flow to increase the U-value of the heat exchanger.

Routine maintenance and testing of the CCS HXs will be performed according to the manufacturer's recommendations and will include routine changeover of the HXs allocated to duty and standby roles. No specific surveillance test requirements are identified.

Component Cooling Water System Surge Tanks (CCS-MT-01A/B)

The CCS surge tanks are mounted at a high elevation that allows them to be open to atmosphere while still inherently providing acceptable net positive suction head for the CCS pumps.

Whilst the tanks are constructed from carbon steel, the internal surfaces are coated to provide protection against corrosion from the CCS fluid. The tanks are constructed to ASME Boiler and Pressure Vessel Code, Section VIII, Division 1 (Reference 17.9). The design is very similar to like tanks on currently operating PWRs and on other nuclear power stations. This gives considerable confidence that the tank will be able to perform as expected.

Routine maintenance and inspection of the CCS surge tanks will be performed according to the manufacturer's recommendations. No specific surveillance test requirements are identified.

CCS CIV Relief Valve (CCS-PL-V220)

A relief valve is provided to prevent overpressurisation of the return component cooling water line containment penetration. This relief valve prevents overpressurisation that might

be caused by thermal expansion of the fluid between the containment isolation valves following an event causing containment isolation. The valve is manufactured from carbon steel which is compatible with the CCS water with corrosion inhibitor that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the CCS CIVs are based on the ASME programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

Containment Isolation Valves (CCS-PL-V200, -V207, -V208)

The CIVs are motor operated, which means they will inherently fail "as is" and clearly this is not fail-safe with respect to the containment isolation function itself. Given that spurious actuation of this function when not required could, in itself, give rise to safety concerns, this arrangement is judged appropriate.

All valves are manufactured from carbon steel which is compatible with the CCS water with corrosion inhibitor that passes through them. They are designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the CCS CIVs are based on the ASME programmes appropriate for these types of valves as used in existing nuclear power stations. The testing is:

- A full stroke operability test is performed in accordance with the ASME Boiler and Pressure Vessel Code.

- Visual confirmation of valve operation during the stroke testing is performed every 2 years.

- Given that they are CIVs, seat leakage limits will be tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

CCS CIV Check Valve (CCS-PL-V201)

This CIV is a check valve and operation depends only upon the pressure difference across it and not on any method of powered actuation. This passive approach offers a high degree of inherent safety and reliability.

The valve is manufactured from carbon steel to ensure compatibility with the water that passes through it. It is designed to ASME Boiler and Pressure Vessel Code, Section III-2.

The maintenance and testing arrangements for the CCS CIVs are based on the ASME Boiler and Pressure Vessel Code, Section III programmes appropriate for these types of valves as used in existing nuclear power stations. Given that they are CIVs, seat leakage limits will be

tested to verify leak tightness. This test will be performed as an LLRT in line with the CIV leak test programme (Reference 17.11).

17.10.2 Onsite Diesel Generator System (ZOS)

17.10.2.1 Role

A detailed description of the onsite diesel generator system is given in Chapter 18. Further design details of this system and its constituent components are delineated in Reference 17.34 and Section 6.10.

While the system does not provide direct support to any primary safety function in itself, the diesel generators do support a number of systems used as defence in depth to fulfil these primary safety functions. This support is through the provision of standby electrical power supplies that can be made available in the event of a loss of offsite power supplies.

The plant design provides for two independent, self-contained standby diesel generator systems. Each has its own diesel engine, electrical generator, control, and fuel systems. Each onsite diesel generator is connected to separate parts of the main electrical power system as described in Section 6.10 and Chapter 18. In the event of a loss of voltage detected on the associated main 11-kV switchboards, both onsite standby diesel generators are started and some loads from the supported systems are reconnected to the supplies by a sequencer that aims to ensure that the addition of load is done in a way that the diesel engines can accommodate. The remaining loads can be connected manually, as required.

The onsite standby diesel generators provide support to the following systems in performing their defence in depth safety functions:

- RNS
- SFW
- CCS
- SWS
- SFS
- CVS
- FWS (start-up portion)

The standby onsite diesel generators are supported by the standby diesel fuel oil system (DOS); however, this system is used to top off a diesel day tank from which the engines draw their immediate supplies. The standby diesel fuel oil system is therefore only needed in its supporting role for any period of extended loss of offsite power that exceeds 24 hours.

17.10.2.2 System Components and Equipment Contributing to Safety Function

The following subsystems contribute to the diesel generator unit performing its safety function:

- **Diesel Generator Engine (ZOS-MS-05A/B)** – This is a 16-cylinder, turbocharged, four-stroke design with a rated power of approximetly 5 MW. The engine is maintained in a standby mode and is automatically started if low voltage is detected on its associated essential switchboard. The engine then runs up to speed. Fuel is supplied to the engine from a day tank situated at a higher elevation to preclude the need for priming pumps. The requirement to start, run up to speed, and then be loaded up is a safety requirement.

- **Diesel Generator Starting Units (Starting Subsystem)** – This consists of an ac-motor-driven, air-cooled compressor; a compressor inlet air filter; an air-cooled after-cooler; an in-line air filter; a refrigerant dryer; and an air receiver with sufficient storage capacity for three diesel engine starts. The interconnecting stainless-steel piping from the compressor to the diesel engine dual air starter system includes air filters, moisture drainers, and pressure regulators to provide clean, dry, compressed air at normal diesel generator room temperature for engine starting. Provision of air for engine starting is a safety requirement.

- **Air Intake and Exhaust Subsystem** – Each engine is provided with two air intake filters. They are dry-type, replaceable-element paper filters, capable of reducing airborne particulate loading to a level acceptable to the engine before it is fed to a turbocharger. The engine exhaust gas circuit consists of the engine exhaust gas discharge pipes from the turbocharger outlets to a single, vertically mounted outdoor silencer that discharges to the atmosphere. Provision of combustion air and management of exhaust gas is essential to ongoing engine operation and hence is a safety requirement.

- **Diesel Generator Radiators (Engine Cooling Subsystem**) – This is an independent closed-loop cooling system, rejecting engine heat through two separate roof-mounted, fan-cooled radiators. The system consists of two separate cooling loops, each maintained at a temperature required for optimum engine performance by separate engine-driven, coolant water circulating pumps. One circuit cools the engine cylinder block, jacket, and head area; and includes an additional separate motor-driven pump for operation with the engine shut down, while the other circuit cools the oil cooler and turbocharger after-cooler. The cooling water in each loop passes through a three-way contained temperature control valve that modulates the flow of water through or around the radiator, as necessary, to maintain required water temperature. Maintenance of the engine at the correct operating temperature is essential to ongoing engine operation and hence is a safety requirement.

- **Engine Lubricating Oil Subsystem** – This includes an engine oil sump, a main engine-driven oil pump, and a continuous engine prelube system consisting of an ac and dc motor-driven prelube pump and electric heater. The prelube system maintains the engine lubrication system in service when the diesel engine is in standby mode. The safety requirement is to circulate lube oil through the engine and various filters and coolers to maintain the lube oil properties suitable for engine lubrication.

- **Engine Speed Control Subsystem** – This consists of an electrohydraulic governor that provides the primary control and a backup. The system interfaces with the diesel engine fuel rack to ensure that when the engine is running independently with the generator disconnected from the grid supplies, its speed is maintained constant as electrical loads are added or removed, so that the frequency of the generated electrical supply remains within acceptable limits. When the engine is running with its generator connected to the offsite grid, this system is used to regulate output load. The electrohydraulic governor also provides control of the engine acceleration following starting to minimise the risk of overspeed during the run-up. The safety requirement is to accelerate the engine to nominal speed and then maintain engine speed within acceptable limits when operated independently from the offsite grid.

17.10.2.3 Claims on Components and Equipment

Diesel Generator Engine (ZOS-MS-05A/B)

The diesel engines provide power for the onsite electrical system which supports the ac electrical power driven defence in depth functions such as removal of decay heat. Removal of decay heat is a Category A function and the diesel engines are Class 2. See Appendix 15A.

Whilst the two engines are connected to different parts of the main ac power system, each engine feeds respective trains of redundant components in the supported systems. As a result, each diesel can have the same end-duty with respect to the primary safety functions. As such, either engine successfully starting and continuing to run will achieve the safety function. The requirement is therefore that one engine will start on demand, and then, having started, will continue to run until offsite power supplies are restored.

Diesel Generator Starting Units (Starting Subsystem)

The starting subsystem supports the diesel engines. The diesel engines are supporting a Class A function. The starting subsystem is Class 2. See Appendix 15A.

The starting air system maintains enough air stored at pressure to attempt three starts of the engine. As a result, there is no claim against the air compressor and associated systems; the claim is that the air storage receivers and air start valves will operate on demand to deliver enough air, at the correct pressure, for three start attempts.

Air Intake and Exhaust Subsystem

The air intake and exhaust subsystem supports the diesel engines. The diesel engines are supporting a Class A function. The air intake and exhaust subsystem are Class 2. See Appendix 15A.

The requirement against the air intake is that it will provide adequate air supply to the engine, both in terms of volume and quality. The requirement against the exhaust system is that the exhaust products are taken away and discharged in a way that does not lead to unacceptable backpressure for the engine and also does not lead to recirculation back into the air intake.

Diesel Generator Radiators (Engine Cooling Subsystem)

The engine cooling subsystem supports the diesel engines. The diesel engines are supporting a Class A function. The engine cooling subsystem is Class 2. See Appendix 15A.

The requirement against the engine cooling system is that it will provide adequate cooling capacity to ensure that the engine temperatures are maintained within acceptable limits.

Engine Lubricating Oil Subsystem

The engine lubricating oil subsystem supports the diesel engines. The diesel engines are supporting a Class A function. The engine lubricating oil subsystem is Class 2. See Appendix 15A.

The requirement against the lubricating oil system is that it will provide oil, at a suitable temperature, pressure, and quality, to ensure that the diesel engine is adequately lubricated.

Engine Speed Control Subsystem

The engine speed control subsystem supports the diesel engines. The diesel engines are supporting a Class A function. The engine speed control subsystem is Class 2. See Appendix 15A.

The requirement is that the engine speed control subsystem will ensure that the ac frequency does not drop below the specified percent of nominal value at any time during the loading sequence and subsequent operation; and that during each step of the load sequencing, the ac frequency will recover to within specification in no more than specified percentage of the sequence step time interval.

17.10.2.4 Justification of Claims on Components and Equipment

Diesel Engine (ZOS-MS-05A/B)

Diesel engines are a well-established form of standby power supply both in the nuclear power industry and elsewhere. Consequently, there is a large body of evidence supporting the expected reliability and significant effort is put into developing maintenance and testing regimes to maximise reliability.

Reliability data collected from in-service plants (Reference 17.7, Table 5-1) indicate that the claims being made are conservative.

Whilst there are many potential failure mechanisms, the routine surveillances and the surveillance programme are intended to minimise the risks associated with them. Routine maintenance will be performed in line with the manufacturer's recommendations. The testing regime is:

- Verification that the day tank contains more than a minimum volume of fuel oil will be performed monthly.
- Verification that the engine starts correctly and can be loaded in excess of 4 MW and run for more than 1 hour will be performed quarterly.
- Verification that the engine starts correctly and can be loaded in excess of 4 MW and run for more than 24 hours will be performed every 10 years.

Diesel Generator Starting Units (Starting Subsystem)

The starting subsystem air receivers are sized to store sufficient air for three start attempts at the coldest possible ambient air conditions. Given that they are charged up to provide this condition during normal operation and can be monitored at all times, this provides inherent assurance of a start capability for the engine.

The air receivers will be manufactured from carbon steel to the ASME Boiler and Pressure Vessel Code, Section VIII pressure vessel code (Reference 17.9) but will be provided with an interior coating to minimise corrosion. A drain valve is provided at the lowest point to allow any condensate that has collected to be drained as required. Two air start motors and associated starting air valves are provided.

There are no separate figures available for the specific reliability of starting system components, and testing is effectively covered by the arrangements identified above for the

engine. Given that the air receivers will be statutory pressure vessels, however, they will be subject to insurance inspection arrangements.

Air Intake and Exhaust Subsystem

The air intake and exhaust subsystem comprises passive components and are therefore of inherently high reliability. They are not required to change state when the engine starts operating and therefore are subject only to gradual degradation through ageing.

There are no separate figures available for the specific reliability of air intake and exhaust system components, and testing is effectively covered by the arrangements for the engine identified in Section 17.10.2.4.1. Ongoing maintenance will be carried out in accordance with the manufacturer's recommendations to minimise the impact of degradation through ageing.

Diesel Generator Radiators (Engine Cooling Subsystem)

The jacket water cooling subsystem has a separate motor-driven pump that allows the system to be operated with the main diesel engine shut down. This feature, along with an associate jacket water system heater, means that the engine can be maintained warm at all times in preparation for starting. The lubricating oil cooling system is effectively kept warm through transfer of heat from the main lubricating oil warming system.

Once the engine is started, the requirement changes from warming to cooling. The cooling radiators are passive components and the temperature control valve design relies on the inherent properties of materials within the valve and not on external control mechanisms. The active radiator fans provide heat removal from the radiators.

There are no separate figures available for the specific reliability of engine cooling subsystem components, and testing is effectively covered by the arrangements for the engine identified in the beginning of Section 17.10.2.4. Ongoing maintenance will be performed in accordance with the manufacturer's recommendations.

Engine Lubricating Oil Subsystem

The lubricating oil subsystem has a separate motor-driven pump that allows the system to be operated with the main diesel engine shut down. This feature, along with the lubricating oil heater, ensures that the engine components are kept warm and the oil is maintained at an appropriate temperature to ease lubrication of the engine during starting. The lubricating oil heater is thermostatically controlled to ensure that the heater element is maintained cool enough to prevent coking of the oil and the consequent risk of blocking filters and cooler tubes.

Once the engine is started, the requirement changes from warming to cooling. The cooling radiators are passive components and the design of temperature control valve relies on the inherent properties of materials within the valve and not on external control mechanisms. The active radiator fans provide heat removal from the radiators.

There are no separate figures available for specific reliability of engine lubricating oil subsystem components, and testing is effectively covered by the arrangements for the engine identified in the beginning of Section 17.10.2.4. Ongoing maintenance will be performed in accordance with the manufacturer's recommendations.

Engine Speed Control Subsystem

The electro-hydraulic governor can be a part of the diesel engine and is therefore covered by the justification in the beginning of Section 17.10.2.4. A supplemental mechanical governor provides diversity in maintaining engine control.

17.10.3 Service Water System (SWS)

17.10.3.1 Role

A detailed description of the SWS is given in Section 6.11 of this PCSR. Further design details of this system and its constituent components are delineated in Reference 17.35.

The system does not directly contribute to any primary safety function in itself, but it does support the CCS; as a consequence, it indirectly supports a number of the systems used as defence in depth to contribute to the primary safety functions. The support is provided through the provision of a heat transport mechanism for the transfer of decay heat, and heat from other sources, away from the CCS.

The system is made up of two interconnected trains that can be segregated into two independent trains each with an SWS pump and independent pipework to a respective CCS HX. The pipework then continues to take each SWS flow to a separate cooling tower. Each train is capable of providing 100 percent of cooling duty during normal operation. There are also cross connections between the two trains that allow either pump to work with either HX, and either HX to work with either cooling tower. Both trains are required to be in service to meet target cooldown rates in preparation for refuelling, but a single train is capable of meeting this duty with extended cooldown times.

The SWS is supported by the ECS and the ZOS in the provision of its safety function.

The SWS supports the CCS in the provision of its safety function.

17.10.3.2 System Components and Equipment Contributing to Safety Function

The SWS pipework is designed and constructed to ASME B31.1 standards. The following components contribute to the SWS performing its safety function:

- **Service Water Pumps (SWS-MP-01A/B)** – These are vertical, centrifugal, constant-speed, electric-motor-driven pumps. The pumping elements of one pump are mounted in each cooling tower basin structure. One pump is normally running and the safety requirement is to continue running to provide adequate SWS fluid flow to meet design cooling requirements.

- **Service Water Cooling Towers (SWS-MA-01A/B)** – These are counter flow, induced-draft towers. Each utilises one fan, located in the top portion of the cell, to draw air upward through the fill counter to the downward flow of water. Each fan is driven by a two-speed electrical motor through a reduction gearbox. The cooling tower cold water temperature is normally automatically controlled by operation of the tower fans. The fan will be on high speed, low speed, or off, depending on the temperature of the heated service water returning to the cooling tower. When necessary, the water flow to each cooling tower cell can be diverted directly to the basin, bypassing the tower internals. This is achieved by opening a full-flow bypass valve and is used to maintain water temperatures within design limits during very cold ambient conditions. The safety

requirement against the service water cooling towers is that they provide adequate heat transfer to ensure that the SWS water temperature to the CCS HXs remains acceptable through the full range of design heat loads.

17.10.3.3 Claims on Components and Equipment

Service Water Pumps (SWS-MP-01A/B)

The service water pumps provide the motive force to circulate water around the system. This flow provides the heat transfer capability to support transfer of decay heat from the reactor core and the SFP via the CCS HXs. Removal of decay heat is a Category A safety function. The SWS pumps are Class 2. See Appendix 15A.

Two service water pumps are provided, either of which can provide sufficient system flow to ensure the provision of adequate cooling. The requirement on the pumps is that they will continue to run reliably as required.

Service Water Cooling Towers (SWS-MA-01A/B)

The service water cooling towers provide the facility for heat transfer to atmosphere. This supports the transfer of decay heat from the reactor core and the SFP via the CCS HXs. Removal of decay heat is a Category A safety function. The SWS cooling towers are Class 2. See Appendix 15A.

Two cooling towers are provided and provide full cooling duty. The requirement on the cooling towers is that the tower fan will start and run as required and that the tower structure breaks the water flow up into a sufficiently fine flow of droplets so that the design heat transfer takes place.

17.10.3.4 Justification of Claims on Components and Equipment

Service Water Pumps (SWS-MP-01A/B)

The service water pumps are designed to Hydraulic Institute standards and are very similar to like pumps on currently operating PWRs. As a result, the information from the operation of these in-service pumps offers a high degree of confidence about the reliability to be expected from these pumps. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate the probability of failure to start and having started, the probability of failure within the first hour of operation and the probability of failure to continue operation thereafter. This indicates that the claims being made are in line with operational experience.

Given that with the unit at power at least one of the service water pumps will be running, the claims applicable to the starting conditions for the majority of fault sequences could be considered conservative.

Routine maintenance and testing of the SWS pumps will be performed according to the manufacturer's recommendations and will include routine changeover of the pumps allocated to duty and standby roles. No specific surveillance test requirements are identified.

Service Water Cooling Towers (SWS-MA-01A/B)

The service water cooling towers enable evaporative heat transfer to the ambient air to take place. Provided that the water supply to the cooling towers has sufficient pressure to pass

through the sprays, the heat transfer will take place and the service water will be cooled. This is an inherently safe approach.

The service water cooling towers as built will be tested to Cooling Tower Institute standards to confirm that performance is in line with design expectations, as discussed in Reference 17.17. While the design of the cooling tower will always ensure some heat transfer, the tower fan must operate correctly to achieve the design rating. Data collected from in-service plants (Reference 17.7, Table 5-1) indicate the probability of failure to start from standby and the probability of failure within the first hour of operation and the probability of failure to continue operation thereafter.

Routine maintenance and testing of the SWS cooling towers will be performed according to the manufacturer's recommendations and will include routine changeover of the towers allocated to duty and standby roles. No specific surveillance test requirements are identified.

APPENDIX 17A
FUEL HANDLING EQUIPMENT OPERATION EXPERIENCE

The fuel handling equipment in the AP1000 design is very similar to the equipment used for the same purpose on previous Westinghouse pressurised water reactors. To understand how well the fuel handling equipment has performed on these older stations, a review of the Institute of Nuclear Power Operations (INPO) operating experience database was carried out. As would be expected, there have been a number of events reported, of varying significance. Four of the most significant are considered to be:

- OE30024 – Fuel Transfer System Up-Ender Weld Failure
- OE30103 – Fuel Transfer System Cart Drive Cable Disconnects During Fuel Movement
- OE30245 – Refuelling Equipment Issues
- OE30315 – Manipulator Crane Hoist Fails to Stop Automatically

For these and the other events that were identified, although there was some failure of one or more components on some part of the fuel handling equipment, none of them have led to fuel assembly cladding breaches. Consequently, the AP1000 fuel handling equipment design is based on extensive operating experience.

18 ESSENTIAL ELECTRICAL SYSTEMS

18.1 INTRODUCTION

18.1.1 Architecture

This chapter of the Pre-Construction Safety Report (PCSR) provides a description of the electrical systems for the AP1000 plant, including the main electrical system supply from the grid, the Class 1, 2, and 3 distribution systems, ac and dc supplies, and the standby and ancillary diesel generators. Offsite power is considered general non-safety prior to connection to the high side of the Unit Auxiliary Transformers (UATs). From the low side of the UATs to the medium voltage buses ES3-ES7 are Class 3, ES1 and ES2 are Class 2. A one-line diagram showing the electrical system architecture and classification is provided in the "AP1000 Electrical System Basis of Safety Case," Reference 18.25. Electrical system design principles, equipment layout, installation requirements, and high level safety functions are also described within the arguments and evidence that support the safety claims contained in Reference 18.25.

The AP1000 plant design philosophy uses passive Class 1 structures, systems or components (SSCs) as the principal means of providing Category A safety functions (primarily criticality control, residual heat removal, containment, and spent fuel pool makeup and cooling) with active Class 2 SSCs providing defence-in-depth (DiD). Due to the passive nature of the principal means of providing Category A safety functions, there are no alternating current (ac) motors associated with the AP1000 plant's Class 1 safe shutdown function. The AP1000 plant is designed to achieve safe shutdown in the complete absence of all external or internal ac power supplies, including onsite standby generation, as described in Appendix 9C. Safe shutdown as used in this document is defined in Appendix 9C to be K_{eff} less than 0.99 and an average RCS temperature less than 215.6°C (420°F). The credited electrical systems for a given fault are presented in Chapter 8. Note that DiD considerations result in a plant that is normally operated and shut down utilising available ac power supplies and components.

The AP1000 plant electrical system fulfils a number of electrical functions that are important to nuclear safety and contribute to DiD. To achieve its safety and operational objectives, the AP1000 plant electrical system is subdivided into the following functional units, which are classified in accordance with their importance to nuclear safety using the scheme described in Chapter 6:

- Main grid voltage, 27kV voltage main generator bus and 11kV voltage ac electrical distribution systems (main generation system [ZAS] and main AC power system [ECS] – Classes 1, 2, and 3, note that the only Class 1 portions of this ac power system is the RCP trip breaker.)
- Class 2 Standby 11kV ac diesel generator system onsite standby power system (ZOS)
- Class 1 250V dc electrical distribution system (IDS)
- Class 2 125/250V dc electrical distribution system (EDS)

Safety claims made in regard to the overall electrical system are incorporated in the "Electrical Basis of Safety Case Document", UKP-GW-GL-163 (Reference 18.25).

Simplified one line diagrams of the ac and dc electrical systems are shown in Figures 18-1A, 18-1B, and 18-3 through 18-6. A description of the high, medium, and low voltage ac systems and the low voltage dc systems is provided below.

18.1.2 High Voltage AC Electrical System Interfaces with the Grid

The high voltage system (ZAS and ECS) includes the main generator and its circuit breaker, unit auxiliary transformers, reserve auxiliary transformers (all Class2 and 3 designated SSCs), and the interconnecting busses. The main generation connection (when generator is online) and the plant maintenance connection (when the generator is offline) to the grid is via the main step-up transformers (grid voltage/27kV). An alternate maintenance connection that is also used for fast bus transfer is available to medium voltage busses from the grid via the reserve auxiliary transformers (grid voltage/11kV). The fast bus transfer functionality of the alternate connection is discussed in Section 18.4. This portion of the electrical system includes Class 2 and 3 SSCs.

Seven 11kV busses, including the 11kV standby diesel generators (Class 2), the reactor coolant pumps (RCPs) associated trip circuit breakers (Class 1), and variable frequency drives (VFDs), are connected to the safety SSCs.

The 11kV medium voltage bus ECS ES-1 and ES-2 services the plant DiD loads. These 11kV buses can be supplied by either the unit auxiliary transformers, reserve auxiliary transformers, or the backup standby diesels. The standby diesels are Class 2, and both sets of transformers are Class 3.

18.1.3 Low Voltage AC Electrical Distribution Systems

The low voltage ac electrical distribution system (part of ECS) includes load centres, motor control centres, and distribution panels and interconnecting cables, and are Class 3 electrical systems. The ancillary diesel generators (Class 2) provide means to supply low voltage ac power to selected loads in the post-72 hours Design Basis Event (DBE) scenario of the plant design basis. In the event that the onsite ancillary diesel generators are unavailable, for instance following a seismic event, offsite portable generators can be brought onsite and connected via a Class 1 connection point.

18.1.4 Direct Current Electrical Systems

The dc systems include both the Class 1 250V dc (and the associated 230V ac electrical inverter distribution system [IDS]) and the Class 2 125/250V dc (and the associated 230V ac electrical inverter distribution system [EDS]) that serve plant loads.

Included within IDS are batteries, battery chargers, battery monitors, inverters, transfer switches, regulating transformers, motor control centres, various distribution panels, and interconnecting cables. See Figures 18-3, 18-4, and 18-4A for the IDS functional arrangement diagrams.

Included within the EDS are batteries, battery chargers, battery monitors, inverters, transfer switches, regulating transformers, various distribution panels, and interconnecting cables. Inverters are not included as part of the EDS5 subsystem, however. The EDS functional arrangement diagrams are shown in Figures 18-5 and 18-6.

18.1.5 Human Factors Interface

Human operations of electrical related activities are assessed by the human factors group. As a result of Human Factor analysis, a summary of the human factors is provided for the inputs to the design and safety processes, error identification methodology and classification, and ALARP arguments. The "UK AP1000 Plant Electrical Equipment Maintenance and Surveillance" (Reference 18.24) provides guidance for the human factors input necessary during development of the site specific maintenance procedures for the electrical system. Reference 18.25 provides claims, arguments, and evidence regarding the human factors assessment of human operations in support of the electrical system as well as the development of the site specific procedures.

18.2 ELECTRICAL SYSTEM DESIGN PRINCIPLES

18.2.1 Electrical Equipment Redundancy, Diversity, and Separation Requirements

The design of the AP1000 plant power distribution systems requires physical separation between Class 1 circuits and between Class 1 and Class 2 or 3 circuits. Electrical isolation is also required between Class 1 and interfacing Class 2 or 3 circuits. Redundancy is designed into IDS, EDS, ZOS, and ECS to maintain availability, reliability, and maintainability of these systems.

The diverse mitigation of frequent faults (faults with initiating event frequencies greater than or equal to 1E-3) is assessed in Reference 18.22. Reference 18.22 considers all frequent faults and identifies both a primary and a diverse means of mitigating each fault including the source of electrical power. This assessment provides evidence that the electrical system supports the diversity requirements of the AP1000 safety systems, as claimed in the safety claims of Reference 18.25.

The electrical system supports diversity of PMS and DAS by providing two separate systems. In order to provide a diverse means of performing the necessary safety functions the DAS (powered by the 2 divisions of EDS) requires a different normal input power supply from the PMS (powered by the 4 divisions of IDS). Further detail on the electrical system support of DAS diversity is provided in the claims and arguments made in Reference 18.25. Specific redundancy and separation requirements for the IDS, EDS, ZOS, and ECS are discussed below.

Redundancy (IDS – Class 1)

The IDS has five independent 250V dc battery subsystems organized in four divisions: A, B, C, and D and a full spare battery system. Divisions A and D are each comprised of one battery bank, one switchboard, and one battery charger. Divisions B and C are each composed of two battery banks, two switchboards, and two battery chargers. The battery banks in divisions A through D, designated as a 24-hour battery bank, provide power to the loads required for the first 24 hours following a DBE. The second battery bank in divisions B and C, designated as a 72-hour battery bank, is used for those loads requiring power for the first 72 hours following a DBE. The spare battery system is comprised of one battery bank, one switchboard, and one battery charger. All battery banks in divisions A, B, C, D and Spare are identical.

A fused transfer switch panel is used to connect each battery to its switchboard. Each switchboard connected to a 24-hour battery bank supplies power to an inverter, a dc distribution panel, and a dc motor control centre (MCC). All Class 1 battery banks are

identically sized, including a spare to allow for easy replacement and continued availability of dc power. The batteries have been designed based upon a calculated load profile with margin for thermal aging and other design factors.

Safe shutdown of the reactor at any time can be achieved with any three of the four 24 hour IDS divisions. As described in Appendix 9C, the necessary ADS actuation is driven by a timer to automatically occur within the 24 hour capacity of the IDS batteries. The IDS 72 hour batteries provide the power to support plant monitoring of the safe shutdown state.

The IDS inverter system provides power at 230V ac within each of the four independent divisions, primarily for powering of controls and instrumentation (C&I) loads. Under normal operation, the inverters receive power from the associated charger with the associated battery bank in standby. If an inverter is inoperable, the static switch featuring a make before break contact automatically switches to regain power from the backup AC power source. Backup power is provided by a regulating transformer connected to a low voltage/medium voltage bus arrangement supplied from a standby diesel generator backed Class 2 bus.

To supply power following the post-72-hour period following a DBE, two ancillary ac generators are provided to supply power to the Division B and Division C ac loads via the regulating transformers. This ac power source can be used to power post-accident monitoring (PAM) loads, lighting in the main control room (MCR), and portable ventilation in the MCR and Division B and C C&I rooms. Figure 18-4 shows the post-72-hour power distribution subsystem.

If the permanently installed Class 2 ECS ancillary generators are not available, then temporary portable generators can be used. Power cables from these generators would be connected to the ancillary diesel generator panels or to the secondary of the IDS regulating transformers. The connection details for the portable generators are discussed in detail in the "AP1000 Plant Post-Fukushima Assessment," UKP-GW-GGR-201 (Reference 18.4). These portable generators are assumed to be stored for enough from the plant that they will be isolated from the event, and a Class 1 connection point is provided in order to ensure post-72-hour support is available following a seismic event.

Reference 18.25 contains safety claims relating to post-72 hour support and portable generators.

Figure 18-3 shows the functional arrangement of the 24-hour IDS subsystem for Divisions A and D, which provides the electrical supply to the Class 1 systems. Figure 18-4 shows the functional arrangements of the 24-hour and 72-hour IDS for Divisions B and C. As these figures show, these systems have electrical supplies through the following three alternatives:

- Supply from the battery
- Supply from the main generator or offsite sources through the ECS and the charger
- Supply from the standby diesel generator (ZOS) through the ECS and the charger

Segregation (IDS – Class 1)

Segregation of the divisions within the IDS is incorporated into the design. The AP1000 plant cable and cableway system comprises five distinct and physically separated groups, namely Groups A, B, C, D, and N. Separation Group A contains power, control, and instrument cables connected to Class 1 components of division A only. Likewise, separation of Group B serves Class 1 components of Division B only and similarly for Divisions C and D. Cables and cableway designated as separation Group N serve equipment not assigned to the four

groups performing Class 2 safety functions. Group N cableways are allowed to be routed in the same areas as Groups A, B, C, or D as long as the established horizontal and vertical separation distances, defined in APP-GW-E1-001, "Electrical Systems Design Criteria," (Reference 18.31) are strictly observed. The IDS equipment is physically separated. The IDS ac and dc panels are split up amongst four different rooms at elevation 100 m (100') and 102.134 m (107'). The 72 hour battery racks are located at elevation 94.666 m (82'-6") in two independent rooms. Likewise the four divisions of IDS 24 hour battery racks are located in four individual rooms at elevation 89.789 m (66'-6") along with the spare battery rack in a separate room. The battery chargers and regulating transformers are organized by division at elevation 94.666 m (82'-6") in four separate rooms.

Cableway separation and segregation criteria are defined by Reference 18.1.

Redundancy (EDS – Class 2)

The EDS has four dc battery systems (EDS1 to EDS4) organized in two subsystems, 1 and 2 (Figure 18-5), with another dc system – EDS5 (see Figure 18-6). A spare EDS battery system (EDSS) is also provided and can be used in place of any of the EDS battery subsystems.

Figure 18-1B shows the arrangement of the EDS1, EDS2, EDS3, and EDS4, which provide the electrical supply to the Class 2 systems. Figure 18-5 shows that EDS1, EDS2, EDS3, and EDS4 have three supplies from the following:

- Supply from the battery
- Supply from the main generator or offsite sources through the ECS and the charger
- Supply from the standby diesel generator (ZOS) through the ECS and the charger

Segregation (EDS – Class 2)EDS battery chargers and inverters are separated. The EDS battery racks are located in two rooms in the annex building with EDS2 and EDS4 grouped together and EDS1 and EDS3 together. In the turbine building EDS1 and EDS3 dc distribution panels are located in switchgear room #1, and EDS2 and EDS4 dc distribution panels are located in switchgear room #2. The EDS ac distribution panels are located in the annex building two electrical switchgear rooms.

Redundancy and Segregation (ZOS – Class 2)

Provision for redundancy and segregation within the ZOS/ECS Class 2 standby diesel generator system is as follows:

- Only one of two standby diesel generators is required as each one is rated at 100 percent of the load required to supply the Class 2 DiD loads.

- Redundant sets of Class 2 ac powered equipment (ZOS-MG02A & ZOS-MG02B) are provided – each connected to one of the two diesel generators (DGs).

- The switchgears are in separate rooms within the annex building and the standby diesel generators in separate rooms within the diesel generator building.

Redundancy and Segregation (ECS – Class 2 and Class 3)

Provision has been made in the design of the Class 3 ECS to maintain supplies to the Class 1and 2 inverter systems through the Class 2 switchboards ECS-ES-1 and ECS-ES-2 by having alternative supplies from separate sources to each switchboard (Figures 18-1A and

18-1B). The Class 3 ECS switchboards are located in both the annex and turbine buildings in separate locations to the Class 2 switchboards, providing segregation between the two classes of systems. The Class 1 RCP breakers are located in the auxiliary building and its Class 2 distribution boards are situated in the annex building. Redundancy is provided by the use of two RCP breakers in series with each breaker's control supplied from a different division of IDS (Figure 18-1C). Segregation is provided by having each of the breakers in a pair located in separate areas of the auxiliary building.

There are two ancillary diesels provided for redundancy purposes. Each ancillary diesel is rated to power the necessary systems to support post-72-hour maintenance of safe shutdown including one train of post-accident monitoring. The preferred supply is from the ECS with the alternative supply provided by the corresponding ancillary diesel generator, see Figure 18-7. In addition to the ancillary diesel generators, offsite portable generators can be brought on site in the event the ancillary diesel generators are not available. The offsite diesel generators can be connected to where the ancillary diesel generators connect or directly to the IDS in the auxiliary building.

18.2.2 Cable and Cableway System Design and Installation

18.2.2.1 Cable and Cableway Design Principles

All cables are sized to carry steady state load current and calculated fault current as well as to minimize voltage drop. Class 1 cables are qualified in accordance with the "AP1000 Environmental Conditions for Equipment Qualification," APP-GW-VP-030 (Reference 18.5). This requirement is captured in the design specifications referenced within Reference 18.25. All Class 1 cables are appropriately protected from mechanical damage using cable trays and/or rigid metal conduit. Separation and segregation is in accordance with defined nuclear and conventional installation standards; the standards are referenced in subsection 18.2.1 of the PCSR. Class 2 and 3 designated cables and cableways are electrically and physically isolated from the safety cables, cableways, and Class 1 power sources.

The IDS, EDS, and ECS cables and cableways are routed such that required separation between redundant components and systems is maintained.

Different levels of cable separation are applied for the various safety classes commensurate with the safety category of the component function. Complete electrical isolation and physical separation is applied for Class 1 DC and inverters (IDS) performing Class 1 functions. Physical separation is maintained between the different groups as well as between the IDS and other Class 2 and 3 systems.

Separation is provided for Class 2 electrical cables which provide power to redundant functions required for normal shutdown. The redundant trains are routed in separate raceways with fire protection or fire suppression within the rooms provided between the trains. Individual cables and conduits are used to separate the trains of the ancillary diesel power cables.

18.2.3 Earthing and Lightning Protection System Design and Installation

18.2.3.1 Earthing and Lightning Design Principles

The earthing and lightning protection system (EGS) of the AP1000 plant summarises the functions, design criteria, and design data of the EGS and its components (Reference 18.3). It also includes the layout, instrumentation and control, interfacing system, and

environmental requirements, describes system operations, identifies monitoring, testing, and maintenance guidelines, and summarises the system design compliance with external criteria (Regulatory, Industry, Utility, etc.). Below provides a high level overview of what the schemes the system grounds and its utilization for investment protection and personnel safety.

This scheme includes the following:

- Station earthing grid
- System earthing
- Equipment earthing
- Instrument/computer earthing
- Management of electromagnetic compatibility (EMC)

EGS provides the following principal functions to provide personnel safety and investment protection:

- Maintains safe voltages across the station grid during system transients
- Provides a low impedance return path
- Maintains safe voltages in station structures during system transients
- Minimizes noise interference in instrumentation systems
- Minimizes the effects of lightning surges to equipment and structures

Lightning protection (direct stroke) is provided for all major structures and outdoor electrical equipment. Lightning arresters, main and down conductors, and air terminals are connected directly to the earthing system. The rolling sphere design concept is used for lightning protection.

Reference 18.25 contains the claims, arguments, and evidence relating to resiliency to transients and disturbances.

Detailed earthing design is site specific; evidence of the earthing design will be provided during the site design phase in alignment with Reference 18.3.

18.2.3.2 Earthing and Lightning Installation Requirements

The plant electrical system neutral, equipment, instrumentation, and lightning protection grounding systems shall be connected to the station grounding grid through the equipment grounding subsystem in accordance with international and local standards as identified in Section 7 of Reference 18.2.

18.2.4 Electrical Protection Device Design

18.2.4.1 Neutral Point Arrangements

The neutral point arrangements for the power distribution system are as follows:

AC Power System (ZAS, ECS, ZOS)

- Main Generator – high resistance ground
- Main Step-up Transformer (high voltage side) – solid ground
- Isolated Phase Bus Duct –solid ground
- Unit Auxiliary Transformers (low voltage side) – low resistance ground

- Start-up Unit Auxiliary Transformers (low voltage side) – low resistance ground
- Reserve Auxiliary Transformers (low voltage side) – low resistance ground
- Standby Diesel Generator – high resistance ground
- Ancillary Diesel Generator –solid ground
- Load Centre Transformer – solid ground
- Lighting and Distribution Transformers – solid ground

DC and Inverter Power Systems (IDS, EDS)

- The DC power systems are ungrounded. The neutral of the inverters is solidly grounded.

18.2.4.2 Electrical Protection Devices

Industry-proven, microprocessor-based, multifunction protective relays are used to provide coordinated protection, monitoring, and control of AP1000 plant ECS electrical components. The protective relay directional and non-directional overcurrent functions are used to protect the electric plant feeders, transformers, motors, and generators. The individual protective relays are connected to a centralised server that provides a graphical interface for mapping serial and Ethernet monitoring data between the protective devices. The relays communicate with the central server via one way communications paths. This safeguarding measure prevents common cause failure of the networked relays as claimed in Reference 18.25.

Class 1 and Class 2 electrical protection devices are used for protection of electrical components in the IDS and EDS respectively.

All protective relays which are considered SMART devices will have their software and hardware assessed according to the guidelines described in section 18.8.2.

Refer to the Electrical Basis of Safety Case (Reference 18.25) for arguments on the protective relaying systems.

18.2.5 Electrical Penetration Assemblies (EPAs) Design

EPAs are used to facilitate the passing of electrical conductors for instruments and electrical devices through the containment vessel and auxiliary building walls. They are designed to meet seismic requirements and to maintain containment integrity under DBE conditions, including pressure, temperature, and radiation. Safety claims on the electrical penetration assemblies are provided in Reference 18.25.

The EPA is a canister design containing multiple feed through modules (solid conduits) mounted between two header plates. Field cables are terminated at each end of the EPA in inboard/outboard enclosure assemblies (junction boxes). Each EPA is designed to carry cables of one voltage class only. Note that the EPAs for the AP1000 plant design conform to the same service level as the cables inside them.

EPA protection panels containing two fuses in series are provided for conductor feedthrough to ensure its containment sealing mechanism is maintained in the event of a short circuit on the containment cable inside. Double isolation is provided for all EPAs. At any boundary of Class 1 and Class 2 circuits there must be a qualified isolation device per the AP1000 plant electrical system design philosophy (Reference 18.31). Refer to the Reference 18.25 for the safety claims on the EPAs.

EPAs are separated according to safety classification and voltage.

18.2.6 Electrical Lighting Design

The normal lighting for ELS is provided by ECS through the MCCs for the AP1000 plant except for the remote shutdown workstation (RSW) and MCR which are provided Class 1 power. During the first 24 hour critical period following a loss of normal lighting, illumination is maintained in all areas required for the performance of emergency operations. Power is maintained jointly by the 24 and 72 hour batteries for the zero to 24 hour period and by the 72 hour batteries for the remaining period after 24 hours. During the post-72-hour period, power is delivered to the emergency lighting and to the normal lighting panels in the MCR and RSW by the ancillary or portable diesel generators through the regulating transformers.

Safety claims on adequate lighting for the MCR and RSW are contained in Reference 18.25.

18.2.7 Electromagnetic Compatibility (EMC) Design

EMC is addressed to ensure electromagnetic compliance, particularly the reduction and mitigation of potential electromagnetic interference (EMI) with regard to Class 1, 2, and 3 systems in accordance with "AP1000 Equipment Qualification Methodology" (Reference 18.30).

The approach to EMC is detailed in Reference 18.13. Further details on the management and mitigation of EMI are given in Sections 11 and 12.

18.2.8 Qualification

All Class 1, 2, and 3 equipment is environmentally and seismically qualified in accordance with Reference 18.5. Class 1 equipment is seismically qualified to function following seismic events, while Class 2 and 3 equipment are required to maintain their integrity following a seismic event so that they do not limit the performance of Class 1 equipment.

18.3 ELECTRICAL SYSTEM ARCHITECTURE/LAYOUT

18.3.1 Containment and Shield Buildings

The components that make up the AP1000 plant electrical systems are located in various plant areas as shown in Figure 18-2. The EPAs are installed in containment and pass through to the auxiliary building. These EPAs serve designated Class 1, 2, and 3 electrical loads in containment including the reactor vessel integrated head package, RCPs, motors, heaters, overhead cranes, lighting, communication, and C&I circuits.

18.3.2 Auxiliary Building

18.3.2.1 General Arrangement

Figure 18-2 shows the general arrangement of electrical system equipment components in the AP1000 plant. The Class 1 IDS equipment and the RCP switchgear are located within the auxiliary building which is a seismic Class I structure.

18.3.2.2 Equipment Rooms

Various Class 1 electrical equipment rooms are provided in the auxiliary building.

The walls between the Class 1 equipment rooms are designed with a 3 hour fire rating. Fire detection is provided in each room. Fire safety case information is provided in Chapter 11.

18.3.2.3 Battery Rooms

The Class 1 IDS divisional batteries including Divisions A, B, C, D and spare are located in separate battery rooms. The 24 hour battery divisions are located on the 89.789 m (66'-6") level. The 72 hour battery divisions are located on the 94.666 m (82'-6") level.

Each battery room is provided with a ventilation system. The supply and exhaust duct serving each division can be isolated from other divisions with combination fire/smoke dampers. Failure of a single combination fire/smoke damper serving a division is accommodated by the presence of combination fire/smoke dampers in the ducts serving other divisions. The system design provides for two fire/smoke dampers in series between electrical divisions. A hydrogen detector in each battery room provides an alarm on a high hydrogen concentration, and exhaust airflow monitors provide an alarm on low airflow.

Safety claims on the separation of equipment in terms of external and internal hazards are contained in in Reference 18.25.

18.3.2.4 Equipment Access

Design for personnel access has been incorporated into the auxiliary building and includes:

- Access, egress, and communications are designed to facilitate personnel in undertaking all necessary operational, maintenance, inspection, and testing activities.
- General lighting is provided for all areas. Provisions for access to the components of the IDS for maintenance and operation are in accordance with the requirements of "The Electricity at Work Regulations" (Reference 18.17) and "Requirements for electrical installations, IEE Wiring Regulations, BS 7671:2008 (Reference 18.18), and local fire and safety requirements.
- All IDS equipment is located in the auxiliary building outside of radiological areas requiring controlled access.
- For those facilities and control functions essential to carrying out Class 1 functions and that may require local manual intervention, two alternative means of access are provided.

18.3.3 Annex Building

18.3.3.1 General Arrangement

Figure 18-2 shows the general arrangement of electrical system equipment components in the AP1000 plant. The annex building is a limited seismically rated structure which contains the Class 2 EDS battery systems 1 through 4 (which serve the redundant system loads that are important to plant operation and investment protection), ECS switchgear rooms 1 and 2 and panel boards, and the ancillary diesel generators (see Figures 18-1B and 18-7).

The Class 2 ECS switchboards are mounted in the annex building away from the Class 3 ECS switchboards located in the turbine building, providing segregation between the two classes of systems.

18.3.3.2 Electrical Switchgear Rooms

Two ECS electrical switchgear rooms are located in the annex building. Separation of Class 2 distribution boards ES1 and ES2 and load centres is provided. The two Class 2 ECS switchboards are located in different switchgear rooms in the annex building away from the Class 3 ECS switchboards in the turbine building, providing segregation between the two classes of systems.

The walls between the Class 2 equipment rooms are designed with a 2 hour fire rating. Fire detection and suppression systems are provided in each room. Fire safety case information is provided in Chapter 11.

18.3.3.3 Battery Rooms (EDS)

The Class 2 EDS battery chargers and dc distribution equipment are located in the annex building in two separate rooms next to the two EDS battery rooms. Two separate power supply groups (EDS1 and EDS3, EDS2 and EDS4) are used to supply the Class 2 loads.

Each battery room is provided with a ventilation system. The supply and exhaust duct serving each EDS subsystem is isolated from other subsystems with combination fire/smoke dampers. Failure of a single combination fire/smoke damper serving a division is accommodated by the presence of combination fire/smoke dampers in the ducts serving other divisions. The system design provides for two fire/smoke dampers in series between electrical divisions. A hydrogen detector in each battery room provides an alarm on a high hydrogen concentration, and exhaust airflow monitors provide an alarm on low airflow.

Safety claims on the Class 1 and Class 2 battery room ventilation are contained in Reference 18.25.

18.3.3.4 Equipment Access

Design for personnel access has been incorporated into the annex building and includes:

- Access, egress, and communications are designed to facilitate personnel in undertaking all necessary operational, maintenance, inspection, and testing activities.
- General lighting is provided for all areas. Provisions for access to the EDS equipment for maintenance and operation are in accordance with the requirements of References 18.17 and 18.18, and local fire and safety requirements.
- EDS equipment located in the annex building is outside of radiological areas requiring controlled access.
- For those facilities and control functions essential to the operation of the plant that may require local manual intervention, an alternative means of access is provided.

18.3.4 Turbine Building

18.3.4.1 General Arrangement

Figure 18-2 shows the general arrangement of electrical system equipment components in the AP1000 plant. The turbine building contains the RCP VFDs, the EDS5 and EDSS battery systems and ECS switchgear rooms 1 and 2 (Figure 18-6).

18.3.4.2 Equipment Rooms

The turbine building contains the Class 3 ECS buses (ES3, ES4, ES5, and ES6) that are separated into two switchgear rooms (ES3 and ES5 in one room, ES4 and ES6 in another room). The ECS EK-31 load centre is located in the same equipment room as ES3 and ES5. Similarly, the ECS EK-41 load centre is located in the same equipment room as ES4 and ES6. The VFDs for the RCPs are located at the other end of the turbine building – above the EDS5 and EDSS batteries.

18.3.4.3 Battery Rooms

EDS5 and the spare EDS batteries are located in the same battery room in the turbine building. The Class 2 EDS5 and EDSS battery chargers and their associated dc distribution equipment are located in the turbine building in a separate room next to the EDS5/EDSS battery room.

18.3.4.4 Equipment Access

Design for personnel access has been incorporated into the turbine building including:

- Access, egress, and communications are designed to facilitate personnel in undertaking all necessary operational, maintenance, inspection, and testing activities.
- General lighting is provided for all areas. Provisions for access to the EDS equipment for maintenance and operation are in accordance with the requirements of Reference 18.17 and 18.18, and local fire and safety requirements.
- The EDS equipment located in the turbine building is outside of radiological areas requiring controlled access.
- For those facilities and control functions essential to the operation of the plant that may require local manual intervention, an alternative means of access is provided.

18.3.5 Standby Diesel Generator Buildings

Figure 18-2 shows the general arrangement of system components in the AP1000 plant. Two independent standby diesel generators (ZOS MG-02A and MG02B) and their auxiliaries are located in separate rooms in a separate diesel generator non-seismic building. The contents and location of the standby diesel generator equipment room are shown in Figure 18-8A.

18.3.6 Power Transformer Yard

The power transformer yard containing the main step-up transformers, unit auxiliary transformers, reserve auxiliary transformers, excitation transformer, interconnecting

iso-phase bus and non-segregated bus (part of ZAS) are located outside of the plant adjacent to the turbine building.

18.3.7 Switchyard Interface

Two interfaces to the high voltage switchyards are made to provide the main ac power connection and the maintenance ac power connection to the grid. The main ac power connection ties the main step-up transformers to the transmission lines coming from the 400kV switchyard. The maintenance ac power connection ties the reserve auxiliary transformers to the transmission lines coming from the switchyard.

18.4 MAIN ALTERNATING CURRENT ELECTRICAL SYSTEM (ECS AND ZAS)

18.4.1 Safety Class 2 and Safety Class 3 Functions and Requirements

18.4.1.1 Safety Functions

The ECS supplies ac power to the AP1000 plant in all normal modes of operation.

The ECS utilizes preferred, maintenance, and standby power supplies to distribute power to Class 2 and Class 3 loads. Onsite standby diesel generators are provided as back up supplies to two Class 2 11 kV buses (ECS ES1 and ES2) so that unnecessary actuation of the passive safety system is prevented.

Additional generator capacity is provided for post-72-hour functions that support post-72-hour maintenance of safe shutdown by the Class 2 ancillary diesel generators.

18.4.1.2 Safety Function Requirements

For transients or faults where operation of the core makeup tanks (CMTs) is claimed to provide criticality control via boration and/or residual heat removal, it is necessary to trip the RCPs to enable proper operation of the CMTs.

Upon loss of all offsite power and the standby diesel generators, if it is not possible to restore power to IDS by the end of the 72-hour period, the ECS ancillary diesel generators (ECS MG-01 and MG-02) will provide power to essential 72-hour loads supporting monitoring and habitability safety Category B safety functions via the IDS voltage regulating transformer of IDS Divisions B and C. The ancillary diesels are designated as Class 2 on this basis. In the event that the ancillary diesel generators are unavailable due to a seismic or other event, offsite portable diesels will be brought onsite and connected via the Class 1 IDS regulating transformers to power the necessary loads.

The safety claims made in the Reference 18.25 place the following functional requirements on the ECS:

- ES1 and ES2 (Class 2) have separate onsite sources
- ES1 – ES6 (Class 2 and Class 3) have preferred and maintenance offsite sources
- RCP circuit breakers
  - To trip the RCPs on signals that actuate the CMTs. The RCP breakers must be tripped in response to faults which credit CMT injection as identified in the fault schedule, Table 8A-2, and explained in Chapter 9. The protection and safety monitoring system (PMS) sends the trip signal to the RCP circuit breakers. The RCP circuit breakers, which are part of ECS, therefore, are classified as Class 1 on this basis.

- Onsite Standby Diesel Generators
  - To provide power to selected Class 2 equipment in the event of the loss of offsite power and the main generator

- Ancillary diesel generators
  - To provide power to selected loads for the coping period between 72 hours and 7 days in the event of loss of all ac electrical power. After 7 days re-supply of consumables (fuel oil and water) allow for continued passive system support. Note that the function of these DGs can be provided by DGs brought in from offsite within 72 hours.

18.4.2 Main Connection to Grid via Main Step-Up (MSU) Transformers (Part of ZAS)

18.4.2.1 Description

The connection to the grid via the MSUs is used to support main generator operation:

- Main generator is supplying power, enabling the transmission of electrical power to the grid minus the power used to supply the plant's auxiliary loads and generator excitation.

- Plant in start-up or shutdown mode, it uses the UATs as the preferred source to supply auxiliary loads from the MSU transformer grid connection. The reserve auxiliary transformers (RATs) can be used as an alternate source when the UATs or MSUs are not available. Onsite standby diesel is an alternate for supplying DiD loads.

The main connection to the grid also has the following purposes:

- Coupling the main generator to the grid and connecting the UAT tie bus via the closing of the generator circuit breaker

- Transitioning of the plant from generation to shutdown and from start-up to generation

- Maintaining main generator operation with auxiliary loads during a grid disturbances (with 100% load rejection capability)

The offsite power source is not required in order to achieve safe shutdown of the AP1000 Plant.

18.4.2.2 Operation

Switching of the main grid connection is used for the majority of plant operating regimes. Switching operations typically used for the plant's main connection to the grid are outlined below:

- Removing the main connection to the grid from service by opening the generator circuit breaker. The transmission line and MSU provide power to the plant auxiliary loads via the UATs.

- Placing the main connection to the grid into service by closing the generator circuit breaker. The generator simultaneously provides power to the plant auxiliary loads via the UATs.

- Grid faults:

  1. If the fault is in the plant connected substation, then the line circuit breaker opens and the generator circuit breaker remains closed and continues to provide power to the plant auxiliary loads. The line circuit breaker is reclosed to restore generation from the plant to the grid after the fault has cleared.

  2. If the fault is on the main transmission line from the switchyard or in the MSU, then the substation power circuit breaker(s) open and the generator circuit breaker opens to isolate the fault. The substation and generator circuit breakers are reclosed to restore normal alignment.

Note that the ac voltage and frequency ranges must be maintained within the following limits:

- Rated bus voltage (V ac):
  - 400kV (±5%) – Normal Range
  - 400kV (±10%) – Maximum Range
  - 275kV (±10%) – Normal Range
  - 132kV (±10%) – Normal Range
- Frequency: Continued operation in range (47Hz – 52Hz)
  - Note: The required operation times for particular ranges are specified in the Grid Code (Reference 18.28).

For safety claims on the electrical system to operate within the grid code specified ranges see the Reference 18.25.

18.4.2.3 Design Basis

The electrical design has taken into account the following factors when designing the main connections to the grid:

- Two UATs connected to the 27kV main connection (ZAS) via a tie bus, both having two equally sized auxiliary secondary buses (11kV)

- One UAT connected to the auxiliary boiler loads.

- Two RATs connected to the grid (primary windings) via an alternate grid connection source both having two equally sized auxiliary secondary buses (11kV)

- UAT and RAT transformers are equally sized (except auxiliary boiler UAT)

- MSUs are sized to accommodate maximum generator output without consideration of house loads

- Phasing between grid voltage and ECS 11kV bus voltage for the RATs vs. MSU + UATs must be the same.

- Preference for supplying plant loads through the UATs

- The electrical distribution system (ECS) connects to each of the UATs and RATs equally sized 11kV secondary windings via four Class 3 buses (ES3, ES4, ES5 and ES6) and two Class 2 buses (ES1 and ES2).

- Each UAT and RAT connects to two unique Class 3 ECS buses and one unique Class 2 ECS bus

- Alternate supplies to plant loads via ZOS (standby diesel generators) or RATs.

Other design requirements include the following:

- The main generator has to be able to sync to the grid via its circuit breaker or via switchyard breaker(s)

- The ability to disconnect the main generator by opening its circuit breaker for disturbances to the grid or plant as allowed by the Grid Code. The capability to remain connected during a grid disturbance as specified by the Grid Code is addressed in Reference 18.25. A disconnector is required for isolation during maintenance of the generator circuit breaker. Plant auxiliary loads must continue to be supplied by the grid.

- Short circuit studies are completed determining short circuit impedance, current and MVA requirements for all medium and high voltage electrical equipment (to be completed during site licensing)

- A coordination study be completed for protective relays and fuses equipment (to be completed during site licensing)

- Use of firewalls for large power transformers to prevent damage to adjacent transformers and other equipment during a fire.

- The main step-up transformer consists of three single-phase transformers with a fourth spare transformer installed alongside.

18.4.2.4 United Kingdom (UK) AP1000 Plant Site-Specific Design

The primary voltage of the MSUs and RATs are site specific design requirements. For the UK the MSU and RAT primary voltages are 400 kV, 275kV, or 132kV. The MSUs will have a load tap changer on its primary winding. The RATs will have a load tap changer on the secondary winding.

18.4.2.5 Inspections, Testing and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to equipment involved with the main connection to the grid.

18.4.3 Unit Auxiliary Connection (ZAS and ECS)

18.4.3.1 Description

The unit auxiliary connection is used in all main generator conditions except for the reserve auxiliary connection:

- The 27kV isophase unit auxiliary connection enables the distribution of electrical power supplied by the generator or the grid to supply the plant's auxiliary loads via the UATs

- The unit auxiliary connection to the UATs supplies plant auxiliary loads from either the generator during normal operation or the preferred MSU transformer grid connection.

The unit auxiliary connection to the main connection also has the following purposes:

- Connects the primary windings (27kV) of the three UATs together via isophase bus
- Connects the three UATs to the main connection (includes the generator circuit breaker, MSUs, and voltage transformers (VTs))
- Connects each UAT secondary (two equally sized secondary windings) to the four Class 3 ECS buses (ES3, ES4, ES5, and ES6), auxiliary boiler bus and to the two Class 2 ECS buses (ES1 and ES2) via physically separated and electrically isolated non-segregated bus.

During power generation, the supplies for the plant auxiliary system are typically drawn from the main generator via the UATs. This is the normal arrangement as it is the most economical and efficient way of providing a stable supply with maximum buffering from external grid perturbations. When the main generator is not running (e.g., during normal start-up and shutdown when the generator circuit breaker is open), auxiliary power is typically drawn from the utility grid, via backfeed through the (MSU and the UATs, as above. In this situation, voltage compensation is mitigated by the use of load tap changers on the main step-up transformer.

This is a Class 3 designated connection.

18.4.3.2 Operation

Switching of the unit auxiliary connection is used for the majority of plant operating regimes. Switching operations typically used for the plant's auxiliary connection to the grid are outlined below:

- 27kV bus faults: A 27kV isophase bus fault, a UAT fault or a potential transformer fault will initiate a fast bus transfer from the UATs to the RATs to enable plant loads to continue to operate.
- Other faults in protective zone.

18.4.3.3 Design Basis

Electrical design has taken into account the following factors in the design of the unit auxiliary connection to the grid:

- Two UATs connected to the 27kV main connection (ZAS), both having two equally sized auxiliary secondary buses (11kV)
- UAT and RAT transformers are equally sized (except auxiliary boiler UAT)
- Phasing between grid voltage and ECS bus voltage for the RATs vs. MSU + UATs be the same.
- Preference for supplying plant loads through the UATs

- The electrical distribution system (ECS) connects to each of the UATs 11kV secondary windings via two Class 3 buses and one Class 2 bus.

- Each UAT connects to a unique ECS high voltage bus

Other design requirements have included:

- Short circuit studies will be updated to determine short circuit impedance, current, and MVA requirements for medium voltage isophase bus and UATs (to be completed during site liensing)

- Coordination studies will be updated for protective relays and fuses (to be completed during site liensing)

- Installation of firewalls for large power transformers to prevent damage to adjacent transformers and other equipment during a fire.

- Installation of fire barriers, deluge systems, and other equipment to minimize the risk for an unplanned power outage

All UATs are three-phase transformers and have the same power rating (except for the auxiliary boiler UAT). Each transformer has a primary winding with dual secondary windings (except for the auxiliary boiler UAT). Primary voltages of the unit auxiliary transformers are set according to their source – the generator voltage. Load tap changers are provided on the low voltage winding of the UATs to mitigate voltage fluctuations.

18.4.3.4 Inspections, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the unit auxiliary connection.

18.4.4 Reserve Auxiliary Connection (Part of ZAS)

18.4.4.1 Description

The reserve auxiliary connection is used in specific main generator conditions:

- The reserve auxiliary connection from the RATs is an alternate offsite source to supply plant auxiliary loads; supply via the RATs is not used during power operation

- Supplying electric power to the plant auxiliary loads after a fast bus transfer or residual bus transfer has occurred

The components of the reserve auxiliary connection are described as follows:

- The reserve auxiliary connection begins with a high voltage connection to the grid. Connects each RAT secondary (two equally sized secondary windings) to the four Class 3 ECS buses (ES3, ES4, ES5, and ES6) and to the two Class 2 ECS buses (ES1 and ES2) via 11kV non-segregated bus.

This is a Class 3 designated connection.

18.4.4.2 Operation

Switching operations typically used for the reserve auxiliary connection to the grid are outlined below:

- Faults in the protection zone (yard side Power Circuit Breaker to incomer M1 breakers on busses ES1 through ES6) will initiate a fast bus transfer to serve plant loads via the RATs.

- Manual operation: The RATs and their associated ECS buses can be energized separately for maintenance purposes.

Plant auxiliary loads are drawn from either the UATs or the RATs, but not a combination of both. Supplies may be transferred from the UATs to the RATs by manually or automatically initiated switching. There is no provision for the automatic transfer of supplies from the RATs back to the UATs. Manually initiated switching must be used for this purpose. Electrical interlocking is used to ensure that both sets of breakers cannot be manually closed together.

18.4.4.3 Operational Requirements for Fast Bus Transfer

Automatic switching is affected by a detected fault in the protection zone which initiates a fast bus transfer scheme triggered only by the differential protection covering the zone of protection containing the switchyard circuit breaker(s), iso-phase bus, main step-up transformer, excitation transformer, and generator field circuit breaker, UATs, VTs, and their associated non-segregated 11 kV bus bars. Fast bus transfer reduces the reliance on the standby diesels by automatically providing an alternate grid connection in the event the preferred power source is unavailable.

18.4.4.4 Design Basis

Electrical design has taken into account the following factors into in the design of the reserve auxiliary connection to the grid:

- Two reserve auxiliary transformers (RATs) connected to the grid (ZAS) through a second independent source, both having two equally sized (11kV) secondary windings

- RAT and UAT transformers are equally sized

- Phasing between grid voltage and ECS bus voltage for the RATs vs. MSU + UATs be the same.

- The electrical distribution system (ECS) connects to each of the RATs 11kV secondary windings via two Class 3 buses and one Class 2 bus.

- Each RAT connects to a unique ECS high voltage bus

Other design requirements included the following:

- Short circuit studies are completed determining short circuit impedance, current, and MVA requirements for the RATs (to be completed during site licensing). Installation of firewalls for large power transformers to prevent damage to adjacent transformers and other equipment during a fire.

- Installation of fire barriers, deluge systems, and other equipment to minimize the risk for an unplanned power outage.

All RATs are three-phase transformers and have the same power rating. Each transformer has a single primary winding with dual secondary windings. Primary voltages of the reserve auxiliary transformers are set according to their source (grid voltage). The UATs are fed at the main generator voltage, whereas the RATs are fed at an alternative grid connection. Load tap changers are provided on the secondary side of the RATs to mitigate external grid voltage fluctuations.

18.4.4.5 Inspections, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the reserve auxiliary connection.

18.4.5 Medium and Low Voltage Distribution System (ECS)

18.4.5.1 Description

The design of the ECS system has many components. The ECS represents the electrical distribution system for the AP1000 plant containing 11kV and 400V buses. See Figures 18-1A, 18-1B, and 18-1C. The ECS distributes high voltage station power at 11 kV, and distributes low voltage power through load centres (Class 2) at 400 volts. The 400V ac supply to the IDS and EDS is provided through load centres supplied at 11 kV by the ECS standby diesel-backed switchboards ES1 and ES2.

Several large motors, MCCs, switchgear (including the RCP trip switchgear), panel boards, bus work, and power cables make up the ECS. Six designated buses are included in the ECS. Four are Class 3 buses (ES3, ES4, ES5, and ES6) that connect to the RCPs and two are Class 2 buses that connect to the load centres, standby diesel generators, and the Class 1 and Class 2 IDS/EDS battery systems. A seventh bus serves site specific auxiliary plant loads and the auxiliary boiler.

The RCP trip switchgear consists of two 6.9 kV/60 Hz breakers connected in series downstream of the VFDs fed from ES3, ES4, ES5, and ES6.

ECS provides power to the Plant Control System (PLS) Motor Generator sets.

18.4.5.2 Operation

The ECS contains the ancillary diesel generators and various circuit breakers that can be used to switch various Class 1, Class 2, and Class 3 plant loads. During normal operation the ECS circuit breakers are closed to energize plant loads via the normal UAT source. The Class 2 ancillary diesels generators are switched on after a DBE when post-72-hour ac power is needed to supply power to the passive containment cooling system (PCS) pumps, MCR lighting, MCR, and C&I room ventilation. These loads can also be powered by offsite portable diesel generators in case the ancillary diesel generators are unavailable.

18.4.5.3 Design Basis

Equipment making up the Class 3 ECS is of a design that has been type tested to the specified extremes of environmental and operational conditions.

The RCP switchgear is of a design that is type-tested and qualified to conditions equal to at least the most severe DBE conditions as described in Chapter 11.

The general status and alarms for the ECS are displayed in accordance with the applicable equipment specifications. The monitoring function and equipment are appropriately designated in accordance with the categorisation and classification scheme.

The ECS electrical system has a layout design that facilitates access for necessary operation and maintenance activities. The main aspects of the design are as follows:

- Provisions for access to the components of the ECS for maintenance and operation are in accordance with local fire and safety requirements.
- Access, egress, and lighting are designed to facilitate personnel in undertaking all necessary operational, maintenance, inspection, and testing activities. General and emergency lighting is provided for all areas in accordance with the applicable equipment specifications.
- For those facilities and control functions essential to the operation of the plant that may require local manual intervention, an alternative means of access is provided.

18.4.5.4 Inspection, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the medium and low voltage distribution system (ECS).

18.4.6 Ancillary Diesel Generators (Part of ECS)

18.4.6.1 Description

The ancillary diesel generators ECS MG-01 and MG-02 are Class 2 equipment (Figure 18-7 and Figure 18-8B) providing alternative supplies to their corresponding PCS recirculation pumps and 72-hour IDSs (Figure 18-4). The PCS recirculation pump supports the Category B safety function of providing post-72-hour heat removal. The ancillary generator supply to the IDS provides an alternative supply to the system monitoring, MCR lighting, RSW, and C&I room ventilation if no other sources of ac power are available and the IDS batteries are discharged.

These loads can also be powered by offsite portable DGs in the case ancillary diesel generators (ADGs) are unavailable. Once brought on site, portable DGs can be connected via the Class 1 IDS voltage-regulating transformers in the dc equipment rooms, or via the Class 2 ECS ancillary diesel distribution panels. The connection of the portable DGs was reviewed in "UK AP1000 Plant Post-Fukushima Assessment" UKP-GW-GGR-201 (Reference 18.4). Resulting enhancements to facilitate the connection of the diesels via the Class 1 IDS are described in Section 18.8.5.

18.4.6.2 Operation

The ancillary diesel generators are provided with necessary controls and indicators for local monitoring of the operation of the units. Generator control is manual from a control integral with the diesel skid package.

18.4.6.3 Design Basis

The ancillary generators are located in the portion of the annex building that is a seismic Category II structure. For additional detail about design basis for external hazards, refer to chapter 12. The ancillary diesel generator's fuel storage tank is located in the same room as the generator. The fuel tank, piping, and valves are analysed to show that they withstand a safe shutdown earthquake (SSE), for additional information on SSEs refer to Chapter 12. The tank includes provisions for venting to the outside atmosphere and for refilling from a truck or other mobile source of fuel. The tank is classified as seismic Category II and holds sufficient fuel for four days of operation.

Each ancillary diesel generator output is connected to a distribution panel located in the same room as the generators. Each distribution panel has an incoming circuit breaker and outgoing feeder circuit breakers.

The distribution panels provide power to:

- The transfer switch that feeds the Class 1 voltage regulating transformers that power the post-accident monitoring loads, emergency lighting in the MCR and the ancillary fans for ventilation of the MCR and C&I rooms.

- The transfer switch that feeds the passive containment cooling system recirculation pumps.

Redundancy for the ancillary diesels is provided by duplicating essential post-72-hour loads on the ECS Class 2 buses and providing each bus with two alternative supplies. The preferred supply is from the ECS with the alternative provided by the corresponding ancillary diesel generator. These loads can also be powered by offsite DGs in case the ADGs are unavailable.

18.4.6.4 Inspection, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the ancillary diesel generators.

18.4.6.5 Post-72-Hour Operation

During the post-72-hour period following a DBE, power is required for Class 1 post-accident monitoring, lighting in the MCR, ventilation in the MCR, and for the pumps to provide cooling for the PCS. Provisions are made to connect offsite portable diesel generators to the Class 1 voltage regulating transformers (divisions B and C only) when all other sources of ac power are unavailable, including the Class 2 ancillary diesel generators. Figure 18-4 shows the functional diagram for serving post-72-hour loads.

Safety claims, arguments, and evidence regarding post-72-hour operations are provided in Reference 18.25.

18.5 SAFETY CLASS 1 ELECTRICAL DISTRIBUTION SYSTEM

18.5.1 Class 1 Safety Requirements

18.5.1.1 Class 1 Safety Functions

IDS provides power to the PMS to provide and action Class 1 engineered safety features (ESF) actuation signals and for the actuation of a number of Class 1 SSCs providing the Category A safety functions including decay heat removal safety function under different circumstances or at different stages of a Design Basis Accident (DBA).

Claims regarding Class 1 safety functions are contained in Reference 18.25.

18.5.2 Class 1 Electrical Distribution System

18.5.2.1 Description

The roles of the IDS are to provide continuous power supplies to Class 1 loads required for plant instrumentation, control, and monitoring and other vital functions needed for safe shutdown of the AP1000 plant. Class 1 IDS power is supplied to the MCR and RSW for normal lighting; the rest of the normal lighting is provided by ECS through the MCCs. In addition, the IDS provides power to the emergency lighting in the MCR and to the RSW.

The IDS is a battery-backed power supply that provides dc and ac power (via inverters) to Class 1 loads. In the event of loss of power from the ECS, the batteries are sized to provide power for the 24-hour and 72-hour Class 1 loads without any external ac power supply.

Reference 18.25 provides claims regarding the proper sizing and rating of the IDS system and components in Section 8.4.

The IDS is capable of providing power for the safe shutdown of the plant without the support of battery chargers during a loss of all ac power sources coincident with a DBE. The system is designed so that no single failure will result in a condition preventing the safe shutdown of the plant.

The Class 1 IDS consists of ungrounded stationary batteries, battery chargers, dc distribution equipment, and inverters. The functional schematic diagrams for the IDS are shown in Figure 18-3 and Figure 18-4.

The 400V ac supply to the IDS and EDS is provided through load centres supplied at 11kV by the ECS standby diesel-backed switchboards ECS ES1 and ES2.

The IDS includes only safety designated Class 1 components, which are seismically qualified. They are described in the following sections.

18.5.2.2 Batteries

The 24-hour battery banks and the 72-hour battery banks provide adequate power to the load duty cycle requirement for 24 hours and 72 hours, respectively, without support from the battery chargers.

To maximize the availability of DC power supply to the plant safety DC loads for all normal and emergency conditions, the system's design provides for connection of a spare battery bank to any of the six (6) batteries in the four divisions. The availability of this spare battery bank will permit continuous plant operation in accordance with the technical specifications; this is not an indefinite operating condition. The spare battery is normally maintained in a fully charged condition via a separate, dedicated charger.

Each battery bank is installed on a two-step, restraining side braced seismically qualified rack. A liquid tight spill containment area is provided with each rack.

The operating voltage range of the batteries is 210 to 280V dc with a nominal system voltage of 250V dc. The maximum equalising charge voltage for batteries is 280V dc. Each battery bank is connected to a Class 1 dc switchboard through a set of fuses and a disconnect switch.

If offsite power is lost, the batteries will maintain the system while the standby diesel generator (ZOS) starts. Once started, the standby diesels will power the IDS battery chargers maintaining the supply to the Class 1 equipment.

In the event of a loss of offsite power and failure of the standby diesels to start, the batteries are sized to maintain the supplies to the Class 1 actuation for 24 hours and for post-accident monitoring for 72 hours. The design of the AP1000 plant is such that the reactor will go into a safe shutdown state if all external ac electrical power is lost.

18.5.2.3 Fused Transfer Switch Panels

The fused transfer switch panels are provided to facilitate battery testing, off-line recharging and maintenance. The spare fused transfer switch enables the spare IDS battery bank and spare battery charger to be connected to any other fused transfer switch panel (Figure 18-4A). This allows replacement of any battery bank and battery charger during maintenance or testing.

18.5.2.4 Battery Chargers

The battery chargers provide power to Class 1 250 V dc loads and maintain the batteries fully charged. During normal operation, the IDS battery chargers are supplied with power from the ECS. In turn, the battery charger supplies power to the primary 250V dc switchboard while maintaining the battery charged. The battery chargers also restore discharged batteries to a fully charged state. The spare battery charger maintains a fully charged spare battery bank and powers a Class 1 250 V dc bus in the case of a failure or unavailability of its own battery bank or battery charger. The battery chargers provide the required isolation between the Class 2 and 3 ac and Class 1 dc electrical systems. The battery chargers are qualified as isolation devices.

In the event of loss of offsite power, the standby diesel generators will start and provide power to the chargers through the ECS.

Figure 18-4 shows the connections to post-72-hour loads. During normal operation, the IDS battery chargers can be energised either through the offsite power source or from the station's own generation. The inverters and dc equipment are supplied from the battery chargers.

The battery chargers are classified as seismic category I. They are designed and manufactured to withstand the effects of the SSE and to maintain their specified functions.

18.5.2.5 DC Switchboards

The Class 1 250 V dc switchboards employ fused disconnect switches. The main bus bar is braced to withstand mechanical forces expected during a short circuit current event. The switchboards are capable of operating continuously at the maximum equalization voltage of 280 V dc.

The Class 1 250 V dc switchboards provide power to motor control centres, dc distribution panels, and the IDS inverters. The Class 1 250 V dc switchboard is used to interconnect each battery bank to a battery charger. The Class 1 250 V dc switchboards are powered from the battery chargers and battery banks.

Monitoring of the 250 V dc Class 1 System is included in the Class 1 250 V dc switchboard. Each dc switchboard supplied from a 24-hour battery bank (Divisions A through D) supplies power to an inverter, a 250V dc distribution panel, and a 250V dc MCC. Each switchboard supplied from a 72-hour battery bank (divisions B and C) provides power to an inverter.

18.5.2.6 Inverter

The inverters, static transfer and manual by-pass switches provide ac power to distribution panels. Each inverter is powered from its respective battery bank switchboard. If an inverter is inoperable or the Class 1 250V dc input to the inverter is unavailable, the power is transferred automatically to the backup ac source by a static transfer switch featuring a make-before-break contact arrangement. The backup power is received from the ZOS-backed 400V ac bus through the Class 1 voltage-regulating transformer. In addition, a manual mechanical bypass switch is provided to allow connection of a backup power source when the inverter is removed from service for maintenance.

18.5.2.7 Regulating Transformer

The regulating transformers provide a backup source of ac power to the Class 1 inverter through a static transfer switch. The regulating transformers are powered from the diesel generator backed Class 2 motor control centres. Two regulating transformers are used to connect each ancillary or portable diesel generator to the IDS system and power the necessary loads for the post-72-hour scenario. The Class 1 regulating transformers provide the required isolation between the Class 2 and the Class 1 electrical systems. The regulating transformers are qualified as an isolation device.

18.5.2.8 Battery Monitor

A battery monitor system is a design feature used to monitor each Class 1 IDS battery bank. The battery monitors detect and annunciate open-circuit conditions in the IDS dc system. The battery monitoring function is not safety related as it is an additional observation tool for maintenance in between the required surveillance testing activities. Surveillance requirements are already in place to verify and test the batteries on a regular basis as claimed in the Reference 18.24.

18.5.2.9 250V DC Distribution Panels

The Class 1 250 V dc distribution panels provide dc power distribution and protection between the 250V dc power sources and the assigned loads. The Class 1 250 V dc distribution panels are powered from Class 1 250V dc switchboards. The Class 1 250 V dc

distribution panel is capable of operating continuously at the maximum equalization voltage of 280 V dc along with the equipment downstream of the Class 1 250 V dc distribution panel.

18.5.2.10 250V DC Motor Control Centres (MCCs)

The Class 1 dc motor MCCs operate in the 250V dc two-wire, ungrounded distribution system. The loads fed from the MCCs are protected by fusible disconnect switches from short-circuit faults. The MCCs are capable of operating continuously at the maximum equalization voltage of 280 V dc along with the equipment downstream of the MCCs.

18.5.2.11 Operation

During normal operation, the four division battery chargers are supplied with power from the ECS MCCs. In turn, the battery charger will supply power to the primary dc switchboard, powering dc distribution panels, and the ac inverter while maintaining the battery charge. This allows the ac inverter to supply power to the ac distribution boards. In the event of loss of offsite power, the standby diesel generators will start and provide power to the chargers through the ECS. In the event of a loss of offsite power and failure of the standby diesel generators to start, the batteries are sized to maintain Class 1 loads.

The IDS consists of ungrounded stationary batteries, battery chargers, dc distribution equipment, regulating transformers, and inverters. The functional arrangement diagrams for the IDS system is shown in Figure 18-3 and Figure 18-4.

The IDS is divided into four divisions, A, B, C, and D, which are electrically independent and physically separated. Each division uses a Class 1 stationary battery bank connected to a separate Class 1 dc switchboard through a disconnect switch panel. Divisions B and C are each composed of two battery banks, two switchboards, and two battery chargers. The first battery bank in each of the four divisions, designated as a 24-hour battery bank, provides power to the loads required for the first 24 hours following an event of loss of all ac power sources concurrent with a DBE. The second battery bank in divisions B and C, designated as a 72-hour battery bank, is used for those loads requiring power for 72 hours following the same DBE. Following a DBE MCC loads will be supported by the IDS 24 hour batteries, and are not required to be supported by the 72 hour batteries. These loads are not necessary to support plant safety past the first 24 hours following a DBE. The 72-hour battery banks of Divisions B and C contain batteries the same cell size as the 24-hour batteries but they are discharged over a longer time with smaller loads. Battery chargers are powered from ac load centres fed from standby diesel generator-backed buses. An additional battery and charger unit is provided as a full spare. Each switchboard supplied from a 24-hour battery bank (divisions A to D) supplies power to an inverter, a 250V dc distribution panel, and a 250V dc MCC.

Only loads required during the 24 hours following a DBE are supplied by the IDS 24-hour batteries, so no load shedding or load management programme is needed to maintain power during the required 24-hour safety actuation period. Each switchboard supplied from a 72-hour battery bank (Divisions B and C) provides power to an inverter.

The IDS provides power for the safety-designated equipment required for the plant instrumentation, control, monitoring, and other vital functions needed for shutdown of the plant. In addition, the IDS provides power to the emergency lighting in the MCR and at the remote shutdown workstation. The IDS is capable of providing power for the safe shutdown of the plant without the support of battery chargers during a loss of all ac power sources

coincident with a DBE. The system is designed so that no single failure will result in a condition preventing the safe shutdown of the plant.

The IDS is not directly bonded to ground. A single ground fault does not cause immediate loss of the faulted system. Ground detection relays that alarm in the MCR are provided for each division of power so that ground faults can be located and removed before a second ground fault could disable the affected circuit.

The capacity of each battery is determined based upon formally prepared, reviewed, and issued calculations. Conservative measures are taken to ensure that each battery is sized to supply its assigned load profile for the entire postulated (standby) time without the benefit of the battery charger or forced ventilation.

The following methodology, as defined in the nuclear industry standards for batteries, is employed to achieve conservative battery sizing and validate the design:

- Ambient correction factor of 11 percent to account for the assumed minimum temperature of 15.5°C (60°F)
- Battery aging factor of 125 percent to ensure acceptable voltage at the postulated end of life
- Sizing design margin of 110 percent to account for potential future load growth
- All similar batteries specified at the same capacity and the sizing based upon the worst-case battery duty cycle

Claims on the electrical system being designed with margin are made in in the Basis of Safety Case document (Reference 18.25).

A comprehensive formal sizing calculation has been developed to establish the proper size for the worst-case battery, battery charger, and inverter. The largest size, based upon the worst-case load and allowing for aging and other factors, is applied for all Class 1 battery banks.

Reference 18.25 provides claims on the isolation and transient withstand of the battery chargers. Suitably selected and rated protection on both the ac and dc components of the IDS will prevent an electrical fault on one item of equipment from resulting in an excessive electrical disturbance to other equipment.

18.5.2.12 Inspection, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the Class 1 IDS equipment.

18.5.2.13 Post-72-Hour Operation

During the post-72-hour period following a DBE, power is required for Class 1 post-accident monitoring, lighting in the MCR, ventilation in the MCR, and for the pumps to refill the PCCWST. Provisions are made to connect the offsite portable diesel generators to the Class 1 voltage regulating transformers (divisions B and C only), when all other sources of power are unavailable including the Class 2 ancillary diesel generators. Figure 18-4 shows the

connections to post-72-hour loads. During normal operation, the IDS battery chargers can be energised either through the preferred offsite power source or from the station's own generation. The inverters and dc equipment are supplied from the battery chargers. These loads can also be powered by offsite DGs in case the ADGs are unavailable.

18.6 CLASS 2 ELECTRICAL DISTRIBUTION SYSTEM (EDS)

18.6.1 Class 2 Safety Requirements

18.6.1.1 Class 2 Safety Functions

EDS provides power to a number of Class 2 SSCs which provide a DiD means of providing residual heat removal safety functions, including:

- Startup feedwater system (FWS)
- Normal residual heat removal system (RNS)
- Component cooling water system (CCS)
- Service water system (SWS)
- Spent fuel pool cooling system (SFS)

EDS provides power to a number of Class 2 SSCs, which provide a DiD means of providing criticality control safety functions including the chemical and volume control system (CVS).

Claims regarding the design, qualification and adequacy of the Class 2 systems are made in Reference 18.25.

18.6.1.2 Class 2 Safety Function Requirements

Fail-to-safety criteria specific to the EDS are the following:

- The inverter units serve as isolation for the EDS from faults for the downstream ac system and protect the EDS load group it serves from faults, surges, and backfeeds. This ensures that the operation of the batteries and associated supplies and equipment are preserved, including if the inverter operation fails.

- Overcurrent and fault protection are suitably rated and specified to protect the EDS from faults with downstream ac and dc equipment.

- The inverter dc input protection is set higher than the battery charger trip setpoints to prevent the inverter from tripping before the battery charger.

The safety claims place the following functional requirements on the EDS:

- To supply a continuous power source to the safety designated plant Class 2 and 3 loads.

- In the event of loss of offsite power (normal, preferred, and maintenance sources), the ZOS will provide power to the EDS for up to 7 days without the necessity for offsite fuel supplies.

- In the event of loss of offsite power and failure to start the standby diesel generators, the EDS batteries are to provide power for the priority loads for a minimum of two hours following the loss.

- Through a site-specific transmission switchyard, the EDS will utilise offsite power for startup and shutdown under normal conditions.

18.6.2 Class 2 DC Electrical Distribution System

18.6.2.1 Description

The EDS provides battery backed continuous electric power to the plant Class 2 and 3 C&I loads during normal operation and in the event of loss of offsite power.

EDS provides power to C&I loads important for plant operation and investment protection and to the hydrogen igniters located inside containment. The Diverse Actuation System (DAS) cabinets are located in the auxiliary building. Two sources of ac power from EDS are provided to the DAS. Additional information about the DAS and squib valves are in Chapter 19.

The EDS is divided into five battery systems, identified as EDS1 to EDS4 and EDS5 (turbine bearing oil pump and airside seal oil backup pump).

Divisions EDS1 to EDS4 consist of the following elements:

- Battery bank
- Battery charger
- Fused transfer switch panel
- dc switchboards
- dc distribution boards
- Inverter
- Voltage-regulating transformer
- ac distribution panels

EDS5 consists of the following:

- Battery bank
- Battery charger
- Fused transfer switch panel
- Transfer switch box
- 250V dc switchboard

Normal ac power to the EDS battery chargers and regulating transformers is supplied from the standby diesel generator-backed 400V ac distribution system (ES1 and ES2).

EDS1 and EDS3 are considered as one functional subsystem, with EDS2 and EDS4 forming the second subsystem of the same configuration. Figure 18-5 shows the functional arrangement schematic diagram for these subsystems. Systems EDS2 and EDS4 are arranged in an identical manner. EDS5 and the EDS spare are standalone systems and are outlined in Figure 18-6.

The EDS1 through EDS4 dc buses provide dc power to their associated inverter units that supply the ac power to the associated Class 2 ac system. An alternative regulated ac power source for the inverter buses is supplied from the associated regulating transformers. The EDS5 dc bus supplies dc motors associated with the main generator. The EDS spare battery bank can supply any of the five EDS system (EDS1-EDS5) through a connection in the fused transfer switch panel.

18.6.2.2 Operation

During normal operation, the EDS1-EDS4 battery chargers are supplied with power from the ECS MCCs. In turn, the battery charger will supply power to the primary dc switchboard, powering dc distribution panels and the ac inverter while maintaining the battery charge. This allows the ac inverter to supply power to the ac distribution boards. In the event of loss of offsite power, the standby diesel generators will start and provide power to the chargers through the ECS. In the event of a loss of offsite power and failure of the standby diesel generators to start, the batteries have been sized to maintain supplies to DiD loads.

During normal operation, the EDS5 battery charger is supplied with power from the ECS MCC. In turn, the battery charger will supply power to the primary 250V dc switchboard while maintaining the battery charge. This allows the dc switchboard to supply power to the Class 2 dc loads. In the event of loss of offsite power, the diesel generators will start and provide power to the charger through the ECS. In the event of a loss of offsite power and failure of the generators to start, the batteries have been sized to maintain Class 2 loads and systems that are identified in Reference 18.25.

18.6.2.3 Design Basis

The EDS electrical system design and layout facilitates access for necessary activities and minimises adverse interactions during such activities. The main aspects of the design are as follows:

- Provisions for access to the components of the EDS for maintenance and operation are in accordance with the requirements of References 18.17 and 18.18, and local fire and safety requirements.

- Access, egress, and lighting are designed to facilitate personnel in undertaking all necessary operational, maintenance, inspection, and testing activities. General and emergency lighting is provided for all areas in accordance with the applicable equipment specifications.

- For those facilities and control functions essential to the operation of the plant that may require local manual intervention, an alternative means of access is provided.

A comprehensive sizing calculation has been developed to establish the proper size for the worst-case battery load and battery charger. The largest size, based upon the worst-case load and allowing for aging and other factors, is applied for all EDS battery banks. The batteries are sized to supply the system loads for at least two hours after loss of all ac power sources.

The design of the electrical system provides diverse power supplies to equipment supplied by the EDS. Under normal operating conditions, the supply to the dc switchboards and the inverter units is through the battery chargers. The supply to these battery chargers is from 400V load centres, which in turn derive their supply from the diesel-backed 11 kV distribution boards. Normal supply to the 11 kV boards is from the offsite supply through the UATs. Alternative offsite supplies are available through the RATs. In the event of loss of the offsite supplies, the diesel generators will start to provide power to the 11 kV boards. Should the diesels fail, the batteries are sized to maintain power to the connected loads for a minimum of two hours.

Suitably selected and rated protection on both the ac and dc components of the EDS will prevent an electrical fault on one item of equipment resulting in an excessive electrical disturbance to other equipment.

Claims on the conservative margin of the electrical system and the ability to withstand transients and disturbances are made in Reference 18.25.

18.6.2.4 Inspection, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the Class 2 EDS equipment.

18.7 STANDBY DIESEL GENERATORS (ZOS – SAFETY CLASS 2)

18.7.1 Safety Requirements

18.7.1.1 Safety Functions

The onsite standby diesel generators provide power to Class 2 loads in the event of loss of normal/preferred (ECS via the UATs) and reserve (ECS via the RATs) ac power supplies.

18.7.1.2 Safety Function Requirements

The safety case places the following functional requirements on the standby diesel generators and their associated distribution equipment:

- Each generator shall be capable of supplying the necessary Class 2 loads.
- Each generator shall be independent.

Claims in regard to the standby diesel generators are made in Reference 18.25.

18.7.2 Standby Diesel Generators (Safety Class 2)

18.7.2.1 Description

In the event of the loss of offsite power and loss of the main generator, power can be provided to the two 11 kV switchboards (ECS ES-1 and ES2) from the onsite standby diesel generators (see Figure 18-1B). Each bus is backed by one of the Class 2 onsite standby diesel generators. Priority loads for DiD functions based on their specific functions (permanent loads) are assigned to buses ES1 and ES2. Plant permanent loads are divided into two functionally redundant load groups. Each load group is connected to either bus ES1 or ES2.

These standby diesel generators are located in their own building, forming part of the onsite power system.

18.7.2.2 Operation

When a successful fast bus transfer from the UATs to the RATs occurs due to a fault in the protective zone, the standby diesel generator (ZOS) will not be connected. The Class 2 standby diesel generators are switched on once the offsite power has been lost and the main generator is offline. This creates an undervoltage on bus ES1 or ES2, allowing the diesel

generators to be automatically started. The diesel generator, however, is capable of being manually paralleled with the preferred or maintenance power supply for periodic testing.

Claims and arguments regarding the conservative margin that is included in the ZOS equipment are provided in Reference 18.25.

An independent air starting system is provided for each standby diesel generator. The standby diesel generators will provide power for up to seven days from the onsite fuel storage tank without the necessity for offsite fuel supplies.

The onsite standby diesel generators are provided with necessary controls and indicators for local or remote monitoring of the operation of the units.

18.7.2.3 Design Basis

Auto sequencing is designed and tested to ensure that the diesel generators are not overloaded. If loads fail to auto sequence onto the generator, loads can be started manually. Refer to Reference 18.25 for claims made on auto sequencing. The control scheme, while protecting the diesel generators from excessive loading, does not compromise the onsite power supplies ability to support the DiD loads.

Upon detection of an under-voltage condition on the medium voltage diesel bus, the under-voltage relays in the ECS system send a start signal to the diesel generator. When the DG ramps up to synchronous speed, the DG control system will send a "ready to load" signal to the PLS via a programmable logic controller or other approved equivalent gateway device). The PLS will provide the sequencing logic to the medium voltage buses.

The standby diesel generator is type-tested to the expected extremes of environmental and operational conditions. Installation is in accordance with manufacturer's recommendations.

Claims on the operating conditions of the equipment are addressed in Reference 18.25.

Provision for redundancy within the ECS Class 2 standby diesel generator system is as follows:

- Only one of two standby diesel generators is required in power modes with SFP decay heat less than the limit defined in the Technical Specifications as each one is rated at 100 percent of the load required to supply all the Class 2 DiD designated systems. If SFP decay heat is higher than the limit defined in the Technical Specifications and during certain times in Modes 5 and 6, 2 of 3 ac power sources are required. The Class 1 batteries provide the necessary power for the safety actuations, while the Class 2 batteries provide power for monitoring. The standby diesel generators provide support for the defence in depth active system functions. Reference 18.25 contains claims made on the electrical system availability.

- To provide redundancy, the Class 2 DiD systems equipment supplied by the ECS is duplicated; for example, the ZOS MG-02A normal loads are also supplied from MG-02B.

18.7.2.4 Inspection, Testing, and Maintenance

Refer to "UK AP1000 Electrical Equipment Maintenance and Surveillance" (Reference 18.24) for details on Inspections, Testing, and Maintenance in regards to the Class 2 ZOS equipment.

18.8 EXTERNAL ELECTRICAL SYSTEM INTERFACES

The Electrical Basis of Safety Case (Reference 18.25) captures all safety claims made on the electrical systems in the PCSR and describes how the electrical system supports those claims. Fault studies for internally initiated faults (Chapter 9) imply claims on the electrical system through their support of SSCs providing Category A and B safety functions listed in that chapter.

Internal and external hazards assessments (Chapters 11 and 12) make claims in reference to the electrical system, for example, considerations of separation and segregation. The equipment forming the IDS, EDS, ECS, and ZOS is designed, specified, qualified, and installed to protect against internal and external events. This includes the dc battery systems, the RCPs, its circuit breakers, the ac distribution system, and the standby diesel generators.

Electrical and EMC hazards are to be managed per the EMC management philosophy (Reference 18.13). Further details are given in Sections 11 and 12, which discuss internal and external hazards, respectively.

18.8.1 Spent Fuel Pool Cooling

The ECS ES1 and ES2 buses supply power to the SFS and RNS pumps, which provide flow for removal of the design basis heat load. DC power is used for safety containment isolation MOVs, and ac power is used for AOVs. Class 1 IDS is provided as control power for the relays/switchgear to start and stop the containment isolation valve motors. Refer to Chapter 6 for details on the operation of the Spent Fuel Pool Cooling System.

In order to provide DiD for decay heat removal, two of three ac power supplies (2 standby diesel generators and offsite power) and their associated switchgear should be available in accordance with the criteria defined in in UKP-GW-GL-502, “Recommendation for the Development of the AP1000 Technical Requirements Manual”(Reference 18.6) and approved design changes. These requirements support the decay heat removal described in Section 9.2.7.

18.8.2 SMART Devices/Verification and Validation of Software

Chapter 5, Section 5.12 provides the criteria for the use of digital and smart devices in the UK AP1000 plant. Per the criteria, digital devices performing Category A functions in the electrical system are required to be compliant with the appropriate International Electrotechnical Commission (IEC) nuclear standards to be justified as Class 1.

Digital devices which are performing Category B and C functions in the electrical system will be identified and the software and hardware will be justified in accordance with the guidelines of the “AP1000 Smart Device Assessment Process,” UKP-GW-J0Y-004 (Reference 18.26) and the “AP1000 SMART-Device Justification Plan,” UKP-GW-GL-017 (Reference 18.7). The assessment performed will be commensurate with the classification of the device. Additionally, should isolation between the smart aspect and a higher class function be required evidence of this isolation will be provided.

In addition to the criteria provided in Section 5.12, additional information on SMART devices can be found in Chapter 19. Reference 18.25 provides the claims, arguments, and evidence relating to digital devices in the Class 1 IDS system including software diversity claims to reduce the potential for common-cause failure. Reference 18.25 also provides the

claims on the justification of smart devices performing Category B and C functions within the electrical systems.

18.8.3 Reactor Trip

When less than three of the four IDS divisions are in service, the reactor will automatically trip.

18.8.4 Post Accident Monitoring

After a DBE, the IDS provides power to the PMS for post-accident monitoring. After 72 hours, if no other sources of power are available, the two ancillary diesels provide ac power for post-accident monitoring. These loads can also be powered by offsite DGs in case the ADGs are unavailable. Post-accident monitoring provides indication for containment pressure, containment water level, containment radiation intensity, and noble gas effluents. ESF actuation signals and Class 1 isolation valves provide the Category A containment safety functions.

18.8.5 Fukushima Electrical System Assessment

Per the results of the internal flooding assessment in "UK AP1000 Plant Post-Fukushima Assessment" UKP-GW-GGR-201 (Reference 18.4), the minimization of potential flooding sources in the safety-related areas (e.g., IDS battery banks), in addition to the physical separation of redundant safety-related components and systems from each other and from non-Class1 related components, reduces the consequences of internal flooding. The Core Damage Frequency (CDF) and Large Release Frequency (LRF) arising from flooding events during shut down operations are not appreciable contributors to overall AP1000 plant design risk.

Design provisions resulting from the post Fukushima assessment for the UK AP1000 increase the ability of the AP1000 electrical system to withstand or mitigate the effects of beyond-design-basis events. These design provisions and the safety claims made on them are contained in Reference 18.25.

APPENDIX 18A ELECTRICAL CODES AND STANDARDS

To comply with UK, European, and 50-Hz requirements, Westinghouse has conducted an in-depth analysis of the appropriate codes and standards to be employed in the UK AP1000 plant. The results of this analysis have been reported in Reference 18.2. This report concludes that the majority of the UK AP1000 plant electrical system design and construction can be encompassed by the comprehensive suite of UK and European codes and standards without any significant impact on the standard AP1000 plant design. Where this is so, the appropriate UK and European codes and standards are used. For certain specialised areas, United States (US) standards are applied; these standards are discussed in detail in the appropriate areas of this chapter.

Following completion of the codes and standards analysis, it has been determined that IEC codes and standards are utilised throughout the UK AP1000 plant electrical system except for the following limited applications, where it has been determined that the requirements of the Institute of Electrical and Electronics Engineers (IEEE) standards equal or exceed those of the equivalent IEC standards:

- Class 1 and 2 dc systems, including the switchgear supplying the essential loads from the dc system, are IEEE-qualified equipment
- RCP isolation breakers
- Reactor electrical penetrations
- Generator circuit breakers

To fully accommodate the translation of the AP1000 plant to 50 Hz and the use of 11 kV and 400V auxiliaries, all ac motors are subject to individual assessment during the detailed design phase.

TABLE OF CONTENTS

LIST OF TABLES

LIST OF FIGURES

LIST OF ABBREVIATIONS, ACRONYMS, AND TRADEMARKS

AC	alternating current
ADS	automatic depressurisation system
AFD	automatic fire detection
ALARP	as low as reasonably practicable
APS	alarm presentation system
BSC	basis of safety case
BEACON™	best-estimate analysis core optimisation
BOP	balance of plant
BPL	bistable processor logic
C&I	control and instrumentation
CCF	common-cause failure
CFVMS	CRDM fan vibration monitoring system
CIM	component interface module
CMT	core makeup tank
CPS	computerised procedures system
CRDM	control rod drive mechanism
CVS	chemical and volume control system
DAS	diverse actuation system
DB	design basis
DBA	design basis accident
DC	direct current
DDS	data display and processing system
DiD	defense in depth
DMIMS-DX	digital metal impact monitoring system
EDS	Class 2 DC and uninterruptible power supply system
EMC	electromagnetic compatibility
EQ	equipment qualification
ESF	engineered safety feature
FB	function block
FID	fixed in-core detector
FMEA	failure modes and effects analysis
FWVMS	feedwater vibration monitoring system
GDA	generic design assessment
GNS	general non-safety
HSI	human-system interface
IAEA	international atomic energy agency
IDS	class 1 dc and uninterruptible power supply
IEC	International Electrotechnical Commission
IEEE	Institute of Electrical and Electronics Engineers
IIS	in-core instrumentation system
ILP	integrated logic processor
I/O	input/output
IRWST	in-containment refuelling water storage tank
LAN	local area network
LCO	limiting conditions for operation
MCR	main control room
MDEP	multi-national design evaluation programme
MG	motor generator
MTP	maintenance and test panel
NAPs	nuclear application programmes
NIS	nuclear instrumentation system
NPP	nuclear power plant

19 CONTROL AND INSTRUMENTATION

19.1 Introduction

19.1.1 Purpose and Scope

The objective of this Pre-Construction Safety Report (PCSR) chapter is to give a high-level description and provide engineering substantiation of the control and instrumentation (C&I) systems that deliver nuclear safety as part of the overall Westinghouse Electric Company AP1000 reactor. Chapters 1 and 2 of the PCSR provide information on the overall PCSR production process and its relationship to the Office for Nuclear Regulation (ONR) Generic Design Assessment (GDA).

In terms of the C&I systems, the AP1000 reactor is controlled by a Class 2 plant control system (PLS), which maintains the plant within its defined operational limits and conditions. Should there be a failure to control the plant within these limits and conditions, there are systems important to safety (SIS) that respond to the fault conditions and allow the safe shutdown of the reactor before unacceptable conditions occur. Other C&I systems will also be available on the reactor to provide support functions during fault conditions. There are also C&I control and protection systems associated with non-reactor based operations, e.g. the fuel route.

The key objective of this engineering substantiation is to demonstrate that the safety requirements placed onto the C&I systems have been delivered and to an appropriate level of integrity. It is also a requirement to demonstrate that the engineering principles (Chapter 5) have been followed in the development of the safety led design solutions. The safety requirements specified for the C&I systems include safety functions and performance/design requirements of the structures, systems or components (SSCs) that deliver the safety functions. The source documentation for the C&I safety requirements, including the relevant sections of the safety case, are given within this chapter. Evidence is also provided in this chapter or referenced lower tier documentation to show that the safety requirements have been delivered at the correct level of integrity.

In addition to the individual C&I systems, justification and substantiation of the overall C&I architecture is provided, i.e. how the individual systems are configured to provide the plant with sufficient defense in depth (DiD) to meet the requirements of the safety case and the expectations for a modern nuclear power plant (NPP). This chapter, therefore, provides a demonstration that the design of the C&I systems and their interfaces within the AP1000 reactor are fit-for-purpose to deliver their nuclear safety functions and use technology and modes of operation that are commensurate with applicable standards. Reference is made in this chapter to the detailed descriptions and substantiation of the individual systems that are provided in, amongst other documents, the relevant Basis of Safety Case (BSC) documents. A number of BSCs also refer to lower tier BSCs where specific aspects of the systems require detailed substantiation.

Due to the fundamental importance of the overall architecture, justification of the architecture takes prominence in this chapter. The overall AP1000 design and manner of operation are described in Chapter 6.

This chapter demonstrates that the design of the AP1000 C&I systems helps to reduce radiological risks to as low as reasonably practicable (ALARP), which is a legal requirement within the United Kingdom (UK). This is achieved by making reference to Westinghouse Electric Company's ALARP guidance (Reference 19.37) and demonstrating that:

- the potential for control system faults to be initiated has been reduced as far as reasonably practicable and C&I protection consists principally of automated protection systems, i.e. the position of the C&I design in the safety hierarchy;

- relevant good practice (RGP) has been applied in the design and is applied in detailed design, installation and operation. Where necessary, this is with respect to established codes and standards that are considered to represent RGP;

- safety functions have been substantiated and that required reliability requirements have been satisfied (or that there is a programme of work to complete the analysis); and

- suitable optioneering has been undertaken to underpin design and configuration selection.

Section 19.1.4 describes how ALARP has been met for the C&I architecture. The supporting ALARP document produced for this chapter (Reference 19.61) provides further supporting evidence that the design of the C&I architecture, its systems and sub-systems contribute to the reduction of radiological risk to the public and workers to a level that is considered to be ALARP. The system BSC documents also support the high level claim that ALARP principles have been applied in the development of the systems.

In terms of the C&I systems themselves, this chapter primarily focuses on the overall architecture of the C&I systems, i.e. how they are configured and interface with each other to ensure an operable and maintainable plant that delivers security and safety requirements. Figure 19-1 illustrates the control and instrumentation architecture for the AP1000 plant. Detailed engineering substantiation of the architecture is provided in this PCSR chapter in lieu of lower tier documentation. However, the principal C&I systems themselves are described at a summary level in this PCSR chapter due to the detailed substantiation being available in the individual BSCs, i.e. the following systems:

- Plant control system (PLS);

- Protection and Safety Monitoring system (PMS);

- Diverse Actuation System (DAS);

- Data Display and Processing Systems (DDS).

Note that full compliance is not claimed within the system safety case documents or the supporting documents for this Chapter 19. The safety plans within these documents identify the gaps in compliance and the associated compensating measures which will be completed during the Nuclear Site Licensing Phase.

Figure 19-8 shows the scope boundary for coverage between the PCSR and system BSCs.

In addition, a number of supporting C&I systems are also briefly mentioned. Detailed safety specifications for these systems have yet to be fully developed as they are outside the scope of the GDA and the BSCs for these systems (where appropriate) have not been written. Further safety specification and design of the following systems, together with production of BSCs, are anticipated to be developed during the Nuclear Site Licensing Phase:

- Special Monitoring System (SMS);

- In-core Instrumentation System (IIS);
- Radiation Monitoring System (RMS);
- Other C&I.

The scope of the engineering substantiation undertaken for the C&I systems in this chapter at this phase of GDA only includes the logic components of the systems. The other aspects required to deliver the relevant safety functions, i.e. detection and termination is anticipated to be included at the Nuclear Site Licensing Phase PCSR submission. The Nuclear Site Licensing Phase will also substantiate the use of smart devices within systems. The methodology for justification of smart devices for the AP1000 SSCs is in Chapter 5. Chapter 11 (Internal Hazards) and its supporting references justify how C&I safety functions (particularly Category A) will be delivered through design basis internal hazards that may affect multiple systems, e.g. fire and flooding. Chapter 11 describes how this delivery will be achieved by use of segregation and separation, e.g. via redundant divisions being within segregated fire compartments or separated by distance. Therefore, the layout of the systems to deliver internal hazard requirements is not discussed in this chapter and reference should be made to Chapter 11 and its supporting fire barrier matrix (Reference 19.54). The C&I systems that are required to be seismically qualified will be fully substantiated at the Nuclear Site Licensing Phase.

It is important to note that where reliability requirements for C&I systems have been specified, this chapter demonstrates that the requirements have been achieved or that there is a programme of work to complete this demonstration. The overall adequacy of the configuration with respect to meeting overall radiological fault risk reduction (the purpose of probabilistic safety assessment (PSA) and the modelling of the PLS/PMS/DAS as a conglomerate) is provided within Chapter 10. It is important to note that the C&I design process has been iterative to ensure that the C&I configuration supports the overall qualitative and quantitative radiological risk reduction required.

A key aspect of design standards is the concept of a safety life cycle, which includes planning, requirements, design, installation, commissioning, operations and maintenance. Whilst the UK AP1000 is still at the requirements stage, this chapter outlines how the latter aspects of the design life is anticipated to be managed via application of the relevant codes and standards.

The chapter is structured to facilitate an understanding of the C&I architecture and give evidence that the required safety functions of the systems are understood and delivered, i.e. that that they are fit-for-purpose. Therefore, this chapter includes sections that describe:

- how the safety case has been constructed and the categorisation and classification of safety functions and the C&I systems that deliver the safety functions;
- the codes and standards that have been used in the design process and how these reflect RGP, e.g. comparison of the original Institute of Electrical and Electronic Engineers (IEEE) design standards with those of the International Electrochemical Commission (IEC) of which the latter are considered to represent RGP in the UK;
- the high level requirements of the individual systems and their overall architecture;
- the individual systems and how they deliver the safety functions and required reliability; and

- how ALARP is demonstrated for the overall C&I architecture and the individual systems.

As necessary, this chapter makes reference to

- operations and maintenance philosophy;
- security; and
- life-time records.

19.1.2 Control and Instrumentation Architecture Safety Case Overview

There are a number of key interfaces between this Chapter 19 and other chapters within the PCSR. In particular:

- Chapter 5 (Engineering Principles) describes the safety led design approach to ensure that the provision of design solutions is based upon good engineering solutions, hence meeting the requirements of RGP.
- Chapter 8 (Fault and Accident Analysis) includes the methodology for the assessment of design basis (DB) and beyond design basis. The chapter also includes a fault schedule defining the DB class of the fault groups, the relevant safety functions/categories and the classification (e.g., PMS is Class 1 and DAS is Class 2) that deliver the safety functions. The C&I systems must be demonstrated to be delivered in this chapter;
- Chapter 9 (Internally Initiated Faults) includes design basis accident analysis for internally generated faults;
- Chapter 10 (Reactor Faults Probabilistic Safety Analysis and Severe Accident Analysis) confirms the adequacy of the C&I configuration with respect to overall risk reduction requirements;
- Chapter 11 (Internal Hazards) specifies faults for which the C&I systems are to be tolerant (e.g. fire or flooding);
- Chapter 12 (External Hazards) specifies faults for which the C&I systems are to be tolerant (e.g. seismic);
- Chapter 13 (Human Factors) describes the human factors engineering programme, the integration of human factors in the AP1000 design, and the verification and validation of the design. Chapter 13 also examines the role of the operator and how the potential for error has been minimised through design and specifies specific design standards to be applied, for example for the control room layout;
- Chapter 15 (Engineering Schedule) consolidates safety functions and system classifications. Therefore, the C&I SSCs and their classification identified within Chapter 15 form the basis of the descriptions and engineering substantiation provided in this Chapter 19.

The above analyses presented in Chapters 8 to 15 reflects one input into the derivation of safety requirements for the C&I systems substantiated in this chapter. Designation of systems

as Class 1, 2 or 3 in line with IEC 61513 (Reference 19.16) drive safety design/performance requirements that may complement or be in addition to those specified explicitly in Chapters 8 to 15. Moreover, the original design process for the AP1000 C&I systems was undertaken in line with Nuclear Regulatory Commission (NRC) endorsed IEEE standards. The specification of safety requirements via this design route was via the production of documents such as a System Requirements Specification (SyRS) and System Design Specification (SyDS).

19.1.3 Overall Control and Instrumentation High Level Claims

As outlined above, the fault assessment presented within Chapter 8 identifies specific safety functions delivered by the C&I SSCs (summarised in Chapter 15). The requirements of the safety case influences the overall C&I architecture. Chapters 8 to 15 of the PCSR make the following fundamental claims that influence the C&I architecture:

- The reactor is controlled by the PLS, which can initiate faults that if uncorrected can lead to unacceptable consequences (Chapters 8 and 9).

  An unacceptable consequence, as defined in IEC 61226 (Reference 19.22), is a consequence of an operational state or of a postulated initiating event (PIE), that exceeds specified limits for the corresponding plant states, in terms of releases at the site or to the wider environment.

- The DB requirements require two independent safety measures to protect against defined reactor faults, as detailed in the Fault Schedule (Chapter 8). One measure must be Class 1 and the other is specified as Class 2 in the Engineering Schedule (Chapter 15);

- A Remote Shutdown Room (RSR) is required should the Main Control Room (MCR) (Chapter 11) need to be evacuated and there is an Automatic Fire Detection (AFD) system (Chapter 11);

- The operator receives input from the operation and control centre system (OCS) that interfaces with the PMS, DAS, IIS, and RMS, as specified in the Engineering Schedule (Chapter 15);

- The RMS provides monitors to enable action to maintain habitability of the MCR (Chapter 15).

In simple terms, the safety case requires a plant protection system with two independent safety measures to satisfy DB requirements to prevent significant consequences potentially associated with a design basis event. There must be a remote shutdown facility in case of a MCR evacuation and operator interface systems to provide feedback to the operator on the normal plant control condition and the status of the two independent safety measures. These fundamental requirements are shown schematically in Figure 19-7.

It is important to note that the schematic in Figure 19-7 represents the basic building blocks of the C&I architecture. The development of the architecture is explained and justified in Section 19.3. Additional architecture requirements are sourced from the use of the relevant C&I design standards, e.g. IEC 61513 (Reference 19.16).

In addition to the architectural requirements stemming from the safety case, the safety functions require consideration. Table 19-1 summarises the principal safety functional claims made upon the individual C&I SSCs (classification 1 and 2 only), which are further expanded

in the relevant sections with more detail on the definition of the classification numbers and the implication for C&I design in Section 19.2.

It is important to note that for the PLS/PMS/DAS in particular, the design basis analyses place requirements on independence, segregation and diversity between the systems. This ensures that the plant is fault tolerant (i.e., can withstand an unrevealed failure in a safety measure), and the potential for common cause failure (CCF) between the PLS, PMS, and DAS is minimised. Thus, in developing the fundamental C&I architecture, an understanding of these aspects is required.

19.1.4 Overall Control and Instrumentation ALARP Demonstration

19.1.4.1 Introduction

Demonstration that the AP1000 design is ALARP is a stated aim within Chapter 1 of the PCSR. To support the demonstration of ALARP, Westinghouse has produced specific ALARP guidance (Reference 19.37). An outline of how Chapter 19 is structured to provide ALARP arguments, in line with the Westinghouse Electric Company guidance, is given below.

19.1.4.2 ALARP Demonstration

The principal purpose objective of Chapter 19 is to present the C&I architecture and its component systems to demonstrate that they meet the requirements placed upon them from the overall safety case. There is a clear ALARP hierarchy to be demonstrated in terms of architecture, systems and sub-systems. Therefore, the sections associated with the overall C&I architecture and systems make reference to the explicit safety case demands (e.g. from the Engineering Schedule), which include the:

- origin of the demand;
- demand itself, i.e. the safety function and performance requirement where specified (e.g. reliability).

A supporting C&I architecture ALARP justification document has been produced for Chapter 19. It provides justification that the safety case requirements specified in the relevant fault analysis (Chapters 8 to 12), the human factor programme (Chapter 13), fault analysis conclusions (Chapter 14) and the Engineering Schedule (Chapter 15) have been included in the design.

The Plant C&I Architecture ALARP Justification, (Reference 19.61) summarises the ALARP justification. This in addition to the supporting documents and system BSCs provide positive demonstration that the safety case requirements have been satisfied.

19.2 Codes and Standards

19.2.1 Introduction

The AP1000 plant C&I systems were originally designed to United States (US) codes and standards. Subsection 19.2.2 describes this further.

In order to demonstrate that the AP1000 plant C&I design conforms with appropriate UK codes and standards, a conformance exercise has been carried out to provide an evidence

trail of how the UK requirements have been addressed and mapped against the Westinghouse design.

The UK codes and standards requirements can be considered to constitute three main groups:

- the high level guidance provided by the international atomic energy agency (IAEA), augmented by material published by Western European Nuclear Regulators Association (WENRA), Multi-National Design Evaluation Programme (MDEP) and other similar technical bodies;

- the more detailed requirements and recommendations contained in the IEC SC45A series of nuclear sector standards for which IEC 61513 (Reference 19.16) is the head document;

- the UK regulatory expectations as embodied in the ONR safety assessment principles (SAPs), the associated technical assessment guides (TAG) and other documents referenced from the SAPs and TAGs.

Subsections 19.2.3 through 19.2.5 provide further details on the above 3 groups and discusses the conformance of the AP1000 C&I design to their requirements.

19.2.2 Design to US Codes and Standards

The control and instrumentation systems were designed in accordance with guidance provided in applicable portions of the following standards:

- IEEE 379-2000; "IEEE Standard Application of the Single-Failure Criterion to Nuclear Power Generating Station Safety Systems"

- IEEE 383-1974; "IEEE Standard for Type Test of Class IE Electric Cables, Field Splices, and Connections for Nuclear Power Generating Stations"

- IEEE 384-1981; "IEEE Standard Criteria for Independence of Class 1E Equipment and Circuits" (Reference 19.11)

- IEEE 420-1982; "IEEE Standard for the Design and Qualification of Class 1E Control Boards, Panels, and Racks Used in Nuclear Power Generating Stations"

- IEEE 603-1991; "IEEE Standard Criteria for Safety Systems for Nuclear Power Generating Stations" (Reference 19.5)

- IEEE 627-1980; "IEEE Standard for Design Qualification of Safety Systems Equipment Used in Nuclear Power Generating Stations"

- IEEE 1050-1996; "IEEE Guide for Instrumentation and Control Equipment Grounding in Generating Stations"

- IEEE 1074-1995; "IEEE Standard for Developing Software Life Cycle Processes"

- EPRI TR-102323, Revision 1, "Guidelines for Electromagnetic Interference Testing in Power Plants"

19.2.3 Conformance to UK high level principles

19.2.3.1 Relevant guidance documents

The Safety Guides that record the most applicable guidance provided by the IAEA in relation to the design of C&I architectures are:

- IAEA SSR-2/1 (Reference 19.34)
- IAEA SSG-39 (Reference 19.35)

Other publications of specific relevance include:

- WENRA RHWG Report "Safety of new NPP designs" (Reference 19.38);
- MDEP Common Position № DICWG-09 (Reference 19.3); and
- Licensing of SC software for nuclear reactors (Reference 19.40).

The approach adopted in this PCSR chapter is to conduct an assessment to distil from the above sources, and record in this section, the High Level principles that would be considered Relevant Good Practice. With reference to subsection 19.2.3.2, these High Level principles may be organised into the following 3 broad stages of the C&I design safety life cycle:

- those that constitute "inputs" to the C&I design process;
- those that constitute Engineering Principles to be adopted by the C&I design, including those discussed in Chapter 5 of this PCSR;
- those that mainly (but not exclusively) address the later stages of the safety life cycle.

The Engineering Principles may be further organised into three sub-groups and the full set of principles then used to structure the discussion of the C&I architecture in Section 19.3.

The distilled principles are discussed in subsection 19.2.3.2.

19.2.3.2 High Level Principles

The distilled High Level principles are included below.

1. C&I is designed to be consistent with the Plant Design and Safety Analysis
    a. Constraints from the plant design framework (including Defense-in-Depth (DiD) concept)
    b. Constraints from the plant operational and maintenance philosophies
    c. Functional requirements arising from safety analysis
    d. Performance requirements arising from safety analysis
    e. Safety importance (categorisation) arising from safety analysis
    f. Reliability requirements arising from safety analysis

2. C&I is designed to provide DiD
    a. Functional allocation to levels of defense and specific systems
    b. Independence (between levels of defense and redundant parts)
    c. Diversity (of systems in response to frequent PIE)

d. Separation (to prevent hazard spread) / isolation (to prevent failure propagation)
e. C&I supporting systems adhere to requirements arising from the above considerations

3. C&I conforms to standards appropriate to the category and class
   a. Categorisation of functions
   b. Classification of C&I systems
   c. Conformance to codes and standards
   d. Qualification (environmental and functional)
   e. Validation / commissioning

4. C&I is designed to be robust and reliable
   a. Identification of faults (within C&I systems)
   b. Actions upon fault identification (within C&I systems)
   c. Application of single failure criterion
   d. Communication between C&I systems / prevention of fault propagation
   e. Defense against CCF (within C&I systems)
   f. Avoidance of complexity
   g. Demonstration of reliability
   h. Defense against malicious attack

5. C&I is designed to be safely operated and maintained
   a. Human-system interface (HSI) design
   b. Testability
   c. Maintainability
   d. Ageing and obsolescence management
   e. Design for ease of modification / replacement
   f. Establishment / maintenance of lifetime records

19.2.4 Conformance to UK codes and standards

19.2.4.1 Relevant Codes and Standards

As stated in subsection 19.2.1, IEC 61513 (Reference 19.16) is the head document for the IEC SC45A standards series. In particular, IEC 61513 (Reference 19.16) describes the safety life cycle that should be adopted for the C&I design process. This ensures the required level of confidence that the systems will reliably fulfil their design function through their life cycles.

The normative parts of IEC 61513 (Reference 19.16) are clause 2 (references) and clauses 5 to 8 inclusive.

The C&I architecture High Level Claim regarding conformance with IEC 61513 (Reference 19.16) is documented in UKP-GW-GLR-038 (Reference 19.59) and the BSC documents for the individual C&I systems as follows:

- The overall safety life cycle (clause 5): UKP-GW-GLR-038 (Reference 19.59)
- Systems safety life cycle (clause 6): BSC for systems
- Overall integration and commissioning (clause 7): UKP-GW-GLR-038 (Reference 19.59) and BSC for systems

• Overall operation and maintenance: (clause 8)	UKP-GW-GLR-038 (Reference 19.59) and BSC for systems

Reference 19.59 addresses the safety life cycle requirements that are judged to be applicable to the overall C&I architecture in the form of Claims Arguments and Evidence. It also includes a safety plan which identifies any gaps and compensating measures at the overall C&I architecture level. The safety plan within Reference 19.59 has identified several deficiencies and remedial activities respectively, as well as future work in design or safety case development. These gaps are not considered to be significant. The gaps and compensating measures are identified so that all future work (remedial or not yet performed) is captured and planned appropriately.

In addition to IEC 61513 (Reference 19.16), the most important IEC SC45A standards from the point of view of the C&I architecture are judged to be the following:

- IEC 61226 (Reference 19.22) addressing safety categorisation
- IEC 62340 (Reference 19.15) addressing coping with CCF
- IEC 60709 (Reference 19.41) addressing separation

and to a lesser extent:

- IEC 60671 (Reference 19.42) addressing surveillance testing

Other IEC SC45A standards then address:

- Software-reliant systems important to safety:
    - IEC 60987 (Reference 19.23)
    - IEC 60880 (Reference 19.24)
    - IEC 62138 (Reference 19.25)
    - IEC 62566 (Reference 19.43)
    - IEC 62671 (Reference 19.44)
- Suitability for the environment:
    - IEC 60780 (Reference 19.48)
    - IEC 61000 (Reference 19.6)

but these apply to individual C&I systems for which conformance is addressed, where applicable, within the corresponding BSCs.

In addition to the above, other IEC SC45A standards address the control rooms and associated HSI:

- IEC 60964 (Reference 19.45) addressing the (main) control room
- IEC 60965 (Reference 19.46) addressing the supplementary control room
- IEC 61839 (Reference 19.47) addressing assignment of functions

The system-specific aspects of these standards are addressed within the corresponding BSCs, but other aspects apply at the C&I architecture level and are addressed below.

19.2.4.2 Conformance with IEC SC45A standards series

This subsection considers three important standards in terms of the C&I architecture and three other important standards with which conformance has been demonstrated for individual C&I systems.

19.2.4.2.1 C&I architecture

IEC 61513

IEC 61513 (Reference 19.16) sets out the requirements applicable to C&I systems and equipment that perform functions important to safety. In addition to defining the requirements for a safety life cycle, these relate to the following:

- Derivation of C&I requirements from the plant safety basis
- Design of the C&I architecture and assigning safety functions
- Planning
- Integration and commissioning
- Operations and maintenance

Conformance evidence has also been identified in the following documents:

- Reliability, WNA-AN-00038-WAPP (Reference 19.26)
- Defense in depth, APP-GW-J1R-004 (Reference 19.18)
- Allocation of manual and automatic actions, described in the functional requirements.

The system BSCs evaluated the conformance and all gaps are identified in the system BSCs. The gaps for the overall C&I architecture are identified in Reference 19.59.

IEC 61226

IEC 61226 (Reference 19.22) is directly referenced by IEC 61513 (Reference 19.16) and is a second-tier document in the SC45A series that describes the categorisation functions (safety) and classification of C&I systems.

The main references to demonstrate conformance with IEC 61226 (Reference 19.22) are Quality Management System 3.2.1, regarding safety categorisation, and WNA-SQ-00049-GEN (Reference 19.62), regarding classification of C&I systems. These documents are considered to provide good conformance evidence, since in many cases the text is a direct extract from IEC 61226 (Reference 19.22).

IEC 62340

The main purpose of IEC 62340 (Reference 19.15) is to address CCF. This is used in the diversity evaluations that are documented in the system BSCs.

19.2.4.2.2 C&I systems

IEC 60987

IEC 60987 (Reference 19.23) is directly referenced by IEC 61513 (Reference 19.16) and is a second-tier document in the SC45A series that deals with the hardware design of computerised systems.

IEC 60880

IEC 60880 (Reference 19.24) is directly referenced by IEC 61513 (Reference 19.16) and is a second-tier document in the SC45A series that deals with the software aspects for Class 1 systems performing Category A functions.

IEC 62138

IEC 62138 (Reference 19.25) is directly referenced by IEC 61513 (Reference 19.16) and is a second-tier document in the SC45A series that deals with the software aspects for C&I systems performing Category B and C safety functions.

19.2.5 Conformance to UK regulatory expectations

19.2.5.1 Discussion of ONR SAPs

Although not a code or standard, the ONR SAPs (and associated TAGs) may be used as a basis for assessment by licensees as well as regulators.

It is understood that each SAP, together with any explanatory paragraphs, addresses a specific topic for which the ONR require confidence that the design meets their expectations.

It is also understood that the SAPs are aligned with the IAEA guidance and with the more important IEC SC45A standards and so conformance with the SAPs provides useful confirmation that the design is also in conformance with the IAEA guidance and the IEC SC45A standards.

19.2.5.2 Conformance with ONR SAPs

The C&I Architecture SAPs Conformance Assessment (Reference 19.60) demonstrates conformance of the overall C&I architecture with the identified set of applicable SAPs.

UKP-GW-GLR-039 (Reference 19.60) specifically addresses the C&I system architecture and is supported by individual SAP conformance evaluations for the PMS (which includes the component interface module (CIM) and Alternate Spurious Operation Blocker); PLS; DDS and DAS. The SAPs evaluation has not identified any future activities specific to the C&I architecture that is not already planned for the detailed design development during site licensing. The safety plan for the individual C&I systems can be found in the applicable system BSC.

19.3 Overall Control and Instrumentation System Architecture

19.3.1 Design Basis

19.3.1.1 Fundamental Safety Function

In accordance with international consensus C&I is required in the plant to provide information about the plant and control its operation as follows:

(a) To determine the values of all the main variables that can affect the fission process, the integrity of the reactor core, the reactor coolant systems and the containment

(b) To obtain the essential information on the plant that is necessary for its safe and reliable operation;

(c) To determine the status of the plant in accident conditions;

(d) And for making decisions for the purposes of accident management.

Together with the plant systems and structures the C&I assures the accomplishment of the three critical safety functions:

1. Control of reactivity
2. Heat removal from the reactor core
3. Limiting of reactivity release by maintaining the barriers containing radioactive material:
    a. Fuel pellet and fuel elements
    b. Reactor coolant system
    c. Containment

Thus the C&I ensures in all plant conditions and modes of operation that radiation doses to workers and the public do not exceed the dose limits and that they are kept as low as reasonably achievable during, and following, accident conditions as demonstrated by the analysis presented in PCSR Chapter 8 through 11.

19.3.1.2 Functional and Performance Requirements

Functional and Performance requirements of the C&I are derived from the PCSR, the plant design documents and regulations. The C&I System design further receives inputs from industry standards (PCSR Chapter 5), relevant good practice and Westinghouse experience.

PCSR Chapters 8 through 11 (Fault and Accident Analysis) provides an overview of the fault and accident methodology. The C&I functional design implements the essential safety functions credited in the analysis (see the Table 8A-2 of Chapter 8 for a list of those functions). These requirements are captured in the PMS Functional Requirements (Reference 19.122).

The requirements from plant systems design are imposed on the C&I in the following key design documents for plant systems:

- System Specification Document
- System Piping and Instrumentation Diagrams
- System Component Control Requirements
- System Instrumentation and Packaged Mechanical System Interface Requirements

All of the above requirements are collected in the C&I System Requirements Document (Reference 19.21) and SyDS (Reference 19.13) and from there on flow into individual C&I System requirements specifications.

The UK AP1000 process for management of C&I requirements is described in Reference 19.1. Reference 19.1 provides a description and justification for the C&I requirements capture process, including the derivation of C&I requirements from safety analyses into the C&I requirements documents and the management of requirements from sub-system licensing basis documents into lower level C&I documents.

19.3.1.3 Categorisation Resulting from Safety Case

Categorisation is used to identify the safety significance of a C&I function, and defines the class in which the C&I system function must be implemented.

The method for classifying the safety significance of C&I SSCs is primarily based on deterministic methods, complemented where appropriate by probabilistic methods and engineering judgment (see PCSR Chapter 5). This takes account of factors such as:

- Category of safety function(s) to be performed by the SSC;
- Consequences of the failure of the SSC to perform its function;
- Probability that the SSC will be called upon to perform a safety function;
- Time following any initiating fault at which, or the period throughout which, the SSC will be called upon to operate.

The categorisation and classification methodology is further discussed in subsection 19.3.3.1.3.

19.3.1.4 Reliability Requirement Resulting from Safety Case

All SSCs are expected to have a reliability that is commensurate with their safety importance. Class 1 systems, in particular, are expected to have a high level of reliability. The methodology used to assess the reliability of SSCs is described in PCSR Chapter 5.9.

The target probability for failures on demand for each class of system are:

- The reliability claim for Class 1 systems is 1.0×10^{-3} failures/demand
- The reliability claim for Class 2 systems is 1.0×10^{-2} failures/demand
- The reliability claim for Class 3 systems is 1.0×10^{-1} failures/demand

Justification for the reliability claims can be seen in the BSCs for the respective C&I systems.

19.3.2 Overview of Control and Instrumentation Functional Systems

Figure 19-1 illustrates the instrumentation and control architecture for the AP1000 plant. The figure shows two major sections separated by the real-time data network. Figure 19-1 depicts the real-time data highway as a single network. To meet cyber security concerns, the real-time data highway is separated into security levels as described in Reference 19.17.

The lower portion of the figure includes the plant protection, control, and monitoring functions. At the lower right-hand side is the PMS. This system performs the Category A reactor trip functions, the engineered safety features (ESF) actuation functions, and the Qualified Data Processing (QDPS) functions. The C&I equipment performing reactor trip and ESF actuation functions, their related sensors, and the reactor trip switchgear are, for the most part, four-way redundant. This redundancy permits the use of bypass logic so that a division or individual channel out of service can be accommodated by the operating portions

of the protection system reverting to a two-out-of-three logic from a two-out-of-four logic.

The ESF coincidence logic performs system-level logic calculations, such as initiation of the passive residual heat removal system. It receives inputs from the plant protection subsystem bistables and the main control room.

The ESF actuation subsystems provide the capability for on-off control of individual plant loads. They receive inputs from the ESF coincidence logic, remote shutdown workstation and the main control room.

The DAS is a diverse system that provides an alternate means of initiating reactor trip and actuating selected ESF functions, and providing plant information to the operator.

The plant control system performs open and closed loop instrumentation and control functions using both discrete (on/off) and modulating (analogue) type actuation devices. It controls plant within operational limits and conditions. Failure of this function could require directly the actuation or operation of a Category A safety function.

The real-time data network, which horizontally divides Figure 19-1, is a high speed, redundant communications network that links systems of importance to the operator. The PMS is connected to the network through gateways and qualified isolation devices so that the Category A functions are not compromised by failures elsewhere. Plant protection, control, and monitoring systems feed real-time data into the network for use by the control room and the data display and processing system.

The upper portion of the figure depicts the OCS (refer to PCSR Chapter 13) and DDS. The main control room is implemented as a set of compact operator consoles featuring colour graphic displays and soft control input devices. The graphics are supported by a set of graphics workstations that take their input from the real-time data network. An advanced alarm system, implemented in a similar technology, is also provided. The OCS also houses those systems which are required to provide information that allows specified manual actions necessary after the non-hazardous stable state has been reached to prevent a design basis accident (DBA) from leading to unacceptable consequences, or mitigate the consequences of a DBA.

The safe shutdown of the plant can be established and maintained from the RSR should an evacuation of the control room be required.

The data display and processing system is implemented in a distributed architecture. The working elements of the distributed computer system are graphics workstations, although their graphics capability is secondary to their computing performance. The distributed computer system obtains its input from the real-time data network and delivers its output over the network to other users.

The following subsections provide introductions to the functional C&I systems that are covered in this chapter:

- Protection and safety monitoring system
- Diverse actuation system
- Plant control system
- Operation and control centre system
- Data display and processing system
- Special monitoring system

  - Digital metal impact monitoring system (DMIMS-DX™)
  - Reactor coolant pump vibration monitoring (RCPVM) system
- In-core instrumentation system
- Radiation monitoring system
- Fuel handling and storage

19.3.2.1 Protection and Safety Monitoring System

The PMS is a programmable logic controller (PLC) based system that operates on an Advant® AC160 controller. The Advant AC160-based protection system is a digital-process protection system designed for use within both pressurised water reactors and boiling water reactors. The PMS is described in Reference 19.28, PMS Safety Case Basis. It consists of all the necessary equipment to facilitate reliable actuation of the following functions, namely:

- Detection of system transients beyond the normal operational reactor parameters;

- Actuation of the safety protective functions, necessary to achieve and then maintain the plant in a safe shutdown state.

In addition, the PMS provides the equipment necessary to monitor the plant functions during and following any DBA.

Protective functions are those necessary to achieve the system responses detailed in the safety analyses, and those needed to shut down the plant safely. The AP1000 plant protective functions are grouped into two classes:

- Reactor trip
- ESF actuation

The AP1000 plant PMS consists of four redundant divisions, designated as A, B, C, and D, which are depicted in Figure 19-2 (see Reference 19.3, Section 2.1).

The PMS performs the necessary signal acquisition, calculations, setpoint comparison, coincidence logic, reactor trip, and ESF actuation functions, and safety component control functions to achieve and maintain the plant in a safe shutdown condition. The PMS also contains maintenance and test functions to verify correct operation of the system. The PMS includes four redundant safety displays, one for each division, located on the primary dedicated safety panel (PDSP) in the MCR. Four redundant divisions are provided to satisfy single failure criteria and improve plant availability.

19.3.2.2 Diverse Actuation System

The DAS provides a diverse backup to the PMS as described in the DAS BSC (Reference 19.29). The DAS design utilises solid-state hardware that is based on the Westinghouse 7300 series platform. The DAS supports the AP1000 plant risk mitigation by reducing the probability of a severe accident. Without the DAS, a severe accident could occur from the unlikely coincidence of postulated transients and postulated CCF in the protection and control systems.

The specific functions performed by the DAS are selected based on two separate considerations:

- One consideration is PSA-based. In this approach, the DAS provides backup C&I capability in sequences involving CCF of the PMS and PLS that are risk important (subsection 19.4.2.2). Chapter 10.5.15 provides the PSA summary for the DAS.

- Another consideration is deterministic-based. The DAS provides the Class 2 backup for Category A functions required in the mitigation of frequent faults with an initiating event frequency >10-3/yr.

The DAS design is intentionally simple to enhance its reliability. It uses a fault tolerant approach and provides a means for periodic surveillance testing and revealing internal system faults as described in the DAS BSC (Reference 19.29).

The DAS provides, among other things, a diverse means (from the PMS) to achieve the following safety functions:

- Automatic reactor trip
- Automatic turbine trip
- Automatic passive residual heat removal (PRHR) heat exchanger actuation
- Automatic core makeup tank (CMT) actuation and reactor coolant pump trip
- Automatic passive containment cooling system (PCS) actuation
- Automatic containment isolation
- Manual actuations (see Table 19-2)

The DAS operates with different sensors, logic, and electronic hardware from those used by the PMS. It also provides diverse display of its monitored process variables.

19.3.2.3 Plant Control System

The PLS is an Ovation® based distributed control system (described in Reference 19.30) that provides automatic regulation of reactor and other key system parameters to support normal power operations of the plant. The PLS acts to maximise margins according to plant safety limits and to maximise the plant transient performance. The PLS also provides the capability for manual control of plant systems and equipment. Redundant control logic is used in some applications to increase single failure tolerance.

The function of the AP1000 reactor control systems is to establish and maintain the plant operating conditions within prescribed limits while providing control and coordination of the plant in all operating modes. The control systems improve plant safety by minimising the number of situations for which some protective response is initiated and relieves the operator from routine tasks.

The PLS controls components in the plant that are operated from the MCR or RSR. The system integrates the automatic and manual control of the reactor, reactor coolant, and various reactor support processes for required normal and abnormal conditions.

The PLS contains C&I equipment to change reactor power, control reactor coolant system temperature, control nuclear power distribution, control pressuriser pressure and level, control steam generator level (including feedwater flow control), control turbine bypass steam dump, and perform other plant functions associated with power generation.

19.3.2.4 Data Display and Processing System

The DDS (as the PLS) is a distributed Ovation® based system that provides the plant monitoring and control interfaces for the general system and a subset of the SIS, and provides general indication of certain parameters used by the SIS (described in Reference 19.31). The DDS interfacing includes processing, display, trending, and archival of data from the plant. The DDS consists of the plant C&I network, operator and engineer workstations, data link and application servers, process historian, system support workstations and servers, and the communication network gateway.

The DDS interfaces with the OCS to provide the human-system interface for the MCR operators and engineers and includes the alarm presentation system (APS) for indication of pre-set plant parameters that are exceeded. The DDS allows the operators to access all plant procedures via the computerised procedures system (CPS).

The DDS includes the data processing functions such as the nuclear application programmes that perform calculations to monitor AP1000 plant parameters and processes. The DDS logs and archives plant data through the process historian, and provides data links to external plant systems and gateways to interface with the PMS. The DDS also provides system security, system and database maintenance, and system time management functions for the plant C&I systems and the external communications gateway to the site local area network (LAN).

19.3.2.5 Special Monitoring System

The SMS comprises the DMIMS-DX and the RCPVM system.

The SMS provides detection of the presence of metallic debris in the reactor coolant system (RCS) when the debris impacts against the internal parts of the RCS. The DMIMS-DX is composed of digital circuit boards, controls, indicators, power supplies, and remotely located sensors and related signal-processing devices. A minimum of two sensors are located at each natural collection region, connected to separate instrumentation channels, to maintain the impact monitoring function if a sensor fails in service.

The RCPVM system is a continuous monitoring system that provides outputs for diagnostic tools and information to assist in the evaluation of the performance of the reactor coolant pumps (RCPs).

19.3.2.6 In-Core Instrumentation System

The primary function of the IIS is to provide a 3-D flux map of the reactor core. This map is used to calibrate PMS ex-core neutron detectors and to optimise core performance system adjustments using calculations from the best-estimate analysis core optimisation (BEACON™) application. A secondary function of the IIS is to provide the PMS with the thermocouple signals necessary for the post-accident inadequate core cooling monitor. The IIS assemblies house both fixed in-core flux detectors and core-exit thermocouples.

19.3.2.7 Radiation Monitoring System

The RMS provides early indication of a system or equipment malfunction that could result in an excessive radiation dose to plant personnel or lead to plant damage. Radiation monitoring data, including alarm status, are provided to the AP1000 plant operators via the PLS (and in the case of Class 1 monitors, to the PMS).

19.3.2.8 Fuel Handling and Storage

C&I systems are integral to the fuel handling and storage systems. They encompass the handling systems for moving fuel to and from the reactor and the fuel pond. Fuel Handling and Storage is further described in Chapter 17.

The fuel handling system is equipped with machines that are provided with control systems that perform such functions as interlock control, load-weighing functions and control, and boundary zone checking.

19.3.2.9 C&I Network

The plant C&I network is the Ovation® real-time redundant Class 3 network used to interconnect the C&I systems. The network distributes the plant data that is collected by other systems and is the primary communication network for the entire plant. The plant C&I network provides two-way communication between the distributed controllers, and supports both periodic and aperiodic data transfers of general non-safety (GNS) signals and data. The plant real-time data network also provides secure, unidirectional data transfer from the plant real-time network to the plant communication / business network.

19.3.3 Engineering Principles

The purpose of this subsection is to introduce the engineering principles applied in the design of the C&I architecture and its systems (PLS, PMS, DAS, OCS and DDS). The principles explained and the claims made are further detailed and substantiated in the following BSC documents:

- Reference 19.30 - Westinghouse Report UKP-PLS-GLR-001, Rev. 1, "United Kingdom AP1000 Plant Control System (PLS) Basis of Safety Case,"
- Reference 19.28 - Westinghouse Report UKP-PMS-GLR-001, Rev. 2, "United Kingdom AP1000 Protection and Safety Monitoring System Safety Case Basis," December 2016.
- Reference 19.27 - Westinghouse Report UKP-PMS-GLR-002, Rev. 2, "United Kingdom AP1000 Component Interface Module Safety Case Basis,"
- Reference 19.29 - Westinghouse Report UKP-DAS-GLR-001, Rev. 2, "United Kingdom AP1000 Basis of Safety Case for the Diverse Actuation System,"
- Reference 19.31- Westinghouse Report UKP-DDS-GLR-001, Rev. 1, "United Kingdom AP1000 Data Display and Processing System (DDS) Basis of Safety Case,"

These BSC documents are not further referenced in the text below, only additional relevant document are explicitly referenced.

19.3.3.1 Architecture Compliance with Defense in Depth Requirements

19.3.3.1.1 Functions Allocated to Levels of Defense in Depth and Specific Systems

To achieve the required plant safety levels in accordance with international consensus the C&I supports five independent levels of DiD. The DiD concept and approach describe below is based on the ONR/IAEA definitions and associated criteria. The levels of DiD are described below:

DiD Level 1 - The objective of Level 1 is for prevention of abnormal operation and failures by design.

Level 1 is implemented in the PLS which monitors and controls the plant and its systems in order to achieve safe and reliable operation and to maintain plant parameters within prescribed limits. The DDS and OCS provide the means for the operator to monitor plant status.

DiD Level 2 – The objective of Level 2 is for prevention and control of abnormal operation and detection of failures.

Level 2 is implemented in the PLS which is designed to maintain plant parameters under failure conditions in the plant. All of the C&I have self-diagnostics features. Any failures and abnormal plant conditions identified by these features are provided to the operator through the DDS and OCS.

DiD Level 3 – The objective of Level 3 is for control of faults within the design basis to protect against escalation to an accident.

Level 3 is implemented by the PMS and the DAS, which perform the protective functions resulting from the safety analyses, i.e. those needed to shut down the plant safely and mitigate the consequences of design basis accidents. The PMS and DAS are diverse and independent systems.

DiD Level 4 and 5 – The objective of Level 4 is for control of severe plant conditions in which the design basis may be exceeded, including protecting against further fault escalation and mitigation of the consequences of severe accidents.

The objective is Level 5 is mitigation of radiological consequences of significant releases of radioactive material.

Levels 4 and 5 are provided by the PMS, DAS, and PLS. The DDS and OCS, which provide the means for the operator to monitor plant status, alert the operator to off-normal conditions and provide means for manual control plant of equipment. It includes qualified post-accident monitoring/display of variables and manual operator intervention.

Levels of defense are shown in Figure 19-9 where the levels of DiD are mapped to the C&I architecture.

Reference 19.18, “AP1000 Instrument and Control Defense-in-Depth and Diversity Report,” demonstrates the diversity of the C&I architecture and function allocation with respect to the critical functions of:

1. Reactor Shutdown
2. RCS Inventory Control
3. Core Decay heat Removal
4. Containment Cooling
5. Containment Isolation

It should be noted that the DiD concept and approach described in Reference 19.18 is based on US definition and associated criteria.

19.3.3.1.2 Independence between Levels of DiD

Interference between the systems that make up the levels of DiD is prevented by various means such as physical separation, electrical isolation, functional independence, hardware diversity and independence of communication (data transfer).

The PMS (an Advent® PLC based system) is a standalone system, that is electrically, physically and functionally separated from the other systems in the C&I architecture.

Where there are interfaces to other systems the independence of the PMS from the other systems is assured by the following means (see Reference 19.3):

1. Hardwired output signals to the PLS are provided through qualified isolation devices.

2. Information put out to the DDS is provided through unidirectional isolated datalinks.

3. Non-safety manual control of components is electrically isolated through qualified isolation devices and priority logic in CIM provides functional isolation.

The DAS (a hardwired Westinghouse 7300 hardware system) is a standalone system (like the PMS), that is electrically, physically, and functionally separated from the other C&I systems (see subsection 19.4.2.2.6 - Independence).

1. The DAS does not share any of the sensors, operational platforms, or wiring with the PMS or PLS.

2. The DAS has its own independent wiring system from the sensor to the platform (Processor Cabinets PC1 and PC2) and to the actuated field equipment (Squib Valve Controller Cabinet).

3. The DAS includes a dedicated DAS control panel, with indicators and controls, in the MCR, independent from other systems. It also includes a dedicated remote DAS control panel, with indicators and controls, in the DAS cabinets located in the auxiliary building.

The PLS (an Ovation® distributed control platform) has no interfaces to the DAS and is therefore independent from the DAS. The PLS receives hardwired sensor data from the PMS trough qualified isolation devices to control plant variables. Signal selector algorithms in the PLS ensure that faults in the PMS sensors channel cannot cause the PLS control function to fail.

The PLS relies on the DDS (which is part of the Ovation® platform) for communication, however, critical automatic control functions are designed and implemented to be independent of Plant I&C Network signals. Loss of communications on the network shall not cause these critical control functions to malfunction or upset the plant state.

19.3.3.1.3 Supporting Systems Requirements

Chapter 18 of the PCSR (Electrical Power Systems) defines how electrical power is supplied to C&I systems and how the system supports the reliable operation of C&I under normal and accident conditions such as a loss of off-site power. It also defines the power supply conditions that need to be considered for the design of the power supplies to the C&I systems.

The Class 1 C&I is supplied from the Class 1 DC and Uninterruptible Power Supply (IDS) that supplies the Class 1 alternating current (AC) and direct current (DC) loads. This system is normally supplied from the main AC power system, but in case a loss of all on and off-site AC power, the batteries will supply the power to the required Class 1 loads for up to 72 hours.

The Class 2 C&I is supplied from the Class 2 battery backed electrical supply system (EDS). This system is normally supplied from the main AC power system, but in case of a loss of AC power, the batteries are sized to supply the power for up to 2 hours.

The cable and raceway systems requirements such as separation and segregation are also defined in PCSR Chapter 18.

19.3.3.2 Safety Classification

19.3.3.2.1 Categorisation of Functions

Categorisation of functions is used to identify the safety significance of a C&I function. This in turn helps to define the class of the C&I system in which the function must be implemented. Reference 19.4 provides details on the categorisation methodology applied.

C&I functions are categorised as A, B, C in accordance with Reference 19.22. The resulting categorisation can be summarised as follows:

Category A

A Category A safety function is a principal means of maintaining nuclear safety. Category A safety functions are those utilised to achieve and maintain a non-hazardous, stable state within 72 hours of the initiating event. Failure to maintain a Category A safety function has the potential to result in significant core damage and radiation exposure.

Category B

A Category B safety function is a significant contributor to nuclear safety. Category B safety functions are utilized to; 1) to maintain the non-hazardous stable-state after 72 hours following an accident, 2) prevent radiological exposures to onsite personnel and the offsite population from exceeding the design basis limits, or 3) mitigate beyond design basis accidents. Failure to maintain the Category B safety function may reduce safety margins significantly; with radiation exposure less than Category A limits, but greater than normal operating limits.

Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis are Category A. Failure of this could function could lead directly to the actuation or operation of a Category A safety function.

Category C

Category C safety functions are those safety functions that may make a contribution to nuclear safety, but are not categorised as Category A or Category B. Since the removal of nuclear heat during normal operation prevents reactor trips and the actuation of Category A and Category B functions, these normally operating duty systems are recognised as being important to safety.

19.3.3.2.2 Classification of Structures, Systems and Components

Classification of SSCs is used to identify those SSCs that play an important part in ensuring nuclear safety. This in turn helps to define the quality requirements placed on those SSCs during design and manufacture, and through life. In particular, the safety class of a given SSC can be used to determine which codes, standards, and seismic design considerations are appropriate to the design and manufacture of that SSC. Reference 19.4 provides the details on the classification methodology applied.

In summary the classes of C&I systems are as follows:

Class 1 Systems, Structures, and Components

Class 1 SSCs provide the principal means of fulfilling a Category A safety function.

These SSCs are standby or normally operating SSCs required to protect against, or mitigate the consequences of, DBAs (consistent with the DBA analysis). These SSCs provide the principal means for the protection of the health and safety of the public and workforce, and are selected using deterministic methods. The reliability of these features is confirmed using a probabilistic sensitivity analysis.

Class 2 Systems, Structures, and Components

Class 2 SSCs are a principal means of fulfilling a Category B safety function, or are a significant contributor to fulfilling a Category A safety function.

A significant contributor is defined as an SSC that provides a supplementary capability for those SSCs used in the principal response to DBAs. Class 2 SSCs are identified using the AP1000 plant reliability evaluations described in Section 5.9.

Class 3 Systems, Structures, and Components

Class 3 SSCs are all other SSCs that are not Class 1 or Class 2 that provide contributions to maintaining nuclear safety and include SSCs identified to support the operation of Class 1 and Class 2 SSCs.

General Non-Safety Systems, Structures, and Components

SSCs classified as GNS are those SSCs that do not contribute to maintaining nuclear safety as determined by the safety case.

19.3.3.2.3 Protection and Safety Monitoring System Classification

The PMS provides Category A reactor trip and engineered safety functions under differing circumstances or at different stages of a DBA and is therefore a Class 1 system.

The Class 1 SSCs actuated by the PMS include:

- Reactor Trip Breakers
- PRHR heat exchanger air operated valves
- CMT air operated valves
- Automatic depressurisation system (ADS) 1-3 motorised valves
- ADS4 squib valves

- In-containment refuelling water storage tank (IRWST) injection squib valves
- IRWST recirculation squib valves
- PCS air operated and motor operated valves
- Main Steam Isolation Valves
- Main Feed Isolation Valves
- Steam generator (SG) power-operated relief valves
- Class 1 isolation valves providing the Category A containment safety function
- Class 1 control room habitability system

The CIM is the interface between PMS and the SSCs actuated by PMS. CIM therefore has the same safety claims as PMS and is consequently designated as Class 1 on this basis.

19.3.3.2.4 Diverse Actuation System Classification

The DAS is designed as a backup to the PMS in its provision and actuation of reactor trip signals that provide the Category A criticality control safety function, and in its provision and actuation of a number of Class 1 SSCs that provide the Category A residual heat removal safety function under differing circumstances or at different stages of a DBA. On this basis, the DAS is designated as a Class 2 system.

19.3.3.2.5 Plant Control System Classification

The PLS is mainly used for normal operational control of the plant. However, there are a number of safety claims on it where it actuates SSCs which are diverse or DiD means of providing the Category A residual heat removal safety function, including:

- Startup feedwater system
- Normal residual heat removal system
- Component cooling water system
- Service water system
- Spent fuel pool cooling system

PLS also actuates Class 2 SSCs, which are diverse or DiD means of providing the Category A criticality control safety function. On the basis of these functions, the relevant parts of PLS are designated as Class 2.

19.3.3.2.6 Data Display and Processing System Classification

The DDS is a Class 3 system. The safety significant data display and processing functions are included in the PMS or DAS, as appropriate.

19.3.3.3 Conformance to Design and Manufacturing Codes and Standards

The standards to which the C&I systems have been designed and manufactured are defined in the PCSR Chapter 5 – Engineering Principles. C&I design compliance is demonstrated to the standards described in Section 19.2.

19.3.3.4 C&I Reliability and Fault Tolerance

19.3.3.4.1 Functional Reliability

The C&I architecture and its subsystems are designed for high functional reliability to meet and exceed the C&I design basis reliability requirements stated in subsection 19.3.1.3. The

functional reliability is achieved through the application of the entirety of the engineering principles in subsection 19.3.2.9 (e.g., fault tolerance, independence of systems, redundancy, diversity, testability and maintainability, fail-safe design, selection of proven equipment and quality in manufacturing and installation. The BSC documents provide the evidence that the required reliability has been achieved for the systems.

19.3.3.4.2 Single Failure Criterion

Category A functions conform to the Single Failure criterion. A single failure in the system shall not prevent reactor trip nor shall it prevent the required ESF actuation – even with one of the redundant groups bypassed for maintenance or testing. Category A functions are implemented in PMS, and a diverse backup is provided by the DAS. Additional information on this requirement is further detailed in the description of the PMS and DAS – subsections 19.4.1 and 19.4.2.

19.3.3.4.3 Redundancy in the Architecture

The PMS (Class 1 system) is implemented in four safety divisions (A through D). Redundancy and independence is also designed into the system, so that no single failure or removal from service of any component or channel result in the loss of the protection function. Redundancy is provided in the non-Class 1 system such that a single failure will not cause a forced outage.

The DAS (Class 2 system) is implemented in one-out-of-two taken twice or two-out-of-three logic.

The PLS controllers are redundant. One PLS controller operates as primary and the redundant partner operates as backup. Each PLS controller in a redundant controller pair has two connections to the plant C&I network.

The DDS network is dual redundant. Equipment that is used to implement the redundant network is powered from redundant, uninterruptible power sources so that a loss of one power source will not result in the loss of both networks.

Redundancy is maintained in the power sources that feed each set of PLS controllers. Chapter 18.2.1 discusses the means through which redundancy is achieved for electrical equipment.

19.3.3.4.4 Independence

The PMS is independent from the other C&I systems as described in subsection 0.

The PMS conforms to the requirements for channel independence of IEEE 603 (Reference19.7). A discussion of the channel independence is presented in Reference19.9. The signals to initiate a division of the PMS are electrically isolated from the signals to initiate the redundant divisions. Divisions of the PMS are electrically independent and redundant, as are the power supplies for the divisions up to and including the final actuated equipment.

The four PMS divisions exchange partial trip signals for the purpose of voting. To avoid a single component failure or spurious signal causing an inadvertent plant trip while a channel is in test or maintenance, the protection and safety monitoring system uses the bypass logic discussed in Sections 3.4 and 6.1 of the PMS BSC (Reference 19.28).

The PLS is independent from the other C&I systems as described in subsection 19.4.3.2.

The PLS controls the plant from the same measurements which are used by the PMS. This permits the control system to function in a manner which maintains margin between operating conditions and safety limits, and reduces the likelihood of spurious trips.

Compliance to the requirements of IEEE 603 (Reference 19.7) is assured by the provision of isolation devices to guard the protection system against possible electrical faults in the control system.

Functional independence of control and protection is obtained by signal selector algorithms. The purpose of the signal selector algorithm is to prevent a failed signal, caused by the failure of a protection channel, from initiating a control action that could lead to a plant condition requiring that protective action. The signal selector function provides this capability by comparing the redundant signals and automatically eliminating an aberrant signal from use in the control system. This capability exists for bypassed sensors or for sensors whose signals have diverged from the expected error tolerance.

The DAS is independent from the other C&I systems as described in subsection 19.4.2.2.

19.3.3.4.5 Physical Separation

Physical separation and segregation relate to the location of equipment, cable routing, and other factors to limit CCFs of independent circuits and functions. This includes failures from external causes and mutual physical effects between the circuits and functions. The high-level architecture supports the decomposition of the overall functionality into physically separate pieces while allowing the controlled flow of information across the boundaries.

The four PMS divisions are located in four separate rooms, cabling, sensors and actuated devices are physically separated. Separation and segregation for the PMS is discussed in subsection 19.4.1.2.

The DAS is located in a separate area from the PMS as described subsection 19.4.2.2.

Separation and segregation requirements for the PLS is discussed in subsection 19.4.3.2.

19.3.3.4.6 Electrical Isolation

Electrical signal isolation between systems is provided by fibre optic communications and qualified isolation devices. These prevent credible faults (such as open circuits, short circuits, or applied credible voltages) in one circuit from propagating to another circuit.

Electrical isolation of the power supplies is ensured by the use of separate power supplies for separate systems and redundant divisions in the systems

19.3.3.4.7 Functional Independence

The C&I system architecture emphasises functional divisions, rather than divisions based on physical systems or plant layout. Functional divisions in this case refer to major C&I functions such as plant control and protection. Data-gathering hardware and software for digital and analogue input signals ensure that the signal provided meets the requirements for all the assigned uses of that signal.

Signal selector algorithms provide the plant control system with the ability to obtain inputs

from the protection and safety monitoring system. The signal selector algorithms select those protection system signals that represent the actual status of the plant and reject erroneous signals. Therefore, the control system does not cause an unsafe control action to occur even if one of four redundant protection channels is degraded by random failure simultaneous with another of the four channels bypassed for test or maintenance.

Each signal selector algorithm receives data from each of the redundant divisions of the protection and safety monitoring system. The data is received from each division through an isolation device.

The signal selector algorithms provide validated process values to the plant control system. They also provide the validation status, the average of the valid process values, the number of valid process values, an alarm (if one process value has been rejected), and another alarm (if two process values have been rejected).

For the logic values received from the protection and safety monitoring system, such as permissives, two-out-of-four voting is used to provide a valid logic value to the plant control system.

19.3.3.4.8 Diversity – Defense against Common Cause Failures

As demonstrated in Reference 19.32 and Reference 19.55, the DAS is diverse from the PMS and the PLS/DDS. The DAS is based on the Westinghouse 7300 series (analogue) platform, the PMS is based upon the Westinghouse Common Q™ (digital) platform, and the PLS/DDS is based on the Emmerson Ovation™ (digital) platform. These platforms are diverse with respect to:

- Development Processes
- Tools Used
- Development Teams
- Technology
- Hardware Modules
- Components

Diversity analysis of the PLS/DDS and DAS is described in Reference 19.55. Diversity analysis of the PMS and DAS is described in Reference 19.32. Note that the PLS/PMS Diversity Analysis will be developed after GDA as identified in the safety plan for the IEC 61513 compliance document for this chapter (Reference 19.59) and the PMS and PLS BSC (References 19.28 and 19.30 respectively. Diversity for the PMS, DAS and PLS is also discussed in subsections 19.4.1.2.4, 19.4.2.2.5, and 19.4.4.2 .

19.3.3.4.9 Failure Modes

Various features in the C&I design assure a preferred state is obtained in case of equipment (hardware and software) faults and failures. Those features and the definition of the desired safe state may vary from system to system and are described in detail in the BSCs for the systems. The following high level strategies are generally applied (the implementation details vary from system to system):

- Continuous verification of output wiring to actuated devices.
- Definition of preferred failure modes by the system designer in design

documentation.

- Dynamic operation of the systems ensures that hard failures (static failures) are detectable by interfacing systems such that these can take on an appropriate state upon the detection of failure.
- Continuous diagnostics are implemented to reveal faults such that appropriate automatic and manual actions can be taken to prevent a failure of the systems and undertake timely maintenance operations.
- Internal redundancy and comparison between redundant systems parts assures faults are revealed and prevents single faults from leading to a failure of the system.
- Comparison of redundant sensor values.

The fail-safe design for the PMS is justified in subsection 19.4.1.2 of this Chapter and subsection 6.1.9.3 of the PMS BSC (Reference 19.28).

19.3.3.4.10 Environmental Qualification

A qualification program for items important to safety is implemented to verify that items important to safety are capable of performing their intended functions when necessary, and in the prevailing environmental conditions, throughout their design life. The program demonstrates the continued functionality of the systems for design basis events such as earthquake, environmental and electromagnetic compatibility (EMC) events, as required by the system function and classification.

The C&I platforms have undergone generic qualifications programs, but the AP1000 has unique requirements for equipment qualification as described in Section 5.8 of the PCSR. In that section of the PCSR, the standards to be met for equipment qualification are stated. The AP1000 Equipment Qualification Methodology Document (Reference 19.8) describes the implementation of the Equipment Qualification (EQ) program in compliance to the PCSR.

The EQ methodology is based on IEEE standards. The following references demonstrate the equivalence of these IEEE standards to the IEC standards:

- EQ-EV-283, “Electromagnetic Compatibility Standards Evaluation,” Reference 19.33
- EQ-EV-284, “Comparison of IEC Standard 60780-1998 to IEEE Standard 323-1974,” Reference 19.51
- EQ-EV-285, “Comparison of IEC Standard 60980-1989 to IEEE Standard 344-1987,” Reference 19.52

19.3.3.5 C&I Testing and Maintenance

19.3.3.5.1 Defense against Unauthorized Access

Unauthorised access to, or interference with, items important to safety, including computer hardware and software, will be prevented through multiple means as defined in Reference19.3 for the PMS and the BSC for individual systems and the security plans (yet to be produced). Examples of those measures are:

- Procedural control to means of access during installation, commissioning and operation.

- Locked cabinets and key-lock switches to prevent access to maintenance functions.
- Password controlled access to functions.
- Absence of data connections to external systems.
- Cyber security measures as defined in the security plan.

19.3.3.5.2 C&I Testing During Operation

In order to meet the reliability goals and the design standards, the PMS and the DAS are equipped to perform testing and calibration where possible with the plant at power. The frequency/periodicity of these tests vary depending on the reliability goals for the systems. Current typical intervals are defined in the surveillance requirements of the technical specifications.

Periodic surveillance of the PMS through the application of overlapping tests provides an independent means to test system operation (function and response time) and ensure calibration of analogue circuitry is maintained. The testing features of the PMS are discussed in Reference 19.3.

Testing from the sensor inputs of the PMS through to the actuated equipment is accomplished through a series of overlapping sequential tests. The majority of the tests are capable of being performed with the plant at full power. Sensors are generally not accessible, these are calibrated during plant outage. Where testing final equipment at power would upset plant operation or damage equipment, provisions are made to test the equipment at reduced power or when the reactor is shut down. PMS testing is further discussed in subsection 19.4.1.2.

The DAS is provided with the capability for channel calibration and testing while the plant is operating. To prevent inadvertent DAS actuations during online calibration, testing. or maintenance, the normal actuation function is bypassed. DAS testing is performed on a periodic basis, and is further discussed in subsection 19.4.2.2.7.

Testing of the PLS is supported by the inclusion of modular design and built-in diagnostics that assist personnel in routine testing and maintenance, fault finding, and component replacement. Testing for the PLS is covered in subsection 19.4.3.2.

19.3.3.5.3 C&I Maintenance During Operation

Faults in the PMS can be diagnosed and repaired with the plant at power. The redundancy of the PMS combined with the bypass feature for test and maintenance allows for the removal of operation of a redundant protection set (or parts thereof) for repair whilst the minimum required redundancy is maintained. See Reference 19.3 and PCSR subsection 19.4.1.2 for a description of the test and maintenance features of the PMS.

During testing or maintenance, functions are provided to bypass a protection set or individual channel. The coincidence logic is automatically adjusted and the remaining redundant protection sets or channels continue to meet the single failure criterion. The two-out-of- four logic is automatically reinstated when the bypass is removed

The PMS Maintenance and Test Panel provides the means for modifying those setpoints that need to be adjusted during plant operation. Access to this feature is under administrative and

key-lock control.

Test features are provided in the DAS that allow a channel to be bypassed for test or maintenance.

The redundancy built into the PLS supports the maintenance of the system with the plant at power. System status displays aid in fault finding. Redundant controllers can be powered down for repair while the backup controller maintains the functionality of the unit. Input/output (I/O) modules can be replaced while the cabinet is powered and remains operational.

The redundancy in the DDS allows for the repair of the data network in a transparent way without affecting the DDS communication. The redundancy of the OCS workstations allows for taking a workstation out of service without impacting the tasks of the operator.

19.3.4 Overall Planning

19.3.4.1 Management of Safety

Chapter 7 of the PCSR describes the management arrangements associated with the achievement of nuclear safety throughout the design life cycle of the plant considering the design, change control, construction, commissioning, maintenance, ageing, and degradation and decommissioning.

Currently, Westinghouse as the Design Authority for the AP1000 C&I, has an established management system for ensuring that all safety requirements for the design of the C&I are considered and implemented in all phases of the C&I life cycle. The Westinghouse global management system (WGMS) is described in Chapter 3.

At a suitable point, this role is anticipated as being transferred to the licensee, and Westinghouse is anticipated as becoming the responsible designer of the C&I (as described in Chapter 3). Westinghouse will provide support to the licensee until agreed otherwise, and formal procedures are anticipated to be established between Westinghouse and the licensee to define the responsibilities throughout the development of the AP1000 C&I design, procurement, construction, installation, and commissioning phases.

The quality and safety of the C&I is dependent on the abilities and attitudes of the individuals who design, construct, commission, operate, examine, maintain, inspect, test, and modify the equipment. Management is responsible for determining and assuring personnel attains the necessary competencies in terms of skills, education, and experience requirements for the activities affecting quality as directed by the WGMS procedures (as defined in the Chapter 3).

19.3.4.2 Life Cycle Process

The C&I systems are implemented using structured and planned life cycle processes. The integrated C&I design process is described in Reference 19.56. Sections 1, 2, and 3 of Reference 19.56 provide the requirements for the systematic process to be followed for a C&I design, including the following:

- Definition of the phases of the design
- Process for collection and definition of requirements for each design phase

- Development and documentation of requirements for subsequent phases of the design process
- Requirements for configuration management
- Verification and validation of the requirements between the design phases

Section 4 of the PMS BSC (Reference 19.28) provides the requirements and guidance for the system-level requirements engineering phase and the development of a System Requirements Specification (Reference 19.21). The AP1000 requirements documents whether at the overall C&I level or at the subsystem level (e.g., PMS) include both functional and non-functional requirements.

Section 5 of Reference 19.56 provides requirements for the system design process. This process provides the requirements and guidance for the overall C&I system design process, including the development of an C&I SyDS and the allocation of requirements to subsystems. The I&C SyDS (Reference 19.13) is one of the results of this phase of the process.

The processes applied are compatible with the safety classification of the systems and compatible with the relevant IEC standards (IEC 61513 (Reference 19.16), IEC 62138 (Reference 19.25) and IEC 60987 (Reference 19.23).

19.3.4.3 C&I Validation/Testing

C&I is exhaustively validated/tested during manufacturing, installation and plant start-up in accordance with the strategy defined in the I&C test strategy (Reference 19.63). A "bottom-up" approach is applied to the testing, such that test are performed at increasing levels of complexity and integration.

During design and manufacturing, test activities are performed on the parts, components, assemblies, and subsystems that make up the subsystems that comprise the integrated plant C&I system. These activities are associated with the subsystem design organisations or their independent verification and validation organizations when required by regulation. The activities typically include a combination of one-time design tests and recurring manufacturing tests. For SIS, the activities include any required commercial dedication activities.

The scope of these activities includes all functions of the entire subsystem inclusive of all interfaces, both internal and external, and all manufacturing and design requirements (including performance and capacity requirements).

The next level of activities focuses on the interfaces that interconnect the individual subsystems that comprise the integrated C&I system. It validates the interfaces between subsystems from a connectivity or functionality point of view, where testing at earlier levels is not sufficient to provide adequate coverage of the interface.

19.3.4.4 C&I Commissioning - Validation/Testing

C&I testing on site after installation is coordinated with the plant test and commissioning activities described in PCSR Chapter 7. After installation of the equipment validation and testing focuses on cabinet installation verification and initial energisation. Inspection and testing is performed to verify absence of shipping/installation damage, correct equipment and cable and power supply installation. Basic functionality is confirmed for controllers, modules, and workstations after the equipment is powered. Software is anticipated as also being loaded (if needed) during this phase of testing.

Along with construction progress testing focuses on C&I system interface testing as the C&I equipment is installed and progressively interfaced to other C&I equipment as well as field equipment associated with plant systems. The testing then progresses to include component and system-level testing of mechanical and electrical systems utilizing the C&I system for controls and indications.

19.3.4.5 C&I Overall Integrated Commissioning - Validation/Testing

Once plant systems can be put to work testing focuses on preoperational testing of all the plant systems and the emphasis is on integrated system testing with process systems using the C&I systems as a resource. This level of testing is performed prior to initial fuel loading to demonstrate the capability of plant systems to meet performance requirements.

The tests demonstrate that equipment and systems perform in accordance with design criteria so that initial fuel loading, initial criticality, and subsequent power operation can be safely undertaken.

The general objectives of the preoperational test program are the following:

- Demonstrate that C&I systems, including alarms and indications, meet appropriate criteria based on the design;
- Provide documentation of the performance and condition of equipment and systems;
- Provide baseline test and operating data on equipment and systems for future use and reference;
- Operate equipment for a sufficient period to demonstrate performance;
- Demonstrate that C&I and plant systems operate on an integrated basis.

Plant operating, emergency, and surveillance procedures are incorporated into the initial test program procedures. The capability of the C&I to support the procedures is verified through use, to the extent practicable, during the preoperational test program and revised if necessary, prior to fuel loading.

Start-up Testing continues to validate the C&I systems properly perform during integrated plant testing. Final tuning and adjustments of controls are performed based on real-time plant responses to transients. This testing phase will begin during initial fuel load and will not complete until the end of the 100% power accession plateau.

Start-up tests begin with the initial fuel loading and are performed to demonstrate the capability of individual systems, as well as the integrated plant, to meet performance requirements. Start-up test verify that the operating characteristics of the reactor core and associated control and protection equipment are consistent with design requirements and accident analysis assumptions.

These tests facilitate gathering of the required data to calibrate equipment used to control and protect the plant and to verify that the plant is operating within the limits imposed by the Technical Specifications.

19.3.5 Overall Operation

19.3.5.1 Provision of Control Locations

A MCR is provided from which the plant can be safely operated in all operational states, either automatically or manually, and from which measures can be taken to maintain the plant in a safe state or to bring it back into a safe state after anticipated operational occurrences and accident conditions. The MCR is further described in the PCSR Chapter 13.

Instrumentation and control equipment is provided at an alternate location - the Remote Shutdown Room (RSR). This room is so equipped to enable the reactor to be be placed and maintained in a shutdown state, to allow residual heat to be removed, and to allow essential plant variables to be monitored if there is a loss of ability to perform these essential safety functions in the main control room.

The RSR will provide a Safety Panel with Class 1 displays complete with accompanying PMS soft blocks/resets. Class 1 System Level dedicated controls will also be provided that will be hardwired to the PMS cabinets. The RSR is further described in PCSR Chapter 13 (Human Factors).

A SAP compliance document (Reference 19.50) has been produced which provide the claims, arguments, and evidence to demonstrate that the UK AP1000 RSR provides adequately classified displays and controls to comply with the applicable SAPs selected from "Safety Assessment Principles for Nuclear Facilities" (Reference 19. 2). An ALARP document (Reference 19.53) has also been produced which provides the claims, arguments, and evidence to demonstrate that the UK AP1000 RSR design, including Class 1 displays and controls satisfies ALARP principles. Reference 19.53 also documents the optioneering exercised to determine the ALARP design for the UK AP1000.

19.3.5.2 Human-System Interface Design

Chapter 13 (Human Factors) describes the application of human factors engineering in the plant and provides requirements for the application of human factors engineering in the C&I design – particularly in the human-system interface.

19.3.5.3 Operational Limits and Limiting Conditions for Safe Operation

A set of operating rules (operational limits and conditions) for safe operation of the plant is established and applied to the operation of the C&I systems through the application of the surveillance requirements, adherence to the limits for operability, response time and accuracy, and application of the action requirements in the plant Technical Specifications. The development of these operating rules is described in Chapter 5 and Reference 19.58.

Trip setpoints in the C&I will be selected to provide sufficient allowance between the trip setpoint and the analytical limit to account for uncertainties. The safety analysis establishes the analytical limit based on the parameter that is measured and the required time response for the protective action. After the detailed design is completed, the uncertainty in each channel is evaluated based on operating experience, equipment qualification, design specifications, engineering analysis, laboratory tests, and engineering drawings. This evaluation will include process and measurement uncertainties. The results of the evaluation will be used to select the trip setpoint so that the analytical limit will not be exceeded under all conditions.

19.4 Control and Instrumentation System Descriptions

This section provides description of the major C&I systems.

19.4.1 Protection and Safety Monitoring System

19.4.1.1 Protection and Safety Monitoring System Definition

The PMS is a Class 1 PLC based system that operates on an Advant® AC160 controller. The Advant AC160-based protection system is a digital-process protection system designed for use within both pressurised water reactors and boiling water reactors. It was originally developed as a commercial system and has since gone through a qualification regime to achieve Class 1 status as a dedicated nuclear power plant protection system in accordance with European codes and standards.

19.4.1.2 Protection and Safety Monitoring System Design Basis

A basis of safety case for the PMS containing arguments and detailed evidence in support of how the safety principles and standards in relation to the design of the PMS have been met has been produced. See Reference 19.28 "United Kingdom AP1000 Protection and Safety Monitoring System Safety Case Basis."

A detailed description of the design process for the PMS is described in subsection 6.1.5.2 of Reference 19.28.

As a Class 1 system, the PMS plays a principal role in achieving or maintaining a safe state in the reactor and prevents a DBA from leading to unacceptable consequences. The function of the PMS is essential at the beginning of the transient when no alternative actions can be taken, even if unforeseen faults are detected.

The following factors are considered in this design approach section to provide evidence of the design philosophy:

- Separation/segregation
- Manual actuation
- Power
- Diversity
- Redundancy
- Software
- Common Cause Failure Independence
- Independence
- Fail-safe
- Testing
- Operator interfaces
- Safety display functions
- Spurious Actuation

19.4.1.2.1 Separation and Segregation

The PMS provides four divisions of equipment that are in different locations of the plant, which meets the requirement for divisions of equipment to be in areas separated from each other and from other areas in the plant by fire barriers with a minimum 3-hour fire-resistance rating. The cabling is segregated in accordance with Reference 19.7.

Isolation devices are used to maintain independence where redundant equipment is required to communicate with other systems. For example, electrical separation of the IDS and the EDS is maintained through the use of isolation devices in the interconnections between the PMS and the DDS.

There is a gateway in each of the PMS divisions that connects the Class 1 system maintenance and test panel (MTP) to the Class 2 and Class 3 systems, and the flow of information between the two gateway subsystems is strictly from the Class 1 subsystem to the lower class subsystem (i.e., it is unidirectional, and therefore prevents the lower class system from adversely affecting the system).

19.4.1.2.2 Manual Actuations

The PMS allows the "permit manual trip or bypass" function of each individual automatic reactor trip function and permits manual actuation or bypass of each individual automatic ESF actuation function.

The PMS manual trip facility is wired directly to the reactor trip circuit breakers (RTCBs). Therefore, a failure of the automatic system cannot prevent a manual tripping of the reactor (Reference 19.3, Figure 2.2).

The manual reactor trip consists of two controls in the MCR, either of which trip all eight of the RTCBs. There are no interlocks or bypasses associated with the manual trip function.

19.4.1.2.3 Power

The power supply for the PMS is the IDS. The power in a division is converted from IDS power to DC power for the PMS cabinet equipment using power supplies (see subsection 3.4.2.1.4 of Reference 19.28).

The IDS provides power for the Class 1 equipment required for plant instrumentation, control, monitoring, and other vital functions. In addition, the IDS provides power for the emergency lighting in the MCR and at the remote shutdown workstation.

The IDS can provide power for the safe shutdown of the plant for 72 hours without the support of battery chargers during a loss of all AC power sources coincident with a DBA. The system is designed so that no single failure will result in a condition that prevents the safe shutdown of the plant.

The IDS is further described in Chapter 18.

19.4.1.2.4 Diversity

The PMS also provides automatic and manual actuation of ESFs in response to DBAs, particularly those ascribed to CCF.

DiD is provided by the ESFs and the DAS. These systems utilise diverse hardware functions. System diversity is substantiated in Reference 19.18 and provides supporting evidence.

As part of the overall C&I systems, the PMS has been included in Reference 19.18. In addition to this report, Westinghouse has produced a specific diversity analysis between the DAS and PMS for the UK AP1000 C&I that addresses requirements from additional standards including IEC-62340 (see Reference 19.32).

Diversity is addressed by the provision of the DAS for frequent faults as shown in the Fault Schedule of Chapter 8. It is a completely separate system for actuation of Class 1 reactor protection systems. The employment of a completely separate system for reactor protection has been implemented to address the issue of DiD. The DAS is addressed in detail in subsection 19.4.2.

19.4.1.2.5 Redundancy

The PMS includes redundancy to ensure that a single failure of any component part of the system will not cause either a failure to trip or the operational failure of any ESF.

Four redundant measurements using separate sensors are made for each of the reactor trip variables. The processing of these variables is carried out by each of the PMS's four redundant sections (in an identical manner). The outputs are passed to the system logic circuitry; each of the redundant divisions sends its partial trip status to each of the other three redundant divisions over isolated data links. A reactor trip signal is generated if two or more of the redundant channels of a single variable are in the partial trip state. In respect to reactor trip functionality, the PMS employs two-out-of-four logic voting (reduced to two-out-of-three voting with one allowable bypass). This allows for a single equipment failure, or the execution of plant maintenance on a single division, while still ensuring adequate protection by the use of the remaining two-out-of-three voting logic.

Redundancy provides confidence that ESFs are actuated on demand, even when the PMS is degraded by a single sensor failure.

ESF coincidence logic functions are performed by two ESF logic processors per division for more reliable accident mitigation and protection against spurious actuation. The primary functions of the ESF logic processors are to perform the two-out-of-four vote for each ESF safety function and transmit the data to the integrated logic processors (ILP). To perform the ESF coincidence logic calculations, the ESF processors require data from the Bistable processor logic (BPL) subsystems.

The ESF logic processors perform the following functions:

- Receive bistable data supplied by the four divisions of BPL subsystems and perform two-out-of-four voting on this data.
- Implement system-level voting logic and transmit the output to the ILP processors for ESF component fan-out and actuation.
- Process manual system-level actuation commands received from the MCR or RSR.

19.4.1.2.6 Software

The PMS software will be designed, produced and installed in accordance with Reference 19.9, which specifies the process used.

The programming language C is used for the Common Q platform flat panel display system and the custom PC elements. The PMS application software for the AC160 is written in a function block (FB) oriented language. The requirements for FB-oriented software are found in the Common Q coding standard and guidelines document Reference 19.10.

The CIM does not contain software. However, software is used in its design. The development of the CIM is based on IEEE standards and US NRC Regulatory Guides. Subsection 6.1.3 of the CIM BSC Reference 19.27 describes compliance with relevant UK Safety Assessment Principles and Industry Standards.

19.4.1.2.7 Common-Cause Failure

For the PMS to be able to provide high levels of reliability, CCF needs to be minimised.

The PMS and DAS safety features are sufficiently dissimilar and separate that a CCF that fails both need not be considered, e.g., the PMS and DAS achieve reactor trip and required ESF functions by using different functions and diverse equipment.

To minimise CCF mechanisms within the PMS, for example, the following environmental effects have also been taken into consideration:

- **EMC** – Susceptibility and emissions testing of the digital equipment will be carried out to meet the prevailing legislative requirements for both conductive and radiated signals.

- **Separation and isolation requirements** – Physical separation and segregation have been used in the placement of equipment and in the routing of cables to mitigate the effects of external hazards and those effects mutually induced. Particular attention has been paid to the separation of IDS divisions, as well as supply voltage levels within groups. Different signal routing is used to ensure the application of diversity (e.g., by equipment diversity or functional diversity).

19.4.1.2.8 Independence

The PMS meets the requirements of independence in Reference 19.11.

The PMS is a Class 1 PLC-based system. The system is designed to incorporate enough redundancy to mitigate single failure trip operation. The system is divided into four redundant divisions, each housed in separate cabinets with each division in separate rooms.

To ensure that subsystem independence is not compromised, the following features are used:

- Separate DC power sources with output protection to prevent interaction between redundant BPL and local coincidence logic subsystems upon failure of a subsystem.
- Separate input or output circuitry to maintain independence at the subsystem interfaces.
- Dead man signals that force a predefined operating condition upon the cessation of a normally dynamic input parameter to improve the reliability of discrete data crossing the subsystem interface.
- Optical coupling between subsystems. Optical transmission media are employed to meet Class 1 independence requirements between safety divisions and between Class 1 and lower class equipment (Reference 19.13).

- Four separate sensors for each variable.

The PMS independence features are further described in subsection 6.9.16 of the PMS BSC (Reference 19.28).

19.4.1.2.9 Fail-safe

Extensive, detailed failure modes and effects analysis (FMEAs) have been performed on the PMS modules to determine the effectiveness of self diagnostics. In general, the results indicate that a high percentage of faults that could occur will be detected by diagnostics and cause the system to assume a default state. These results are incorporated into unavailability equations as percentages of faults that are detectable or fail-safe or both in Chapter 10 and WCAP-16438-P (Reference 19.14).

The reactor trip coincidence logic provides the logic function to combine the partial trip signals and outputs a fail-safe trip signal to the RTCBs. In the case of the PMS, this results in the release of the control rods into the reactor under gravity resulting from the loss of power to the rod drive mechanism coils. The two-out-of-four voting allows bypass of a single channel or division while still maintaining the single failure criterion. The bypassing of two or more redundant channels or divisions is not permitted.

The PMS is designed such that a loss of power to the system will result in a reactor trip.

The loss of AC power sources (low IDS battery charger input voltage) is detected and initiates ESFs. The ADS timer in the PMS actuates ADS on low battery charger input voltage after 22 hours. The PRHR heat exchanger, and supporting passive features (reactor trip, CMTs, PCS) all self-actuate on loss of all AC and DC. On an extended loss of AC power, the Class 1 systems revert to a fail-safe configuration and the failure is alarmed in the MCR.

The fail-safe design of the PMS is further described in subsection 6.1.9.3 of the PMS BSC Reference 19.28.

19.4.1.2.10 Testing

The PMS includes the features of continuous self diagnostics and on-line verification testing. The system utilises two-out-of-four voting, which allows for the bypass of a single channel or division to allow test and maintenance operations to be carried out without compromise of the safety function, as this leaves the system running in two-out-of-three logic mode. Periodic surveillance is carried out manually to verify that the system is performing its safety function.

Testing is carried out via the four independent MTP subsystems, each located within one of four divisions of the PMS (see Figure 19-3). The divisions are physically separated and electrically isolated from each other. Therefore, an MTP subsystem can only make changes to its associated division and does not require additional physical means of restricting it from accessing other divisions. (i.e., cable disconnects and key lock switches). The following description illustrates the operation of one of the four identical divisions.

The MTP provides the human interface to the system and is used for maintenance and test functions. The MTP provides the means for the technician to perform the following functions (Reference 19.3, subsection 2.2.6):

- Periodic surveillance testing to verify operability

- Corrective maintenance
- Enter and change setpoints and calibration coefficients
- Place a protection function in partial trip mode via key lock switch to prevent unintended action
- Place a protection function in bypass mode via key lock switch to prevent unintended action
- Display partial trip or actuation and bypass status for each bistable trip function in each division
- Display reactor trip status in each division
- View detailed system status and diagnostic messages
- Load software into the Advant Controller 160 processor modules, via key lock switch to prevent unintended action
- Provide interface to the real-time data network

A detailed description of the maintenance, testing, and calibration procedures for the PMS is given in Reference 19.3, Section 6.

19.4.1.2.11 Operator Interfaces

The HSI for the PMS will be situated in the MCR and the RSR and is referred to as the Safety Displays.

19.4.1.2.12 Safety Display Functions

There is one Class 1 safety display associated with each of the four independent divisions of the PMS located in the MCR. The C&I in the MCR contains separate interfaces with the PMS as shown in Figure 19-3, and provides the following functionality:

- Operator access to control the system permissives, blocks, and resets in accordance with the functional requirements documents and functional logic diagrams.
- Provides manual control of safety components with onerous consequences.
- Displays the values of system parameters.
- Provides the capability to trend system parameters that permit operators to select variables for trending and enter the required trend control parameters.
- Provides high-level status of the health of the system.
- Provides the operator with the ability to perform periodic calibration of the nuclear instrumentation system (NIS) and over temperature/ΔT calculations. The purpose of the testing and calibration is to demonstrate that the protection system is operable by verifying that the division is capable of performing its protective function.
- Provides display of QDPS variables.

19.4.1.2.13 Spurious Actuation

Spurious actuation within the PMS software has a potential CCF that could result in the simultaneous activation of the system.

Potential initiating events follow:

- Actuation of CMT isolation valves results in no significant consequence
- Actuation of PRHR isolation valves results in no significant consequence.
- Actuation of PCS isolation valves results in no significant consequence
- Spurious actuation of ADS Stages 1 through 4 resulting in an intermediate to large hot leg loss-of-coolant accident. Stage 4 spurious actuation would expose piping / supports to loads beyond their capability, which could result in degraded ADS vent capacity.
- Actuation of IRWST squib valves would expose piping / supports to loads beyond their capability, which could result in degraded ADS vent capacity.
- Actuation of recirculation squib valves resulting in potential draining of IRWST into sump

The squib valves are discussed in further detail in Chapter 17.5.

The Alternate Spurious Operation Blocker is a diverse Class 1 module physically located within each of the PMS divisions. It accepts the two CMT narrow-range upper-level measurements in that division, two battery charger low input voltage signals and a manual unblock control as inputs, and provides block signals to the outputs that control the ADS valves assigned to that division. To block ESF actuation, it interrupts the arm signal from the CIM outputs to the squib valve termination unit or the open signal to the motor-operated valves motor control centres.

The ADS blocker device provides a reliable capability independent of the PMS computers that significantly reduces the likelihood of spurious actuation while maintaining the safety function of the system. As a result, such spurious signals do not need to be analysed with respect to plant performance and radiation releases.

There is a separate basis of safety case for the PMS Spurious Actuation Blocking Device, Reference 19.49.

19.4.1.3 Protection and Safety Monitoring System Function

The PMS provides detection of system excursions beyond the normal operational limits and automatic actuation of the protective functions necessary to ensure that the plant reaches and remains in a safe shutdown state. The system is designed to incorporate sufficient redundancy to mitigate single failure trip operation. In addition, the PMS includes all the equipment necessary to monitor the plant functions during and following any design basis accident.

The main PMS system functions are:

- Acquire and analyse sensor inputs required for reactor trip and ESF actuation calculations
- Perform computation and logic operations on variables based on acquired inputs

- Perform coincidence logic voting for reactor trip
- Initiate a reactor trip to the RTCBs
- Provide ESF actuation commands to the Class 1 safety components.
- Permit manual trip or bypass of each individual automatic safety function
- Provide data to external systems
- Provide isolation for control functions requiring input from sensors, which are also required for protection functions
- Provide displays on the MCR PDSP

19.4.1.4 Protection and Safety Monitoring Safety Function

The PMS performs the Category A reactor trip functions, the Category A ESF actuation functions, the Category B QDPS functions, and Category C Sequence of Events (SOE) functions. The Category B QDPS is executed on Class 1 equipment. The Category C SOE functions are functionally and electrically isolated from the rest of the PMS. For a more detailed description of the PMS function categorisation and equipment classification, see Section 6.1 of Reference19.28.

The PMS monitors key plant parameters and automatically initiates various protective functions to prevent violation of any of the three barriers, or if violation of a barrier cannot be prevented, to maintain the integrity of the remaining barriers. The system performs its functions by actuating a variety of equipment and by monitoring the plant process using a variety of sensors and operations performing calculations, comparisons, and logic based on those sensor inputs.

The PMS generates an automatic reactor trip for the following conditions and therefore are Category A functions. All of these functions two-out-of-four coincidence functions.

1. High Source Range High Neutron Flux
2. High Intermediate Range High Neutron Flux
3. Power Range High Neutron Flux (Low Setpoint)
4. Power Range High Neutron Flux Trip (High Setpoint)
5. Power Range High Positive Flux Rate
6. Over-temperature ΔT
7. Overpower ΔT
8. Low Pressuriser Pressure
9. Low Reactor Coolant Flow
10. Reactor Coolant Pump Underspeed
11. Reactor Coolant Pump Bearing Water Temperature
12. High Pressuriser Pressure
13. High Pressuriser Water Level
14. Low Water Level in any Steam Generator
15. High Steam Generator Water Level in Any Steam Generator
16. Automatic Depressurization Systems Actuation
17. Core Makeup Tank Actuation
18. Safeguards Actuation
19. Manual Reactor Trip
20. PRHR Actuation

The PMS senses accident situations and initiates ESF functions. The occurrence of a limiting fault, such as a loss of coolant accident or a secondary system break, requires a reactor trip plus actuation of one or more of the ESF functions. This combination of events prevents or mitigates damage to the core and reactor coolant system components and provides containment integrity.

The PMS is actuated when system setpoints are reached for selected plant parameters. The selected combination of process parameter setpoint violations is indicative of primary or secondary system boundary challenges. Once the required logic combination is generated, the PMS equipment sends the signals to actuate the appropriate ESF components.

The following is a list of the ESF system-level actuations initiated by the PMS and these functions are Category A functions:

1. Safeguards Actuation
2. Containment Isolation
3. In-Containment Refueling Water Storage Tank Injection
4. Core Makeup Tank Injection
5. Automatic Depressurization System Actuation (Stages 1-4)
6. Main Feedwater Isolation
7. Reactor Coolant Pump Trip
8. Passive Residual Heat Removal Actuation
9. Turbine Trip
10. Containment Recirculation
11. Steam Line Isolation
12. Steam Generator Blowdown System Isolation
13. Passive Containment Cooling Actuation
14. Startup Feedwater Isolation
15. Boron Dilution Block
16. Chemical and Volume Control System (CVS) Isolation
17. Steam Dump Control
18. Main Control Room Isolation
19. Auxiliary Spray and Purification Line Isolation
20. Containment Air Filtration Isolation
21. Refueling Cavity Isolation
22. CVS Letdown Isolation
23. Pressuriser Heater Block
24. Steam Generator Relief Isolation
25. Normal Residual Heat Removal Containment Isolation
26. Demineralized Water Transfer and Storage System Isolation
27. Reactor Vessel Head Vent Valve Control

The PMS provides signal conditioning, communications, and display functions for post-accident monitoring. The portion of the PMS that is dedicated to providing the post-accident function is referred to as the QDPS. The QDPS calculates post-accident variables for the safety displays in the control room.

The QDPS performs the following functions:

1. Support display of key post-accident variables so that the operator can monitor the effectiveness of the following systems:

    a. RCS
    b. Containment
    c. PRHR
    d. Related systems (Steam Generator (SG), CMT, Radiation, Spent Fuel Pool)

2. Support display of Critical Safety Functions:

    a. Subcriticality
    b. Core Cooling
    c. Heat Sink
    d. Integrity
    e. Containment
    f. Inventory

19.4.1.5 Protection and Safety Monitoring System Architecture

A detailed description of the PMS architecture can be found in Section 3.4 of Reference 19.28. The following subsections provide an overview of the PMS architecture.

19.4.1.5.1 Divisional Architecture

A description of the single-division architecture follows and is shown in Figure 19-3. An overview of the four-division architecture is shown in Figure 19-2.

Each of the divisions of the PMS incorporates the following subsystems:

- NIS, which provides the interface to the ex-core nuclear instrumentation.
- BPL unit that facilitates data acquisition and generates the partial trip signals that are passed to the local coincidental logic of all the divisions.
- Local coincidental logic, which uses two-out-of-four voting logic for generation of both reactor trip and ESF actuation.
- ILP for ESF component fan out and actuation.
- Integrated communications processor for inter-divisional and external interfaces.
- Interface and test processor for testing and diagnostics.
- MTP for maintenance, testing, and calibration, and for communication to the PLS/DDS.
- QDPS, divisions B and C only for support of post-accident safety display.
- Safety Displays in the MCR for system status, post-accident information, control of selected system components, and changing nuclear instrumentation calorimetric constants.

19.4.1.5.2 Platform and Components

The PMS uses two major platforms: the Common Qualified (Q) Platform and the CIM.

1. Common (Q) Platform

The Common Q Platform is comprised of commercially developed components that undergo qualification for use in Class 1 systems. It consists of the following major components that are used in the PMS:

- AC160 with PM646A Processor Module.
- Input and Output Cards
- Power Supply
- Flat Panel Display System.
- AF100 Communication
- High Speed Link Communication

2. Component Interface Module

The CIMs receive component control signals from the PMS and the PLS and arbitrate the signals to the plant component. Signal arbitration is between the PLS and the PMS with the PMS having priority over PLS. The CIM is a field-programmable gate array based Class 1 module for safety critical component control.

Additional features provided by the CIM include the following:

- Continuous controller-to-CIM testing for the system command outputs.
- Continuous CIM diagnostics with local fault indications allow problems to be quickly identified.
- Surge-withstand capability qualified to industry standards.
- Continuous CIM monitoring of the external field relay voltage.
- Ability to disable control system inputs (alarmed) for testing.
- Local manual output relay control (alarmed) for testing.
- Hot swappable; repairs can be accomplished by plug-in module replacement with power on, without disturbing cabling.
- Circuit voltage monitor ensures component control power availability and circuit continuity on a continuous basis. Output relay contact is tested when device is actuated.
- Wetting voltage on field inputs is continuously monitored.

19.4.1.6 Protection and Safety Monitoring System Qualification

The PMS equipment qualification program is a type test that demonstrates the continued functionality of the PMS for design basis events such as earthquake, environmental and EMC events.

Although the Common Q Platform had undergone a generic equipment qualification

program, the AP1000 has unique requirements for equipment qualification as described in the AP1000 Equipment Qualification Methodology Document (Reference 19.8). The EQ methodology is based on IEEE standards. The following references demonstrate the equivalence of these IEEE standards to the IEC standards:

- EQ-EV-283, "Electromagnetic Compatibility Standards Evaluation," Reference 19.33
- EQ-EV-284, "Comparison of IEC Standard 60780-1998 to IEEE Standard 323-1974," Reference 19.51
- EQ-EV-285, "Comparison of IEC Standard 60980-1989 to IEEE Standard 344-1987," Reference 19.52

Details of the justification for the type test for hardware and software Configuration of the PMS can be found in subsection 6.1.8.4 of the PMS BSC Reference 19.28.

The results of the PMS EQ tests are summarised in Reference 19.36.

19.4.2 Diverse Actuation System

19.4.2.1 Diverse Actuation System Definition

The DAS design utilises solid-state hardware that is based on the Westinghouse 7300 series platform. The DAS is a Class 2 system that provides diverse actuation of reactor trip and ESF functions with one-out-of-two taken twice or two-out-of-three logic as specified in the safety case and examination, maintenance, inspection, and testing requirements.

19.4.2.2 Diverse Actuation System Design Basis

The DAS functions contribute to the delivery of Category A safety functions. Since the PMS provides the principal means and DAS provides only a supplemental means, the system is Class 2. The DAS functions are performed using solid-state logic, which has been used in Class 1systems in the past.

The following points are included in this design approach section to provide evidence of the design philosophy:

- Separation and Segregation
- Reliability Requirements
- Manual Trip
- Power
- Diversity
- Independence
- Testing
- Operator Interface

19.4.2.2.1 Separation and Segregation

The DAS provides indicators and manual control capability in the auxiliary building that are physically separated from and independent of the DAS equipment located in the MCR. The purpose of this remote DAS control location is to provide the capability to actuate the DAS functions for a beyond design basis event in which the MCR and the RSR are unavailable.

19.4.2.2.2 Reliability Requirements

To defend against postulated CCF of the PMS, the DAS automatic and manual functions do not interface with other controls for given components.

The DAS design has a maximum unavailability of 1E-2 demands/failure for each of the automatic and manual safety functions. This value includes the unavailability for test and maintenance. The unavailability requirement does not account for failures from sensors or transmitters, output signal conversion devices (such as electromechanical relays and solenoid valves), electrical power sources, or the heating, ventilation, and air conditioning system.

The DAS includes design features that prevent spurious and inadvertent actions. For example the probability of spurious actuation is minimised through the voting logic, such as two-out-of-three, and two-switch operation for manual actuation functions.

19.4.2.2.3 Manual Actuation

The DAS manual functions are listed in Table 19-2.

The DAS provides the capability for manual initiation of reactor trip and ESF functions from a DAS control panel that is located in the MCR. These actions are accomplished by actuating a master enable handswitch to provide DC power to the DAS control panel and then actuating two handswitches on the DAS control panel. The two handswitches are wired so that an actuation signal from both handswitches is required.

The DAS manual actuation functions are implemented by connecting the controls on the DAS control panel in the MCR and the controls on the remote DAS control panel in the DAS cabinets located in the auxiliary building to the actuated field devices, independent of the PMS logic. In addition, the DAS manual actuation relays are separate from and independent of the DAS voter actuation logic and associated automatic actuation relays. (The coils of the DAS manual actuation relays are wired independently from the DAS voter actuation logic and the coils of the associated DAS automatic actuation relays. The contacts of the manual actuation relays and the automatic actuation relays are commonly wired to the actuated field devices.)

The manual controls on the remote DAS control panel are provided in the event of a large catastrophic casualty to the clean portion of the auxiliary building on the nuclear island, which could significantly debilitate the C&I capabilities of the AP1000 plant. The four divisions (A, B, C, and D) of PMS and IDS, all electrical containment penetrations, all methods of PLS instrumentation and control, the MCR, and the remote shutdown workstation are all concentrated in the same region of the auxiliary building. A large, multilevel fire could render all the aforementioned systems/locations unusable for a significant amount of time. The remote DAS control panel provides a means for limited indication and plant control, primarily for the purposes of long-term decay heat removal and plant stability, that is physically separated from the clean auxiliary building. The remote DAS manual controls are a subset of the manual controls located on the DAS control panel.

19.4.2.2.4 Power

The DAS includes two fully redundant, 100% capacity, power supply and distribution subsystems (internal to the DAS cabinets). Each of these subsystems receives a separate and independent power feed from the EDS (see Chapter 18 for a full description of the EDS).

In the event one of the EDS power feeds is lost, the remaining EDS power feed and the associated DAS power supply and distribution subsystem are capable of providing power to the entire DAS. In the event both EDS power feeds are lost, each DAS power supply and distribution subsystem includes a battery-backed uninterruptible power supply that is capable of providing DAS power for up to four hours.

19.4.2.2.5 Diversity

Diversity is addressed by the provision of the DAS for frequent faults as shown in the Fault Schedule of Chapter 8. The DAS is a completely separate system for actuation of Class 1 reactor protection systems. The employment of a completely separate system for reactor protection has been implemented to address the issue of DiD.

19.4.2.2.6 Independence

The DAS is an independent system and does not share any of the sensors, operational platforms, or wiring with the PMS or PLS.

The DAS sensors are shown in Table 19-3. These sensors are used solely to generate inputs to the DAS.

The DAS uses exclusively solid-state hardware. Therefore, the platform is independent of the PMS and PLS.

The DAS has its own independent wiring from the sensor to the platform (via Processor Cabinets PC1 and PC2) and to the actuated field equipment (via the Squib Valve Controller Cabinet).

19.4.2.2.7 Testing

The PSA model assumes that the DAS functionality is tested at power every 92 days, and that capability is provided for testing the DAS instrument channels and testing the DAS voter actuation logic and associated automatic actuation relays. The PSA model also assumes that the DAS is returned to service within 14 days if it is out of service.

Each DAS instrument channel includes manual switches that provide the capability to test the channel (and calibrate, if necessary) by simulating the process input value. During this test, the output of the channel comparators are bypassed so that an actuation signal is not generated, and the likelihood of a spurious actuation is minimised. In addition, during this test, the redundant instrument channels remain operable to support actuation of the DAS functions.

The voter actuation logic and associated automatic actuation relays are tested by bypassing the output of the relays that are associated with the voter to be tested, thereby minimising the likelihood of spurious actuation. All voting logic combinations are then tested using simulated test signals at the output of the instrument channel comparators. The status of the associated automatic actuation relays is monitored locally to ensure correct operation of the voting logic and the relays. During this test, the redundant voter and the associated automatic actuation relays remain operable to support actuation of the DAS functions.

19.4.2.2.8 Operator Interfaces

The DAS HSI is located in the MCR and in the auxiliary building.

Alarms and annunciators are used to alert the operator of excursions beyond the designed safety parameters.

19.4.2.3 Diverse Actuation System Functions

The DAS provides a diverse backup to the PMS to reduce the probability of excessive offsite doses that may occur from the unlikely coincidence of frequent faults and postulated CCFs in the protection and control systems.

The DAS provides automatic reactor trip and automatic actuation of specific ESF functions. It also supports manual reactor trip and actuation of specific ESF functions.

The DAS has its own set of sensors and signal processing equipment, which is located in Processor Cabinets PC1 and PC2 and the Squib Valve Controller Cabinet. Control interface, with indicators and manual controls, is provided on the MCR DAS control panel and on the DAS cabinet remote DAS control panel.

The DAS cabinets are segregated from the PMS cabinets, which are located in Class 1 instrument rooms. This segregation minimises the potential for location-related influences such as radiation, EMC, radio frequency interference, missiles, water spray, fire, and flooding to affect both systems.

19.4.2.4 Diverse Actuation System Safety Functions

The DAS provides a backup to the PMS and provides a diverse means of actuating the Class 1 protective functions (i.e., reactor trip and ESF).

The DAS safety functions are listed in subsection 19.3.2.2.

The DAS reactor trip function opens the rod drive motor generator (MG) set field breakers, de-energising the MG set outputs and the control rod drive mechanism (CRDM) coils. The control rods then drop into the reactor by gravity.

19.4.2.5 Diverse Actuation System Architecture

A detailed description of the DAS architecture is presented in Section 3.4 of the DAS BSC (Reference 19.29). The following subsections provide an overview of the DAS architecture.

19.4.2.6 System Architecture

An overview of the DAS architecture is shown in Figure 19-1. The DAS consists of the following three cabinets and a control panel interface (in the MCR):

- DAS-JD-001 Processor Cabinet PC1
- DAS-JD-002 Processor Cabinet PC2
- DAS-JD-003 Squib Valve Controller Cabinet
- OCS-JC-020 MCR DAS Control Panel

DAS Processor Cabinets PC1 and PC2 process the sensor input signals, generate the associated comparator outputs, perform the voter logic (one-out-of-two taken twice or two-out-of-three), and pass the voter outputs to the automatic actuation relays in the Squib Valve Controller Cabinet. Processor Cabinets PC1 and PC2 also include test switches and indications (that support testing of the 7300 process instrument channels, the voters, and automatic actuation relays), local indicators for each monitored process variable, and manual system-level actuation handswitches for certain functions.The DAS Squib Valve Controller Cabinet includes automatic and manual actuation relays. The automatic actuation relays receive signals from the voters in Processor Cabinets PC1 and PC2. The manual actuation relays receive signals from the manual actuation handswitches in Processor Cabinets PC1 and PC2 and the manual actuation handswitches in the MCR. For non-squib valve field equipment, the automatic and manual actuation relays provide individual actuation signals to the components. For squib valves, the manual actuation relays provide ARM and ACTUATE signals to the squib valve controllers that are also mounted in the cabinet. These controllers, in turn, actuate the squib valves. During normal plant operation, the compartment in which the squib valve controllers are mounted is void of all power as a defensive measure to prevent spurious actuation. The DAS Squib Valve Controller Cabinet also includes the bypass relays that are used to prevent actuation of plant equipment during testing.

The DAS Control Panel is located in the MCR. It contains indicators for each monitored process variable, and manual system-level actuation handswitches for the DAS safety functions.

19.4.2.7 Platform and Components

The DAS is implemented using the Westinghouse 7300 series platform. This platform consists of input signal processing (printed circuit) boards, comparator boards, output boards (for the monitored process variable indicators), test boards, and power supplies.

19.4.2.8 Diverse Actuation System Qualification

Although the 7300 Platform had undergone a generic equipment qualification program, the AP1000 has unique requirements for equipment qualification as described in Section 5.8 of the PCSR. In that section of the PCSR the standards to be met for equipment qualification are stated. The AP1000 Equipment Qualification Methodology Document (Reference 19.8) describes the implementation of the EQ program in compliance to the PCSR.

19.4.3 Plant Control System

19.4.3.1 Plant Control System Definition

The PLS controls the nuclear process, conversion of nuclear energy into heat energy, and the transport of the heat energy from the nuclear reactor to the main steam turbine. The PLS provides automatic regulation of reactor and other key system parameters in response to changes in operating limits (load changes) for required normal (including startup, ascent to power, powered operation, shutdown, and refuelling) and off-normal conditions.

The PLS also acts to maximize the plant transient performance and margins to plant safety limits. Additionally, the PLS provides the capability for manual control of plant systems and equipment. Redundant controllers are used to increase single-failure tolerance, where necessary.

19.4.3.2 Plant Control System Design Basis

The following factors are considered in this design approach section to provide evidence of the design philosophy:

- Independence from Instrumentation and Control Network
- Separation and Segregation
- Maintenance, Diagnostics and Testing
- Power

19.4.3.2.1 Independence from Instrumentation and Control Network

The C&I network is not qualified to Class 2 and cannot be claimed for Category B safety functions. Therefore, all PLS Category B functions must operate correctly without the C&I network (Reference 19.13, Section 12.2).

19.4.3.2.2 Separation and Segregation

In order to eliminate single failures of PLS components the following hardware redundancy has been incorporated into the PLS design:

- Redundant controllers – Category B and Category C functions will be implemented on redundant controllers that do not depend upon each other for operation
- Redundant network connections to each redundant controller
- Redundant power supplies in each PLS cabinet
- Redundant I/O modules (where necessary)
- Two or more Category B function controllers will not share the same input signal.

Class 2 portions and control element of the PLS, which are separated by fire zones or power sources, will be implemented on separate controllers (Reference 19.13, Section 12.2). Fire zones, in many cases, will dictate how plant-based items are physically segregated. This specification requires that the physical separation of any controlling equipment is segregated along the same lines.

Cable separation and segregation requirements are defined in Reference 19.7.

19.4.3.2.3 Maintenance, Diagnostics, and Testing

The requirements for maintenance, diagnostics, and testing are specified in Reference 19.13, Section 3.5. One of the key elements of these requirements is the inclusion of modular design and built-in diagnostics that assist personnel in routine testing and maintenance, fault finding, and component replacement.

Requirement specifications are also in place to facilitate maintenance, diagnostics, and testing whilst the plant is online and without compromising plant control functionality (except those elements that are within the nuclear island that are not accessible while online). This includes the removal of individual inputs and outputs without disturbing field cables.

19.4.3.2.4 Power

Factors concerning the reliability of the power supply to the PLS will not compromise the overall ability of the PLS to deliver its safety duty.

The PLS will be fed from the EDS, as described and substantiated in Chapter 18. The supply will be subject to the requirements of EMC (subsection 19.4.3.6).

The PLS system design will be tolerant to power loss through the following design provisions:

- On loss of power, all outputs are set or driven to a safe state (this may be by keeping the pertaining setting).
- On resumption of power, the system will be set to manual control.

19.4.3.3 Plant Control System Functions

The PLS controls the majority of the AP1000 plant duty control elements through either automatic control or manual operator control. It also has monitoring functions. The following parameters are controlled by the PLS automatic controls:

- Nuclear steam supply, by controlling the reactivity, reactor pressure, coolant and turbine steam demand, and steam and coolant inventory
- Control rod movements, as required by the reactivity control (not including the shutdown banks)
- Control and protection of the turbine
- Various miscellaneous control functions required for subsidiary activities and day-to-day running of the plant

The following are the PLS measurement and monitoring functions:

- Rod position, including facility for rod drop time testing
- Post-accident monitoring of non-Class 1 plant

These functions are described in more detail in the PLS BSC (Reference 19.30)

19.4.3.4 Plant Control System Safety Function

The PLS is composed of individual controllers with local and remote I/O. Each controller communicates point data via the plant C&I network. Details of the functionality are included in PLS BSC (Reference 19.30). The PLS performs the following functions:

- turbine control and protection
- fluid systems control
- diesel generator control and load sequencing
- ventilation systems control
- electrical systems control
- balance of plant system control

- rod position indications
- nuclear steam supply system (NSSS) control

NSSS Control includes the following:

- rod control
- reactor power
- pressuriser pressure
- pressuriser level
- steam generator level
- reactor coolant system inventory
- turbine steam demand control
- T_{avg}
- steam pressure

19.4.3.5 Plant Control System Architecture

A detailed description of the PLS Architecture can be found in the PLS BSC (Reference 19.30). The following subsections provide an overview of the PLS architecture.

The PLS is divided into cells, each comprised of a multiple of cabinets. Cells are selected according to functional groupings to minimize the number of signal interfaces that cross between cells. Cell definitions also support design standardization by collecting site specific applications into one cell. This also enables the through-life design, implementation, manufacturing, and test of the system.

Architectural features for critical functions are:

- all controllers used within the PLS have redundant controllers, cabinet power supplies, network connections, and power feeds. I/O signal redundancy is supported, and is applied as necessary to meet single failure criteria
- the PLS controllers attach to the plant C&I network (the network is part of the DDS) which is based on redundant switches and data paths. Automatic reconfiguration occurs quickly (typically less than one second) following detected switch or media failure
- each controller processor is dual attached to the network so that loss of a network interface will not disrupt operation or require failover to the backup processor
- the controllers in the NSSS cell are distinctly grouped into segments, each responsible for the control of a major plant function (e.g. reactor power, RCS inventory, etc.). This ensures that total failure of a controller will not lead to a plant accident that is more severe than those analysed as design basis events
- critical automatic control functions (Category B) are designed to be independent of plant C&I network signals. Loss of communications on the network will not cause spurious operation of these control functions. This entails hardwired inputs and outputs for all principle signals of the control function. If communication is required between controllers, this is also done by hardwired connections. (Note: network communications may be used for non-critical sub-functions such as manual operator control of the outputs)

19.4.3.6 Plant Control System Qualification

Although the Ovation Platform had undergone a generic equipment qualification program,

the AP1000 has unique requirements for equipment qualification as described in Section 5.8 of the PCSR. In that section of the PCSR the standards to be met for equipment qualification are stated. The AP1000 Equipment Qualification Methodology Document (Reference 19.8) describes the implementation of the EQ program in compliance to the PCSR.

19.4.4 Data Display and Processing System

19.4.4.1 Data Display and Processing System Definition

The DDS is a Class 3 system that provides the plant monitoring and control interface for the duty system and a subset of the SIS. This interface requires the processing, display, and archiving of data gathered from the plant. It contains the equipment necessary to accomplish this purpose, including the plant C&I network, servers, and the operator and engineer workstations.

The DDS provides the main real-time data network (the plant C&I network) for all of the plant data. The data is collected by other systems and distributed through the network by the DDS. The DDS displays the information to the operators through operator displays; this also includes data processing functions. The DDS includes the APS, which alerts the operators when preset parameters are exceeded. The DDS includes the CPS, which allows the operators to access all plant procedures at any operator workstation in the MCR, including those for normal operation and emergency situations. It includes nuclear application programmes (NAPs), logs and archives plant data through the process historian, provides gateways to an interface with balance of plant (BOP) monitoring and control equipment, and provides an interface with external systems.

The DDS consists of operator workstations, engineer workstations, data link server, plant C&I network, process historian/report server, communication network gateway, and wall panel information system .

The DDS resources include the following:

- Plant C&I network to provide communication with the other plant C&I systems
- Operator stations for the human-system interfaces
- Process historians for historical data collection, archiving and report building
- Application servers for the APS, CPS, and BEACON
- Application servers and nuclear application programmes
- Datalink servers for interfacing to external plant C&I systems
- Database servers to provide database management functions for the plant C&I systems
- Engineer stations and system support workstations to provide system security, system maintenance, and time management functions for the plant C&I systems
- Enterprise data servers for external communications to the LAN

Figure 19-5 shows a schematic of the DDS resources and their interfaces to the other functional systems.

The DDS provides the main real-time data network (plant C&I network) for all of the plant data, which includes the following:

- Data processing
- Supporting APS
- Supporting CPS
- Supporting NAPs
- Data collection, archiving, and report building
- Providing gateways to interface with BOP monitoring and control equipment
- Providing an interface with external systems

19.4.4.2 Data Display and Processing System Function

The DDS nuclear application programmes provide plant personnel with information to assure safe plant operations and effective use of the plant equipment. These programmes execute on a redundant application server and monitor AP1000 plant parameters and processes.

The nuclear applications receive their input data from the plant C&I network and output their results onto the plant C&I network. The calculated data is in a form that can be used in plant alarms, displays, trending functions, and historical storage and retrieval.

A modular approach for implementing software applications is used for the development of the application programmes in the DDS. Applications are specified and implemented using basic FBs and sub-applications, or any combination of these three functional units. The use of FBs provides the ability to comprehensively and consistently apply the functional requirements for DDS applications and interfaces to all application programmes using the FBs.

When application programmes execute on a redundant pair of application servers, one application server operates in the primary mode and the other in the backup mode. The application programme software is installed and executes on both application servers. Each application server executes the software independently; however, only the application server operating in the primary mode broadcasts the calculated results to the plant C&I network. Should the primary application server fail, the backup application server assumes the role of primary application server. This redundancy scheme is inherent in the application server operating environment (Reference 19.20, Section 3).

The scope of the DDS application programmes can be subdivided in accordance with the general objectives of an information system, which are to provide plant personnel with information to ensure safe plant operations and effective use of the plant equipment. The following groups of applications are provided to meet these objectives:

- Plant safety:
  - Technical specification monitoring (TSM)
  - Safety functions display support
  - Computerised operation support
- Effective use of equipment:
  - Plant performance assessment

Two additional groups of applications provide support for the above groups of applications:

- Application support functions
- Transform calculations and signal processing

The TSM group of applications is intended to provide information for effective monitoring of DiD functions. The first barrier, which provides DiD, is related to the plant normal operations and translated to monitoring of plant parameters and equipment. The goal is achieved in accordance with plant Technical Specifications. The operator monitors the following parameters:

- Limiting conditions for operation (LCO) entries
- Required actions, if LCOs are violated
- Timing requirements for completion of the required actions
- Surveillance requirements violation, which contributes to violation of the LCO (Reference 19.20, Section 3.1)

The computerised operator support group of applications is intended to support miscellaneous processes required for execution of plant normal operations associated with the plant Technical Specifications and normal operating procedures.

The safety functions display group of applications perform calculations to support safety parameter displays, the display of critical safety function data, and CPS functions (Reference 19.20, Section 3.3).

The plant performance assessment group of applications is intended to provide accurate data related to plant thermal output and effectiveness of the plant systems involved in the plant thermal cycle.

The application support function group of applications support the applications identified in Table 9-4.

The transform calculations and signal processing group of applications perform the following basic functions to support other applications:

- Correction of flow signals
