- Compensation of level signals
- Calculation of rates of change
- Calculation of averages of redundant sensors
- Calculation of averages of a signal over time

The application programme software will be capable of executing in either an application server operating environment within the plant C&I system or in a simulator environment without modification.

The application programme software can run in the simulator environment without modification. A base application server configurable parameter may be set to enable the simulator interface when the software is implemented in the simulator environment. This is to ensure that when the software is run in the application environment, the simulator interface cannot be run. If the simulator interface functions when the application programme is installed in an application server, the C&I system could cause erroneous results to be

provided to those using the application programme results (Reference 19.20, subsection 2.1.4.2).

The following are the modes of operation:

- Normal operation
- Initialise
- Update configuration
- Restart with primary application server operating

19.4.4.3 Data Display and Processing System Architecture

19.4.4.3.1 Plant Control and Instrumentation Network

The plant C&I network is a real-time redundant network used to interconnect the controllers, workstations, and communication gateways. The network distributes the plant data that are collected by other systems and is the primary communication network for the entire plant. The plant C&I network provides two-way communication between the distributed controllers, and supports both periodic and aperiodic data transfers of signals and data. The plant real-time data network also provides secure, unidirectional data transfer from the plant real-time network to the plant communication / business network.

The Ovation redundant high-speed network uses Fast Ethernet standards to send input and output data to all DDS workstations and PLS controllers connected to the network.

The plant C&I network is redundant and network segmentation is configured to consider potential network failures and facilitate the various plant commissioning phases (Reference 19.13, Section 8.5).

The EDS electrical power distribution is designed with two load groups to support redundant Class 2 and general equipment. Power connections are critical to the reliable operation of the plant C&I network and to network-attached devices. The load groups are aligned with redundant plant components, and the controls for this equipment should be aligned to the supporting load group. The redundant components of the plant C&I network shall each be powered from separate EDS power sources.

The plant C&I network shall have software tools to configure, modify, and monitor network devices and attachments, and shall provide features to permit the detection and identification of faulty network devices and network attachments.

For analogue input and output values, the engineering unit high- and low-range limits, expressed in engineering units, are used to range-check each analogue calculated or external input value. The PMS shall have quality information for data values it transmits to the Advant to Ovation interface gateway, consistent with Reference 19.19. The plant C&I network data has both signal quality information that is transmitted along with the data, and signal identification information that is associated with the data.

The Ovation distributed control system shall provide the ability to interface to the package local control system through discrete I/O devices and serial data links.

19.4.4.3.2 Application Server

The application server provides general purpose processing functionality to support the needs of nuclear applications processing. The application server provides the platform for the nuclear applications, the APS, the CPS, BEACON, and data link servers. These servers can be arranged in an active/standby configuration or a non-redundant configuration. The application server has an application builder tool, which is a graphical tool for building combination logic.

19.4.4.3.3 Process Historian

The basic role of the process historian is to perform the collection of process values and messages generated by the workstations and controllers into a data-file-based management system. The process historian will execute the collection, summary processing, archiving, and retrieval of data from across the system.

19.4.4.3.4 Reduced Functionality Operator Work Stations

Reduced functionality workstations provide the ability to navigate display pages and to review plant data. This configuration is necessary to limit the ability to control the plant to the operators while allowing the plant status to be reviewed by other personnel (Reference 19.13, Section 8.9).

The senior reactor operator's workstation will have the capability for the soft controls to be normally off, with the capability to activate them.

The DDS will provide workstations with no control capability in plant areas where the only need is to view the plant processes and equipment status.

The technical support centre workstations, and the operations support centre workstation, will have displays consistent with MCR displays but will have no control capability.

Local control operator workstations will only have controls for the plant systems associated with that workstation.

19.4.4.3.5 Computerised Operating Procedures

The CPS is an online system that assists the operational staff in the execution of plant procedures. The CPS may be used for normal, abnormal, and emergency operating procedures. The system guides the operator step by step through the procedures by monitoring the appropriate plant data, processing the data, identifying the recommended course of action, and providing necessary parallel information that allows the operator to assess other plant conditions that may require attention. Computerised plant procedures can be accessed at operator workstations in the MCR (Reference 19.13, Section 8.10).

19.4.4.3.6 Data Link Servers

Data link servers allow the network to communicate with components that do not support Ovation highway interfaces. Data links can provide two-way communication and will comply with cyber security considerations.

19.4.4.4 Data Display and Processing System Qualification

The AP1000 has unique requirements for equipment qualification as described in Section 5.8 of the PCSR. In that section of the PCSR the standards to be met for equipment qualification are stated. The AP1000 Equipment Qualification Methodology Document (Reference 19.8) describes the implementation of the EQ program in compliance to the PCSR.

19.4.5 Special Monitoring System

19.4.5.1 Special Monitoring System Definition

The SMS is a Class 3 system that processes data from specialised sensors. It consists of specialised subsystems that interface with the C&I architecture to provide diagnostic and long-term monitoring functions. The monitoring functions are:

- The DMIMS-DX
- The vibration integrity monitoring system (VIMS), which includes the RCPVM system, the CRDM fan vibration monitoring system (CFVMS), and the feedwater vibration monitoring system (FWVMS)

The SMS uses internal data networks that interface with the C&I networks using dedicated data links.

19.4.5.2 Special Monitoring System Function

19.4.5.2.1 Digital Metal Impact Monitoring System

The DMIMS-DX provides for the detection of the presence of metallic debris in the RCS when the debris impacts against the internal parts of the RCS.

The DMIMS-DX comprises digital circuit boards, controls, indicators, power supplies, and remotely located sensors and related signal processing devices. A minimum of two sensors are located at each natural collection region, connected to separate instrumentation channels, to maintain the impact monitoring function if a sensor fails in service.

The DMIMS-DX uses two methods of detection: automatic data analysis and audio monitoring. For automatic data analysis the system performs impact detection and alarm generation and records the signal waveforms and frequency spectra whenever an impact is detected (Reference 19.13, subsection 10.2.3). Audio monitoring is valuable because the impact signals are in the audio frequency range and knowledgeable listening can identify additional signal characteristics.

The DMIMS-DX provides sensor data for display in the MCR or a printed output for analysis (Reference 19.21, Table A-1).

19.4.5.2.2 Vibration Integrity Monitoring System

The VIMS is a continuous monitoring system that provides information to assist in the evaluation of the performance of the RCPs, CRDM fans, and feedwater pumps.

The RCPVM system uses vibration sensors on each RCP and one phase reference sensor to monitor pump speed and shaft position. At the cabinet, a local display allows for operator

interaction. The instrumentation rack communicates with the DDS to provide process data and alarms for MCR display.

The CFVMS receives signals from vibration sensors on each of the fans. The instrumentation rack communicates with the DDS to provide process data and alarms for the MCR display. The CFVMS will provide a vibration warning alarm for each CRDM fan.

The FWVMS receives signals from vibration sensors on each of the feedwater pump packages, each of which consists of a feedwater booster pump, main feedwater pump, gearbox, and motor.

Data and alarms from the FWVMS are provided to the operator through the Modbus™ connection to the DDS.

19.4.6 In-Core Instrumentation System

19.4.6.1 In-Core Instrumentation System Definition

The primary function of the IIS is to provide a continuous 3-D measured power distribution of the reactor core. The measured power distribution is used to confirm margin to thermal limits as per LCO 3.2.5 and is used to periodically calibrate PMS neutron detectors. A secondary function of the IIS is to provide the PMS with the thermocouple signals necessary for the post-accident inadequate core cooling monitor. The IIS assemblies house both fixed in-core flux detectors and core-exit thermocouples.

19.4.6.2 In-Core Instrumentation System Function

The IIS is a Class 3 system. It has two functions: one is to provide a continuous 3-D measured power distribution of the reactor core; its secondary function is to supply the PMS with thermocouple temperature measurement signals for the post-accident inadequate cooling monitor, as well as to provide the DAS with dedicated indication of core temperature.

The in-core thermocouple signals used for the QDPS are Class 1. Therefore, the fixed in-core detector (FID) signals will be independent from the thermocouple signals for all credible failures of the Class 3 portion of the system.

The in-core instrument thimbles assemblies are inserted into the active core through the upper head and internals of the reactor vessel. During plant operation, the in-core instrument thimble assembly is positioned within the fuel assembly. Thimbles exit through the top of the reactor vessel head to the integrated head package. For each assembly, there is a separate cable for the core-exit thermocouple and the FIDs, which are combined at the reactor vessel head into one cable guide. The FID and core-exit thermocouple cables are then routed to different data conditioning and processing stations. The data are processed, and the results are available for display in the MCR. All power distribution calculations are carried out using the BEACON core monitoring system which resides on dedicated servers. Additional information on BEACON is provided in Reference 19.57.

The IIS cables will be grouped and routed to signal termination equipment in accordance with their associations with different systems. The system will incorporate two independent sets of IIS FID electronics including the cabinets, power supplies and multiplexed data output links, so that the requirements for single failure criteria are met and one failure does not disable the power distribution measurements.

Figure 19-6 shows the IIS system configuration.

19.4.7 Radiation Monitoring System

19.4.7.1 Radiation Monitoring System Definition

The RMS supports safe operation of the plant under normal conditions, and provides DiD capability during fault conditions. It provides signals for automatic actuation functions and information to the plant operating staff so that actions may be taken to protect the health and safety of the public and plant personnel.

- The RMS provides early indication of a system or equipment malfunction that could result in an excessive radiation dose to plant personnel or lead to plant damage.
- Radiation monitoring data, including alarm status, are provided to the AP1000 plant operators via the PLS (and in the case of Class 1 monitors, to the PMS).
- The safety channels are environmentally qualified and are powered from the IDS.

The functions of RMS include the following:

- Providing radioactivity monitoring of selected plant fluid (gaseous and liquid) process streams
- Providing radioactivity monitoring of plant liquid and gaseous effluents
- Providing plant airborne radioactivity monitoring
- Providing area radiation monitoring
- Providing alarms to warn plant personnel of unusual radiological conditions
- Providing alarms to warn of RMS equipment malfunctions
- Providing process effluent radiological data for the effluent measuring and reporting.

19.4.8 Instrumentation

Process instrumentation is used to measure plant status during normal and abnormal conditions. The instruments provide input to all C&I systems, and they will be classified in accordance with the function that is being provided, and will be qualified in accordance with Chapter 5. If smart instrumentation is proposed to be used, additional justification for the use of the smart instrument will be provided using the processes in Chapter 5.

19.5 Conclusions

This chapter has provided justification and substantiation of the overall C&I architecture, i.e. how the individual C&I systems are configured to provide the plant with sufficient DiD to meet the requirements of the safety case and the expectations for a modern NPP. This chapter has, therefore, provided a demonstration that the design of the C&I systems and their interfaces within the AP1000 reactor are fit-for-purpose and use technology and modes of operation that are commensurate with modern standards. Reference has been made in this chapter to the detailed descriptions and substantiation of the individual systems that are provided in, amongst other documents, the relevant BSC documents.

This chapter has also provided evidence that the design of the C&I architecture and systems ensures that the radiological risks to the public and workers are reduced to ALARP. This has been achieved by demonstrating that:

- the potential for control system faults to be initiated has been reduced as far as reasonably practicable and C&I protection consists principally of automated protection systems, i.e. the position of the C&I design in the safety hierarchy;

- RGP has been applied in the design and will be applied in detailed design, installation and operation. Where necessary, this is with respect to established codes and standards that are considered to represent RGP;

- safety functions have been substantiated and that required reliability requirements have been satisfied (or that there is a programme of work to complete the analysis as identified in the safety plans of system BSCs and the PCSR Chapter 19 IEC 61513 and SAP compliance documents); and

- suitable optioneering has been undertaken to underpin design and configuration selection.

Section 19.3 has described and justified the design of the overall C&I architecture. The Engineering Principles described in Chapter 5 were utilised in the design of the architecture and its individual systems. The architecture of the C&I was originally designed to recognised and reputable US NRC standards. Therefore, a benchmarking exercise has been undertaken to compare the design process with IEC 61513 (Reference 19.16), which is considered to represent RGP in the UK. Closure of the compensatory measures will demonstrated that the design of the architecture has followed a process that is aligned with IEC 61513 (Reference 19.16). Thus, a key ALARP test has been demonstrate that RGP has been utilised in the design of the architecture. It is recognised that at this GDA stage not all C&I systems have been designed, e.g. the fuel route control and protection systems. However, the C&I architecture is sufficiently mature to enable these systems to be developed during the licensing phase and feed into the overall configuration.

The development of the architecture of the C&I, as described in Section 19.3, has taken into account a number of key inputs. The design process has ensured that the architecture delivers an operable and maintainable NPP that shall offer secure and safe operations that minimise unavailability of the NPP due to breakdown, maintenance and functional testing. The architecture delivers a PLS that shall have operator oversight and ultimate operator control from the MCR. The PLS is described and substantiated in subsection 19.4.3.

The principles of DiD have been incorporated into the design of the C&I architecture. Together with the passive containment features of the AP1000 and ultimately, the emergency arrangements for severe accidents, the C&I architecture and individual systems ensure that the potential for core damage or large radiological releases is minimised, as far as reasonably practicable. Particular aspects of the C&I that support the provision of DiD include the provision of:

- A robust plant control system (the PLS) that will minimise the potential for control system errors in the first instance and hence minimise the demand on the safety measures;

- Independent, diverse and segregated systems (the PMS and DAS) that will respond to system failures and return the plant to a defined safe state without operator intervention, e.g. reactor trip and provision of cooling functions and provide feedback to the operator (the OCS and DSS);

- A system to ensure MCR habitability (the RMS) in the unlikely event of a severe accident and provision of reactor and environmental diagnostics to facilitate recovery operations;

- An alternative safe shutdown facility should the MCR become uninhabitable (the RSR).

In final conclusion, the C&I architecture and the individual systems utilise proven technology that includes a significant number of design improvements that enhance tolerance to failure and maximise reliability. The requirements of the safety case and the safety requirements of the relevant IEC standards that represent RGP in the UK have been delivered and evidence for this has been provided in the individual BSCs and their supporting references. As far as practicable, conformance with IEC standards that represent RGP in the UK has been achieved by final close out of the compensatory measures. There has been the consideration of options in the selection of technology platforms. In addition, by the use of FMEA and PSA, systems have been optimised to maximise their reliability. The C&I systems contribute to the overall DiD of the AP1000 plant and provide the necessary mixture of engineered protection systems (high in the safety hierarchy) and support functions to facilitate recovery from unlikely severe accidents. It is therefore concluded that due to:

- delivery of safety requirements;

- alignment of the design with RGP;

- use of option selection in the design process; and

- optimising the design to improve reliability (risk reduction),

the design of the C&I architecture and systems is ALARP and shall support the overall demonstration of ALARP for the AP1000 plant as a whole.

Table 19-1. Principal Claims on C&I Equipment in the Safety Case

System	Highest Cat/ Class	Principal Claims in the Safety Case
PLS	B/2	Controls plant within operational limits and conditions. Failure of this function could lead directly to the actuation or operation of a Category A safety function. Functions that considerably reduce the frequency of an initiating event as identified by the DBA analysis, i.e. the PLS is required to minimise the demand on safety systems.
PMS	A/1	PMS is the primary C&I system to initiate reactor trip and engineered safety functions such as containment isolation, decay heat removal, and safety injection. PMS initiates functions required to reach the non-hazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Initiates reactor trip when plant conditions reach specified limits. The PMS should be independent to the PLS and DAS.
DAS	A/2	DAS is the diverse C&I system to initiate reactor trip and engineered safety functions such as containment isolation, decay heat removal, and safety injection. DAS initiates functions required to reach the non-hazardous stable state, to prevent a DBA from leading to unacceptable consequences or to mitigate its consequences. Initiates reactor trip when plant conditions reach specified limits. The DAS should be independent to the PLS and the PMS and diverse to the PMS.
OCS	A/1	Required to provide information and control capabilities that allow specified manual actions necessary to reach the non-hazardous stable state. The OCS provides the primary hardware used to manually initiate and monitor Class 1 SSCs. The OCS provides the human interface design as well as the location and mounting arrangement for the operator interface equipment necessary to support DiD safety functions.
IIS	B/2	Required to provide information that allows specified manual actions necessary after the non-hazardous stable state has been reached to prevent a DBA from leading to unacceptable consequences, or mitigate the consequences. Core exit temperature measurements are not used for reactor trip or ESF functions. Some of the measurements are inputs to the PMS and DAS for post-accident monitoring.
RMS	A/1	Maintaining the integrity of the containment; thereby minimising the release of radioactive material from the containment. Maintaining habitability of the MCR.

Table 19-2. DAS Manual Functions

Function	MCR DAS Control Panel	Remote DAS Control Panel
Reactor and Turbine Trip	X	X
Passive Containment Cooling Actuation	X	X
CMT Actuation and RCP Trip	X	X
Open Stage 1 ADS Valves	X	
Open Stage 2 ADS Valves	X	
Open Stage 3 ADS Valves	X	
Open Stage 4 ADS Valves	X	X
Open PRHR Discharge Isolation Valves and Close IRWST Gutter Isolation Valves	X	X
Selected Containment Penetration Isolation	X	X
Containment Hydrogen Igniter Actuation	X	
Initiate IRWST Injection	X	X
Initiate Containment Recirculation	X	X
Initiate IRWST Drain to Containment	X	X

Table 19-3. DAS Sensors

Item No	Sensor Tag	Description	Scale	Use
1	RCS-TE300A	Hot Leg 1 Temperature Channel 1	288C° to 343°C (550° to 650°F)	Protection
2	RCS-TE300C	Hot Leg 1 Temperature Channel 2	288C° to 343°C (550° to 650°F)	Protection
3	RCS-TE300B	Hot Leg 2 Temperature Channel 1	288C° to 343°C (550° to 650°F)	Protection
4	RCS-TE300D	Hot Leg 2 Temperature Channel 2	288C° to 343°C (550° to 650°F)	Protection
5	SGS-LT044	Steam Generator 1 Level Channel 1	0 to 100% of span	Protection
6	SGS-LT 045	Steam Generator 1 Level Channel 2	0 to 100% of span	Protection
7	SGS-LT 046	Steam Generator 2 Level Channel 1	0 to 100% of span	Protection

20 STRUCTURAL INTEGRITY

20.1 INTRODUCTION

This chapter presents safety arguments to demonstrate how the structural integrity of the AP1000 plant United Kingdom (UK) Class 1 systems, structures, and components (SSCs) can be assured over the 60-year design life of the plant to a level of structural reliability and a degree of rigour commensurate with the consequences of gross failure.

To achieve this, a classification methodology has been developed based on an evaluation of the direct and indirect consequences of postulated gross failure. Based on this classification, structured arguments are presented for each major component and are tailored to support the structural reliability claimed for that component. They are presented as a series of individual Component Safety Reports (CSRs), which are included as appendices to this chapter.

For components for which the consequences of gross failure are intolerable, and hence for which the claim is that the probability of gross failure is so low as to be discounted, a multi-legged safety argument has been presented as described in Section 20.6.4. For such components, the arguments include supplemental requirements for defect tolerance and the use of qualified manufacturing inspections to provide a robust demonstration that the component will enter service free from defects that could be of concern through life. For components for which the postulated consequences are less severe, the safety arguments are based on design in accordance with recognised standards.

The safety arguments for each component are presented in the form of a series of claims, arguments, and evidence. Further support is provided by a suite of referenced documentary evidence that provides specific details of the design and functional specifications, code design assessments, manufacturing specifications, material specifications, and inspectability assessments applicable to each component. This documentary envelope is presented as a Technical Index within each individual CSR.

20.2 SCOPE

The broad scope of this chapter is to substantiate the structural integrity of a number of plant SSCs for all conditions within the design basis. A series of individual CSRs are included as appendices to this chapter, which establish safety arguments to support structural integrity claims for the following SSCs:

- Reactor vessel (RV) — Appendix 20A
- Pressuriser — Appendix 20B
- Steam generators (SGs) — Appendix 20C
- Main steam lines (MSLs)[1] — Appendix 20D
- Reactor coolant loop (RCL) piping — Appendix 20E
- Reactor coolant pump (RCP) — Appendix 20F
- Passive residual heat removal heat exchanger (PRHR HX) — Appendix 20G
- Core makeup tank (CMT) — Appendix 20H
- Accumulator — Appendix 20I
- RV internals and core support structures — Appendix 20J
- Containment vessel (CV) — Appendix 20K

1. The main steam line assessment in Appendix 20D includes the MSL inside containment and outside containment, up to the main steam isolation valve located at compartment wall 11.

The rationale for the selection of SSCs included for detailed evaluation within is summarised in Section 20.5.1. The SSCs addressed in these appendices include the major components that constitute the primary and secondary system pressure boundaries within containment. Each appendix listed above includes definition of a detailed scope that is specifically applicable to that CSR. Concrete structures and fluid systems are not included within the scope of this chapter. These are covered in Chapters 16 and 17, respectively.

20.3 OBJECTIVES

At a high level, the objective of each CSR is to support the claim established in Chapter 14 that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. Satisfying the safety design bases for each SSC and the associated structural integrity safety functional requirements (SFRs) provides support to this claim. The SFRs correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety; the basis for the derivation of these SFRs is described in Section 20.4. Several components addressed in this chapter feature design enhancements adopted as ALARP measures to minimise frequency of failure, and these are identified in the relevant appendices.

20.4 DERIVATION OF SAFETY FUNCTIONAL REQUIREMENTS

Each SFR of any particular SSC establishes a specific role required to maintain nuclear and radiological safety under normal operating and fault conditions. SFRs are identified for each AP1000 plant component addressed in Appendices 20A to 20K, to specify the required safety functional performance in each case.

Performance and safety design bases provide the basis for identifying the SFRs. The performance and safety design bases of the reactor coolant system (RCS) and its major components are interrelated, and are applicable to the derivation of SFRs for the RCS pressure boundary components addressed in the appendices to this chapter. The performance and safety design bases for the RCS are identified in Reference 20.1.

For the structural integrity CSRs appended to this chapter, SFRs have been identified by a review of the performance and safety design bases relevant to a particular component to establish where, and to what extent, structural integrity must be justified to maintain the required safety functional performance. Table 20-1 lists the SFRs allocated to each AP1000 plant component addressed in Appendices 20A to 20K. The range of operating conditions included within the design basis for each component are detailed in the relevant CSR and include all those associated with normal operations and planned tests; a range of upset, emergency, and faulted conditions are also included. Each CSR specifies a deterministic assessment to substantiate the structural integrity of the AP1000 plant components for all conditions within the design basis. The capability of the AP1000 plant to maintain nuclear safety in response to design basis internal hazards is addressed in Chapter 11, and to external hazards in Chapter 12.

Postulated failure modes, which result in a loss of SFRs, lead to the identification of a structural classification that is commensurate with the consequences of gross failure, as determined through the process of component classification described in Section 20.5. The CSRs are provided to substantiate that the structural reliability will be commensurate with the consequences of gross failure. The basis for the safety case presented in the CSRs is established according to the classification allocated to a particular component.

20.5 STRUCTURAL INTEGRITY CLASSIFICATION

Key to the AP1000 plant component structural integrity is the understanding of the radiological consequences of any postulated failure mode. Based on this, a structured and systematic basis has been developed for establishing the level of rigour applied during the design assessment, material procurement, fabrication, in-manufacture inspection, testing, in-service testing, maintenance, and inspection of the components. This level of rigour is based on the component structural integrity classification scheme, as presented in the AP1000 UK Structural Integrity Classification (Reference 20.2).

For a component with a high degree of redundancy or with diverse means of protection, a minimum level of structural reliability based on the demonstration of good design, manufacture, and inspection in accordance with relevant design code requirements, may be appropriate. However, for those components for which no redundancy or diverse means of protection can be provided, it must be shown the likelihood of gross failure is so low that it can be discounted. For such components it is necessary for a higher degree of structural reliability to be sought and substantiated. This requires measures to be implemented over and above design code requirements, with a particular emphasis on demonstrating that a structure is free of structurally significant manufacturing defects and is tolerant to in-service degradation. That is, an acceptable margin must be shown to exist between a qualified examination defect size (QEDS) and the maximum allowable start of life (SoL) defect size.

The structural integrity classification scheme has been developed to be consistent with the overall AP1000 plant safety categorisation and classification scheme as described in Chapter 5. The categorisation process for the AP1000 plant is performed by identifying the high-level safety functions that a specific SSC delivers or supports. These safety functions are categorised A to C, based on the nuclear safety significance of delivery failure. Once a safety function category has been assigned to a specific SSC in line with the safety function it delivers (or supports the delivery of), the SSC is assigned a Safety Class between 1 and 3. This safety class takes the safety category into account, and considers the extent to which the SSC supports the associated safety function.

In practice, the AP1000 plant safety categorisation and classification methodology is too coarse to determine component structural integrity requirements, since Class 1 covers a very broad range of initiating event frequencies and consequences and hence, a commensurately broad range of structural reliability targets.

Consistent with accepted UK practice, an alternative classification methodology for determining structural integrity requirements for passive structures has been established, which subdivides Class 1 SSCs according to the consequences of postulated gross failure. The details of this classification methodology and the conclusions from the application of the methodology are presented in Reference 20.2.

20.5.1 Structural Integrity Classification Process

The starting point in the process was to use the safety classification and categorisation methodology described in Section 5.2 to identify each Class 1 SSC. A high-level review was then undertaken to identify a short list of SSCs for which postulated gross failure could conceivably lead to intolerable consequences, through direct or indirect means, and hence, meriting a more detailed evaluation.

All valves were excluded from the structural integrity classification process on the basis that their consequences of gross failure would be bounded by the assessment of a selection of piping systems. Similarly, civil structures and cranes, included within the scope of Class 1 components, were also excluded as these are covered in Chapters 16 and 17. The CV was not included in the initial assessment since the primary reliability claim against the CV is under faulted plant conditions and this does not lend itself to consideration using the established method. Nonetheless, the CV is included within the scope of this chapter, and the basis for determining the structural integrity requirements for the CV are detailed in Appendix 20K.

For the selected components, a thorough review of the radiological consequences of gross failure was performed. An important element of the process was the assumption of gross failure, which was assumed irrespective of any anticipated material properties and crack development behaviour. Hence, supplemental design practices were not considered as part of the classification process. These practices do, however, feature as a defence in depth element in certain CSRs.

The consequences were considered in a broad sense and included the direct effects on plant safety, for example, a loss of coolant inventory or reactivity excursions; and the indirect effects from, for instance, missiles, blast, pipe whip, flooding, and water/steam jets. This also considered any longer-term effects on the availability of essential safety systems and instrumentation required to maintain plant safety in the faulted condition. The first step in the process was to hold an expert review meeting with relevant specialist input. The AP1000 design 3-D model was used to establish the proximity of adjacent essential systems and enabled secondary consequences to be robustly evaluated. The approach ensures that the final classification has been reached following extensive engagement with the appropriate AP1000 design technical experts.

20.5.2 Component Structural Integrity Classifications

The structural integrity classification scheme for the AP1000 plant is summarised in Table 20.2. The following classes are identified:

- Highest safety significance (HSS)
- High integrity (HI)
- Standard Class 1
- Standard Class 2 or 3

Highest Safety Significance

HSS is assigned to failure modes for which there is no protection, failure is intolerable, and where it is not reasonably practicable to provide protection. In practice, this applies to fault sequences where the assessed consequences include both severe core damage and potential large uncontrolled releases. The Demonstration of Incredibility of Failure in Structural Integrity Safety Cases (Reference 20.5), prepared in response to a question asked of the UK Technical Advisory Group on Structural Integrity (TAGSI), provides an authoritative view on when an incredibility of failure (IoF) case is required and how such cases should be presented. In the context of the methodology described here, IoF and HSS are considered equivalent. The basis and format of the safety case arguments for HSS components are summarised in section 20.6.4.

High Integrity

The failure of HI components can lead to severe core damage but, in general terms, it can be shown that effective containment will limit the offsite consequences. HI is assigned where the component can be described as single-failure intolerant, i.e., where there is a single line of protection, but no redundancy. In this case, it is therefore possible to make a consequence argument, but this is deemed not to provide the same degree of confidence from a fully qualified line of protection with redundancy. Thus, partial protection may be available and this is reflected in the degree of substantiation required. The basis and format of the safety case arguments for HI components are summarised in section 20.6.3.

Standard Class 1 Systems, Structures, and Components

It is required to demonstrate that only limited core damage can result in the event of failure of a component classified as Standard Class 1. The basis and format of the safety case arguments for Standard Class 1 components are summarised in section 20.6.2.

Standard Class 2 or 3 Systems, Structures, and Components

Failure of components classified as Standard Class 2 or 3 SSCs should not result in any core damage although contamination can lead to worker exposure in excess of annual statutory limits. The basis and format of the safety case arguments for Standard Class 2 or 3 SSCs are summarised in section 20.6.1.

20.5.3 Results of Structural Integrity Classification

Reference 20.2 describes the application of the classification methodology at a component level. It should be noted that where a component has been categorised as HSS, this highest level of classification does not necessarily apply to all regions of the component. To address this, a more detailed assessment of individual locations has been carried out. Specifically, this includes the identification of HSS weld locations where additional measures will be applied in terms of the assessment of defect tolerance and the application of qualified inspection to detect defects of structural significance.

The results of the assessment are presented in Reference 20.2. A summary of the basis for structural integrity classification of each component assessed is reproduced in Table 20-3 to Table 20-21.

The following components have been assessed as HSS:

- RV
- Pressuriser
- SG channel head, tube sheet, and secondary shell

The main coolant loop piping hot leg and cold leg to RV nozzle safe end welds have been classified as HI. The remaining components have been classified as Standard Class 1.

20.6 BASIS OF THE COMPONENT SAFETY CASES

Each CSR presents a safety argument to establish that the structural reliability of the component is commensurate with the consequences of gross failure. A system of structural integrity classification that establishes appropriate structural integrity requirements has been described for the AP1000 plant components addressed in Appendices 20A to 20K.

The structural integrity design of the piping and pressure vessels considered in these appendices is substantiated by demonstrating sound engineering practice. This is argued to provide a high level of confidence in the ability of a component to deliver its required safety functions throughout its life. A qualitative approach to demonstrate defence in depth for nuclear plant components, such as those addressed in Appendices 20A to 20K, is commonly adopted within the nuclear industry worldwide because of a general lack of sufficiently reliable data to support quantitative substantiation of the low frequencies of failure typically claimed. Various elements of sound engineering practice are identified in each CSR that confirm quality of design, construction, inspection, and testing in accordance with relevant nuclear codes. In combination, this evidence establishes robust defence in depth against failure of structural integrity without resort to quantitative statistical or modelling approaches.

20.6.1 Standard Class 2 or 3 Components

For Standard Class 2 or 3 components, reliance can be placed on the application of the appropriate design codes (Reference 20.2). This, in combination with either redundancy or diversity in the plant protection leads to structural integrity cases and the inspection requirements for component failures in this class being based on the compliance with design code requirements. Standard inspection techniques in accordance with code requirements are used to underpin integrity claims. Specific measure may be required where known degradation mechanisms exist. Specification and procurement of materials in accordance with the requirements of the applicable design codes, including the application of operating experience (OE) to provide further evidence, ensures that appropriate materials, relative to the importance of the component, are used.

Table 15A-1 presents, among other details, the UK safety class associated with each mechanical SSC. As noted in Reference 20.2, all UK Safety Class 2 or 3 SSCs have a corresponding structural integrity classification of Standard Class 2 or 3, respectively. Table 15A-1 identifies the principal design code used for each Class 2 or 3 SSC. Note that for the design AP1000 plant UK Class 2 SSCs, with their limited safety significance, non-nuclear codes and standards, and additional regulatory oversight proposed (enhanced quality programmes, design / operational reliability assurance program (D-RAP / O-RAP), and availability control programs), provide the evidence to support the arguments for the claim that it is proper to design UK Class 2 SSCs to non-nuclear codes and standards (Reference 20.22).

20.6.2 Standard Class 1 Components

As noted in Reference 20.2, the failure statistics for industrial pressure vessels and piping built according to the good practice embodied in modern codes and standards supports the inference of a failure rate that is in accordance with the structural integrity requirements for Standard Class 1 components. Substantiation of the structural reliability of the Standard Class 1 components in Appendices 20D to 20K is accordingly based on demonstrating a high quality of design and build by compliance with relevant aspects of the American Society of Mechanical Engineers (ASME) Boiler & Pressure Vessel Code (Code) as a minimum.

The ASME Code prescribes rules governing the design, fabrication, and inspection of boilers and pressure vessels that are internationally recognised to be well established for application in the nuclear industry. The following sections of the ASME Code establish requirements that address key aspects of component design for the AP1000 plant:

- Section II Materials

- Section III Rules for the construction of nuclear facility components
- Section V Nondestructive examination
- Section IX Welding and brazing qualifications
- Section XI Rules for in-service inspection of nuclear power plant components

The safety arguments for the Standard Class 1 components are structured according to a series of claims to demonstrate compliance with relevant requirements of the ASME Code. The key topics addressed in each Standard Class 1 CSR are summarised below.

Each safety argument presented in Appendices 20D to 20K identifies applicable codes and standards, including relevant sections of the ASME Code, as one element of the evidence presented to demonstrate good design. The codes, standards, and regulations specified to control quality of design and manufacture embody extensive operating experience relevant to the AP1000 plant components. This ensures a structurally robust design and provides a means to prevent, minimise, and control component degradation at the design stage. Compliance with the codes, standards, and regulations, therefore, provides a foundation for assuring that structural integrity of the AP1000 plant components will be maintained for the design lifetime. The revision or edition of codes and standard applicable to the AP1000 plant vary by component. For example, the reactor vessel has been designed in accordance with the ASME Code Section III, 1998 Edition with addenda up to and including 2000. The Licensee will need to review newer editions of the ASME Code, and possibly other codes and standards, to determine what changes might be required to comply with newer editions, and either make those changes or justify why the changes are not practical.

Evidence is provided in the Standard Class 1 safety arguments to demonstrate good choice of materials. Specification and procurement of materials in accordance with the requirements of the ASME Code, Section II ensures that well-proven materials are chosen, and that the materials have good resistance to fracture and are of suitable chemical composition to limit the effect of through-life degradation mechanisms. OE provides further evidence to support the material choice.

The rules prescribed in ASME Code, Section III provide control of a diverse range of aspects of nuclear component construction. The applicable criteria and requirements of Section III are identified on the basis of the definition of various classes of SSCs for nuclear power plants. The ASME class applicable to components or subcomponents is identified in the safety arguments presented in Appendices 20D to 20K where it is necessary to define the applicable requirements of the ASME Code.

The ASME Code, Section III includes a requirement to conduct structural analyses to support the design for all conditions within the design basis. This supports the claim that the AP1000 components can fulfil their SFRs over the required period of service. Assessments are specified in each CSR to deterministically justify the structural integrity of AP1000 components against stress and fatigue limits established in the ASME Code, Section III. These assessments are based, in part, on a common set of RCS design transients. A summary of the RCS design transients and associated frequency of occurrence is presented in Table 20-22, as specified in Reference 20.3.

Other design aspects controlled by the requirements of ASME Code, Section III include mechanical testing to confirm material properties, manufacturing inspections to confirm the achievement of quality, and functional testing to confirm pressure boundary integrity. Welding procedures, testing of weld materials, and welder qualification are controlled by rules prescribed in ASME Code, Sections III and IX. The full range of design aspects

controlled by Section III of the Code is described in detail in the CSRs in a manner specifically applicable to the particular component.

The aspects of compliance with the ASME Code as summarised above provide a high level of confidence that the AP1000 plant components categorised as Standard Class 1 will enter service sufficiently free of defects so that their safety functions are not compromised. Assurance that the structural integrity of the Standard Class 1 components will be maintained throughout the design lifetime is provided by the in-service inspection (ISI) requirements prescribed in the ASME Code, Section XI. Like ASME Code, Section III, ISI requirements for the Standard Class 1 components are established in accordance with ASME classification. The planned programme of ISI for each Standard Class 1 component is identified in the CSRs on the basis of the requirements of the ASME Code Section XI, supplemented by requirements specified in the United States Code of Federal Requirements (CFR) 10 CFR 50.55a, as applicable. ISI constitutes the preferred means of providing forewarning of in-service failure for Standard Class 1 components, and this is supplemented by leak-monitoring and detection arrangements.

In the case of the MSLs and the RCL piping, supplemental mechanistic design requirements have been applied to improve reliability. The measures are applied where an improvement in reliability has an appreciable beneficial impact on plant safety, radiation exposure, and plant examination, maintenance, inspection, and testing (EMIT) obligations. These supplementary mechanistic design requirements, which are discussed in Reference 20.23, are included in the relevant CSRs as evidence of supplementary defence in depth, in addition to the robust demonstration of structural integrity provided by compliance with the ASME Code.

20.6.3 High Integrity Components

It is necessary for the structural integrity of the HI welds to be substantiated to a higher degree of rigour than that required for the Standard Class 1 components. When applicable, this is provided by a claim with evidence to demonstrate that these welds will be subject to appropriately qualified manufacturing inspections, supported by an elastic-plastic fracture assessment to demonstrate tolerance to all defects smaller than a QEDS by a size margin of two. In addition to the structural reliability justified by compliance with the ASME Code, these additional measures are claimed to support a degree of structural reliability commensurate with an HI classification. The role of defect tolerance assessments, in combination with qualified inspections, to support claims of a high degree of structural reliability are also important in the justification of HSS components, and described further in section 20.6.4.

20.6.4 Highest Safety Significance Components

Appendices 20A to 20C, respectively, provide justification of the structural reliability claimed for the following HSS components:

- RV
- Pressuriser
- SG secondary shell, tube sheet and channel head

The safety argument for each HSS component is presented according to a four-legged format well established in the UK for the safety justification of nuclear plant components that share similar structural reliability targets. The format of the safety argument follows that recommended by TAGSI (Reference 20.5). As noted previously, the approach for these passive mechanical components has been to substantiate structural integrity claims by

demonstrating sound engineering practice; in each of the four legs, diverse defence in depth measures are identified that, in combination, substantiate the structural reliability claimed for the HSS components. The four legs of the HSS arguments are as follows:

- Leg 1: Interpolation/extrapolation of experience – good design and manufacture
- Leg 2: Functional testing
- Leg 3: Failure analysis
- Leg 4: Forewarning of failure

In Appendices 20A to 20C, it is claimed that the four-legged safety arguments identify a suitable and sufficient diversity of evidence to demonstrate that their safety functions will not be compromised over the component lifetime. This is achieved through demonstration that the component will enter service free from defects of concern, that any manufacturing defect smaller than a QEDS will remain tolerable over the lifetime of the component, and the existence of defects that could compromise their safety function can be established through their life cycle. This is judged to substantiate the structural reliability claimed for the HSS components.

20.6.4.1 Good Design and Manufacture and Functional Testing

The first two legs of the safety argument provide evidence of high quality achieved through good design and manufacture, supplemented by functional testing to demonstrate fitness for purpose at the start of life. This forms a keystone for demonstrating high reliability and benefits from design code requirements and plant operating experience to achieve a high quality of build and the avoidance of defects. The basis for these claims is established, as a minimum, through compliance with relevant sections of the ASME Code. As such, legs 1 and 2 share many common features with the justification of Standard Class 1 components described in section 20.6.2.

Since the ASME requirements are identified as a minimum standard for all aspects of the design and construction of HSS components, additional measures are specified within these legs that exceed the requirements prescribed in the ASME Code. These supplementary requirements cover aspects such as chemical composition, mechanical testing of materials and heat treatment of components, and are specified in the relevant CSRs. Each HSS CSR specifies that manufacturing inspections for the HSS locations will be qualified in accordance with the European Network for Inspection Qualification (ENIQ) methodology (Reference 20.6). These qualified manufacturing inspections are specified in support of defect tolerance claims for the HSS locations. A procedure has been outlined (Reference 20.7) for the qualification of manufacturing nondestructive testing (NDT) for application to UK AP1000 manufacturing inspections. It establishes the qualification strategy (procedures, equipment, personnel), defines the link to defect tolerance analyses, and specifies the requirement for an independent qualification body. This procedure will also be applied to HI components in situations where small tolerable manufacturing defects need to be defended using targeted qualified NDT inspections (see section 20.6.3).

20.6.4.2 Failure Analysis

Leg 3 of the safety argument substantiates a claim that the HSS components are tolerant to through-life degradation over the design life of the plant. The demonstration of defect tolerance is an especially important element of a structural integrity safety case for components requiring the demonstration of high reliability (i.e., HSS and HI locations) because it is defect tolerance combined with effective manufacturing inspections that explicitly supports the argument that such components enter service free of structurally significant defects.

For Class 1 locations, design, manufacture and inspection in accordance with established codes and standards is considered sufficient. For Class 1 locations, defect tolerance is demonstrated by an assessment of through-life crack growth to show that such mechanisms will not threaten integrity over a specific interval. This assessment is based on the linear elastic fracture mechanics approach to the demonstration of non-ductile failure prescribed in Appendix G of ASME Code, Section III.

The assessment performed for Class 1 locations is performed as the base level of defect tolerance for HSS and HI locations. For HSS and HI locations, the demonstration of defect tolerance goes beyond ASME Code requirements to provide a further demonstration of integrity by acknowledging that flaws (smaller than a QEDS) may be present and demonstrating tolerance to them. This additional assessment is performed in accordance with the elastic-plastic fracture mechanics procedures specified in R6, Revision 4 (Reference 20.18). The R6 methodology is an accepted best practice within the UK nuclear industry. The R6 methodology differs from established US practice; and provides a complimentary demonstration of both defect avoidance and defect tolerance.

Where the defect tolerance is shown to be high, such that there is a large margin between the allowable SoL defect size and the QEDS, the requirements for inspection qualification may be straightforward to demonstrate. However, where this margin is small, robust qualification measures, as discussed in Section 20.6.4.1, will be applied in accordance with the ENIQ methodology to provide the necessary confidence regarding the absence of such defects.

In combination with the use of rigorous manufacturing controls and inspection qualification, the defect tolerance assessment provides the necessary understanding to support the claim, to an appropriate degree of confidence, that the specified component will enter service free from defects that could be of concern throughout the component's designed life. These measures, which exceed the requirements of ASME, provide the key argument that supports the claim that the gross failure of the specified component can be discounted during its operational life.

There are two important aspects to the defect tolerance assessment. Firstly, from the determination of the limiting defect size in a particular orientation and location, it is possible to apply reverse fatigue crack growth laws to determine the maximum allowable SoL defect size. This value is necessary to inform the NDT designers and qualification body of the required maximum QEDS. In many circumstances, depending upon the examination geometry and materials, it will be possible to support a smaller QEDS, thus representing margin in the defect tolerance assessment. Therefore, once the QEDS has been established, the second step is to evaluate the margin against the allowable SoL defect size. As has been stated in Reference 20.19, the regulatory expectation is that a defect size margin (DSM) of 2 will be achieved.

Reference 20.8 provides details of the assessment methodology and specifies input parameters to be used in the R6 analysis. The calculation steps are summarised as follows:

- Using transient stress data, calculate the lifetime fatigue crack growth (LFCG), considering an initial crack size equal to an assumed QEDS.

- Calculate the end of life limiting defect size (ELLDS) using the R6 methodology. The R6 approach includes consideration of both brittle and ductile failure as well as limit load failure of the net cross section.

- Verify the criterion in Equation (1), shown below, for a DSM of 2 and adjust the target QEDS if required.

$$QEDS + LFCG \leq \frac{ELLDS}{DSM}$$

Equation (1)

Reference 20.8 also provides the materials data required for the analyses (including tensile properties, fracture toughness data and fatigue crack growth rates for the applicable materials) as well as the required inputs in terms of postulated flaws, crack sizes for which detection is highly reliable, stress intensity factor solutions, plastic limit load solutions, treatment of weld residual stresses and the selection of the limiting loading combination for the ELLDS calculation. The LFCG and ELLDS calculations are initially performed using the aspect ratios (crack length to depth ratio) as determined from assumed detectable crack sizes given in Reference 20.8. In cases where this initially assumed QEDS gives rise to a DSM of less than 2, a new (smaller) target QEDS is defined as an output of the damage tolerance assessment such that a DSM greater than or equal to 2 is obtained.

A final definition of QEDS is thus established and adopted as a performance requirement for inspection qualification. The results of the defect tolerance assessments and the technical justification for qualification of inspection capability are discussed in the relevant appendices to demonstrate that a DSM of at least 2 can be justified for all of the assessed HSS and HI welds.

Supplementary testing detailed in Reference 20.24, which is above and beyond that which is prescribed by ASME, will be performed to underpin the fracture toughness values used as input to the defect tolerance assessments.

The full implementation of the R6 methodology to all identified HSS and HI locations within the plant requires extensive analysis. Completion of this work was precluded by timescales for the production of the safety case documents to support the generic design assessment (GDA) submissions. Therefore a phased implementation was agreed with the UK Regulator, whereby, at the end of GDA, sufficient information has been made available to provide confidence that there are no HSS or HI locations where either low defect tolerance or low NDT inspectability would preclude the component from being able to satisfy regulatory expectations and support the safety case claims for the UK AP1000 plant.

The GDA evaluation focused on weld regions (and the associated heat affected zones) since it is at these locations where it is most likely a structurally significant defect may be present. In the longer term, vulnerable locations in the parent material, such as nozzle crotch corners, will be included in the R6 assessment. Their exclusion at this stage is on the basis that they are bounded by the weld locations, which have an increased propensity for manufacturing defects to be introduced and hence have more onerous inspection requirements. In the interim, design and manufacture in accordance with established standards provides assurance high quality is achieved through the forging process.

The phases of implementation to support the GDA are as follows:

Phase 1: Weld Defect Tolerance and NDT Ranking

To evaluate those locations with the greatest risk of entering service with a defect of structural significance, either as a result of small allowable SoL defect sizes or a large QEDS, a ranking exercise was undertaken. The weld ranking involved screening and review of analyses produced per the ASME Code to establish a ranking of the welds based on their defect tolerance (e.g. primary stresses, fracture stress intensities and fatigue usage factors). The combination of this ranking with the NDT inspectability ranking (Reference 20.20) determined the final ranking of the weld locations. The details of this evaluation and the rationale behind the selection of the limiting locations are reported Reference 20.21.

Phase 2: Assessment of Bounding Locations

Of the welds identified in Phase 1, a limited number of locations were selected for more detailed demonstration of defect tolerance to support the GDA. For each of the selected locations, the R6 defect assessment methodology was used to determine the limiting SoL defect size. This work provides evidence that established NDT techniques are capable of screening out defects of structural significance. Quantitative arguments are presented in each HSS component CSR to show that de-selected regions are bounded by the locations selected for detailed assessment.

Phase 3: Assessment of Remaining Locations

The full defect tolerance assessment of the remaining HSS locations, including the selected locations in the parent material, will be carried out in due course. Once completed, the R6 assessment work will provide assurance that the QEDS is based on a robust assessment of the maximum allowable SoL defect size with appropriate consideration of materials ageing and degradation and through life crack growth.

The results for each of these phases of the defect tolerance evaluation performed to support the GDA are discussed in the relevant CSRs.

20.6.4.3 Forewarning of Failure

The fourth leg of the HSS safety argument establishes that effective systems are in place to provide forewarning of failure. These systems confirm the absence of unanticipated degradation mechanisms and also that known degradation mechanisms do not significantly compromise structural integrity. This provides a means of safely controlling anticipated component degradation and a contingency arrangement against the unexpected. ISI represents the preferred method for providing forewarning of failure, and ISI of the HSS locations is specified to be qualified in accordance with the ENIQ methodology. Surveillance, leak detection, and periodic leak testing are secondary, defence in depth measures to provide diversity in the arrangements that forewarn of structural failure.

20.6.4.3.1 Qualified In-Service Inspection of HSS Components

Implementation of a qualified ISI programme is the primary defence against failures in high energy systems. The inspection programmes for HSS components are qualified in line with the ENIQ methodology. The role of an effective ISI programme is to confirm the absence of any unknown degradation mechanisms and to confirm the known degradation mechanisms are not significant to integrity or will have limited consequences. ISI is used to confirm the absence of defects that could eventually lead to failure when the maximum tolerable defect

size (as determined using fracture mechanics as described in Section 20.6.4.2) is combined with a conservative assessment of in-service defect growth throughout the inspection interval.

In order to be effective, ISI requirements are identified according to established good practice and are determined relevant to the characteristics of each component and each inspection location. For the HSS locations on each of the components identified in section 20.6.4, the associated CSR (Appendices 20A, 20B and 20C) details the qualified ISI for the HSS locations relative to that component.

20.6.4.3.2 Leak Detection

The reactor coolant pressure boundary (RCPB) is monitored for leaks from the reactor coolant and associated systems by a variety of components located in multiple systems. The leak detection systems provide information that will prompt plant operators to take corrective action if any detected leakage exceeds the limits and conditions of the technical specifications. The leak detection system design incorporates good practice outlined in US NRC Regulatory Guide 1.45 (Reference 20.13). The system provides a means to detect and, to a limited extent, identify the source of the RCPB leakage.

Diverse measures including level, flow, and radioactivity measurements are provided to detect and monitor leakage from the RCPB. Per the UK categorisation and classification methodology detailed in section 5.2, the leakage detection is a Category C safety function in that leakage detection components monitor for the occurrence of, and alert personnel to take mitigating action following, an internal hazard event (RCPB break or leak). However, the safety classification for each of the systems and components used for leak detection is generally determined by the highest level requirements and functions of the system in which it is located. Section 9.2.1.7 of Reference 20.1 provides detailed information on the leakage detection measures.

Limits which satisfy position 9 of Regulatory Guide 1.45 for identified and unidentified reactor coolant leakage are identified in the generic technical specifications (Reference 20.14). Limiting conditions of operation are established to address RCS leakage (LCO 3.4.7), main steam line leakage (LCO 3.7.8), and leak detection instrumentation availability (LCO 3.4.9). If these limits are exceeded the plant is required to promptly shutdown to prevent propagation of the leak.

20.7 CONCLUSIONS

CSRs for AP1000 plant components are presented in Appendices 20A to 20K. These provide safety arguments to establish that the structural reliability of each component is commensurate with the consequences of gross failure. The AP1000 plant components addressed in this chapter are identified in Section 20.2.

SFRs have been identified for the components. These are to be maintained to ensure plant nuclear and radiological safety. Assurance that the SFRs will be maintained over the lifetime of the component is provided by substantiating structural integrity against qualitative reliability targets. These targets are based on a procedure of structural integrity classification, as described in Section 20.5. The components addressed have been variously ascribed structural integrity classifications of HSS, HI, and Standard Class 1. The safety arguments presented in each appendix are structured according to the structural integrity classification, as described in Section 20.6. The format applied to each level of classification ensures that the safety argument presented is robust and appropriate for justification of structural reliability commensurate with the consequences of gross failure of a particular component.

In Appendices 20A to 20K, it is concluded that the safety arguments presented identify a suitable and sufficient diversity of evidence to substantiate the structural integrity claimed for the AP1000 components addressed. Detailed substantiation of these claims is provided in the individual CSRs.

Table 20-1. Component Integrity Safety Functional Requirements

Component	SFR	Description
Reactor vessel	20.1.1	The RV is required to provide the highest reliability pressure boundary to contain the primary coolant, heat-generating reactor core, and fuel fission products during normal and faulted design basis conditions for the design life of the plant.
	20.1.2	The RV is required to provide support for the reactor internals and core to ensure that the core remains in a coolable configuration.
	20.1.3	The RV is required to direct main coolant flow through the core by close interface with the reactor internals and flow skirt.
	20.1.4	The RV is required to provide for core internals location and alignment.
	20.1.5	The RV is required to provide support and alignment for the control rod drive mechanisms and in-core instrumentation assemblies.
	20.1.6	The RV is required to provide support and alignment for the integrated head assembly.
	20.1.7	The RV is required to provide an effective seal between the refuelling cavity and sump during refuelling operations.
	20.1.8	The RV is required to support and locate the main coolant loop piping.
	20.1.9	The RV is required to provide support for safety injection flow paths.
	20.1.10	The RV is required to serve as a heat exchanger during core meltdown scenario with water on the outside surface of the vessel.
Pressuriser	20.2.1	The pressuriser is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.2.2	The pressuriser is required to provide the point in the RCS where system pressure is controlled during steady-state operations and transients, to ensure that minimum pressure requirements associated with core coolant boiling and departure from nucleate boiling (DNB) limits are maintained.
	20.2.3	The pressuriser is required to provide the controlled volume from which the level of reactor coolant can be measured.
	20.2.4	The pressuriser is required to contain the water volume used to maintain RCS volume in the event of a minor system leak for a reasonable time without replenishment.

Table 20-1. Component Integrity Safety Functional Requirements (cont.)

Component	SFR	Description
Steam generator	20.3.1	The SG pressure boundary is required to maintain the integrity of the primary and secondary coolant boundaries during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.3.2	The SG secondary side is required to provide a heat sink for the RCS during power operations and anticipated transients and under natural circulation conditions in accordance with component performance requirements (not required to provide safe shutdown of the plant).
Primary pipework	20.4.1	The pipework is required to maintain the integrity of the RCP during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.4.2	The pipework is required to exhibit leak behaviour in the event of a through-wall defect developing (defence in depth).
MSL	20.5.1	The MSL is required to maintain the integrity of the secondary coolant pressure boundary during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.5.2	MSLs are required to exhibit leak behaviour in the event of a through-wall defect developing (defence in depth).
	20.5.3	The pipework in the vicinity of the containment penetrations is required to maintain the integrity of the secondary coolant pressure boundary during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.5.4	The pipework in the vicinity of the containment penetrations above DN 50 is required to exhibit leak behaviour in the event of a through-wall defect developing (defence in depth).
PRHR HX	20.6.1	The PRHR HX is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.6.2	The PRHR HX is required to remove core decay heat in accordance with the component performance requirements.
CMT	20.7.1	The CMT pressure boundary must remain intact during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.7.2	The CMT is required to store borated water under reactor coolant system pressure for high-pressure reactor coolant makeup in accordance with the component performance requirements.
	20.7.3	The CMT is required to deliver borated water to the RCS in the event of a loss-of-coolant accident (LOCA) or non-LOCA when the normal makeup system is unavailable or insufficient.

Table 20-1. Component Integrity Safety Functional Requirements (cont.)

Component	SFR	Description
Accumulator	20.8.1	The accumulator tanks' pressure boundary must remain intact during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.8.2	The two accumulators are required to store borated water and a compressed nitrogen cover gas to provide rapid injection of borated makeup water to the RCS in the event of a large LOCA.
	20.8.3	The accumulator tanks are required to deliver a large volume of borated water to the RV at a high flow rate in the event of a LOCA in accordance with the component performance requirements.
CV	20.9.1	The CV is required to provide a leaktight barrier against the uncontrolled release of radioactivity to the environment under postulated accident conditions for the design life of the plant to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require and to retain coolant inventory in the event of a LOCA.
	20.9.2	The CV is required, along with the shield building, to provide shielding for the reactor core and the reactor coolant system during normal operations.
	20.9.3	The CV is required to provide core residual heat removal during postulated accidents when active cooling is not available.
	20.9.4	The CV is required to act as a support for the polar crane at all times, including normal and faulted conditions, including seismic events.
RV internals	20.10.1	The RV internals are required to support, orient, and guide the core components, namely the in-core instrument thimble assembly (IITA), fuel assemblies, and rod cluster control assemblies (RCCAs) during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.10.2	The RV internals are required to direct the main coolant flow to and from the fuel assemblies and convey cooling water to the core for a postulated LOCA.
	20.10.3	The RV Internals are required to absorb control rod dynamic loads, fuel assembly loads, and other loads, and transmit these loads to the RV.
	20.10.4	The RV internals are required to provide protection for the RV against excessive irradiation exposure from the core.
	20.10.5	The RV internals are required to position and support RV irradiation capsule assemblies.
RCP casing	20.11.1	The RCP casing is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation, and under design basis faulted conditions for the design life of the plant.
	20.11.2	The RCP casing is required to retain missile fragments arising from a disruptive failure of the RCP flywheel without gross failure of the RCS pressure boundary.

Table 20-2. Component Structural Integrity Classification

Classification	Available Mitigation	Consequence
HSS	No protection	Severe damage to reactor core and large offsite release of radioactivity.
HI	At least one line of protection, without redundancy.	Severe damage to reactor core. Some protection against large offsite release. Limited release of radioactive material.
Standard Class 1 SSCs	At least one line of protection, with redundancy.	Localised fuel melt or damage to fuel. Minor release of radioactive material offsite. Release of significant quantities of radioactive material within nuclear island.
Standard Class 2 or 3 SSCs	At least two lines of protection, with diversity.	No core damage. Fault within capability of protection systems. Contamination within nuclear island.

Table 20-3. Detailed Assessment for Classification of the Reactor Vessel and Closure Head

Postulated Failure Modes	Disruptive failure of the RV, fragmentation of the pressure boundary, generation of missiles.

Introduction

The scope of the RV review included the assessment of the consequences arising from the failure of the RV body, including the nozzles and nozzle safe-ends, closure head, up to the CRDM penetration housing tubes and the bolting arrangements. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the RV and closure head. The review considered the direct consequences arising from gross failure of the RV pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems in the RV compartment, in adjacent compartments and within the CV.

Unmitigated Direct Failure Consequences

Gross failure of the RV has the potential to result in the most severe consequences, that is, severe core damage arising from disruption to core assembly, loss of coolant inventory, and loss of coolable core geometry. Other possible consequences include loss of core support or control rod alignment, or control rod withdrawal leading to potential reactivity addition.

Indirect Failure Consequences

The large energy release due to catastrophic RV failure could result in RV cavity structural damage and containment over-pressurisation.

The rupture of passive core cooling injection piping, delayed floodup and cooling of core would lead to increased core damage.

Missiles can cause consequential damage to:

i) RV sensors and core flux sensors.

ii) Possible containment damage and possible large offsite dose release.

Lines of Protection

There is no claimed protection against gross failure of the RV. Partial protection is provided by:

i) RV compartment and biological shield structure provides some protection against most missile damage.

ii) RV cavity is still flooded by coolant loss, and passive core cooling system (PXS) operation can restore core cooling even with failed lower RV.

iii) RV closure head bolts evaluated to show that single bolt failure does not cause RV/head separation.

Discussion

The direct consequences arising from a postulated gross failure of the RV are, in the worst case, assumed not to be protectable; it is, therefore, assumed that core damage would occur. The effects of postulated missiles and the overpressurisation of the CV introduce the possibility of large offsite release. In accordance with the methodology, an HSS classification has been assigned to gross failure of the RV.

While the RV compartment structure may withstand RV failure, promote long-term cooling of fuel, and protect against significant offsite release, this has not been analysed and consequently no credit has been claimed.

Table 20-4. Detailed Assessment for Classification of the SG Secondary Shell

Postulated Failure Modes	Disruptive failure of the SG secondary shell. Fragmentation of the pressure boundary, generation of missiles.
Introduction In applying the classification methodology to the SG, the secondary shell, channel head, and tube sheet were considered separately because of differences in the consequences of failure. The scope of the secondary shell review included the assessment of the consequences arising from the postulated failure of the secondary shell, including the steam and feedwater nozzles, up to but not including the pipe welds, and the manway. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the SG shell. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems in the SG compartment, in adjacent compartments and the CV.	
Unmitigated Direct Failure Consequences The gross failure of the SG secondary shell is a severe transient that is beyond the analysed main steam line break (MSLB) assumed within the design basis, and takes credit from the flow restrictor in the main steam nozzle. It is, therefore, assumed that the direct consequences could lead to violation of core thermal limits (core damage) and pressurisation of the containment above its design pressure.	
Indirect Failure Consequences Disruptive failure of the secondary shell could lead to consequential damage to tube bundle and so result in a large unisolable primary LOCA. The LOCA would be bounded by a double-ended guillotine break (DEGB) of the primary loop, which is protectable, but a simultaneous secondary and primary break in the containment is beyond the design basis and is, therefore, assumed to be unprotectable. The high-energy release rate or generation of high-energy missiles from shell fragments introduces the possibility for a loss of containment integrity, resulting in a release of activity outside containment. Damage to containment would not prevent the passive protection systems from core cooling but the release rate from loss of containment integrity would be increased.	
Lines of Protection Large LOCA protection is provided by passive protection systems. SG compartment provides significant protection against missiles generated within the SG compartment, although it is recognised that this barrier does not extend to the full height of the SG steam drum. It is conservatively assumed that no mitigation exists.	
Discussion A gross failure of the SG shell is outside the AP1000 design basis and so has conservatively been assumed not to be protectable. The high-energy release rate and associated containment demand and direct pathway for missiles to impact the CV means that containment integrity cannot be ensured, introducing the possibility of large offsite release. In accordance with the methodology, gross failure of the SG secondary shell has been classified as HSS.	

Table 20-5. Detailed Assessment for Classification of the SG Channel Head

Postulated Failure Modes	Disruptive failure of the SG channel head. Fragmentation of the pressure boundary, generation of missiles.
Introduction The scope of the SG channel head review included the assessment of the consequences arising from the postulated failure of the channel head pressure boundary, including the inlet and outlet nozzles (including safe ends/buttering). The inlet nozzle safe end to pipe weld was outside the scope of the assessment, but the outlet nozzle to RCP weld was considered as part of this review. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the SG channel head. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems in the SG compartment, in adjacent compartments and the CV.	
Unmitigated Direct Failure Consequences Gross failure of the channel head would result in a large unisolable LOCA. This would be bounded by a DEGB of the primary loop, included within the large break LOCA safety analysis (section 9.6.4), which includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The failure described here would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.	

Table 20-5. Detailed Assessment for Classification of the SG Channel Head (cont.)

Indirect Failure Consequences

Loss of SG Support

A disruptive failure of the channel head could cause the SG support to fail, leading to collapse of the SG onto the RCPs. This event has not been analysed and so has conservatively been assumed to lead to a simultaneous steam line break with possible pressurisation of the containment above its design pressure.

Missiles

The postulated initiating event assumes that the channel head will fail in a disruptive manner, leading to the generation of energetic missiles. The channel head is located at the lower end of the SG, down low in the SG compartment. These compartments are constructed of thick steel/concrete/steel modules. Although the resulting missiles would be more energetic than those analysed in the AP1000 design basis (section 16.7.5.3), judgementally, it is considered that the module walls would act as a barrier, preventing energetic missiles from escaping outside the boundary of the compartment and so threatening containment integrity. It is recognised that the SG compartment is open to the containment volume at its upper end; however, given the location of the channel head, the potential for an energetic fragment to travel up the space between the SG secondary shell and the SG compartment wall was considered so low as to be discounted.

Blast/Jet Loading/Compartment and Containment Pressurisation

A disruptive failure of the channel head would result in jet loading from blowdown of the RCS and internal pressurisation of the SG compartment. A disruptive failure of the channel head would be beyond the design basis in terms of jet loading and compartment pressurisation. Nonetheless, on a best-estimate basis, it is judged that this failure would not lead to the most severe offsite consequences. The containment integrity analysis considers, as its design basis, the complete double-ended severance of the largest RCS pipe (Section 9D) and hence containment integrity would not be challenged by this postulated break.

Pipe Whip

Disruptive failure of the channel head would result in a loss of support to the hot leg and RCP in the casualty loop. An evaluation of the dynamic effects of a guillotine break in this location has not yet been performed. Best-estimate judgment is that the shield wall between the RV and SG compartments would provide support for the cold leg and that, due to the short distance between the wall and the SG, pipe whip is unlikely. In the absence of a deterministic assessment to support this, the effects of pipe whip hinging at the compartment wall were evaluated using the 3-D model. Based on this, it was concluded that further escalation of the consequences as a result of pipe whip would not occur.

Flooding/Spray

Flooding of the SG compartment is within the design basis.

Lines of Protection

Large LOCA protection is provided by passive protection systems.

SG compartment provides significant protection against missiles generated within the SG compartment.

Table 20-5. Detailed Assessment for Classification of the SG Channel Head (cont.)

Discussion
The direct consequences arising from a gross failure of the SG channel head is within the AP1000 plant design basis and would, therefore, be considered protectable. Furthermore, the indirect consequences arising from missiles or pipe whip have been assessed and discounted as not being credible. However, due to a lack of evidence to evaluate the effect of the postulated channel head failure on the integrity of the SG support column (attached to the channel head), it has conservatively been assumed that this would lead to intolerable consequences. In accordance with the methodology, gross failure of the SG channel head (including the SG-to-RCP weld) has been classified as HSS.

Table 20-6. Detailed Assessment for Classification of the SG Tube Sheet

Postulated Failure Modes	Disruptive failure of the SG tube sheet. Fragmentation of the primary to secondary pressure boundary, generation of missiles.

Introduction

As the boundary between the primary and secondary systems, the consequences arising from a postulated gross failure of the tube sheet are specific to this failure mode. As a result, the tube sheet was assessed separately. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the tube sheet. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of overpressurisation of the secondary shell or the effects of resulting missiles on the operability of essential safety systems in the SG compartment, in adjacent compartments and the CV.

Unmitigated Direct Failure Consequences

The direct consequences arising from gross failure of the tube sheet would lead to a large primary to secondary LOCA, the direct consequences of which would be bounded by a DEGB of the primary loop, included in the large-break LOCA safety analysis for the AP1000 plant (section 9.6.4). This includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The LOCA analyses consider the limiting single failure. The direct consequences of the primary to secondary LOCA would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.

Indirect Failure Consequences

The review of the indirect consequences identified that the tube sheet failure and associated primary to secondary leak would open and may lead to a stuck-open SG safety valve(s) and result in direct release of primary coolant into the containment. Furthermore, a large tube sheet failure could damage or fail the secondary side pressure boundary, resulting in a simultaneous primary and secondary break, an unanalysed and beyond design basis transient. In the absence of a more detailed analysis, it has been conservatively assumed that the resulting containment overpressurisation and/or high-energy missile generation from failure of the SG shell could result in damage or loss of containment boundary. Damage to containment would not prevent the passive safety systems from providing core cooling but the rate of release of radioactivity due to loss of containment integrity would be increased.

Lines of Protection

Large primary to secondary LOCA protection is provided by passive protection systems.

SG compartment provides significant protection against missiles. Missile protection is provided for lower portion of the secondary shell only.

Discussion

The direct consequences arising from a gross failure of the SG tube sheet is within the AP1000 design basis and is, therefore, protectable; however, a large primary to secondary LOCA could fail the secondary side pressure boundary leading to a simultaneous primary and secondary break, an unanalysed transient, conservatively assumed to lead to core damage and overpressurisation of the containment with possible offsite release. In accordance with the methodology, a HSS classification has therefore been assigned to gross failure of the SG tube sheet.

Table 20-7. Detailed Assessment for Classification of the Pressuriser

Postulated Failure Modes	Disruptive failure of the pressuriser. Fragmentation of the pressure boundary, generation of missiles.
Introduction The scope of the pressuriser review included the assessment of the consequences arising from the postulated failure of the pressuriser shell and nozzles, up to but not including the safe end to pipe welds. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the pressuriser. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems in the pressuriser compartment, in adjacent compartments and the CV.	
Unmitigated Direct Failure Consequences A postulated gross failure of the pressuriser would result in an unisolable large LOCA. The leak rate would be limited by surge line diameter, and is included within the large-break LOCA safety analysis (section 9.6.4), which includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The analysis includes consideration of the limiting single failure. The direct consequences of the pressuriser failure would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.	

Table 20-7. Detailed Assessment for Classification of the Pressuriser (cont.)

Indirect Failure Consequences

Missiles

It is conservatively assumed that the pressuriser shell fails in a disruptive manner, leading to the generation of energetic missiles. The pressuriser is located in the pressuriser upper and lower compartments, constructed of thick steel/concrete/steel modules. Although the resulting missiles would be more energetic than those analysed within the AP1000 design basis (section 16.7.5.3), judgementally it is considered that the module walls would act as a barrier, preventing energetic missiles from escaping outside the boundary of the compartment and so threatening containment integrity or the operability of essential safety systems in adjacent compartments. It is recognised, however, that the pressuriser compartment is open at the top and so high-energy missile generation could impact and damage the containment shell. Damage to containment would not prevent the passive safety systems from core cooling but the release rate due to loss of containment integrity would be increased.

Blast/Jet Loading/Compartment & Containment Pressurisation

A disruptive failure of the pressuriser would result in jet loading and internal pressurisation of the pressuriser upper and lower compartments. Failure of the pressuriser within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves (Reference 20.23). A disruptive failure of the pressuriser would, therefore, be beyond the design basis in terms of jet loading and compartment pressurisation. Nonetheless, on a best-estimate basis, it is judged that this indirect failure mode would not lead to the most severe offsite consequences. The containment integrity analysis considers the complete double-ended severance of the largest RCS pipe (Section 9D) and hence containment integrity would not be challenged by this postulated break.

Pipe Whip

Disruptive failure of the pressuriser would result in a loss of support to the surge line. The pipe whip effects of a surge line failure were judged in Table 17 of Reference 20.23 to be consistent with those of a reactor coolant loop pipe impacting the module wall. Pipe whip resulting from a reactor coolant line break has been determined to not result in unacceptable consequences. As such, it is concluded that further escalation of the consequences as a result of a surge line pipe whip would not occur.

Flooding/Spray

Flooding of the pressuriser compartment is within the design basis.

Lines of Protection

Direct consequences of a pressuriser LOCA are mitigated by passive protection systems.

The pressuriser is mostly located within its own structural compartment, which would absorb a significant proportion of the energy and missiles that could affect other systems.

Discussion

The direct consequences arising from a gross failure of the pressuriser is within the AP1000 design basis and is therefore protectable. Although the pressuriser is mostly located within its own structural compartment, which would absorb a significant proportion of the energy and missiles that could affect other safety systems, the pressuriser compartment is open at the top and hence a postulated circumferential failure of the shell could result in ejection of the pressuriser fragments from the compartment, which could challenge containment. Under such circumstances, it has been conservatively assumed that the effectiveness of core cooling could be degraded, leading to core damage and offsite release. In accordance with the methodology, gross failure of the pressuriser has been classified as HSS.

Table 20-8. Detailed Assessment for Classification of the RCP

Postulated Failure Modes	Disruptive failure of the RCP casing pressure boundary resulting in fragmentation of the casing. Disruptive failure of the flywheel leading to the generation of high-energy missile fragments.
Introduction The scope of the RCP review includes the failure of the RCP pressure boundary and the rotating parts of the RCP internals, including the flywheel. Failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the RCP casing and flywheel. The welds connecting the RCP to the loop pipework and the RCP to SG channel head welds were not considered as part of this review as they are considered part of the pipework and SG assessment respectively. The review considered the direct consequences arising from gross failure of the RCP casing pressure boundary, and the effect of missiles on the operability of essential safety systems in the SG compartment and in adjacent compartments.	
Unmitigated Direct Failure Consequences The direct consequences arising from gross failure of the RCP casing will be bounded by a DEGB of the cold leg and is included within the large-break LOCA safety analysis (section 9.6.4) for the AP1000 plant, which includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The analysis has been performed using the WCOBRA/TRAC code, a best-estimate thermal-hydraulic computer code used to calculate realistic fluid conditions in the PWR during blowdown and reflood of postulated large-break LOCAs. The direct consequences of the RCP failure would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1. The design specification for the RCP (Reference 20.9, Section 3.2.4.2) requires demonstration that the pump casing can contain fragments arising from disintegration of the RCP flywheel. A scoping assessment to substantiate this claim is presented in Reference 20.10. Appendix 20F presents the structured argument supporting the integrity of the RCP and cites the relevant evidentiary documentation.	

Table 20-8. Detailed Assessment for Classification of the RCP (cont.)

Indirect Failure Consequences

Missiles

The postulated initiating event assumes that the pump casing will fail in a disruptive manner, leading to the generation of energetic missiles. In reviewing the indirect consequences of this failure mode, the potential for indirect effects to lead to more severe consequences were considered, in this case, leading to intolerable offsite consequences (i.e., resulting in a possible HSS classification). RCPs are located directly beneath the SGs within the SG compartments. These compartments are constructed of thick steel/concrete/steel modules. Although the resulting missiles would be more energetic that those analysed within the AP1000 design basis (section 16.7.5.3), judgementally it is considered that the module walls would act as a barrier, preventing energetic missiles from escaping outside the boundary of the compartment and so threatening containment integrity. It is recognised that the SG compartment is open to the containment volume at its upper level; however, given the location of the pumps, the potential for an energetic fragment to travel up the space between the SG compartment and the SG was considered so low as to be discounted. Consideration was given to the potential for missile fragments from the RCP casing to lead to a disruptive failure of the SG channel head or secondary shell, which would in itself attract a HSS classification. Although no impact analysis has been presented relating to the impact on the channel head, the consequences of this would be bounded by the guillotine break of the loop. A missile penetrating the tube sheet (784 mm / 30.9 in) was discounted as incredible. The assumption of two consecutive disruptive failures, the second of which is postulated to breach the containment boundary, is considered out with the methodology and hence was dismissed.

Consideration was also given to the possibility that a missile from the RCP casing would lead to failure of the SG support. Analysis has been performed which demonstrates that core cooling would be maintained in the unlikely event that the vertical support should fail (Reference 20.26).

Blast/Jet Loading/Compartment and Containment Pressurisation

A disruptive failure of the RCP would result in jet loading from blowdown of the RCS and internal pressurisation of the SG compartment. Failure of the RCP within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves (Reference 20.23). A disruptive failure of the RCP would, therefore, be beyond the design basis in terms of jet loading and compartment pressurisation. Nonetheless, on a best-estimate basis, it is judged that this failure would not undermine the operability of the passive protection systems so meriting a higher classification. The containment integrity analysis considers, as its design basis, the complete double-ended severance of the largest RCS pipe (Section 9D), and hence containment integrity would not be challenged by this postulated break.

Pipe Whip

Disruptive failure of the RCP casing would result in a loss of support to the cold leg in the casualty loop. Reference 20.23 concludes that pipe whip of the cold leg does not propagate a failure to other systems, does not result in unacceptable loading conditions on claimed barrier and does not adversely affect the required safety functions for mitigation of the postulated failure. Based on this, it was concluded that further escalation of the consequences as a result of pipe whip would not occur.

Flooding/Spray

Flooding of the SG compartment is within the design basis.

Core Depressurization Forces

The core depressurization forces resulting from a gross failure of the RCP case would be less limiting those resulting from a gross failure of a cold leg. A detailed evaluation of the gross failure of a cold leg (Reference 20.25) has demonstrated that grid crush may occur in low power peripheral assemblies, however, the core geometry would remain coolable. As a result, significant core damage is not expected.

Table 20-8. Detailed Assessment for Classification of the RCP (cont.)

Lines of Protection i) The RCP casing provides protection against missiles arising from RCP internals. ii) The SG compartment structure will prevent missiles damaging the containment. iii) The containment structure will remain intact and prevent large offsite release.
Discussion The direct consequences arising from a postulated gross failure of the RCP would be bounded by a DEGB break of the cold leg. This postulated fault is within the design basis and it has, therefore, been concluded that this would not lead to severe core damage. Consideration of indirect consequences concludes that there were no effects that could escalate the consequences leading to core damage or offsite release. According to the methodology, a Standard Class 1 classification has been assigned to the RCP casing. Failure of the flywheel is also within the design basis and so has also been assigned a Standard Class 1 classification.

Table 20-9. Detailed Assessment for Classification of the Reactor Coolant Loop Hot and Cold Legs (RV Safe End to Loop Welds)

Postulated Failure Modes	Guillotine break of a primary loop hot or cold leg to RV safe end weld.

Introduction

The review considered a postulated guillotine break occurring at the weld between the RV nozzle safe ends and the attached hot and cold leg primary loop pipework. The assessment assumes a DEGB of the pipe and also considers the risk from pipe whip, flooding, and pressurisation of the RV compartment.

Unmitigated Direct Failure Consequences

Guillotine failure of the primary loop pipework is included within the AP1000 design basis and can be protected by the passive safety systems without significant fuel damage or containment overpressurisation. The failure would result in a large unisolable LOCA. The large-break LOCA safety analysis for the AP1000 plant (section 9.6.4) includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The analysis has been performed using the WCOBRA/TRAC code, a best-estimate thermal-hydraulic computer code used to calculate realistic fluid conditions in the PWR during blowdown and reflood of a postulated large-break LOCA. This analysis includes the effects of a rapid depressurisation of the primary loop. The postulated failure described here would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.

Indirect Failure Consequences

The indirect failure consequences associated with RCS coolant loop failure in the RPV nozzle area is the subject of Case 1 presented in Section C.5 of Reference 20.23. Below is a summary of the conclusions presented relative to pipe whip, jet impingement, asymmetric pressurisation and subcompartment pressurisation.

Therein it is determined that pipe whip of the cold leg does not propagate a failure to other systems, does not result in unacceptable loading conditions on claimed barrier and does not adversely affect the required safety functions for mitigation of the postulated failure. The effects of asymmetric pressurisation were included in the evaluation of the loading conditions.

With respect to jet impingement, the RV supports are expected to exceed minimum elastic stress allowable limits but remain functional as a result of the failure; i.e., minor deformation will likely occur. Additionally, the RV and the remainder of the RCS are adequately restrained and remain intact. The direct vessel injection (DVI) lines are susceptible to high stresses outside of Room 11205; however, their injection ability is not compromised using conservative linear modelling techniques. Therefore, it was concluded that jet impingement following a failure of the RCS cold leg will not adversely affect the plant safety case as the post-failure RCS conditions and Class 1 injection capability is retained.

The gross failure of a RCS cold leg will result in significant pressurisation of Room 11205 which is expected to challenge the availability and operation of Class 1 SSCs; however, the consequential failure of these SSCs is consistent with the plant safety case and the analysis of the direct effects of a large break LOCA event.

The containment integrity analysis considers the complete double-ended severance of the largest RCS pipe (Section 9D), and hence containment integrity would not be challenged by this postulated break.

Depressurisation of the reactor vessel coupled with thrust from the pipe break and asymmetric reactor cavity pressurisation hold the potential to damage the fuel. A detailed evaluation of the scenario (Reference 20.25) has demonstrated that grid crush may occur in low power peripheral assemblies, however, the core geometry would remain coolable. As a result, significant core damage is not expected.

Table 20-9. Detailed Assessment for Classification of the Reactor Coolant Loop Hot and Cold Legs (RV Safe End to Loop Welds) (cont.)

Lines of Protection i) Passive core and containment cooling systems. ii) Biological shield wall offering restraint against pipe whip. iii) Minimisation of number of welds.
Discussion A guillotine failure of the primary loop piping is included within the design basis and can be protected by the passive safety systems. A deterministic evaluation of this transient has been undertaken to substantiate this. In relation to the indirect consequences such as pipe whip, missile, blast, and compartment, a deterministic evaluation of the dynamic effects arising from a guillotine break of the large bore pipework has also been undertaken. Based on consideration of the anticipated effects of a postulated pipe break, it has been concluded that significant core damage is not anticipated. In accordance with the methodology, the welds joining the RV safe ends to the primary loop have been classified as **Standard Class 1**.

Table 20-10. Detailed Assessment for Classification of the Reactor Coolant Loop Hot and Cold Legs (Loop to SG/RCP Welds)

Postulated Failure Modes	Guillotine break of a primary loop hot leg to SG channel head or cold leg to RCP weld.

Introduction

The review considered a postulated guillotine break occurring at the weld between the SG channel head nozzle safe ends and the attached primary loop hot leg pipe work and the RCP to primary loop cold leg welds. The assessment assumes a DEGB of the pipe and also considers the risk from pipe whip, flooding, and pressurisation of the SG compartment.

Unmitigated Direct Failure Consequences

Guillotine failure of the primary loop pipework is included within the AP1000 design basis and can be protected by the passive safety systems without significant fuel damage or containment overpressurisation. The failure would result in a large unisolable LOCA. The large-break LOCA safety analysis for the AP1000 plant (section 9.6.4) includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The analysis has been performed using the WCOBRA/TRAC code, a best-estimate thermal-hydraulic computer code used to calculate realistic fluid conditions in the PWR during blowdown and reflood of postulated large-break LOCAs. This analysis includes the effects of a rapid depressurisation of the primary loop. The postulated failure described here would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.

Indirect Failure Consequences

The indirect failure consequences associated with RCS coolant loop failure at the SG/RCP are enveloped by the consequences associated with a failure occurring at the RPV nozzles as indicated in Table 17 of Reference 20.23. Additionally, based on the expert review undertaken in support of SI classification the following conclusions were reached.

The potential for pipe whip to occur from a failure at the SG/RCP side of the hot and cold legs is considered low, limited by the relatively short lengths of pipe available to whip due to the small distances between the RV compartment outer wall and the SG. In the absence of a deterministic pipe whip assessment, however, pipe whip was conservatively assumed to occur with a hinge occurring at the penetration through the RV compartment wall. The consequences were assessed using the AP1000 plant 3-D model. The steel/concrete/steel construct of the module wall was considered to provide protection from dynamic effects to essential systems outside the compartment. The only aspect of the PXS in the SG compartment was identified as the PXS sump screens in the east compartment. A more detailed evaluation of this concluded that downward whip of east hot leg would be limited by interference between the bottom-mounted RCS to normal residual heat removal system (RNS) suction nozzle and pipe (DN 500 (nominal pipe size (NPS)) 20) and the RV compartment wall. This is judged to prevent impact damage to the PXS sump screens.

Whip impingement on the SG support column was not considered credible because of its position relative to the RCPs.

The core depressurization forces resulting from a gross failure of a hot or cold leg at the SG/RCP would be less limiting than those resulting from a gross failure of a cold leg at the reactor vessel. A detailed evaluation of the gross failure of a cold leg (Reference 20.25) has demonstrated that grid crush may occur in low power peripheral assemblies, however, the core geometry would remain coolable. As a result, significant core damage is not expected.

Table 20-10. Detailed Assessment for Classification of the Reactor Coolant Loop Hot and Cold Legs (Loop to SG/RCP Welds) (cont.)

Lines of Protection i) Passive core and containment cooling systems. ii) Biological shield wall offering restraint against pipe whip. iii) Minimisation of number of welds.
Discussion A guillotine failure of the primary loop piping is included within the design basis and can be protected by the passive safety systems. A deterministic evaluation of this transient has been undertaken to substantiate this. In relation to the indirect consequences such as pipe whip, missile, blast, and compartment, an equivalent deterministic evaluation of the dynamic effects arising from a guillotine break of the large bore pipework has not been undertaken since the consequences are anticipated to be enveloped by those of a failure of a reactor coolant line at the RPV. Based on consideration of the anticipated effects of a postulated pipe break, it was concluded that pipe whip, although unlikely, cannot be dismissed. Considering the effects of whip in more detail using the 3-D model, however, it was concluded that whip would not compromise the effectiveness of passive protection systems and hence core damage would be mitigated. Best judgment was that the thick module walls would prevent consequential effects outside the casualty SG compartment. In accordance with the methodology, the welds joining the primary loop hot and cold legs to the RCP and SG channel head have been evaluated as Standard Class 1.

Table 20-11. Detailed Assessment for Classification of the CMT

Postulated Failure Modes	Disruptive failure of the CMT. Fragmentation of the pressure boundary, generation of missiles.

Introduction

The scope of the CMT review included the assessment of the consequences arising from the postulated gross failure of the CMT pressure boundary, including the inlet and outlet nozzles. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the CMT. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems adjacent to the CMTs and the CV.

Unmitigated Direct Failure Consequences

The CMT is not isolated during normal operation and is at loop pressure but ambient temperature. The LOCA caused by a gross failure of a CMT is limited by the cold leg balance line. This LOCA is analysed and shown not to lead to core damage and is within the design basis. Loss of a CMT is bounded by the postulated failure of either of the DVI lines, which is included within the AP1000 design basis and can be protected by the passive safety systems. Section 9.6.5 describes the small-break LOCA analyses, including the DVI line break. The small-break LOCA analyses show that the performance of the AP1000 plant design in small-break LOCA scenarios is excellent and that the passive safeguards systems in the AP1000 design are sufficient to mitigate LOCAs. The analyses demonstrate that cladding temperatures will remain near the coolant saturation temperature, well below the peak cladding temperature acceptance criterion in section 9.6.5.0.

The isolation for a failed CMT does not have single-failure protection and so the LOCA is assumed to be unisolable but the break is small enough to prevent the core from becoming uncovered.

Indirect Failure Consequences

Missiles/Blast

Failure of the CMT within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves (Reference 20.23). It is conservatively assumed that the CMT shell fails in a disruptive manner, leading to the generation of missiles. Such a failure is outside the AP1000 design basis and so the consequences of missile damage have not been analysed using deterministic approaches. The best judgment is that the energy of these missiles will be limited by the low temperature of the makeup tank inventory. Nonetheless, because of the proximity of the CMTs to the CV, along with their size and operating pressure, it is conservatively assumed that damage to the containment could occur. On the basis of best-estimate analyses performed in support of the probabilistic safety assessment (PSA) (Reference 20.11, Chapter 4), damage to containment (i.e., failure to achieve containment isolation) would not prevent the passive protection systems from maintaining core cooling but release rate due to loss of containment integrity would be increased.

The potential for missile damage to Category 1 control and instrumentation (C&I) cables was also identified; however, it was concluded that this damage would not prevent the redundant train of affected safety system equipment from operating properly.

Table 20-11. Detailed Assessment for Classification of the CMT (cont.)

Lines of Protection The LOCA caused by gross failure of the PXS CMT is bounded by the more limiting DVI line failure, which has been analysed and shown not to lead to core damage. Containment cooling with damaged containment has been analysed and results show that CV pressure is reduced to and maintained near atmospheric pressure. Also, CMT failure cannot impact the containment below elevation 102.1 m (107 ft), thus, the mass loss from CV does not deplete the water inventory inside containment quickly.
Discussion A disruptive failure of the CMT would result in a LOCA limited in diameter to the DN 200 (NPS 8) cold leg balance line. This failure is bounded by the DVI line break and so can be protected by the passive safety systems. A deterministic evaluation of this transient has been undertaken to substantiate this. A disruptive failure of a CMT is not considered as part of the AP1000 design approach and hence there has been no deterministic evaluation of the effects of missiles. Because of the proximity of the CMT to the CV, it has been conservatively assumed that damage to the containment could occur. On the basis of best-estimate analyses performed in support of the PSA (Reference 20.11, Chapter 4), damage to containment would not prevent the passive protection systems from maintaining core cooling. In accordance with the methodology, the CMT has been evaluated as Standard Class 1.

Table 20-12. Detailed Assessment for Classification of the Accumulator

Postulated Failure Modes	Disruptive failure of the Accumulator. Fragmentation of the pressure boundary, generation of missiles.

Introduction

The accumulators contain cold borated water with a 4.83 MPa (700 psig) nitrogen overpressure injected into the RV through the DVI nozzles in the event of falling loop pressure. The scope of the accumulator review included the assessment of the consequences arising from the postulated gross failure of the accumulator pressure boundary. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the accumulator. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems within the accumulator compartments and in adjacent compartments.

Unmitigated Direct Failure Consequences

Gross failure of the accumulator will not lead to LOCA due to the check valves on injection line. Isolation is achieved through two tilt disk-type check valves that will close quickly in the event of reverse flow. Nonetheless, if these valves failed to shut or were damaged by the accumulator failure, the LOCA would be bounded by the postulated failure of either of the DVI lines, which is included within the AP1000 design basis and can be protected by the passive safety systems. Section 9.6.5 describes the small-break LOCA analyses, including the DVI line break. The small-break LOCA analyses show that the performance of the AP1000 plant design to small-break LOCA scenarios is excellent and that the passive safeguards systems in the AP1000 plant are sufficient to mitigate LOCAs. The analyses demonstrate that cladding temperatures will remain near the coolant saturation temperature, well below the peak cladding temperature acceptance criterion in section 9.6.5.0.

Indirect Failure Consequences

Missiles/Blast

Failure of the accumulator within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves (Reference 20.23). It is conservatively assumed that the accumulator shell fails in a disruptive manner, leading to the generation of missiles. Such a failure is outside the AP1000 design basis and so the consequences of missile damage have not been analysed using deterministic approaches. The best judgment is that the resulting energy of these missiles will be restricted by the low temperature of the makeup inventory (ambient) and comparably low overpressure of 4.38 MPa (700 psig). On the basis of expert judgment, it is considered that the steel/concrete/steel structures of the accumulator compartment (wall thickness between 76 and 137 cm (30 and 54 inches) and floor thickness of 61 cm (24 inches)) would prevent missile and blast damage to essential safety systems in adjacent compartments. This judgement is based on a deterministic evaluation of the missile withstand for the nuclear island structures. The compartment walls surrounding the accumulator are structurally similar in design to the nuclear island for which deterministic impact analysis is completed. Failure may lead to damage of other passive core cooling components within the accumulator compartment but will not affect the redundant train of the PXS.

A review of 3-D models confirms that failure of the accumulator would not lead to missile damage to the hot leg to RNS suction line and isolation valves in the adjacent area.

Table 20-12. Detailed Assessment for Classification of the Accumulator (cont.)

Lines of Protection The accumulators are isolated from the RCS by two series check valves. The accumulators are situated within protected compartments that would contain this energy and would not lead to consequential damage to the containment, RCS components, or redundant train PXS components. Failure is within the plant design basis.
Discussion The LOCA resulting from a failure of an accumulator would be expected to be isolated by virtue of the two flap-type check valves. In the event that these are made ineffective by the initiating failure, the resulting LOCA would be bounded by the DVI line break and so be protected by the passive safety systems. A deterministic evaluation of the DVI line break substantiated the claim such breaks would be protected by the passive safety systems (section 9.6.5). A disruptive failure of an accumulator is not considered as part of the AP1000 design approach and hence there has been no deterministic evaluation of the effects of missiles; however, the accumulators are located within their own compartments and judgmentally, it is believed that the steel/concrete/steel module walls would prevent secondary damage to essential systems in adjacent compartments and to the CV. A review of the 3-D model were undertaken to identify potentially vulnerable systems and none were identified. In accordance with the methodology, the accumulator has been evaluated as Standard Class 1.

Table 20-13. Detailed Assessment for Classification of the PRHR HX

Postulated Failure Modes	Gross failure of the headers or tube assembly.
Introduction The PRHR HX provides core residual heat removal during postulated non-LOCA events where SG heat removal is not available or is insufficient. The component consists of an HX and inlet and outlet lines connected to the RCS. The systems is normally pressurised at loop pressure. The scope of the PRHR HX review included the assessment of the consequences arising from the postulated gross failure of the pressure boundary, including the inlet and outlet channel headers and the tube assembly. Postulated failure modes were conservatively assumed to be disruptive, i.e., no credit has been given to the inherent ductility of the materials used in the manufacture of the PRHR HX tubes or headers. The review considered the direct consequences arising from gross failure of the pressure boundary, as well as the indirect effects, such as the effect of missiles on the operability of essential safety systems within the in-containment refuelling water storage tank (IRWST) and in adjacent spaces.	
Unmitigated Direct Failure Consequences The direct consequences of failure of the PRHR HX will be equivalent to the guillotine failure of one of the PRHR HX lines. This is included within the AP1000 design basis and can be protected by the passive safety systems. Although the failure would be isolable, it is assumed that isolation cannot be achieved since there is no single-failure protection. This LOCA would be bounded by a DEGB of the primary loop, included within the AP1000 large-break LOCA safety analysis (section 9.6.4), which includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The failure described here would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1. It should be noted that the loss of the decay heat removal function is not a concern in the case of the large LOCA where rejection of heat is achieved through the LOCA itself rather than via the PRHR HX.	
Indirect Failure Consequences Failure of the PRHR HX within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves (Reference 20.23). Additionally, risk of consequential damage due to a failure of the PRHR HX tubing is considered to be small because of the location of the HX in the IRWST. As discussed in Table 20-21, an evaluation of indirect consequences resulting from the failure of a PRHR return line has concluded that failure of the PRHR HX outlet plenum is not anticipated. This event is discussed further in Section 20G.3.2.	
Lines of Protection i) PXS and PCS ii) The passive safety injection system would not be damaged as a result of a PRHR failure.	
Discussion A gross failure of the PRHR HX is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been evaluated and it is considered that these would not be significant because of the submerged position of the HX. In accordance with the methodology, the PRHR HX has been evaluated as Standard Class 1.	

Table 20-14. Detailed Assessment for Classification of the RV Lower Internals Core Barrel and Lower Core Support Plate (Core Support Structure)

Postulated Failure Modes	Circumferential failure of a core barrel weld.

Introduction

The RV internals (RVI) provide the appropriate guidance, protection, alignment, and support for the core and control rods to enable safe and reliable reactor operation. Although the RVI do not have a pressure boundary function, the review considered the potential effects arising from failure of any of the major welds, in this case on the core barrel or barrel flange, and the potential for vertical displacement of the RVI and the subsequent implications in terms of control of reactivity or maintaining core cooling.

Unmitigated Direct Failure Consequences

Failure of core barrel weld would result in the downward displacement of the core and core support plate. Through the radial clevis supports and the secondary core support structure (designed to mitigate a postulated core drop event), however, this vertical displacement would be limited and as such would not lead to an intolerable increase in reactivity or loss of coolant flow. A hypothetical core drop accident has been analysed to ensure that engagement of the fuel alignment pins and control rods is maintained, and impact load to the RV is minimised. Details of this analysis are provided in Appendix 20A. The criteria for the postulated core drop accident are based on analyses that determine the total downward displacement of the internal structures, following a hypothetical core drop resulting from loss of the normal core barrel supports. The initial clearance between the secondary core support structures and the RV lower head in the hot condition is approximately 1.27 cm (0.5 inch).
An additional displacement of approximately 1.52 cm (0.6 inch) would occur from the strain of the energy-absorbing devices of the secondary core support. Therefore, the total drop distance is about 2.79 cm (1.1 inches). That distance is less than the distance that permits the tips of the RCCA to come out of the guide thimble in the fuel assemblies. The secondary core support is only required to function during an accident involving the hypothetical catastrophic failure of core support (such as core barrel or barrel flange). There are four supports in each reactor. This structure limits the fall of the core and absorbs much of the energy of the fall, which otherwise would be imparted to the vessel.

Indirect Failure Consequences

Since the RVI are not part of the pressure-retaining boundary, indirect consequences as described in this methodology are not directly applicable because there is little stored energy to lead to secondary effects such as missiles or blast. The effects on reactivity and flow conditions are considered as direct effects.

Lines of Protection

Secondary core support structure limits downward movement of the core such that control rod insertion capability is maintained as follows:

- RCCAs do not disengage from guide tubes in the fuel assemblies.
- Fuel assembly upper guide pins do not disengage from the upper core support plate.
- Radial keys in the RV bottom head maintain alignment of the lower core support plate with the RV axial centreline.
- Limited downward movement ensures that adequate core flow (cooling) is maintained.

Discussion

Failure of a core barrel circumferential weld will only result in an allowable vertical displacement of the lower RVI and the core on account of the secondary core support structure and radial clevis supports. Consequently, coolant flow and control rod insertion will be retained. On this basis, the RVI have been categorised as Standard Class 1 components.

Table 20-15. Detailed Assessment for Classification of the RV Upper Internals

Postulated Failure Modes	Gross failure of weld in upper internals.
Introduction The RVI provide the appropriate guidance, protection, alignment, and support for the core and control rods to enable safe and reliable reactor operation. Although the RVI do not have a pressure boundary function, the review considered the potential effects arising from failure of any of the major welds, specifically the potential for vertical displacement of the RVI and the subsequent implications in terms of control of reactivity or maintaining core cooling.	
Unmitigated Direct Failure Consequences There is a potential for disruption to internal flow, leading to fuel damage or inability to insert control rods. Consequences are limited because of the design of the upper internal structures.	
Indirect Failure Consequences Since the RVI are not part of the pressure-retaining boundary, indirect consequences as described in this methodology are not directly applicable because there is little stored energy to lead to secondary effects such as missiles or blast. The effects on reactivity and flow conditions are considered as direct effects.	
Lines of Protection Upper internals are supported by a flanged barrel that is independent of the core barrel. Upper internals' supporting structure is sandwiched between fuel assemblies (springs) and RV head closure flange such that weld failure will not result in movement. Stuck RCCA assumption in safety analyses covers any local failures of RCCA guides.	
Discussion The review concluded that the direct consequences of gross failure of the upper RVI would be the potential for either disruption to internal flow leading to fuel damage or an inability to insert control rods. As the upper RVI are supported by an independent flange to the core barrel and have their supporting structure sandwiched between the (spring-loaded) upper core plate and the RV closure head, however, there will be no significant displacement as a result of a failure of an upper support assembly circumferential weld. In addition, evaluation demonstrates that even with the highest-worth control rod assembly stuck in the fully withdrawn position, the necessary shutdown margin (with combined use of chemical shimming) is maintained during long-term xenon decay and plant cooldown, thus accounting for any local failures of the RCCA guides. On the basis, the RVI have been categorised as Standard Class 1 components.	

Table 20-16. Detailed Assessment for Classification of the MSLs Inside Containment

Postulated Failure Modes	Guillotine break of the MSL inside containment.
Introduction The review considered a DEGB of an MSL inside containment. Consideration was given to the direct consequences in terms of the effect of the transient on the thermal-hydraulic conditions and reactivity control. The review also considered the indirect consequences arising from pipe whip, jet spray and flooding. Flow restrictors are installed in the SG outlet nozzle as an integral part of the SG. The effective throat area of the nozzles is 0.13 m^2 (1.4 ft^2), which is considerably less than the main steam pipe area; thus, the flow restrictors serve to limit the maximum steam flow for a break at any location.	
Unmitigated Direct Failure Consequences With respect to maintaining specified, acceptable fuel design limits and radiological consequences, a DEGB of the MSL inside containment is bounded by a DEGB outside containment. A failure of the MSL (MSLB) outside the containment vessel is analysed at hot zero power (section 9.1.5) and at full power (section 9.1.6) to demonstrate the event can be mitigated without core damage. The limiting break size is dependent on the transient conditions as detailed in each section. Both core analyses conservatively model the hypothetical core configuration (that is, stuck RCCA, nonuniform inlet temperatures, pressure, flow, and boron concentration) and directly evaluate the total reactivity feedback including power, boron, and density redistribution in an integral fashion. The effect of void formation is also included. The MSLB analyses show no DNB occurs for the MSL rupture assuming the most reactive RCCA is stuck in its fully withdrawn position. With respect to containment integrity, an analysis of the peak containment pressure incurred due to a MSLB inside containment is provided in Section 9D.3. The results are summarised in Table 9D.1-1. The containment pressure response is shown in Figure 9D.1-1. These analyses take consideration of a single failure of one of the three valves available for delivery of passive containment cooling water flow as well as failure of the main steam isolation valve (MSIV) in the faulted loop. The availability of ac power is assumed to maximise the mass and energy releases to containment. The containment pressure is maintained within acceptable limits following a DEGB of the MSL inside containment.	

Table 20-16. Detailed Assessment for Classification of the MSLs Inside Containment (cont.)

Indirect Failure Consequences As indicated in Reference 20.23, the main steam line is piping with supplemental mechanistic design requirements but was not selected as a supplemental gross failure scenario for GDA. There is, therefore, a potential for pipe whip since the pipe supports are not designed to prevent it. Based on the expert review undertaken in support of SI classification, the following conclusions were reached: The review, based on detailed interrogation of a 3-D model, indicates that damage to containment as a result of pipe whip is not credible if the main steam line retains its curvature. Any straightening out of the steam line is likely to result in impact with the containment and potential jet spray damage; therefore, a breach of containment could not be ruled out. Damage to containment would not prevent the passive protection systems from core cooling; but the release rate from loss of containment integrity would be increased. There exists the potential for the loss of one group (half) of the automatic depressurisation system (ADS) Stages 1, 2, and 3 valves as a result of pipe whip affecting safety-related conduit. However, as described in section 9.1.5.2.3, the ADS is not actuated during a MSLB event. Additionally, best estimate probabilistic safety analysis (Chapter 6, Reference 20.11) further demonstrates a loss of one group of ADS Stages 1, 2, 3 is acceptable in this scenario. Steam generator movement as a result of pipe whip could not be ruled out. There may be some twisting and bending, but significant failure (SG falling off vertical support, for example) is not expected. It is not considered feasible that the casualty line could rupture the non-casualty MSL, leading to a double MSLB, as the geometry does not allow for this. The valves included in these lines have been designed to prevent missiles as discussed in Reference 20.27.
Lines of Protection The following functions provide the protection for a steam line rupture that is within design basis and is protectable: i) CMT actuation. ii) The overpower reactor trips (neutron flux and DT) and the reactor trip occurring in conjunction with receipt of the “S” signal. iii) Redundant isolation of the main feedwater lines. iv) Redundant isolation of the startup feedwater system. v) Fast-acting MSL isolation valves. vii) Flow restrictors in the SG outlet nozzle.
Discussion The consideration of a guillotine failure is considered to be a very conservative assessment. The direct consequences arising from a guillotine break of the MSL are within the AP1000 design basis and are therefore protectable. In relation to the indirect consequences, however, an equivalent deterministic evaluation of the dynamic effects arising from a guillotine break of the MSL has not been undertaken. Based on consideration of the anticipated effects of a postulated pipe break, it was concluded that pipe whip, although unlikely, cannot be dismissed because pipe whip restraints are not included in the design. The review concluded that pipe whip impinging on the containment could not be ruled out and hence it has conservatively been assumed that a breach of the containment boundary could occur. However, no core damage is anticipated to occur. In accordance with the methodology, a Standard Class 1 classification has been assigned to a DEGB of an MSL inside containment.

Table 20-17. Detailed Assessment for Classification of the MSL and Main Feedwater Line in MSIV Compartment

Postulated Failure Modes	Guillotine break of the MSL or main feedwater line in the main steam isolation valve (MSIV) compartment.

Introduction

The review considered a DEGB of main steam and feedwater lines outside containment within the MSIV compartment and upstream of the MSIV. Consideration was given to the direct consequences in terms of the effect of the transient on the thermal-hydraulic conditions and reactivity control. The review also considered the direct and indirect consequences arising from compartment pressurisation, pipe whip, and flooding. Flow restrictors are installed in the SG outlet nozzle as an integral part of the SG. The effective throat area of the nozzles is 0.13 m^2 (1.4 ft^2), which is considerably less than the main steam pipe area; thus, the flow restrictors serve to limit the maximum steam flow for a break at any location. The main steam and feedwater lines inside the MSIV compartment are described as break exclusion zone piping, primarily because of their proximity to the main control room (MCR) and the potential for leakage outside containment, resulting in the application of standards that exceed ASME requirements for Class 3 pipework.

Unmitigated Direct Failure Consequences

As with the MSLs inside containment, a guillotine break of the MSL is analysed within the design basis and is protectable without core damage. The MSLB is analysed at hot zero power (section 9.1.5) and at full power (section 9.1.6) to demonstrate the event can be mitigated without core damage. The limiting break size is dependent on the transient conditions as detailed in each section.

Both core analyses conservatively model the hypothetical core configuration (that is, stuck RCCA, nonuniform inlet temperatures, pressure, flow, and boron concentration) and directly evaluate the total reactivity feedback including power, boron, and density redistribution in an integral fashion. The effect of void formation is also included.

The analyses show that no DNB occurs for the MSL rupture assuming the most reactive RCCA is stuck in its fully withdrawn position.

Indirect Failure Consequences

Supplemental analysis Case 3 of Reference 20.23 reflects the gross failure of a main steam or main feedwater line in the main steam isolation valve B compartment. The space was selected by the expert panel based on the magnitude of the mass and energy release rate and the close proximity of the compartment to vital areas of the plant including the MCR and the Class 1 C&I spaces. The MSIV A Compartment is larger and does not have the same layout constraints as those identified for the MSIV B Compartment. The following is a summary of the indirect failure consequences determined for Case 3 of Reference 20.23:

A review concluded that the main steam lines do not pose a pipe whip concern and the reaction of the main feedwater line poses a risk of structural impact to the floor and east wall of the respective MSIV compartment. The initial plant response to the postulated main feedwater pipe whip was considered unacceptable and remedial actions were applied. After applying these measures it was concluded that the effects of pipe whip within the MSIV B compartment resulting from the gross failure of a main steam or main feedwater line do not result in unacceptable loading conditions on claimed barriers, and do not adversely affect the required safety functions for mitigation of the associated plant-level event.

With respect to jet impingement, it has been concluded that the failure of either the main steam or main feedwater line in the MSIV B compartment will not adversely affect the plant safety case as the pipes are adequately restrained or experience limited displacement such that the resulting jet effects are reduced.

The MSIV compartments do not contain SSCs that are sufficiently large such that the time required for the pressure wave to travel from the break point to the opposite side of the SSC could result in significant differential pressures; therefore, asymmetric pressurisation is not a concern.

The gross failure of a main steam or main feedwater line in the MSIV B compartment will result in significant pressurisation of the compartment but will not affect the barriers claimed for protection of the operators and Class 1 C&I equipment. Therefore, the plant response to these postulated failures are consistent with the plant safety case.

The valves included in these lines have been designed to prevent missiles as discussed in Reference 20.27.

Lines of Protection

The following functions provide the protection for a steam line rupture that is within design as is and is protectable:

i) CMT actuation.

ii) The overpower reactor trips (neutron flux and temperature differential) and the reactor trip occurring in conjunction with receipt of the “S” signal.

iii) Redundant isolation of the main feedwater lines.

iv) Redundant isolation of the startup feedwater system.

v) Fast-acting MSL isolation valves.

vi) Flow restrictors in the SG outlet nozzle.

Further mitigation is provided by the following:

i) Whip restraints and jet barriers in the MSIV B compartment.

Discussion

A guillotine failure of a MSL outside containment is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been reviewed and shown not to escalate the consequences of failure. In accordance with the methodology, the MSLs outside containment have been evaluated as Standard Class 1.

The evaluation of the main feedwater line is bounded by the MSL.

Table 20-18. Detailed Assessment for Classification of the DVI Line

Postulated Failure Modes	Guillotine break of a DVI line, including failure of the RV DVI nozzle safe end to pipe weld.

Introduction

The review considered a DEGB of one of the DVI lines that inject makeup water directly into the core in the event of a LOCA, so maintaining core cooling. The review considered the direct consequences in terms of the degraded core cooling as well as the indirect consequences arising from pipe whip, jet spray, and flooding.

Unmitigated Direct Failure Consequences

Guillotine failure of either of the DVI lines is included within the AP1000 design basis and can be protected by the passive safety systems. Section 9.6.5 describes the small-break LOCA, including the DVI line break. The small-break LOCA analyses described in the referenced section show that the performance of the AP1000 plant design to small-break LOCA scenarios is excellent and that the passive safeguards systems in the AP1000 design are sufficient to mitigate LOCAs.

The DVI line break analyses evaluate the ability of the plant to recover from a moderately sized break with only half of the total emergency core cooling system capacity available. The vessel side of the break of the DVI line break is DN 100 (NPS 4). The double-ended nature of this break means that in effect, two breaks are modelled as follows:

- Downcomer to containment. The DVI nozzle includes a venturi, which limits the available break area.
- DVI line into containment from the cold leg balance line and the broken-loop CMT.

A sensitivity case was also performed to assess the effect of higher than expected entrainment in the upper plenum and hot legs on the overall system response and core cooling.

The analyses demonstrate that cladding temperatures will remain near the coolant saturation temperature, well below the peak cladding temperature acceptance criterion in section 9.6.5.0.

Indirect Failure Consequences

The gross failure of a DVI line in the PXS A compartment was evaluated as Case 2 of Reference 20.23. The PXS A Room was chosen as it is a smaller compartment volumetrically and therefore is anticipated to yield a greater magnitude of subcompartment pressurisation. Furthermore, the complement of Class 1 SSCs between the PXS rooms differs only by the RNS isolation valves, which are located in an adjoining room to the PXS B room, and do not have an active response to the postulated event of full pressure DVI line rupture. The consequences presented in Reference 20.23 are summarized as follows.

The analysis of the piping response to the reaction loads caused by the gross failure of the DVI A line will cause a pipe whip. Pipe impact with the IRWST injection squib valve (PXS-V125A) will occur which is assumed to incapacitate the Class 1 SSC. The consequential loss of the IRWST injection or containment recirculation squib valve function in the PXS compartment is acceptable in the supplemental case and consistent with the plant safety case. A secondary hinge was formed by the impact of the DVI line against the IRWST injection discharge line, however, the propagation criteria do not result in a gross failure of the IRWST injection discharge line. The specific failure analyzed did not result in an impact to a structure; however, based on the assessment performed to support Case 1 of Reference 20.23, the pipe whip load potential of a DN 200 (NPS 8) pipe is well within the loads applied to containment internal structures by a 55.88 cm (22 in) diameter coolant line and therefore there is sufficient confidence to conclude that PXS compartment barriers are adequate for the spectrum of DVI line failures that can be postulated.

As the upstream piping does not form a plastic hinge, the direction of the jet flow is unaffected by pipe movement. Also, as the upstream side is a non-expanding liquid jet, the resulting zone of influence is effectively reduced to line of sight. The potential targets for this jet are the low pressure IRWST injection and containment recirculation piping. These forces should be considered in the pipe analysis; however, based on the fluid velocity and range it was been concluded that other design effects are more limiting for Class 1 piping analysis; i.e., safe shutdown seismic load combinations. The downstream side piping is subject to dynamic motion and will result in an expanding jet with an unrestrained zone of influence opposed to the thrust vector on the free end of the pipe. Affected components include the Accumulator and various instrumentation lines. Since the initiating event is a loss of injection capability into the reactor vessel, the function of the Accumulator and its associated piping is not accounted for in the safety analysis. Additionally, the incidental instrument lines were considered in the discussion of failure propagation and were not considered to be a risk to the performance of the Class 1 SSCs required to respond to a DVI line break in the PXS A room. Therefore, it was concluded that the jet impingement effects resulting from the failure of the DVI A line in the PXS A room would not adversely affect the plant safety case as the required Class 1 injection capability is retained in this case.

Components within the PXS rooms are not considered for asymmetric pressurisation due to their size and the resulting pressurisation rate of the volume; i.e., transient pressurisation of the compartment does not occur fast enough compared to the velocity of the pressure wave to create an appreciable differential pressure.

The gross failure of DVI A line will result in pressurisation of PXS A compartment; however, the communication between PXS A compartment and the Containment has been shown to be adequate to limit the dynamic differential pressure across structural barriers to a reasonable value. Therefore, the integrity of the room and the claimed barriers is consistent with the plant safety case and the analysis of the direct effects of a DVI line break event.

The valves included in these lines have been designed to prevent missiles as discussed in Reference 20.27.

The core depressurization forces resulting from a gross failure of a DVI line would be less limiting than those resulting from a gross failure of a cold leg. A detailed evaluation of the gross failure of a cold leg (Reference 20.25) has demonstrated that grid crush may occur in low power peripheral assemblies, however, the core geometry would remain coolable. As a result, significant core damage is not expected.

Table 20-18. Detailed Assessment for Classification of the DVI Line (cont.)

Lines of Protection PXS. Containment.
Discussion A guillotine failure of a DVI line is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been shown not to escalate the consequences of failure. In accordance with the methodology, the DVI lines have been evaluated as Standard Class 1.

Table 20-19. Detailed Assessment for Classification of the Pressuriser Surge Line

Postulated Failure Modes	Guillotine break of the surge line.
Introduction The review considered a guillotine break of pressuriser surge line. The assessment assumes a DEGB of the pipe and also considers the risk from pipe whip, flooding, and pressurisation of the lower pressuriser compartment and SG compartment 01.	
Unmitigated Direct Failure Consequences Guillotine failure of the pressuriser surge line is included within the AP1000 design basis and can be protected by the passive safety systems without significant fuel damage or containment overpressurisation. The failure would result in a large unisolable LOCA. The AP1000 large-break LOCA safety analysis (section 9.6.4) includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The analysis has been performed using the WCOBRA/TRAC code, a best-estimate thermal-hydraulic computer code used to calculate realistic fluid conditions in the PWR during blowdown and reflood of postulated large-break LOCAs. This analysis includes the effects of a rapid depressurisation of the primary loop. The postulated failure described here would, therefore, be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1.	
Indirect Failure Consequences As indicated in Reference 20.23, the surge line is piping with supplemental mechanistic design requirements but was not selected as a supplemental gross failure scenario for GDA. Based on the expert review undertaken in support of SI classification, it was concluded that in the unlikely event of a DEGB of the pressuriser surge line, the resulting dynamic effects would not compromise the integrity of the passive safety systems or containment; damage would be contained within the thick steel/concrete/steel module walls of the lower pressuriser compartment and SG compartment 1. It is judged that the DEGB failure of the surge line cannot create a large missile out of the pressuriser.	
Lines of Protection Passive safety systems. Containment.	
Discussion A guillotine failure of the pressuriser surge line is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been evaluated and it is considered that these would not lead to escalated consequences of failure. In accordance with the methodology, the pressuriser surge line has been evaluated as Standard Class 1.	

Table 20-20. Detailed Assessment for Classification of the ADS Piping and Safety Valve Piping

Postulated Failure Modes	Guillotine break of one of the automatic depressurisation system (ADS) pipes.
Introduction Failure of one of the ADS lines is included within the small-break LOCA safety design approach for the AP1000 plant. The approach is to provide for a controlled depressurisation of the primary system if the break cannot be terminated. The controlled depressurisation is required to ensure that the passive protection systems initiate. The assessment assumes a DEGB of one of the lines and also considers the risk from pipe whip and flooding.	
Unmitigated Direct Failure Consequences Guillotine failure of the any of the ADS lines is included within the AP1000 design basis and can be protected by the passive safety systems. Section 9.6.5 describes the small-break LOCA, including the more limiting inadvertent actuation of the ADS. The small-break LOCA analyses described in the referenced section show that the performance of the AP1000 plant design to small-break LOCA scenarios is excellent and that the passive safeguards systems in the AP1000 are sufficient to mitigate LOCAs. A break within the ADS does not, therefore, impair its function to depressurise the RCS.	
Indirect Failure Consequences As indicated in Reference 20.23, the ADS piping is piping with supplemental mechanistic design requirements but was not selected as a supplemental gross failure scenario for GDA Based on the expert review performed in support of SI classification, it was concluded that in the unlikely event of a DEGB of one of the larger-diameter lines not protected by pipe whip restraints, the resulting dynamic effects would not compromise the ability of the passive protection systems to protect the core by virtue of the plant layout and the physical separation of the different sides of the PXS. Pipe whip arising from failure of ADS pipework would therefore not compromise integrity of passive safety systems. The review identified that, in light of the exposed location of the upper ADS valve area, there was the remote potential for a missile impact that damages containment and would result in larger release rates. But the containment cooling with damaged containment has been analysed and shown to effectively reduce the CV pressure to near atmospheric pressure without compromising its effectiveness. The potential for flooding to prevent correct operation of the passive protection systems was considered and discounted. Section 11.3 describes how the AP1000 plant is designed to withstand internal flooding events due to pipe breaks. The valves included in these lines have been designed to prevent missiles as discussed in Reference 20.27.	
Lines of Protection Passive safety systems. Containment	
Discussion A guillotine failure of an ADS line is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been shown not to escalate the consequences of failure. In accordance with the methodology, the ADS pipework has been evaluated as Standard Class 1.	

Table 20-21. Detailed Assessment for Classification of the PRHR HX Inlet and Return Lines

Postulated Failure Modes	Guillotine break of either inlet or return lines
Introduction The PRHR HX inlet and return lines form part of the PXS, which removes decay heat in the event of a loss of normal residual heat removal. The review considered a guillotine break of either of the pipes during normal operation or standby. The assessment assumes a DEGB of one of the lines and also considers the risk from pipe whip and flooding.	
Unmitigated Direct Failure Consequences Guillotine failure of the any of the PRHR HX lines is included within the AP1000 design basis and can be protected by the passive safety systems. The failure would result in a large unisolable LOCA. This would be bounded by a DEGB of the primary loop, included within the AP1000 large-break LOCA safety analysis (section 9.6.4), which includes a range of LOCAs up to and including a break equivalent in size to the double-ended rupture of the largest pipe in the RCS. The failure described here would therefore be protectable without violating the acceptance criteria on core thermal limits in section 9.6.4.1. It should be noted that the loss of the decay heat removal function is not a concern in the case of the large LOCA where rejection of heat is achieved through the LOCA itself rather than via the PRHR HX.	

Table 20-21. Detailed Assessment for Classification of the PRHR HX Inlet and Return Lines (cont.)

Indirect Failure Consequences The containment integrity analysis considers, as its design basis, the complete double-ended severance of the largest RCS pipe (Section 9D) and hence containment integrity would not be challenged by this postulated break. In addition to pressurisation of the containment, a DEGB of the PRHR HX return lines would result in internal pressurisation of SG compartment 1. The PRHR return line is a line with supplemental mechanistic design controls which was not selected for further assessment during GDA (Reference 20.23). Nonetheless, on a best-estimate basis, it is judged that this failure would not lead to offsite consequences because any failure would not compromise integrity of the redundant train of the PXS. A DEGB of the PRHR HX inlet and return lines would result in pipe whip in the maintenance floor/ mezzanine areas and in SG compartment 1. The PXS DN 350 (NPS 14) piping has not yet been assessed deterministically (Reference 20.23). In the absence of a deterministic assessment to support the SI classification review, the effects of pipe whip hinging at the compartment wall were evaluated using the 3-D model. Based on this, it was concluded that pipe whip arising from failure of the PRHR HX system pipework would not compromise integrity of the redundant train of the PXS. Additionally, a DEGB of the PRHR HX inlet and return lines has the potential to cause pipe whip resulting in the failure of conduit for one group (half) of the ADS Stages 1, 2, and 3 valves. Probabilistic safety analysis (Reference 20.11, Chapter 6) has shown a loss of one group of ADS Stages 1, 2, and 3 valves is acceptable in this scenario. The pipe whip resulting from a DEGB of the PRHR HX return line has the potential to affect the IRWST wall at the PRHR outlet. If the IRWST wall were to be damaged, there is potential the IRWST could be drained to a low level by the break. As a result, there exists the potential for insufficient driving head for passive PXS injection to occur when it is needed. However, the IRWST is constructed of thick steel/concrete/steel composite walls. As such, local deformation of the inside liner of the IRWST and global plastic strain of the structural walls have been concluded to not occur as a result of the impact force resulting from a DEGB of a PRHR HX return line. Furthermore, the mounting ring and base metal associated with the PRHR HX outlet plenum have been shown to remain functional. The pipe whip resulting from a DEGB of the PRHR HX return line has the potential to affect the RCPs or the RCP cooling heat exchanger, which would prevent the RCPs from functioning properly. This is of little consequence, as the RCPs are not needed or credited in a large-break LOCA scenario. The valves included in these lines have been designed to prevent missiles as discussed in Reference 20.27. Flooding of the SG compartment is within the design basis.
Lines of Protection PXS and PCS. Containment.
Discussion A guillotine failure of PRHR HX inlet and return lines is included within the design basis and can be protected by the passive safety systems. Indirect consequences have been evaluated and it is considered that they would not lead to escalated consequences of failure. In accordance with the methodology, the PRHR HX inlet and return lines have been evaluated as Standard Class 1.

Table 20-22. Summary of RCS Design Transients

Design Transient	Number of Occurrences
ASME III Service Level A Transients	
Reactor Coolant Pump Startup/Shutdown	
Case A … Pump Startup	3,000
Case B … Pump Shutdown	3,000
Full Plant Heatup …….. (120°F - 557°F) (49°C - 292°C)	200
Partial Plant Heatup …….. (120°F - 350°F) (49°C - 176°C)	200
Partial Plant Heatup …….. (350°F - 557°F) (176°C - 292°C)	200
Full Plant Cooldown ……. (557°F - 120°F) (292°C - 49°C)	200
Partial Plant Cooldown …. (557°F - 350°F) (292°C - 176°C)	200
Partial Plant Cooldown …. (350°F - 120°F) (176°C - 49°C)	200
Unit Loading (Between 0-15% Power)	500
Unit Unloading (Between 15-0% Power)	500
Unit Loading (15-100% @ 5% per minute)	2,000
Unit Unloading (100-15% @ 5% per minute)	2,000
Reduced Temperature Return to Power	(See Note 1)
Step Load Increase (+10% Power)	3,000
Step Load Decrease (-10% Power)	3,000
Large Step Load Decrease (w/Steam Dump)	200
Tie Line Thermal Backup	(See Note 2)
Steady-State Fluctuations	
Case A … Initial	$\leq 1.5 \times 10^5$
Case B … Random	$\leq 4.6 \times 10^6$
Load Regulation	750,000

APPENDIX 20A
REACTOR VESSEL COMPONENT SAFETY REPORT

20A.1 INTRODUCTION

This is the component safety report (CSR) for the reactor vessel (RV). As introduced in Section 20.2, the safety argument herein substantiates the structural integrity of the RV to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentary evidence outlined in Section 20A.6 regarding the quality of design, manufacture, installation and operation of the RV.

20A.1.1 Scope

This report supports the claim that the nuclear and radiological risk potentially arising from gross structural failure of the RV remains tolerably low for the 60 year design lifetime. Conventional hazards to personnel safety are outside the scope of this Appendix 20A.

This CSR demonstrates that the structural reliability for the RV is commensurate with the consequences of failure; which, in the case of the RV, necessitates a demonstration that the probability of gross failure of the RV is so low that it can be discounted for the required period of operation.

The RV is a component of the reactor coolant system (RCS). The scope of the assessment is limited to the RV only and does not include any other components of the RCS or any other systems. The physical boundaries of the RV are identified in Section 20A.1.7.

This CSR is restricted to consideration of those pressure, temperature, and mechanical loadings within the design basis. The design basis includes normal operating conditions, anticipated transients, and postulated accident conditions. Design parameters and transient definitions for the required period of operation are identified in Section 20A.2.1. Severe accident transients, including the ability of the RV to retain molten core debris, are outside the scope of this appendix; but are described in Section 10.3.

20A.1.2 Objectives

This CSR supports the claim the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. These claims are substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the RV are identified in Section 20A.1.9.

20A.1.3 Strategy

The SFRs of the RV provide a basis for the criteria against which the acceptability of the safety argument is to be judged. The RV SFRs are substantiated by means of a structured safety argument which is consistent with United Kingdom (UK) regulatory expectation and in accordance with the relevant safety assessment principles (SAPs). The structure and philosophy of the safety argument are established in Section 20A.1.8.

20A.1.4 Interface with other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data and analyses. These are listed in the technical index (Section 20A.6) and each is specifically identified in the relevant section of the structured safety argument.

20A.1.5 Description

20A.1.5.1 Overview

The RV consists of a cylindrical main section with a transition ring, hemispherical bottom head, and a removable flanged hemispherical upper head (Figure 20A-1). Key dimensions are shown in Figure 20A-2 and Figure 20A-3. The RV, including closure head (CH), is approximately 12.208 m (40 ft) long and has an inner diameter at the core region of approximately 4038.6 mm (13.25 ft). The total weight of the vessel including the CH is approximately 352 tonnes. Surfaces, including the upper shell top surface, which can become wetted during operation and refuelling are clad to a nominal 5.6 mm (0.22 in) of thickness with austenitic stainless steel welded overlay. The RV's design objective is to withstand the design environment of 17.24 MPa (2500 psia) and 343.3°C (650°F) for 60 years.

The cylindrical section consists of two shells, the upper shell and the lower shell. The upper and lower shells and the lower hemispherical head are fabricated from low alloy steel (ASME SA-508, Grade 3, Class 1) and clad with austenitic stainless steel. The upper shell forging is welded to the lower shell forging, and the lower shell is welded to the transition ring, which is welded to the hemispherical bottom head. The removable flanged hemispherical upper head consists of a single forging, which includes the CH flange and the CH dome. The CH is fabricated from a low alloy steel forging and clad with austenitic stainless steel. The base, clad and weld materials used in the construction of the RV are identified in Section 20A.2.1. The removable flanged hemispherical CH is attached to the vessel (consisting of the upper shell-lower shell-bottom hemispherical head) by a ring of 45 studs. Two metal o-rings are used for sealing the two assemblies. Inner and outer monitor tubes are provided through the upper shell to collect any leakage past the o-rings. Material specification for all RV components is provided within the safety argument in Section 20A.2.1.4.2.

There are no penetrations below the top of the core. This reduces the frequency of a loss-of-coolant accident (LOCA) from these penetrations that could allow the core to be uncovered. The core is positioned as low as possible in the vessel to limit re-flood time in the event of an accident. During the beyond-design-basis severe accident core meltdown, the RV bottom head retains the molten core and is cooled by floodup of water on the exterior surfaces of the RV.

20A.1.5.2 Lower Head and Lower Shell

The lower head has an approximate 2 m (6.6 ft) inner spherical radius to the cladding surface. The thickness of the lower head is about 158 mm (6.2 inches). The lower radial supports are located on the head at the elevation of the lower internals lower core support plate. The transition ring is welded to the lower shell course with the weld located outside the high fluence active core region. The lower shell is a ring forging about 213.4 mm (8.4 inches) thick with an inner diameter of approximately 4.038m (159 inches). The length of the shell is greater than 4.267 m (168 inches) to place the upper shell weld outside of the active fuel region. A surveillance programme is used to monitor the radiation damage to the vessel material in the belt line region.

20A.1.5.3 Upper Shell and Nozzles

The upper shell is a large ring forging. Included in this forging are four 558.8 mm (22-inch) inner diameter inlet nozzles, two 787.4 mm (31-inch) inner diameter outlet nozzles and two (DN 200 (NPS 8) schedule 160 pipe connections) direct vessel injection (DVI) nozzles. These nozzles are made from the same material as the RV body and are fabricated by "set in" construction. The inlet and outlet nozzles are offset axially in different planes, which allows pump maintenance without discharging the core. The injection nozzles are approximately 2540 mm (100 inches) below the main flange. The outlet nozzles are approximately 2032 mm (80 inches) and the inlet nozzles are approximately 1587.5 mm (62.5 inches) below the mating surface. A stainless steel safe end is shop welded to each of the four inlet, two outlet and two DVI nozzles to facilitate field welding without heat treatment to the stainless steel reactor coolant piping system. The primary coolant nozzles support one end of the primary coolant system. Reaction loads are transferred into the nozzles and eventually into the support pads.

The top of the upper shell contains a ring of 45 threaded stud holes and has the sealing surface for the CH. Inner and outer monitor tubes are provided through the shell to collect any leakage past the closure region o-rings. Attached to the top surface and along the outer periphery of the upper shell is a seal ledge. During field assembly the seal ledge is welded to the refuelling cavity seal liner. This ring provides an effective water seal between the refuelling cavity and sump during refuelling operations.

20A.1.5.4 Closure Head, Bolting and Closure Head Penetrations

The CH is manufactured from a single forging and has an integral flange. The CH is manufactured from an SA508 Grade 3 Class 1 low alloy steel forgings to minimise size. It has an approximately 1968.5 mm (77.5-inch) inner spherical radius to the cladding surface and an approximately 4775.2 mm (188.0-inch) outside diameter (OD) outer flange. Cladding is extended across the bottom of the flange for refuelling purposes. Studs attach the head to the lower vessel and two metal o-rings are used for sealing. The upper head has sixty-nine 101.6mm (4-inch) outer diameter penetrations for the control rod drive mechanism (CRDM) housings and eight nozzles for the in-core instrumentation (ICI). Each CRDM is positioned in its opening and welded to the CH using a J-prep weld against the inside spherical radius of the head. Lugs are welded to the outside surface of the CH along the outer periphery of the dome section. The lugs provide support and alignment for the integrated head package (IHP).

20A.1.5.5 Vessel Supports

Four vessel supports are located beneath the inlet nozzles and the internals support ledge is machined into the top of the upper shell. The support pad is integral to each of the four inlet nozzles. The pads are simply supported on steel base pads atop a support structure, which is attached to the concrete foundation wall; justification of the support structure is beyond the scope of this document. Thermal expansion and contraction of the vessel are accommodated by sliding surfaces between the support pads and the base plates. Side stops on these plates keep the vessel centred and resist lateral loads.

20A.1.5.6 Reactor Vessel Internals

The RV supports the internals. An internal ledge is machined into the top of the upper shell section. The core barrel flange rests on the ledge. A large circumferential spring is positioned on the top surface of the core barrel flange. The upper support plate rests on the top surface of the spring. The spring is compressed by installation of the RV CH and the upper and lower core support assemblies are restrained from any axial movements.

Four core support blocks are located on the bottom hemispherical head just below the transition ring-to-lower shell circumferential weld. The core support blocks function as a clevis. At assembly, as the lower internals are lowered into the vessel, the keys at the bottom of the lower internals engage the clevis in the axial direction. With this design, the internals are provided with a lateral support at the furthest extremity and may be viewed as a beam supported at the top and bottom.

The interfaces between the RV and the lower internals core barrel are such that the main coolant flow enters through the inlet nozzle and is directed down through the annulus between the RV and core barrel and through the flow skirt and flows up through the core. The annulus is designed such that the core remains in a coolable configuration for all design conditions.

Prior to installation of the internals into the RV, guide studs are assembled into the upper shell. Dimensional relationships are established between the guide studs and the core support blocks such that when the lower internals lifting rig engages the guide studs, the keys at the bottom of the lower internals are in relative circumferential position to enter the core support blocks.

20A.1.5.7 Guide Studs

The guide studs position and align the CH when the head is lowered by the crane onto the vessel, to facilitate drive rod insertion into the CRDMs and head-to-vessel alignment pin engagement in the CH keyways. The guide stud locations are outside the vessel flange area so that the guide studs do not normally have to be removed for outage activities and reactor operation. Therefore, the guide studs are designed with consideration in regard to materials and features to be permanently installed during all operational and outage conditions. The design permits the guide studs to be removed from their positions in a relatively easy and timely manner, if removal becomes necessary.

20A.1.6 Function

The RV is the high-pressure containment boundary used to support and enclose the reactor core. It provides flow direction with the reactor internals through the core and maintains a volume of coolant around the core. The vessel interfaces with the reactor internals, primary loop piping, safety injection piping, head vent piping, insulation, head lifting rig, cavity seal, digital metal impact monitoring system, and steel structures from the IHP and is supported by RV supports on the containment building concrete structure.

Inlet and outlet nozzles are provided to accommodate the flow of reactor coolant that circulates through the core to remove heat and transfer it to the steam generators. DVI nozzles are provided for the passive core cooling system (PXS), which provides flow for a variety of accident conditions. To minimise the potential for draining the RV and exposing the core, all nozzles are located above the core.

In addition to providing access to the inside of the vessel for refuelling and maintenance, the removable CH also serves as the attachment point for the CRDMs, the QuickLoc connections for the ICI, the head vent system penetrations, and the digital metal impact monitoring system. In order to support the IHP and accommodate lifting, supports and lift lugs are attached to the CH.

The vessel flange contains the threaded holes for the closure stud and its top surface provides the mating sealing surface for the CH. Inner and outer monitor tubes are provided through the vessel flange to collect any leakage past the closure gaskets.

To support the reactor internals and core, a support ledge is provided near the top of the vessel flange and core supports are located at the bottom of the core. The lower head supports the reactor core during the postulated core drop accident.

Vessel support pads are provided on the primary inlet nozzles to act as an interface between the vessel and the vessel supports. The pads must limit circumferential motion of the vessel and allow radial thermal growth. The vessel supports provide no restraint to vessel motion in the vertical upward direction.

To provide a means of support and sealing for the cavity seal, a seal ledge is provided near the top of the vessel. The seal ledge also acts as a support for the CH flange insulation.

20A.1.7 Boundaries

The physical boundaries for safety case assessment of the RV, as defined in Reference 20A.2, are shown in Figure 20A-4 and identified below:

- The interface with the RV supports and the containment internal structures is at the integral vessel support pads located under the inlet nozzles.
- The interface between the RV and the main loop piping or the safety injection piping occurs at the nozzle safe-end prep.
- The interface with each CRDM assembly occurs at the bi-metallic weld between the bottom of the one-piece latch housing and the penetration.
- The interface between the QuickLoc pressure boundary and the ICI thimble assemblies (IITA) occurs at the Swagelok fitting on top of the QuickLoc stalk.
- The interface with the head lifting rig is the CH lifting lug pins.
- The interfaces with the reactor internals occurs at the internals support ledge, the outlet and DVI nozzle internal projections and the core support blocks for the internals radial support keys.
- The interface with the head vent system occurs at the first circumferential pipe weld beyond the head junction weld.
- The interface with the IHP occurs at the IHP supports.
- The two interfaces with the closure gasket leak monitor system are at the first circumferential tube welds beyond the two monitor tube-to- vessel junction welds.

- The interface with the cavity seal is the outer edge of the vessel flange seal ledge.
- The interface with the flow skirt is the flow skirt attachment weld.
- The interface with the digital metal impact monitoring system is the mounting bosses/pads

20A.1.8 **Safety Case Requirements**

This report substantiates the claim that the structural reliability of the RV is commensurate with the consequences of gross failure by means of a structured safety argument, supported by suitable and sufficient evidence. The safety argument is presented according to an established four legged structure (Reference 20A.3), to demonstrate an appropriate level of defence in depth by identifying evidence to satisfy safety claims and objectives identified within each leg of the argument, as follows:

Leg 1	**Interpolation/Extrapolation of Experience – 'Good' Design and Manufacture**
Objective:	Provides evidence of good design and manufacture based on a proven track record. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with objective of achieving quality of build, high integrity and the avoidance of defects.
Claim:	High quality is achieved through good design and manufacture.
Leg 2:	**Functional Testing**
Objective:	Incorporates the build experience as embodied in design codes and provides some diversity and redundancy to the pre-service inspection (PSI).
Claim:	Components are shown to be fit for purpose through effective functional testing.
Leg 3:	**Failure Analysis**
Objective:	Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval. Goes beyond design code requirements to provide a further demonstration of integrity. Recognises that flaws may be present and shows tolerance to them. Supplements the Leg 1 aim of avoidance of defects to provide a safety case with both defect avoidance and defect tolerance.
Claim:	Components are tolerant to through life degradation over the design life of the plant.
Leg 4	**Forewarning of Failure**
Objective:	Confirms the absence of a degradation mechanism or that a known degradation mechanism is not significant to integrity or will have limited consequences. Provides contingency for the unexpected.
Claim:	Effective systems are in place to provide forewarning of failure.

The four legged safety argument will substantiate specific SFRs for the RV. The RV SFRs are identified in Section 20A.1.9.

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure. Classification of the RV and its component parts is established in Section 20A.1.10.

The four legged safety argument is provided in Section 20A.2 and the strength of the argument is discussed in Section 20A.3.

20A.1.9 Safety Functional Requirements

The performance and safety design bases for AP1000 SSCs are identified in Section 20.4. These are requirements of plant systems, some duty, some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. Identification of the SFRs for the RV follow from the performance and safety design bases, as follows:

SFR 20.1.1 The RV is required to provide the highest reliability pressure boundary to contain the primary coolant, heat generating reactor core, and fuel fission products during normal and faulted design basis conditions for the design life of the plant.

SFR 20.1.2 The RV is required to provide support for the reactor internals and core to ensure that the core remains in a coolable configuration.

SFR 20.1.3 The RV is required to direct main coolant flow through the core by close interface with the reactor internals and flow skirt.

SFR 20.1.4 The RV is required to provide for core internals location and alignment.

SFR 20.1.5 The RV is required to provide support and alignment for the CRDMs and ICI assemblies.

SFR 20.1.6 The RV is required to provide support and alignment for the integrated head assembly.

SFR 20.1.7 The RV is required to provide an effective seal between the refuelling cavity and sump during refuelling operations.

SFR 20.1.8 The RV is required to support and locate the main coolant loop piping.

SFR 20.1.9 The RV is required to provide support for safety injection flow paths.

SFR 20.1.10 The RV is required to serve as a heat exchanger during core meltdown scenario with water on the outside surface of the vessel.

Postulated failure modes which result in a loss of these SFRs lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20A.1.10. The safety argument in Section 20A.2 is provided to establish that structural integrity of the RV will be maintained for all conditions within the design basis and thus demonstrate that all of the above SFRs will be maintained at all times.

20A.1.10 Reactor Vessel Structural Integrity Classification

Key to the RV structural integrity safety case is the clear understanding of the potential radiological consequences of any postulated gross failure mode. Based on this understanding, a structured and systematic basis can be established for setting the level of rigour applied during the design assessment, material procurement, fabrication, in-manufacture inspection, testing and in-service testing, maintenance, inspection and safety case assessment of the component. Details of the approach for developing AP1000 component structural integrity safety cases are given in Reference 20A.4.

The approach to structural integrity classification is discussed in Section 20.5 and is consistent with the overall AP1000 safety classification scheme as detailed in Chapter 5. Reference 20A.4 details the approach taken whereby a detailed assessment of selected individual components is made to establish the consequences of gross failure, due to both direct consequences such as a LOCA, and indirect consequences, such as the effect of missiles, jet loading or pipe whip on essential safety systems. Based on this assessment, and in accordance with the scheme identified in Table 20-2, components are ascribed one of the five structural integrity classifications described in Section 20.5.2.

For the RV, the unmitigated direct consequences of gross failure have been assessed in Reference 20A.4 as having the potential for severe core damage arising from disruption to the core assembly, loss of coolant inventory and loss of coolable core geometry. Other postulated beyond design basis consequences include loss of core support or control rod ejection leading to a potential reactivity excursion. Failure of the RV could also lead to loss of in-vessel retention of core debris which is a defence in depth measure. Considering the indirect consequences, there exists the potential for secondary damage to essential safety systems or damage to the containment vessel as a result of high energy missile generation. Gross failure of the RV could therefore lead to the most severe offsite consequences against which there is no claimed protection. As such, the RV is classified as a highest safety significance (HSS) component and this safety report seeks to substantiate this claim.

The HSS classification does not however apply to each and every component of the RV or to every postulated failure mode and defect orientation, since certain failure modes will not lead to the most severe off site consequences. Since the identification of HSS locations is important to the safety case arguments at each individual location, as well as for establishing the inspection requirements for individual welds, it is important to consider each location in turn. This is presented in Table 20A-1. Where postulated gross failure could lead to severe core damage, but without threatening containment and so not leading to offsite release of activity, the HI classification has been applied. Where postulated gross failure would not lead to severe core damage, as a result of either direct or indirect means, Class 1 has been

assumed. For HI components, defect tolerance assessments will be carried out and the capability of ultrasonic testing (UT) inspections will be evaluated to establish that the inspection is capable of screening out defects of structural significance.

20A.2 Safety Argument

This section provides a structured safety argument to demonstrate that the RV is fit for purpose for the required component lifetime of 60 years. The safety argument is presented according to the four-legged structure described in 20A.1.8.

Consistency with the appropriate ASME rules for Class 1 components provides the basic demonstration of fitness-for-purpose and is generally inferred as providing substantiation for a component's reliability. In the case of the RV, it is necessary to substantiate a lower frequency of failure such that the probability of gross failure is so low that it can be discounted. This is achieved by identifying supplementary measures to ensure high quality and by demonstrating the tolerance to manufacturing defects above qualified detection limits. Additional qualitative arguments are presented in Section 20A.2.2 and Section 20A.2.4 to demonstrate evidence of defence in depth and to substantiate component reliability commensurate with the structural integrity classification of the RV.

20A.2.1 Leg 1: Interpolation/Extrapolation of Experience – Good Design and Manufacture

The objective of Leg 1 is to provide the evidence to support the conclusions that the design of the RV is based on the highest standards of engineering design, that the chosen materials have well understood characteristics with a proven track record in an RV environment and are subject to tight specification and procurement controls and that the manufacture is carried out using experienced fabricators with a proven track record using established high quality processes and subject to robust examination. A number of elements are built up to support this claim. These are:

- The Design is Well Founded, Designed in Accordance with Internationally Recognised Standards and Takes Into Account Operating Experience (Section 20A.2.1.1).
- Loading, Temperatures and Environment Have Been Well Defined (Section 20A.2.1.2).
- The AP1000 RV Design has Been Assessed Against Relevant Design Code Requirements (Section 20A.2.1.3).
- Components are Manufactured Using a Good Choice of Materials (Section 20A.2.1.4).
- Good Manufacturing (Section 20A.2.1.5).
- Manufacturing Inspection (Section 20A.2.1.6).
- Plant Operation and Maintenance (Section 20A.2.1.7).

Together these provide an important keystone for a demonstration that the vessel is well designed, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the vessel. The arguments and evidence associated with each of these claims are expanded in sections 20A.2.1.1 to 20A.2.1.7 below.

20A.2.1.1 **The Design is Well Founded, Designed in Accordance with Internationally Recognised Standards and Takes Into Account Operating Experience**

In order to demonstrate that the design is well founded, designed in accordance with internationally recognised standards and takes into account operating experience, evidence to substantiate the following arguments is provided.

- Westinghouse design of RVs is well founded and supported by an excellent safety record.
- The design of the RV takes account of in-service experience and known age related degradation mechanisms.
- Design and manufacture in accordance with established codes, standards and regulations provides assurance of high reliability based on experience.
- Novel features of the design are avoided or adequately justified.
- The use of forgings is maximised to limit the number of welds.
- The AP1000 RV arrangement optimises safety.

20A.2.1.1.1 Westinghouse Design of Reactor Vessels is Well Founded and Supported by an Excellent Safety Record

Westinghouse has designed, developed, and manufactured nuclear facilities since the 1950s, beginning with the world's first large central station nuclear plant (Shippingport), which produced power from 1957 until 1982. Westinghouse has since designed and delivered more than 100 commercial nuclear power plants (NPPs) worldwide, including the design of Sizewell B in the UK, with a combined electrical generating capacity in excess of 90,000 MW. The design of the AP1000 reactor pressure vessel is therefore supported by decades of successful plant operating experience which have accumulated many operating years without significant issue. Westinghouse has substantial proven experience, knowledge, and capability to design, manufacture and furnish technical assistance for the installation, start-up and service of NPPs.

The AP1000 RV is of similar design to that of the earlier Westinghouse designs, and also to typical pressurised water reactor (PWR) RV design which use similar proven materials and manufacturing processes. The design has been the subject of regulatory scrutiny overseas: the United States Nuclear Regulatory Commission approved the final design certification for the AP1000 in December 2005 following the earlier approval of AP600 design certification in 1999.

Whilst the substantial record of safe operating experience is insufficient to directly support reliability claims commensurate with a HSS component, it provides confidence that there is a thorough understanding of the in-service performance of these vessels, the management and mitigation of through-life degradation issues and in the avoidance of issues at the design and manufacturing stage that can affect the through life performance.

20A.2.1.1.2 The Design of the RV Takes Account of In-service Experience and Known Age Related Degradation Mechanisms

Historically RVs have encountered in-service issues that have resulted in unscheduled outages and prolonged plant down time. Most prominent among these failure events are RV head penetration and bottom instrumentation tube cracking, leakage from mechanical joints and stuck RV studs. The design of the AP1000 RV therefore takes benefit of lessons learned over the many years of operation and includes a number of design features aimed at mitigating against issues reported on other PWR plants. Reference 20A.6, presents a review of the susceptibility of the AP1000 RV design to known in-service degradation mechanisms. The main conclusions from this review of each of the major in-service issues are summarised below.

Head Penetration and Instrumentation Tube Cracking

Previous reactor designs used CRDM nozzles made of Alloy 600, which operating experience showed was susceptible to primary water stress corrosion cracking (PWSCC). The CRDM nozzles and head vent pipe in the AP1000 RV CH are all Ni-Cr-Fe Alloy 690 material. Alloy 690 has been shown by laboratory testing to be resistant to PWSCC. In addition, a narrow gap J-groove weld is specified for the CRDM penetrations in order to reduce the residual weld stresses that contributed to earlier PWSCC issues.

The AP1000 RV does not have bottom head penetrations, but the lesson learned regarding material selection has been applied to the QuickLoc instrument penetrations in the CH. The material of the pressure boundary parts of the QuickLoc are SA-182, SA-479, and UNS S21800. The AP1000 RV head penetrations are also designed with consideration for the inspections for PWSCC that are currently mandated by the United States (US) Nuclear Regulatory Commission (NRC) and the industry. The internal protrusions of the CRDM penetration nozzles have sufficient length such that there is approximately 50.8 mm (2 inches) of inspectable length below the lowest point on the toe of the J-groove weld in accordance with the current directives.

Leakage from Mechanical Joints

The major cause of RV closure gasket (O-ring) leakage over the years has been debris on the vessel flange seating surfaces that interferes with the sealing of the O-ring. To a large extent the offending debris has been rust particles that have washed or dropped onto the seating surfaces after the flange surface was cleaned and the head was set. The major source of the rust has been eliminated in the AP1000 RV design by applying stainless steel cladding to the RV flange bolting ring and seal ledge. However, prevention of RV closure gasket leakage will still depend heavily on careful cleaning and inspection of the seal surfaces prior to setting the head during refuelling outages. Other leakage from joints above the CH has been eliminated in the AP1000 design by eliminating the joints altogether. The instrumentation ports which have been subjected to conoseal joint leakage in years past are not included in the AP1000 design. In addition, the CRDM lower canopy seal weld is eliminated, and there are no spare penetrations with threaded and canopy seal-welded head adapter plug and capped latch housing joints.

Stuck Reactor Vessel Closure Studs

At several current plants RV closure studs have become bound in their stud holes due to thread galling. The stuck studs have resulted in studs having to be machined out of the stud holes, and in some cases the stud holes had to be sleeved due to thread damage. The galling has been contributed in part to the close thread clearances with the traditional 8N threads. The AP1000 RV closure studs and flange stud holes have 4UN threads. This design provides larger clearances between the stud and stud hole threads in addition to a more robust thread form.

Irradiation Embrittlement

The fracture toughness properties for the low alloy steel material in the core region of the RV are affected over time by fast neutron fluence (energy $\geq$ 1 MeV). In order to comply with the limits for these properties, such as RT_{NDT} and upper shelf energy, that have been established by the NRC, Reference 20A.2 puts restrictions on the core region material chemistry and initial properties with consideration of the end-of-life fast neutron fluence. In addition, the core region shell inside diameter is one inch further removed from the core compared to the standard 3-loop and AP600 reactor designs. This diameter change reduced the maximum fast neutron fluence at the AP1000 vessel inside surface to 9×10^{19} n/cm^2 for 56 EFPY in order to comply with the limits.

Fatigue Cracking

The AP1000 RV fatigue usage at the locations of maximum peak stress intensity range has been analysed in accordance with the ASME Code. As in the case with all of the previous Westinghouse RVs designed in accordance with ASME Code, Section III, the RV was found to be acceptable for cyclic operation for the plant lifetime accordant with the number of cycles of design transients and design mechanical loads specified in the RV Design Specification. To date there have been no fatigue failures in Westinghouse RVs due to conditions that could be anticipated in the design. As a result of the satisfactory ASME Code, Section III fatigue analysis for the AP1000 RV and the years of plant operating experience, no AP1000 RV fatigue failures are anticipated for the 60-year plant lifetime.

Stress Corrosion Cracking

Primary water stress corrosion cracking of Ni-Cr-Fe Alloy 600 materials has been eliminated for the AP1000 RV by eliminating the use of Alloy 600 base and weld materials for the RV design. As previously discussed, Ni-Cr-Fe Alloy 690 is applied in the AP1000 RV in all locations where Alloy 600 was previously used. Stress corrosion cracking of other RV materials is expected to be avoided by careful control of materials and chemicals that come in contact with RV materials as well as elimination of geometry susceptible to stress corrosion cracking, such as canopy seals.

Corrosion Wastage

The most destructive incidents of corrosion wastage on Westinghouse RVs have resulted from instrumentation port conoseal, CRDM lower canopy seal, and head adapter canopy seal leaks. Therefore, corrosion wastage failures have been addressed for the AP1000 RV by eliminating these features from the reactor design. In addition to the corrosion wastage resulting from leaks, the vessel flange outboard of the mating surface has been subject to corrosion during refuelling outages. The corrosion of the flange bolting ring and seal ledge complicated the sealing of the stud hole plugs and the refuelling cavity seal. For the AP1000 RV design, the top surfaces of flange bolting ring and the seal ledge are clad with austenitic

stainless steel, as previously discussed. In addition, the welded cavity seal eliminates the installation of the cavity seal ring during refuelling outages.

Wear and Mechanical Damage

Wear and mechanical damage have not been responsible for any significant failures related to the RV. However, the recent discovery of wear due to the flow excitation of CRDM thermal sleeves has affected both the thermal sleeves and the inside surface of the CRDM nozzles. This wear issue does not affect the AP1000 RV design because the thermal sleeves have been replaced by threaded-on and welded CRDM extensions and funnels. The only other locations in the RV that are subjected to relative motion that can result in wear and mechanical damage are the closure stud and stud hole threads, the flange mating surfaces, and the reactor internals interfaces. The closure studs are lubricated and have weight compensation when they are turned in and out of the stud holes. Furthermore, the frequency of stud installation and removal is not enough to create a wear issue. Reactor vessel and head flange mating surfaces have been damaged by foreign material that has been crushed between them, but these incidents have been extremely rare and could have been avoided by careful visual inspection and/or vessel water level control. Loose objects have also been crushed in the RV/reactor internals interfaces. However, these loose part incidents have not resulted in any significant downtime. Therefore, there are no additional wear and mechanical damage issues that can be addressed in the AP1000 RV design.

Reference 20A.8, issued in 2005, also presents a comprehensive review of the ageing effects in NPP components, including PWR RVs, as covered by generic ageing management programmes. In the context of Leg 1 of the UK AP1000 RV safety argument, these reports provide an up to date list of in-service issues that have previously affected RV integrity and against which it can be shown that the design takes account of worldwide in-service experience. Additional assurance is provided by a structured in-service inspection (ISI) regime as identified in Section 20A.2.4.1.1; for brevity ISI measures are generally not also reproduced in the AP1000 mitigation arguments below.

Recorded Generic In Service Issue (from Reference 20A.8).	AP1000 Mitigation
Stress corrosion cracking of stainless steel bottom-mounted guide tubes.	Bottom-mounted guide tubes are not a feature of the AP1000 design.
Stress corrosion cracking of CH stud assemblies	Specific controls are applied to the material properties of the CH studs, nuts and washers in accordance with NRC Regulatory Guide 1.65 (Reference 20A.9).
Wear of CH stud assemblies	Resolutions found in NUREG-1339 (Reference 20A.10) are incorporated into the design, material selection, fabrication, and maintenance of the AP1000 bolted connections. Because of the emphasis in the design on access for maintenance and inspection, the recommended maintenance practices can be implemented.
Cumulative fatigue damage of CH stud assemblies	AP1000 components are evaluated against a design life of 60 years and fatigue usage factors (FUFs) shown to be below unity for the life of each component.

Recorded Generic In Service Issue (from Reference 20A.8).	AP1000 Mitigation
Stress corrosion cracking of nickel alloy CRDM penetration nozzles, welds and pressure housings	The use of material susceptible to PWSCC is forbidden by the AP1000 RV Design Specification. CRDM penetrations will be manufactured from Alloy 690 tubes with an increased resistance to PWSCC. This is supplemented with additional inspection in accordance with ASME Code Case N-729-1.
Thermal ageing and embrittlement of cast austenitic stainless steel CDRM pressure housings.	CRDM penetrations will be manufactured from Alloy 690 which is not susceptible to the same thermal ageing issues as cast austenitic stainless steel.
Stress corrosion cracking of nickel alloy core support blocks and core guide lugs.	The use of material susceptible to PWSCC is forbidden by the RV Design Specification.
Boric acid corrosion of unprotected external steel surfaces when exposed to borated water leakage	Material selection to minimise component susceptibility to corrosion degradation. ISI of RV head to ASME CC N-729-1 and Code of Federal Regulations 10 CFR 50.55a requires inspection for indications of leakage and boric acid accumulation. Limiting conditions for operation (LCO) 3.4.7 defines RCS operational leakage limits. Leak monitoring confirms leakage within defined limits and provides warning of unidentified leakage. Hydrostatic tests prior to operation and periodically throughout plant life confirm integrity of the reactor coolant pressure boundary (RCPB).
Pitting or crevice corrosion of clad flanges, nozzles, penetrations, pressure housings, safe ends, vessel shells heads and welds.	Material selection, chemistry control and cladding of wetted surfaces minimises the risk of pitting. Features which result in crevice conditions are minimised in the design of the AP1000.
PWSCC of nozzle safe ends and welds with nickel alloy welds or buttering.	The use of material susceptible to PWSCC is forbidden by the RV Design Specification. Nozzle safe ends are manufactured from stainless steel and safe end buttering used Alloy 690 weld with a proven resistance to PWSCC.
Irradiation embrittlement of inlet, outlet and safety nozzles.	The AP1000 core is located low in the RV such that the nozzles are not considered to be susceptible to significant irradiation effects.
PWSCC of nickel alloy CH vent pipes and instrument tubes.	The use of material susceptible to PWSCC is forbidden by the RV Design Specification. CH vent pipes are manufactured from Seamless Alloy 690 pipe with a proven resistance to PWSCC.
PWSCC of nickel alloy instrument tubes in the bottom head.	The design of the AP1000 RV eliminates penetrations in the bottom head.

Recorded Generic In Service Issue (from Reference 20A.8).	AP1000 Mitigation
Fatigue of the RV support skirt and attachment welds.	AP1000 components are evaluated against a design life of 60 years and FUFs shown to be below unity for the life of each component.
Fatigue of RV components.	AP1000 components are evaluated against a design life of 60 years and FUFs shown to be below unity for the life of each component.

20A.2.1.1.3 Design and Manufacture in Accordance with Established Codes, Standards and Regulations Provides Assurance of High Reliability Based on Experience

The RV is designed, fabricated and installed in accordance with the codes, standards and regulations identified in the RV Design Specification (Reference 20A.2) as summarised below. Complying with such proven and established codes, standards and regulations minimises the level of design and manufacturing uncertainty in this respect. Compliance with the ASME Code provides assurance over a wide range of issues from material procurement, component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination (NDE), nondestructive testing (NDT), installation, PSI and ISI requirements. The extensive body of experience that is embodied within the ASME Code and the successful operation of a significant number of pressure vessels (both nuclear and non-nuclear) mean that compliance with the code provides assurance that the vessel reliability will remain high for the design life of the component. However, in order to substantiate a reliability claim commensurate with a component classified as HSS, i.e. where gross failure can be discounted it is necessary to demonstrate that measures have been taken over and above the minimum requirements specified by ASME Code. This is discussed in Section 20A.3. Evidence of compliance with ASME Code requirements will come from the ASME certificate number for the RV.

ASME Boiler and Pressure Vessel Code

The RV is an ASME Code, Section III, Class 1 component. The applicable ASME Code is the 1998 edition up to and including the 2000 Addenda. Specifically,

- Section II Material Specifications
- Section III Rules for Construction of Nuclear Power Plant Components – The subsections of ASME Section III which are applicable to each component are identified in Table 20A-13.
- Section V Non-destructive Examination
- Section IX Welding Qualifications
- Section XI Rules for In-service Inspection of Nuclear Power Plant Components
- ASME Code Case 2142-2, F-Number Grouping for Ni-Cr-Fe Filler Metals Section IX (Applicable to all Sections, including Section III, Division 1, and Section XI)

- ASME Code Case N-729-1, Alternative Examination Requirements for PWR Reactor Vessel Upper Head With Nozzles Having Pressure-Retaining Partial-Penetration Welds, Section XI, Division 1

- ASME Code Case N-782, Use of Code Editions, Addenda, and Case, Section III, Division 1

ANSI/ASME Standards

- ASME NQA-1-1994 Quality Assurance Requirements for Nuclear Facility Applications (Basic Part I Requirements and Supplementary Requirements for Nuclear Facilities)

- ASME NQA-1-1994 Quality Assurance Requirements for Nuclear Facility Applications Part II (Quality Assurance Requirements for Nuclear Facility Applications)

- ANSI/ANS 51.1 Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants

- ANSI N18.2a Nuclear Safety Criteria for the Design of Stationary Pressurized Water Reactor Plants

US Code of Federal Regulations

- 10 CFR 21 Reporting of Defects and Non-compliance

- 10 CFR 50 General Design Criteria for Nuclear Power Plants Appendix A. General Design Criteria 1, 2, 4, 14, 30, 31, and 32 apply.

- 10 CFR 50 Quality Assurance Criteria for Nuclear Power Plants Appendix B and Fuel Reprocessing Plants

- 10 CFR 50 Fracture Toughness Requirements Appendix G

- 10 CFR 50 Reactor Vessel Material Surveillance Program Requirements Appendix H

20A.2.1.1.4 Novel Features of the Design are Avoided or Adequately Justified

AP1000 RV design is broadly similar to that typical of PWR RVs and is consistent with accepted industry practice. As such the RV design includes few novel features. AP1000 emergency core cooling is designed on passive means, where flow of coolant is by gravity and natural circulation. DVI nozzles located in the upper shell are provided as part of the RV design for the PXS, providing flow for core cooling under accident conditions. The PXS was introduced as a design measure to enhance plant safety by improving reliability of the emergency core cooling system as compared with earlier system designs. Incorporation of DVI nozzles to bypass the downcomer and inject coolant directly into the core region may be regarded as a novel feature. However, the DVI nozzle design detail benefits from considerable experience of PWR nozzle design, and justification for the DVI nozzle design is supported by extensive finite element (FE) analyses carried out to evaluate the response to thermal loading, the fatigue usage, and defect tolerance.

The use of QuickLoc assemblies as the pressure boundary interface to the IITA is also relatively novel. QuickLoc assemblies have been used on a number of other plants and hence there is some experience of their use dating back to the early 1990's.

20A.2.1.1.5 The Use of Forgings is Maximised to limit the Number of Welds and Avoid Welds in the Belt Line Region

To minimise welds and reduce ISI, the RPV cylindrical vessel sections will be forged shell courses, thereby eliminating the need for longitudinal seam welds. The beltline forged sections of the vessel are of a length such that the active core region is free of welds where the effects of irradiation embrittlement can be more severe due to the combined effects of the less well controlled composition of weld and the higher propensity for defect formation. The uppermost forged section will be an integral-type design in which the vessel flange and adjacent shell course are formed as a single reinforced ring forging. The shell of the RPV CH will also be a single forging encompassing both the bolting flange and dome geometry.

20A.2.1.1.6 The AP1000 Reactor Vessel Arrangement Optimises Safety

The general arrangement of the RV includes design measures to enhance the robustness of the design without affecting its operational performance. There are no penetrations in the RV below the core, eliminating the possibility for any pipe break or penetration failure to result in immediate core uncovery. The core is positioned as low as possible in the vessel to minimise re-flood time in accident conditions. Finally, in order to assist with the through-life assurance of integrity, the various nozzles are arranged to allow 360° internal and external inspection.

20A.2.1.1.7 Loading, Temperatures and Environment Have Been Well Defined

In order to demonstrate that the loading, temperature and environment have been well defined, evidence to substantiate the following arguments is provided.

- Design and operating parameters used in the design evaluation have been determined using established and conservative procedures and capture all normal and design basis conditions.

- Environment specification is clearly defined.

20A.2.1.1.8 Design and Operating Parameters used in the Design Evaluation have been Determined Using Established and Conservative Procedures and Capture all Normal and Design Basis Conditions

Evaluation of design and build against nuclear standards, as embodied in the ASME Boiler and Pressure Vessel Code, forms a key input to several of the safety-related claims made for the RV. The evaluation is based on valid, relevant and comprehensive data. To substantiate claims based on ASME Code compliance evidence is provided here to demonstrate that design and operating parameters used in the design evaluation have been determined using established and conservative procedures.

The Design and Operating parameters for the AP1000 plant are defined in Reference 20A.49 and are as shown below.

	Design Condition
Design pressure	17.24 MPa (2500 psia)
Normal operating pressure	15.51 MPa (2250 psia)
Design Temperature	343°C (650°F)
No load temperature	292°C (557°F)
Normal operating inlet water temperature	281°C (537.2°F)
Normal operating outlet water temperature	321°C (610°F)

The RV is designed and constructed to the requirements for Class 1 in ASME Code. Section III Subsection NB of the code requires that the design is evaluated against design, service, and test conditions and that the stresses within the vessel are shown to comply with specified allowable stress limits appropriate to the material of construction. The design conditions include those pressure, temperature, and mechanical loadings selected as the basis for the design. Service conditions cover those normal operating conditions, anticipated transients, and postulated accident conditions expected or postulated to occur during operation. The evaluation of the service and testing conditions includes an evaluation of fatigue due to cyclic stresses.

The following five categories of operating condition, as defined in ASME Code, Section III, have been evaluated as part of the design substantiation for the RV. These encompass all operating conditions within the design basis, as summarised in Table 20-22 along with the number of occurrences of each transient over the design life of the plant.

- Level A Service Conditions – Normal Conditions.
- Level B Service Conditions – Upset Conditions, Incidents of Moderate Frequency
- Level C Service Conditions – Emergency Conditions, Infrequent Incidents
- Level D Service Conditions – Faulted Conditions, Limiting Faults
- Testing Conditions – Include primary and secondary hydrostatic tests and steam generator tube leak tests specified.

Cyclic loads are introduced by normal power changes, reactor trips, and start-up and shutdown operations. These design base cycles are selected for fatigue evaluation and constitute a conservative design envelope for the design life. To provide a high degree of integrity for the equipment in the RCS, the transient conditions selected for equipment fatigue evaluation are based upon a conservative estimate of the magnitude and frequency of the temperature and pressure transients that may occur during plant operation.

The specific transients to be considered for equipment fatigue analyses are based upon PWR plant operating experience along with engineering judgment. The plant condition (PC) categorisation defined in ANS N51.1 (Reference 20A.12), which categorises transients on the basis of expected frequency, are also part of the process to define transients and which service condition applies for a given transient. The basis and derivation of the transients for each of these service conditions are specified in References 20A.2, 20A.13, and 20A.14.

Where thermal stratification during PXS operation and natural circulation cooldown is of concern, this is considered by performing a thermal/flow analysis using computational fluid dynamics techniques. This analysis includes thermally-induced fluid buoyancy, heat transfer between the coolant and the metal of the vessel and internals and uses thermal/flow boundary conditions based on an existing thermal/hydraulic transient analysis of the primary RCS. This analysis provides temperature maps that are used to evaluate thermal stresses.

The transients selected are a conservative representation of transients that, used as a basis for component fatigue evaluation, provide confidence that the component is appropriate for its application for the 60-year design objective. These transients are described by pertinent variations in pressure, fluid temperature, and fluid flow. The frequency of these transients in some cases is greater than the maximum frequency that defines the plant condition in American Nuclear Society (ANS) N51.1 (Reference 20A.12). The design transients and the number of events of each that are normally used for fatigue evaluations of components are summarised in Table 20-22 and further specified in the RV Design Specification (Reference 20A.2). Separate transients are defined for the DVI nozzle assessment, as outlined in Reference 20A.15.

Section 6.2.4 of Reference 20A.2 provides a description of the seismic loads and other mechanical loads and loading combinations evaluated. The seismic loading classification, as defined in Reference 20A.16, considers the safe shutdown earthquake (SSE) and low level seismic event. The latter is used only in the fatigue evaluation and considers 5 occurrences of 63 cycles per occurrence (315 cycles) having a magnitude of 1/3 SSE.

The peak ground acceleration of the SSE has been established as 0.30g for the AP1000 design. The vertical peak ground acceleration is conservatively assumed to equal the horizontal value of 0.30g. Both horizontal and vertical design response spectra are based on the Regulatory Guide 1.60 spectra augmented at the higher frequencies. A comparison of these spectra to the UK generic design basis PML spectra is made in Section 12.6.

During containment flood-up thermal transients, the RV is assumed to be immersed in water on the vessel OD up to the bottom of the outlet nozzles. Reference 20A.2 provides details of this transient.

20A.2.1.1.9 Environmental Specification is Clearly Defined

The materials selected for use in the RV are selected to be compatible with the full range of internal and external environmental conditions which may be encountered over the plant life. These environmental conditions include temperature humidity, radiation, chemistry of fluid or materials in contact, and other external conditions which may affect the suitability of a material. These have been determined based on extensive PWR operating experience. The normal limits for internal environment conditions of the primary coolant water are specified in Table 20A-3. The external environmental conditions are listed in Table 20A-4.

20A.2.1.1.10 The AP1000 Reactor Vessel Design has been Assessed Against Relevant Design Code Requirements

In order to demonstrate that the vessel design has been assessed against relevant design code requirements, evidence to substantiate the following arguments is provided:

- The RV design complies with the allowable stress limits and sizing limits as specified in ASME III for a Class 1 component.
- The end of life FUFs are below unity.

20A.2.1.1.11 The Reactor Vessel Design Complies with the Allowable Stress Limits and Sizing Limits as Specified in ASME III for a Class 1 Component

The RV is designed in accordance with relevant and recognised design codes, specifically the ASME Boiler and Pressure Vessel Code, Section III, Division 1 – 1998 Edition with addenda up through and including 2000 Addenda (Reference 20A.7). In order to demonstrate code compliance, the following key aspects are satisfied in the ASME Code Design Report for the RV (Reference 20A.17), which documents analyses substantiating the design against the ASME Code requirements.

- The tentative sizing of vessel wall thickness and head thickness.
- The nozzle openings and reinforcement requirements
- The CH studs are designed to ASME Code, Section III, Appendix E requirements.
- The minimum wall thickness requirements for nozzle ends and safe ends.
- The requirements for no leakage through the Seal O-ring.
- IHP support lugs and RV lift lugs are qualified per ASME Code Section III, Subsection NF. The RV lift lugs are also evaluated for the lift load meeting the NUREG-0612 (Reference 20A.20) criteria. The attachment welds of IHP support lugs and RV lift lugs to the CH are qualified to ASME Section III, Subsection NB criteria.
- The attachment for the nozzles with partial penetration welds for the CH penetrations (CRDM and vent pipe), including transferring the loading above the head.
- The primary stresses in the J-groove weld.
- The primary plus secondary stresses on CH penetrations.

- The ASME Code, Section III, Subsection NB criteria are used for the qualification of each pressure boundary component and studs.

The general FE code ANSYS (Reference 20A.24) was used to perform an analysis for each of the loading conditions and to evaluate the design against ASME III, Class 1 stress limits for design, operational, accident and testing conditions. It has been demonstrated that adequate margins exist in all cases.

Table 20A-11 contains the allowable ASME Code Stress Limits for the general primary membrane stress intensity (P_m) and primary local plus primary bending stress intensities (P_L+P_b) to which different regions of the RV have been assessed against.

Conservative approaches have been adapted to the stress analysis and the interpretation of ASME stress limits. Details of the methodology used in the assessment of individual locations and the associated FE models and the loadings used for the evaluation of each location are documented in each component analysis summarised in the ASME design report for the RV (Reference 20A.17). In the majority of cases, it has been demonstrated that adequate margins exist. In the small number of cases where this has not been achieved, further explanation is provided to support the basis for the design.

20A.2.1.1.12 The End of Life Fatigue Usage Factors are Below Unity

The RV is designed to meet the fatigue design criteria as defined in the ASME Code, Section III without compromising other aspects of the design. Critical RV design features are identified and analysed to demonstrate that the fatigue design criteria are met. The basis for the transient definition is discussed in Section 20A.2.1 of this safety argument.

The FUFs are determined as:

- Membrane plus bending component at each location (end points of each cut).
- A combination of the total components for all thermal cases, resulting in alternating stress intensity ranges in decreasing order until all usage cycles are exhausted.
- A partial usage factor is determined by computing the ratio of the number of cycles determined by the alternating stress range, divided by the allowable number of cycles for the same alternating stress range, as defined in the applicable ASME fatigue curve.
- A cumulative FUF is determined by summing the partial usage factors. The cumulative FUF must be less than 1.0.

The calculated FUFs have been derived in accordance with the design curves specified in the 2001 version of the ASME Boiler and Pressure Vessel Code. Based on the current approach, all assessed RV locations satisfy ASME acceptance criteria for fatigue usage for the full design life. Sensitivity to changes in conservatism in the fatigue assessment is mitigated by the other elements of the safety argument. The RV locations where predicted FUFs exceed 0.75 are specifically included within the ISI programme (Section 20A.2.4). The ISI is designed both to demonstrate freedom from significant defects and to provide timely forewarning of failure and supports the defect tolerance assessment described later in this Leg.

Using the FE based results, code compliance for ASME III Class 1 components has been assessed and the FUFs are reported in Reference 20A.17. Stress limits have been considered

pertaining to Design loadings, Level A service limits and FUFs, Level C design basis accident stress limits and test stress limits.

20A.2.1.2 Components Are Manufactured Using a Good Choice of Materials

In order to demonstrate that the AP1000 RV components are manufactured using a good choice of materials, evidence to substantiate the following arguments is provided.

- AP1000 RV materials have a proven service performance.
- Material specifications meet or exceed ASME specifications.
- Tight control on chemical composition is enforced to minimise the effects of irradiation embrittlement or thermal ageing and ensure that materials remain ductile when significantly stressed.
- Materials are compatible with each other and with the environment and are resistant to environmental degradation over the life of the plant. Degradation characteristics are known and understood.
- Materials testing is sufficient to demonstrate that the material properties are compliant with the relevant specifications.
- RV Surveillance Material.

20A.2.1.2.1 AP1000 Reactor Vessel Materials have a Proven Service Performance

The selection of the AP1000 RV materials reflects international experience in PWR design, manufacture and operation and the lessons learnt, for example in terms of refinement of chemical composition of belt line forgings to minimise the effects of through-life irradiation embrittlement. The vessel shell, lower head, nozzles and CH are manufactured from ASME SA-508 Grade 3 Class 1 which is recognised worldwide as the standard for PWR RV manufacture and its material properties and in-service performance are supported by an extensive body of evidence.

As is standard for PWR ferritic components which are in contact with primary coolant, wetted surfaces are clad with austenitic stainless steel or equivalent corrosion-resistant material; the AP1000 cladding is Type 308L/309L welded overlay. The use of nickel-chromium-iron alloys in pressure boundary components is limited to Alloy 690 or its associated weld metals. The use of Alloy 600 is prohibited which reflects the concerns relating to PWSCC of these nickel based alloys.

20A.2.1.2.2 Material Specifications Meet or Exceed ASME Specifications

The AP1000 RV materials comply with the corresponding material specification permitted by the ASME Code, Section III, Division 1. The material specifications used for the RV assembly are as identified in Table 20A-5. The material specifications detail requirements in terms of compliance with the following ASME Code requirements; limitations on manufacturing requirements and the use of weld repairs, supplementary requirements over and above ASME specifications, heat treatment requirements, chemical composition, mechanical testing, inspection and quality assurance requirements.

To support this argument, a quality assurance compliant certified material test report (CMTR) as per the ASME Code (Section III Div 1 Appendices Article P-1000) will be provided with shipment of the forgings. This will include the material test results and information on:

- Chemical analyses: heat and product
- Mechanical properties: tensile stress-strain, Charpy, drop weight, T_{NDT} and RT_{NDT}.
- Heat treatments
- Information on archive/weldment material
- Sketches or drawings with dimensions
- A statement certifying that no weld repairs had been made (where applicable)
- Start-of-life inspection results
- NDE Reports

For certain materials, Supplementary Requirements are specified within each of the material specifications which exceed the requirements specified in ASME II. The Supplementary Requirements, as detailed for the beltline forging in Reference 20A.25 include:

- S1 Simulated post-weld heat treatment (PWHT) of mechanical test samples
- S3 Charpy V-Notch Impact transition Curve
- S4 Additional Charpy Data
- S9 Additional restrictions on chemical composition
- S10 Alternative Fracture Toughness Requirements to establish a valid T0 fracture toughness Reference temperature.
- S13 Minimum Tempering Temperature
- S15 Product Analysis

Additional Supplementary Requirements are specified for RPV pressure boundary components which exceed the requirements specified in ASME Section II. The Additional Supplementary Requirements, as detailed in Reference 20A.41, are as follows:

- End-of-life Increased Irradiated Weld Metal Toughness for Reactor Vessel Beltline Welds
- Fracture Toughness for SA-182 316LN Material of RPV Nozzle Safe-Ends
- Minimum Yield Strength for Inconel 52/152 (N06690) Material of Dissimilar Metal Welds on RPV Inlet and Outlet Nozzles
- Minimum Yield Strength for SA-182 316LN Material of RPV Nozzle Safe-Ends

Supplementary fracture toughness testing will be performed to underpin the values assumed in the defect tolerance assessment as described in Reference 20A.57.

20A.2.1.2.3 Tight Control on Chemical Composition is Enforced to Minimise the Effects of Irradiation Embrittlement or Thermal Ageing

The RV base material and welding material chemistry will be controlled such that material susceptibility to neutron damage is as low as practicable. In the RV beltline region (i.e., upper shell, lower shell, transition ring, and the two girth welds at the top and bottom of the lower shell) a complete chemical analysis will be performed on the forgings, plates, and as deposited weld metal (excluding cladding) used.

The materials used for the beltline region will be restricted to the following maximum limits of nickel, copper, phosphorus, vanadium, and sulphur due to neutron fluence which is more than 1 x 10^{17} (n/cm^2).

As deposited weld metal:	Base metal:
copper – 0.06%	copper – 0.06%
phosphorus – 0.01%	phosphorus – 0.01%
vanadium – 0.05%	vanadium – 0.05%
sulphur – 0.01%	sulphur – 0.01%
nickel – 0.85%	nickel – 0.85%

20A.2.1.2.4 Materials are Compatible with Each Other and with the Environment and are Resistant to Environmental Degradation over the life of the plant. Degradation Characteristics are Known and Understood.

The materials selected for use in the RV will be compatible with the full range of internal and external environmental conditions which may be encountered over the plant life and are predicted not to degrade to an unacceptable degree in that time. These environmental conditions include temperature, humidity, radiation, chemistry of fluid or materials in contact, and other external conditions which may affect the suitability of a material.

To prevent corrosion of low alloy steel component in contact with primary coolant, all principal pressure-retaining components made from such materials, including the RV, have corrosion-resistant cladding on surfaces exposed to the reactor coolant. Clad surfaces will be "L" grade austenitic stainless steel and welds and buttering will be "L" grade austenitic stainless steel or Ni-Cr-Fe Alloy. The stainless steel cladding surfaces will meet all of the requirements of Westinghouse Material Specification for Austenitic Cladding (Reference 20A.26). For multiple layer stainless steel cladding, the stainless steel cladding will be Type 308L stainless steel weld metal with Type 309L stainless steel weld metal used for the first layer. The corrosion resistance of the cladding material is at least equivalent to the corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy, martensitic stainless steel, and precipitation-hardened stainless steel.

Austenitic stainless steel materials such as those used on the nozzle safe ends and nickel-chromium-iron alloy base materials such as those used on the CRDM penetrations (Alloy 690) are used in the solution-annealed or thermally treated conditions. These heat treatments are as required by the material specifications according to a laboratory-derived treatment process and are generally consistent with industry-accepted procedures. High margins against primary water stress corrosion cracking exist with the specification of thermally treated Alloy 690 over the range of anticipated operating environments. The use of materials with a low resistance to PWSCC is prohibited.

AP1000 design prohibits the use of sensitised stainless steel for safety related components. All austenitic stainless steels are solution annealed and are therefore not in a sensitised condition.

Compatibility with external insulation and environmental atmosphere is also an important consideration both during normal operation and during shutdown plant conditions. The reactor vessel insulation is reflective insulation similar to that in use in current pressurised water reactors. The reactor vessel insulation (including the insulation around the lower head) is mounted on a structural frame supported from the wall and floor of the reactor cavity; and is not in direct contact with the vessel. The insulation for the closure head flange is supported by the seal ledge. In the event of coolant leakage, the ferritic materials will show increased general corrosion rates. Ferritic materials exposed to coolant leakage can be readily observed as part of the in-service visual and/or non-destructive inspection programme to confirm the integrity of the component for subsequent service.

To guard against potential liquid metal embrittlement, all stainless steel and Ni-Cr-Fe Alloy will be free from deliberate addition of low melting point materials as alloying constituents such as lead, zinc, cadmium, tin, antimony, mercury, bismuth, sulphur and their compounds. If any of these impurities exist in the stainless steel and/or Ni-Cr-Fe Alloy, the data will be reviewed and approved by Westinghouse. These low melting-point elements, their alloys and compounds, are also restricted with regard to their use as construction materials, erection aids, cleaning agents and coatings for finished surfaces of the RPV that are in contact with RCS fluid. Lead or aluminium tipped prods may be used for magnetic particle examination of ferritic materials to which the stainless steel or Ni-Cr-Fe Alloy attaches. The use of copper prod tips is prohibited during magnetic particle examinations.

20A.2.1.2.5 Materials Testing Demonstrates that the Material Properties are Compliant with the Relevant Specifications

The mechanical testing requirements for each material are contained within the relevant material specifications as identified in the RV Design Specification and identified in Table 20A-5. For the RV main forgings the mechanical property tests will consist of Tensile Tests, Drop Weight Tests and Charpy V-Notch Impact Tests. These will be carried out in accordance with ASME III Section NB-2000.

Tensile Tests

Tensile tests will be carried out to confirm that the material properties satisfy the minimum tensile strength values given specified by ASME. Of specific note, in addition to the minimum tensile strength values given in SA-540, the closure studs, nuts and washers should not exceed the tensile strength limitations specified in NRC Regulatory Guide 1.65 (Reference 20A.9).

Impact Tests

The impact test specimens will be obtained after both the quenching and tempering operations and the forming operations, regardless of sequence. Each forging will have an equal number of impact test specimens taken at each of 2 locations 180° apart at the 1/4T x T test depth and will be oriented in a direction normal to the Primary Working Direction (PWD) (other than the thickness direction). Additionally all the forgings will have specimens, located as above, removed oriented in a direction parallel to the PWD.

Drop Weight Tests

Sufficient drop weight tests will be run to determine the actual nil-ductility transition temperature (NDTT) or nil-ductility temperature for each forging. The Design Specification requires that the NDTT will not be higher than minus -23.3°C (10°F). T_{NDT} as defined by ASME Code will be considered as the actual NDTT determined by drop weight tests.

Charpy V-Notch Impact Tests

Charpy V-notch impact tests will be performed for each location at a temperature not higher than the T_{NDT} temperature plus 33.3°C (T_{NDT} plus 60°F). For each test location, the RT_{NDT} temperature will not be higher than minus -23.3°C (10°F). The minimum upper shelf impact value will be 101.7 J (75 ft-lbs) for the upper shell, lower shell, and transition ring forging in both the longitudinal and transverse directions.

Fracture Toughness Tests

Fracture toughness tests will be performed on all ferritic base materials and weld metals used for the RV pressure boundary. Testing will be performed to establish the T_0 Reference temperature in accordance with ASTM E1921-05 (Reference 20A.51). Test specimen location and orientation will be in accordance with Code, Section, Section III subsection NB-2300. Except for the core beltline region, the RPV will be designed and fabricated such that the initial nil ductility transition temperature (RT_{NDT}) at the most limiting location is not greater than -12.2°C (10°F). The initial RT_{NDT} in the core belt region forgings will not exceed -23.3°C (-10°F) and the core belt region welds will not exceed -55.5°C (-68°F).

The calculated end-of-life (60 years of service) RT_{NDT} or RT_{PTS} caused by irradiation for core belt materials will not exceed 132.2°C (270°F) for forgings and 148.9°C (300°F) for welds as specified in Regulatory Guide 1.99 (Reference 20A.27) and indicated in Table 20A-6. End-of-Life RT_{PTS} (also equals RT_{NDT}) will be determined for as-built material. The preliminary RT_{PTS} for the beltline forging and beltline weld are 34.4°C (94°F) and 37.8°C (100°F) respectively.

Prior to fuel load, verification of plant-specific belt line material properties will be provided to confirm that assumptions used in the design assessment design assessment remain valid. This will form part of the site specific justification and will include a pressurised thermal shock evaluation based on as-procured RV material data and the projected neutron fluence for the plant design objective of 60 years. The related portions of the supplementary fracture toughness testing described in Reference 20A.57 will also be completed.

20A.2.1.2.6 Reactor Vessel Surveillance Material

To evaluate the effect of radiation damage on beltline fracture toughness properties, a number of surveillance samples will be installed within the RPV. The assessment is based on the comparison of the results from pre-irradiation testing of Charpy V-notch, 1/2-T compact tension (CT) fracture mechanics test specimens and tensile specimens and post-irradiation testing of Charpy V-notch, tensile, and 1/2-T CT specimens removed at different time through the plant lifetime. The programme is directed toward evaluation of the effect of radiation on the fracture toughness of RV steels based on the transition temperature approach and the fracture mechanics approach, and is in accordance with ASTM E185 (Reference 20A.28). Further details of this are included in Section 20A.2.4.3.1.

20A.2.1.3 **Good Manufacturing**

In order to demonstrate that the good manufacturing process will be used, evidence to substantiate the following arguments is provided.

- RV components will be manufactured by experienced suppliers with a track record for producing similar components.
- High confidence in RV manufacturing quality can be taken from compliance with ASME III and the experience embodied within the code.
- Approved welding procedures and qualified operators are used.
- Repairs and deviations from the design intent will be recorded.
- Manufacturing and procedural controls ensure quality of forging material.
- Manufacturing records and Procedures.
- Quality Assurance.

20A.2.1.3.1 Reactor Vessel Components will be Manufactured by Experienced Suppliers with a Track Record for Producing Similar Components Using Proven and Established Techniques

The supplier for the RV has not yet been selected. However, in selecting the manufacturer for the heavy pressure vessels, a detailed technical evaluation of the suppliers ability to comply with the Design Specification (Reference 20A.2) and quality assurance requirements will be undertaken, giving particular attention to the suppliers ability with regard to achievement of the material compositional requirements including minimum fracture toughness requirements, the methods for the qualification of weld procedures and the ability to carry out the required range of inspections during manufacture. The evidence to support this argument form part of a site specific justification.

The RV components will be joined by welding, using the single or multiple wire submerged arc and the shielded metal arc processes or other established techniques. Gas metal arc welding and plasma arc welding are acceptable methods of applying buttering for dissimilar metal welds. The use of severely sensitised stainless steel as a pressure boundary material is prohibited and is eliminated by either a select choice of material or by programming the method of assembly. At locations in the RV where stainless steel and nickel-chromium-iron alloy are joined, the final joining beads are nickel-chromium-iron alloy weld metal in order to prevent cracking. The location of full penetration weld seams in the upper CH and vessel bottom head are restricted to areas that permit accessibility during ISI. The stainless steel clad surfaces are sampled to demonstrate that composition requirements are met.

20A.2.1.3.2 High Confidence in Reactor Vessel Manufacturing Quality can be Taken from Compliance with ASME III and the Experience Embodied Within the Code

Design and fabrication of the RV is carried out in accordance with ASME Code, Section III, Class 1 requirements and manufactured using well established procedures. Details of manufacturing codes and standards are provided in Reference 20A.2 with certain more stringent requirements defined in Reference 20A.29. Compliance with the code and the experience embodied within the code provides a high degree of confidence that high quality

has been achieved and also that the vessel will be tolerant to minor variations in material properties and minor imperfections in fabrication. Measures, described in the following Section, are over and above minimum code requirements and provide additional confidence that the vessel will enter service free from defects of structural significance.

20A.2.1.3.3 Approved Welding Procedures and Qualified Operators are used to Minimise Defect Occurrence

As detailed in Reference 20A.2, welding of all materials will be done in accordance with welding procedures and using certified welders that have been qualified according to the rules of Sections III and IX of the ASME Code as well as the additional requirements identified in the RV Design Specification (Reference 20A.2) and the supplemental requirements detailed in Reference 20A.29. Control of welding variables (as well as examination and testing) during procedure qualification and production welding is performed according to ASME Code requirements. Specific details of welding processes, selection and control of welding consumables, welding procedure qualification, pre-heat, interpass temperatures and post heating requirements and specific control for cladding and buttering are provided in Reference 20A.29.

The penetration to head J-groove welding procedures will be qualified in accordance with the applicable requirements of Section IX of the ASME Code. Full-scale mock-up qualification tests will be performed. The tests will include metallography, measurement of residual stress and ultrasonic examinations to confirm ultrasonic inspectability.

20A.2.1.3.4 Repairs and Deviations from the Design Intent will be Recorded. Approval for Deviations from the Design Intent will be Appropriate with Justification where Necessary.

The requirement to record major/minor repairs and deviations for the design intent is stated within the RV Design Specification (Reference 20A.2). Deviation reports or deviation notices (DNs) will be prepared by the manufacturer for all conditions that do not meet requirements and cannot be corrected using previously approved repair procedures. Deviations/defects that are identified during processing/fabrication, which will not affect the final fit-up/function (e.g., weld defects) of the final component and which may be repaired by previously approved repair procedures, will not need to be submitted for Westinghouse approval as a DN. However, these will be recorded for future reference. The requirements placed on the manufacturer include the reporting criteria and the conditions under which formal review and approval by Westinghouse will be required. The following should be noted:

- All major repairs to base material and pressure boundary welds will be subjected to formal review by Westinghouse before approval to proceeding with the repair is granted.

- All arc strikes on pressure boundary and accessible non-pressure boundary materials will be removed and the areas ground to a smooth contour with a 4:1 taper. Any arc strike that exceeds a depth of 2.54 mm (0.10 inches) will be documented and reviewed by Westinghouse for approval.

- Repairs by welding will be cleared by the same NDE technique/procedure by which the indications were found.

- The location of these repairs will be identified on the as-built weld seam drawing for permanent record and may be required to be permanently marked on the vessel or head when so indicated in the deviation notice disposition.

- No repair welding is permitted to the J-groove welds without first performing full size mock-up qualification tests and measurement of residual stress to optimise the repair technique.

20A.2.1.3.5 Manufacturing and Procedural Controls Ensure Quality of Forging Material

The RV shell, lower head, nozzles and CH will be manufactured from high quality forgings supplied by an experienced forge master, working to approved procedures to meet relevant product specifications, which are compliant with ASME requirements. Individual material specifications for belt line and non beltline SA-508 Grade 3 Class 1 forgings and Stainless steel forgings are provided in the relevant material specifications as listed in the technical index. These provide specific details of controls on chemical composition, microstructures, heat treatment, materials testing, grain size evaluation and ultrasonic examination to ensure that the final product has the desired through thickness properties and is free from forging defects.

20A.2.1.3.6 Manufacturing Records and Procedures

To ensure that there is a high degree of control over the achievement of high quality during manufacture, the following controls on the manufacturing records and procedures are specified as part of the component design specification.

Weld Procedures

To ensure that weld procedures are acceptable, all procedures for weld and weld repair and base metal repair will be submitted to Westinghouse for approval prior to use in fabrication. Review and approval by Westinghouse of these documents is based on compliance with the applicable references, the RV specification and also on technical justification.

All welding procedure specifications to be used in the fabrication the RV will be prepared in accordance with a general welding procedure specification and the requirements of Sections III of the ASME Boiler and Pressure Vessel Code.

Heat Treatment

Heat treatment specifications will be approved prior to manufacture and will include the following (where applicable).

- Holding times for austenitising and tempering
- Rates of heating
- Temperature control
- Temperatures for the austenitising and tempering operations during heating/holding
- Time from the furnace to the quench tank
- Quenching medium
- Cooling method

Material Records

All material ordering specifications (including heat treatment and base metal repair procedures) will be submitted to Westinghouse for approval prior to material procurement. This includes all welding consumables. Each chemical analysis including both ladle and check, physical and mechanical mill test data sheets, supplier test data sheets, weld material certifications, and inspection reports for materials required by the Design Specification and

applicable references will also be provided. The Supplier will provide certified chemical and mechanical properties of the weld metal used for full penetration pressure boundary welds in the vessel and CH, any weld repairs to these welds, and all base metal weld repairs.

Manufacturing Inspections

Each NDE examination report will be submitted to the Westinghouse after the completion of each examination. Defects will be recorded and defect tolerance studies will be carried out by Westinghouse to ensure that recorded indications do not present a concern over the design life of the plant.

Dimensional Checks

The dimensional profile document will be used to record vessel and CH as-built dimensions. This information will be in accordance with the dimensions required by the Westinghouse as-built drawing format.

Cleaning and Contamination Protection Procedures

Materials used in the fabrication, installation, and testing of nuclear steam supply components and systems are handled, protected, stored, and cleaned according to recognised, accepted methods designed to minimise contamination that could lead to cracking.

20A.2.1.3.7 Quality Assurance

Activities affecting the quality of items and services for the AP1000 Project during design, procurement, fabrication, inspection, and/or testing are performed in accordance with the quality plan described in "Westinghouse Electric Company LLC Quality Management System (QMS)", Revision 7 (Reference 20A.30) to satisfy the requirements of 10 CFR 50 Appendix B. The following requirements are identified in Reference 20A.31.

For items designated as ASME Boiler & Pressure Vessel Code (BPVC) Section III, the Quality Assurance Programme applicable to the manufacture of the RV will meet the following requirements:

- 10 CFR 50 Appendix B – "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants"
- US Nuclear Regulatory Commission, Regulatory Guide 1.28, "Quality Assurance Program Requirements (Design and Construction)," Revision 3, August 1985
- ASME NQA-1-1994, "Quality Assurance Requirements for Nuclear Facility Applications"
- ASME B&PV Code, "Section III, Rules for Construction of Nuclear Power Plant Components," 1998 Edition through 2000 Addenda
- The RV Supplier will reference the ASME certificate number and expiration date on the applicable pages of the data package certification(s)

For items designated as Non-ASME B&PV Code, Safety-Related, the Quality Assurance Programme will meet the following requirements:

- 10 CFR 50 Appendix B – "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants"
- US Nuclear Regulatory Commission, Regulatory Guide 1.28, "Quality Assurance Program Requirements (Design and Construction)," Revision 3, August 1985
- ASME NQA-1-1994, "Quality Assurance Requirements for Nuclear Facility Applications"

20A.2.1.4 Manufacturing Inspection

Materials and fabrication processes are well designed in order to demonstrate that the AP1000 RV enters service free of significant defects, which will be confirmed by an effective manufacturing NDT inspection programme. Evidence to substantiate the following arguments required to meet the claimed objective is provided:

- Manufacturing inspections meet or exceed the requirements of ASME.
- Reliability of NDT is assured through a "Design for Inspection" philosophy.
- NDT performed at key stages of manufacture assures the high quality of the completed RV and its steel components.
- Qualified inspection performed on high safety significant components demonstrates a good safety margin.
- Qualified inspection of HSS components confirms the plant is free of defects meeting ASME Section XI criteria.
- The results of NDT performed at key stages of manufacture demonstrate a low frequency of significant defects in forgings and welds.
- The results of NDT performed confirm no degradation during key stages of manufacture.

20A.2.1.4.1 Manufacturing Inspections Meet or Exceed the Requirements of ASME

A diverse range of effective NDT methods and techniques are deployed at various manufacturing stages to ensure that steel forgings, plate, welds and cladding in the RV enter service free of significant manufacturing defects. The scope of the manufacturing NDT and the techniques applied either meet or exceed the requirements of ASME Section III and is summarised in Table 20A-7.

All repairs made as a result of NDT findings are subsequently inspected using the same NDT method(s) that originally detected the defect leading to the repair. For Class 1 welds, this compliance with ASME NDT requirements provides the adequate assurance regarding the achievement of manufacturing quality.

20A.2.1.4.2 Reliability of NDT is Assured through a "Design for Inspection" Philosophy

The AP1000 incorporates a "Design for Inspectability" philosophy (Reference 20A.32) in which the RV welds and surrounding areas are designed to facilitate NDT by:

- Ensuring a good surface finish for deploying the range of techniques.
- Enabling good access for NDT personnel and equipment.
- Providing sufficient access for deploying angle beam ultrasonic to give full volumetric coverage.
- Providing as many inspection surfaces/scanning directions as possible.

20A.2.1.4.3 NDT Performed at Key Stages of Manufacture Assures the High Quality of the Completed RV and its Steel Components

Sensitive volumetric and surface NDT methods are applied at points in the manufacturing programme that ensure any necessary repairs are undertaken at the earliest possible stage and that any degradation resulting from processes such as post-weld heat treatment is identified.

Supplemental inspections, additional to those specified by ASME Section III, are performed that match the pre-service inspection and in-service acceptance criteria of ASME Section XI. Here the objective is to reconcile the difference in acceptance standards between ASME III and ASME XI and ensures that the PSI does not report rejectable defects that were not identified as such during the standard manufacturing NDT (Reference 20A.2)

20A.2.1.4.4 Qualified Inspection Performed on Highest Safety Significant (HSS) Components Demonstrates a Good Safety Margin

Qualified ultrasonic volumetric inspections will be performed on HSS locations, identified in Table 20A-1, after the final post-weld heat treatment to provide a very high level of confidence that the RV enters service free of any defect that could threaten the structural integrity. A procedure for manufacturing NDT qualification of welds has been outlined. Target sizes for manufacturing defects for HSS welds have been derived from elastic-plastic fracture mechanics by calculating the end-of-life limiting defect sizes and fatigue crack growth in accordance with the R6 methodology. NDT performed with currently available tried and tested ultrasonic techniques provides a detect and reject capability that demonstrates a defect size margin (DSM) of 2 or greater. The basis for this is discussed in Section 20A.2.3.1. High reliability for these inspections will be demonstrated through qualifying the inspection system (procedure, equipment, and personnel) using the principles specified in the European Network for Inspection and Qualification (ENIQ) European methodology for qualification of non-destructive tests (Reference 20A.33). For selected HSS welds, a manufacturing inspection plan has been produced which provides the physical reasoning underpinning the claimed inspection capability; this is discussed in Section 20A.2.3.1.4. The manufacturing inspection plans were developed following a process (Reference 20A.56) which is based on the preparation of technical justifications described in ENIQ methodology. A process will be developed in due course to address parent material associated with HSS locations.

A rigorous approach to classification based on failure modes and consequences has identified the following pressure boundary welds as HSS (locations are further described in Table 20A-1):

1. RV shell circumferential welds (Locations 1.1, 1.2, 1.3)
2. RV primary circuit nozzle to shell welds (Location 2.1)
3. DVI Nozzle to shell welds (Location 3.1)
4. RV nozzle to safe end transition welds (Locations 2.2, 3.2)

The RV safe-end to inlet/outlet loop pipe welds have been assessed as HI. This is discussed in Section 20E.3.1.8.

20A.2.1.4.5 Qualified Inspection of HSS Components Confirms the Plant is Free of Defects Meeting ASME Section XI Criteria

The final stage of NDT for HSS welds is the application of qualified mechanised UT systems to confirm the welds are free of any defects that exceed the ASME Section XI criteria. These inspections have two purposes:

- They provide additional high reliability inspections at the end of all manufacturing stages.
- They generate a "finger-print" set of data against which future ISI results can be compared. By establishing that acceptable indications found during ISI were also present at PSI fabrication, potential unnecessary repairs are avoided.

20A.2.1.4.6 The Results of NDT Performed at Key Stages of Manufacture Demonstrate a Low Frequency of Significant Defects in Forgings and Welds

Experience shows that materials and manufacturing processes similar to those chosen for the AP1000 plant lead to a low frequency of defect occurrence. Nevertheless, sensitive volumetric and surface NDT methods are applied at points in the manufacturing programme to confirm that the materials and processes used for the forging and welds are well designed.

20A.2.1.4.7 The Results of NDT Performed Confirm no Degradation during Key Stages of Manufacture

Effective NDT inspections of HSS welds will be performed before and after post-weld heat treatment and hydrotest to confirm that no damage occurs as a result of these processes.

20A.2.1.5 Plant Operation and Maintenance

In order to demonstrate that the plant will be properly operated and maintained, evidence to substantiate the following arguments is provided.

- AP1000 Pressure/Temperature limits are clearly defined in accordance with recognised procedures and are suitably conservative.
- The AP1000 RCS chemistry specification is clearly defined and measures are in place to control corrosion of the reactor vessel.
- Records of operation and maintenance will be maintained to confirm compliance with procedural requirements.
- Incidents involving transgressions of set limits will be investigated.
- Procedures are in place to control maintenance activities.
- ISI will detect defects before they compromise structural integrity.

Westinghouse document UKP-GW-GL-501 (Reference 20A.50) presents the generic AP1000 technical specifications. The AP1000 technical specifications are consistent with the Standard

Technical Specifications – Westinghouse Plants, NUREG-1431, Reference 20A.52, to the maximum extent possible. The AP1000 technical specifications differ from those in NUREG-1431 only as necessary to reflect technical design differences between the "typical" Westinghouse design and the AP1000 design.

In order for the operators to safely operate and maintain the AP1000 plant, operating and maintenance manuals that are fully compliant with the technical specifications will be produced in due course. Regarding the RV, the following issues are considered the most pertinent at this stage in terms of providing assurances that the plant will be properly operated and maintained in such a way that minimises through-life degradation.

20A.2.1.6 AP1000 Pressure/Temperature Limits are Clearly Defined in Accordance with Recognised Procedures and are Suitably Conservative

Irradiation on the beltline regions of RV steels will lead to increasing embrittlement through life. The degree of embrittlement is sensitive to the material composition, most specifically in terms of percentage copper and nickel level, and also the cumulative dose and the flux rate. This embrittlement results in a degradation of the material's fracture toughness and increases the vulnerability to non-ductile failure. It is therefore necessary to demonstrate that the AP1000 reactor pressure vessel is designed with sufficient margin to assure that when stressed under operating, maintenance, testing, and postulated accident conditions that the boundary behaves in a non-brittle manner and that the probability of rapidly propagating fracture is minimised.

To guard against this, heatup and cooldown pressure/temperature (P/T) limit curves are provided to protect the RV during start-up and shut down and so minimise the possibility of brittle fracture. These curves take account of through life degradation effects such as irradiation embrittlement and other ageing effects. The assessment is undertaken using the methods outlined in Appendix G of Section III of the ASME Code. The approach specifies that the allowable stress intensity factors under limiting transients for specified defect sizes, typically T/4, do not exceed the ASME reference stress intensity factor for the metal temperature. Operating specifications include conservative margins for predicted changes in the material reference temperatures due to irradiation and a factor of safety on the primary load for normal and test conditions. Details of the derivation of the P/T limit curves are provided in Reference 20A.34, which has been carried out in accordance with the approach defined in Reference 20A.35.

The P/T limit curves are composite curves established by superimposing limits derived from stress analyses of those portions of the RV and head that are the most restrictive. At any specific pressure, temperature, and temperature rate of change, one location within the RV will dictate the most restrictive limit. Across the P/T span of the limit curves, different locations are more restrictive, and, thus, the curves are composites of the most restrictive regions. The heatup curve represents a different set of restrictions than the cooldown curve because the directions of the thermal gradients through the vessel wall are reversed. The thermal gradient reversal alters the location of the tensile stress between the outer and inner walls.

The through life degradation is measured in terms of the adjusted Reference nil ductility temperature. This includes a reference nil ductility temperature shift (ΔRT_{NDT}), initial RT_{NDT} and margin. Predicted ΔRT_{NDT} values are derived considering the effect of fluence and copper and nickel content for the RV steels exposed to 288°C (550°F) temperature. The approach defined in US NRC Regulatory Guide 1.99 (Reference 20A.27) has been used in calculating the adjusted Reference temperature. The P/T curves are developed considering the

irradiation embrittlement appropriate to 54 effective full power years consistent with the plant design objective of 60 years with 90 percent availability. Copper and nickel contents and initial RT_{NDT} for materials in the RV beltline region and the RV flange and the CH flange region are shown in Table 20A-8 and Table 20A-9, respectively.

The P/T curves are shown in Figure 20A-5 and Figure 20A-6. These are generic curves for AP1000 RV design, and they are the limiting curves based on copper and nickel material composition. However, for a specific AP1000 plant, these curves will be plotted based on measured percentage copper and nickel. The use of plant-specific curves also requires evaluation of the low temperature overpressure protection (LTOP) system. This includes an evaluation of the setpoint pressure for the normal residual heat removal system relief valve by the site licence holder to determine if the setpoint pressure needs to be changed based on the plant-specific pressure-temperature curves. The development of the plant-specific curves and evaluation of the setpoint pressure are required prior to fuel load.

The results of the material surveillance programme described in section 20A.2.4.2.1 will be used to verify the validity of ΔRT_{NDT} used in the calculation for the development of heatup and cooldown P/T limit curves. The projected fluence, copper, and nickel contents along with the RT_{NDT} calculation will be adjusted if necessary, from time to time using the surveillance capsule results. This may require the development of new P/T limit curves.

Due to the magnitude of irradiation embrittlement, the P/T limit curves developed for the beltline region are sufficiently bounding such that no unirradiated ferritic materials in other components of the RCS will be limiting in the analysis.

It is recognised that the imposition of more onerous P/T limits will provide higher safety margins for any single incident but it is likely to result in more unplanned reactor shutdowns throughout the reactor's operational life, each of which will introduce its own series of additional thermal and stress cycles.

20A.2.1.6.1 The AP1000 RCS Chemistry Specification is Clearly Defined and Measures are in Place to Control Corrosion of the Reactor Vessel

The RCS chemistry specifications, the control of chemistry and the compatibility of primary coolant boundary materials with the RCS chemistry are detailed in Sections 21.5.5 and 21.5.9. In summary, the RCS water chemistry is selected to minimise corrosion and routinely scheduled analyses of the coolant chemical composition are performed to verify that the reactor coolant chemistry continues to meet the specifications. Other additions, such as those to reduce activity transport and deposition, may be added to the system. The RCS chemistry specifications conform to the recommendation of US NRC Regulatory Guide 1.44 (Reference 20A.53).

The chemical and volume control system (CVS) provides a means for adding chemicals to the RCS. The chemicals perform the following functions:

- Control the pH of the coolant during pre-start-up testing and subsequent operation.
- Scavenge oxygen from the coolant during heatup.
- Control radiolysis reactions involving hydrogen, oxygen, and nitrogen during power operations following start-up.

The values presented in Table 20A-3 are bounding for chemistry operational control of primary fluids that are in contact with primary system materials and nuclear fuel. The operational chemistry programme may apply stricter limits as deemed appropriate.

20A.2.1.6.2 Records of Operation and Maintenance will be Maintained to Confirm Compliance with Procedural Requirements

Details of the quality assurance requirements during the operational phase are detailed in Sections 3.4.4 and 7.7. This will be considered as part of the Site Specific Justification.

20A.2.1.6.3 Incidents Involving Transgressions of Set Limits will be Investigated

The RV P/T limits, including heatup and cooldown rates will be contained in the pressure and temperature limits report. These pressure and temperature limits will be determined for each fluence period. Plant operation within these operating limits is specified within the technical specification. Limiting conditions for operation (LCOs) specify minimum requirements for ensuring safe operation of the unit. The following LCOs are relevant to the P/T limits.

- LCO 3.4.3, “RCS P/T Limits”
- LCO 3.4.14, “LTOP System”
- LCO 3.4.2, “RCS Minimum Temperature for Criticality”

The consequence of violating the LCO limits is that the RCS has been operated under conditions that can result in brittle failure of the RCPB, possibly leading to a non-isolable leak or LOCA. In the event that these limits are exceeded, an evaluation must be performed to determine the effect on the structural integrity of the RCPB components. ASME Code, Section XI, Appendix E (Reference 20A.7) provides a recommended methodology for evaluating an operating event that causes an excursion outside the limits.

20A.2.1.6.4 Procedures are in Place to Control Maintenance Activities

As specified in the Reactor Vessel Design Specification (Reference 20A.2), the Reactor Vessel Instruction Manual provided by Westinghouse will contain detailed instructions for the maintenance of the RV equipment. This will need to be developed further as part of the site specific safety case.

20A.2.2 Leg 2: Functional Testing

The objective of the functional testing leg of the safety case is to confirm the good standards applied in RV design, fabrication and installation identified in Section 20A.2.1 result in an installed component that is fit for purpose. Hydrostatic pressure tests are conducted to verify that the RV is proofed against its design pressure, and similar tests are periodically carried out to affirm that RCPB integrity will be maintained at the design pressure throughout component lifetime. Two elements are built up to support this claim. These are:

- The RV has been subject to proof testing
- Testing is carried out to confirm RV functionality

These provide evidence that functional testing of the RV will be conducted to ensure fitness for purpose at start of life (SoL) and continued integrity of the pressure boundary for the design life

20A.2.2.1 The Reactor Vessel has Been Subject to Proof Testing

In order to demonstrate that the RV will be subject to proof testing evidence to substantiate the following arguments is provided.

- The RV is subject to hydrostatic pressure testing to verify pressure boundary integrity at design pressure prior to operation.

20A.2.2.1.1 The RV is Subject to Hydrostatic Pressure Testing to Verify Pressure Boundary Integrity at Design Pressure Prior to Operation

The hydrostatic pressure test contributes to the safety case in a number of ways but principally it provides assurance regarding the basic strength of the assembled vessel, the absence of gross manufacturing defects and evidence of out of specification material properties. It is recognised that the hydrostatic pressure test provides less strength to the safety case at locations where defect tolerance may be dominated by thermal stresses. At such locations, assurance is provided by inspection to confirm the absence of structurally significant defects supported by defect tolerance justifications.

Details of the RV hydrostatic pressure testing requirements are specified in Section 8.4 of Reference 20A.2. The test will be conducted in accordance with the requirements of Article NB-6000 of the ASME Code; the hydrotests comply with IWA-5000 and IWB-5000 of the ASME Code, Section XI. Two tests will be carried out, the first a shop hydrotest and the second as part of the system hydrotest following installation.

The minimum hydrostatic pressure test temperature will be 33.3°C (60°F) above the highest RT_{NDT} established from materials testing. The procedure by which RT_{NDT} is established is described in Section 20A.2.1.4. The minimum hydrostatic test pressure will be equal to 1.25 times the design pressure which is 21.55 MPa (3125psi) as defined in Reference 20A.36. This will be held for at least 10 minutes and then reduced to the design pressure of 17.24 MPa (2500 psi) and examined for leaks. Reference 20A.36 describes the RV hydrotest procedure. The CRDM housing is similarly hydrotested to 125% of the system design pressure in the factory, after installation and as part of the assembled system.

No leakage during the hydrostatic pressure test is acceptable. The hydrostatic test will be witnessed by an Authorised Nuclear Inspector (ANI) and a Westinghouse representative. A

report will be provided to confirm that the results of the hydrostatic test of the RV conform to the requirements of the ASME Code Section III.

Section 8.3 of Reference 20A.2 describes a range of NDEs that are to be conducted following the hydrostatic pressure test of the RV. These include liquid penetrant and magnetic particle surface examinations, and repetition of ultrasonic examinations of pressure boundary welds to ensure that the Section XI pre-service examination acceptance criteria can be satisfied. Full details of the pre-service testing arrangements are given in Section 20A.2.1.6.

As shown in Table 20-22, the RCS is designed for 10 cycles of hydrostatic pressure tests through the design lifetime of 60 years if required. Each RCS hydrostatic test is assumed to be conducted at a water temperature compatible with reactor material ductility requirements and a test pressure of 1.25 times design pressure.

20A.2.2.2 Testing is Carried Out to Confirm Reactor Vessel Functionality

In order to support the claim that functional testing demonstrates RV fitness-for-purpose the following arguments are made.

20A.2.2.2.1 Functional Testing Has Been Specified

Section 7.5 describes an initial testing programme for AP1000 plant. The overall objective of the programme is to demonstrate that the plant has been constructed as designed, that systems perform consistent with the plant design, and that activities culminating in operation at full licensed power including initial fuel load, initial criticality, and power ascension are performed in a controlled and safe manner.

Pre-operational tests for all systems with safety related functions are specified to confirm that these functions will be maintained in operation. Pre-operational testing [1] of the RCS is specified in Section 7.5.6. Prerequisites to the pre-operational testing are identified; these include completion of the hydrostatic proof testing of the RV as described in Argument 2.1. Pre-operational testing of the RCS including the RV is conducted to verify that the as-installed RCS will fulfil the following safety-related functions:

- Provide RCS pressure boundary integrity.
- Provide core cooling and boration in conjunction with the PXS.
- Measure process parameters required for safety-related actuations and safe shutdown.
- Measure selected process parameters required for post-accident monitoring.
- Vent the RV head.

Pre-operational testing of the RCS is also performed to verify that the system fulfils the following defence in depth functions:

- Provide forced circulation cooling of the reactor core in conjunction with heat removal by the steam generator(s).

- Provide core cooling by natural circulation of coolant in conjunction with heat removal by the steam generator(s)

1. N.B. Pre-operational tests at elevated pressure and temperature are referred to as hot functional tests.

- In conjunction with the steam generator(s) and normal residual heat removal system, provide the capability to remove core decay heat and cool the reactor coolant to permit the reactor to be refuelled and started up in a controlled manner

- Provide pressuriser pressure control during normal operation

- Provide pressuriser level control in conjunction with the CVS

- Provide pressuriser spray

Pre-operational testing includes measures to confirm the integrity and leak tightness of the RCS and the high-pressure portions of associated systems. The RV is included within the scope of these tests. Structural integrity is verified by performing a cold hydrostatic pressure test in conformance with Section III of the ASME Code. Leakage monitoring during hot functional testing is conducted to confirm that any RCS leakage is within limits specified in the Technical Specifications.

A series of start-up test procedures is developed to confirm safe and controlled operation during activities culminating in operation at full licensed power. As is the case for pre-operational testing, these start-up tests are applicable to systems rather than individual components such as the RV.

20A.2.3 Leg 3: Failure Analysis

Leg 3 of the safety case provides an assessment of the effects of through-life degradation mechanisms on potential manufacturing defects to show that such mechanisms will not threaten vessel integrity over the plant design lifetime. This goes beyond design code requirements to provide a further demonstration of integrity, specifically by recognising that flaws may be present following manufacture and showing tolerance to them. The arguments supplement the Leg 1 aim of avoidance of defects to provide a safety case with both defect avoidance and defect tolerance.

20A.2.3.1 RV Components are Tolerant to Manufacturing Defects for the Design Life of the Plant

This section describes the scope of the analyses undertaken as part of the generic design assessment (GDA) process to demonstrate that the RV is tolerant to potential defects that could remain undetected after manufacturing inspection. In order to demonstrate that the AP1000 RV components are defect tolerant, evidence to substantiate the following key arguments to support the safety case will be provided in due course:

- Established methods are used to evaluate defect tolerance.

- Determination of crack growth rates and through-life crack sizes.

- Consideration of materials ageing and degradation.

- Demonstration of adequate margins between allowable SoL defect sizes and defect sizes based on suitably qualified inspections.

20A.2.3.1.1 Established Methods are used to Evaluate Defect Tolerance

As discussed in section 20.6.4.2, the following sections summarise the results of the R6 assessment for the RV and present a summary of the existing linear elastic fracture

mechanics (LEFM) assessment carried out in accordance with ASME Code, Section III, Appendix G.

Assessment using the R6 Methodology

In combination with the use of rigorous manufacturing controls and inspection qualification, the defect tolerance assessment provides the necessary understanding to support the claim, to an appropriate degree of confidence, that the vessel will enter service free from defects that could be of concern at the end of the RV's designed life. The approach to determination of the limiting defect size in a particular orientation and location and the maximum allowable SoL defect size is discussed in section 20.6.4.2. As has been stated in Reference 20A.38, the regulatory expectation is that a DSM of 2 will be achieved.

Phase 1: Weld Defect Tolerance and NDE Ranking

A detailed evaluation of selected, limiting weld locations has been made available to provide confidence that there are no regions of the RV where either low defect tolerance or low NDT inspectability would preclude the vessel design from being able to satisfy regulatory expectations and support the safety case claim for the RV. To evaluate those locations with the greatest risk of entering service with defect of structural significance, either as a result of small allowable SoL defect sizes or a large qualified examination defect size (QEDS), a ranking exercise was undertaken to consider, on a relative basis, the defect tolerance and the NDT inspectability at each of the AP1000 RV weld locations. The details of this evaluation are reported in Reference 20A.39. The selection of the locations for R6 assessment is summarised in Table 20A-15 of this report. The regions assessed are as follows:

a) Lower Shell to Upper Shell
b) DVI Nozzle to Upper Shell
c) Inlet Nozzle to Safe-End

Phase 2: Assessment of Bounding Locations

Table 20A-15 details the locations selected for detailed evaluation during the GDA. The scope of the locations that will either be directly assessed, or can be shown to be bounded by other locations is indicated in Table 20A-15. For each of the selected locations, the R6 methodology was used to determine the limiting SoL defect size. Details of the assessment methodology are provided in Reference 20A.41.

Assessments have been carried out for defects both parallel and transverse to the weld orientation, considering surface breaking defects on both the inside and outside surfaces of the vessel. Appropriate lower bound fracture toughness data were used to evaluate the margins; the supplementary testing described in Reference 20A.57 will be performed to underpin the values assumed. Material properties appropriate to the end of life conditions taking account of the effects of irradiation embrittlement, as determined using the end of life (EoL) RT_{NDT}, have been used. Fatigue crack growth has been evaluated using the ASME upper bound crack growth laws appropriate to the environment (wet or dry).

The results of the defect tolerance assessment have been used to inform an evaluation of the NDT capability at each of the highest ranked location. The results of this assessment are discussed in Section 20A.2.3.1.4.

Phase 3: Assessment of Remaining Locations

The full defect tolerance assessment of the remaining HSS/HI locations, including the selected locations in the parent material, will be carried out in due course. Once completed, the R6 assessment work for the RV will provide assurance that the QEDS is based on a robust assessment of the maximum allowable SoL defect size with appropriate consideration of materials ageing and degradation and through life crack growth.

ASME Code, Section III, Appendix G Linear-Elastic Fracture Mechanics Assessment

The ASME Code, Section III, Appendix G, "Protection against Non- ductile Failure", presents a method for obtaining the allowable loadings to protect against non-ductile failure for ferritic pressure-retaining materials in Class 1 components. Although this approach is not considered sufficient in a UK regulatory context, the results of the assessment nonetheless provide a conservative assessment of defect tolerance which is recognised internationally.

The assessment provides the basis on which the pressure-temperature limit curves described in Section 20A.2.1.6 of this report are derived. Full details of the assessment are presented in Reference 20A.42. A discussion of the methodology and the results is provided below.

This method is based on the principles of LEFM. At each evaluated location, a postulated defect is assumed. Typically, this is conservatively based on a quarter wall defect although at certain locations, ASME permits smaller defects to be used. At each location, the mode-I stress intensity factor, K_I, produced by each of the specified loadings is calculated. Then, the summation of the K_I values due to primary and secondary stresses resulting from mechanical and thermal loading during normal, upset, and test conditions is compared to a referenced stress intensity factor, K_{IR}. This Reference K_{IR} is the highest critical value of K_I allowed for the material and the temperature involved.

When interpreting the results, which are summarised in Table 20A-16, the following factors should be noted which differ significantly from the R6 methodology:

- The ASME Code, Section III, Appendix G assessment conservatively includes a factor of safety on the primary K_I of 1.5 for test conditions and 2.0 for all other conditions.
- The assessment locations are generally remote from weld locations.
- Residual stresses are not evaluated.
- The stress intensity factor is calculated based on the linearised stress distribution.
- Through life fatigue crack growth is not evaluated.
- Fracture toughness is based on the ASME K_{IR} arrest fracture toughness curve assuming an RT_{NDT} of -23.33°C (-10°F) in the beltline vessel course and -12.22°C (10°F) at other locations. Noting that the ASME Code, Section III Appendix G methodology only takes account of irradiation effects on toughness once the P/T limit curve has been derived.

The fracture mechanics evaluation was performed for several regions of the RV using the stresses and temperatures from the FEA derived stress analyses. The regions and corresponding analyses considered are:

1. Lower shell beltline core region and lower head shell region
2. CH flange and shell region

3. CH penetrations for CRDM, QuickLoc, and vent nozzles
4. Lower head core support block region
5. Inlet nozzle
6. Outlet nozzle
7. DVI nozzle

These results in Table 20A-16 compare the applied crack tip stress intensity factors with the allowable fracture toughness at the transient time and the crack tip metal temperature. The results indicate that the limiting locations are the Inlet, Outlet and DVI nozzle inside corner radius locations. The limiting locations are at the inner crotch corner locations and are remote from as-welded material. At the DVI nozzle to shell weld location, the assessment is based on a defect size of 6.36 mm (0.25 inches) and shows a limiting K_I/K_{IR} of ~0.3, indication that the defect tolerance at the weld location is significantly greater than at the corner radius. The defect tolerance of this weld and the associated inspectability has been confirmed by the R6 analysis and associated inspection qualification activities. The assumed flaw sizes used could be increased using more rigorous analyses to identify the conservatisms in the transient definitions and the use of crack initiation fracture toughness that has already been implemented in to the ASME Code, Section XI Appendix G.

20A.2.3.1.2 Determination of Crack Growth Rates and Through-Life Crack Sizes

As part of the R6 assessment the through life crack growth has been calculated in accordance with the procedures specified in the R6 procedure. This included the use of suitably conservative crack growth rates appropriate to the reactor coolant environment, based on the ASME upper bound FCG curves. As discussed in Reference 20A.41, these are considered to be conservative for modern steels with low sulphur content. The upper bound nature of these curves is supported by extensive testing worldwide.

20A.2.3.1.3 Consideration of Materials Ageing and Degradation

The material properties used in the R6 assessment will be based on lower bound properties as specified by ASME Code, Section II unless otherwise specified in Reference 20A.41. The through life shift in properties will be calculated in accordance with the procedures defined in US NRC Regulatory Guide 1.99 (Reference 20A.27) as discussed in Section 20A.2.1.6.

20A.2.3.1.4 Demonstration of Adequate Margins Between Allowable Start of Life Defect Sizes and Defect Sizes Based on Suitably Qualified Inspections

The results of the R6 defect tolerance assessments for the three RV welds identified in Section 20A.2.3.1.1 are reported in Reference 20A.46. A limiting QEDS, i.e. that leading to a DSM equal or larger than 2, has been calculated for one of two different defect aspect ratios according to flaw orientation. For flaws perpendicular to the weld axis, the QEDS is established for a defect aspect ratio of 2, since the potential length of flaws with that orientation is naturally limited by the weld width. For flaws oriented parallel to the weld axis it is recognised that flaws with higher aspect ratios may potentially occur, and a defect aspect ratio of 6 is additionally considered in determining QEDS.

Reference 20A.46 reports the limiting QEDS (i.e., leading to a DSM equal or larger than 2) for the RV welds as follows:

Weld	Limiting QEDS (mm)

RV Lower shell to upper shell weld	25
RV DVI nozzle to upper shell weld	25
RV inlet nozzle to safe end weld	6

Based on these QEDS values, Reference 20A.46 reports that the calculated values of end of life limiting defect size (ELLDS) and lifetime fatigue crack growth (LFCG) establish a DSM larger than 2 in all cases. Demonstrating the capability for qualified inspection of these RV welds is considered bounded by the inspection techniques defined and assessed for other AP1000 HSS welds as summarised below.

Reference 20A.47 including applicable amendments provides the technical basis for an array of inspection techniques applied on the RPV inner and outer surfaces to support detection and characterisation of both surface-breaking and near-surface breaking planar defects having a height of 25 mm in the RV lower shell to upper shell and DVI nozzle to upper shell welds. This basis included previous work associated with the Sizewell B manufacturing NDT inspections, the United Kingdom Atomic Energy Authority defect detection trials (DDT), qualified inspections used in Sweden and the USA, and common industry approaches. The technical basis of the inspection techniques described in Reference 20A.47 has been reviewed by an independent qualification body, the inspection validation centre (IVC), and the inspection techniques were deemed to be capable of formal qualification.

Reference 20A.48 including applicable amendments provides the technical basis for an array of inspection techniques applied on the RV inlet nozzle to safe end weld inner, outer, and end face surfaces to support detection and characterisation of both surface-breaking and near-surface breaking planar defects having a height of 6 mm. This basis included previous works associated with the Sizewell B manufacturing NDT inspections, qualified inspections used in Sweden and the US, and common industry approaches. The technical basis of the inspection techniques described in Reference 20A.48 has been reviewed by an independent qualification body, the IVC, and the inspection techniques were deemed to be capable of formal qualification.

This demonstrates that suitable systems are available for a subsequent inspection qualification against the limiting QEDS for the three RV welds included in the GDA programme of defect tolerance assessment, such that a satisfactory DSM (≥ 2) is justified.

20A.2.4 Leg 4: Forewarning of Failure

The objective of the forewarning of failure leg of the safety case is to confirm the absence of a degradation mechanism through plant inspection or that where a known degradation mechanism exists, uncertainty in the material behaviour is not significant to integrity or will have limited consequences. Three elements are built up to support this claim. These are:

- Appropriate ISI is carried out to provide forewarning of failure.
- Diverse systems are provided to detect, locate and monitor reactor coolant leakage from the RV.
- In service material surveillance provide forewarning of unanticipated damage behaviour.

The arguments presented provide contingency for the unexpected.

20A.2.4.1 **Appropriate In-Service Inspection is Carried out to Provide Forewarning of Failure**

In order to provide assurances that defects will be detected prior to becoming a threat to the structural integrity of the AP1000 RV, evidence to substantiate the following arguments is provided

- An extensive programme of ISI will identify any degradation long before failure.
- Qualified inspection of HSS welds provides high reliability ISI.
- ISI data enables judgement of in-service defect formation and growth by comparison with 'fingerprint' PSI data.
- A 'Design for Inspectability' philosophy facilitates effective ISI.

20A.2.4.1.1 An extensive Programme of ISI will Identify Any Degradation Long Before Failure

ISI is the preferred method of demonstrating forewarning of failure. The role of an effective ISI programme is to confirm the absence of any unknown degradation mechanisms and that known degradation mechanisms are not significant to integrity or will have limited consequences.

ISI is used to confirm the absence of defects that could eventually lead to failure when the maximum tolerable defect size, as determined from fracture mechanics in Section 20A.2.3, is combined with a conservative assessment of in-service defect growth throughout the inspection interval.

In order to be effective, ISI requirements should be identified according to established good practice relevant to the characteristics of each inspection location. Evidence to substantiate that this is the case for planned RV ISI is provided below.

ISI for the AP1000 RV and Vessel Head is planned in accordance with ASME Section XI, IWB-2500 and supplemented by 10 CFR 50.55a.

The planned ISI programme includes the RV components and welds of importance to nuclear safety. ISI requirements for the following welds and components of the RV are identified in Reference 20A.43[2]:

- Circumferential Shell Welds (lower shell to bottom head transition ring and lower shell to upper shell welds).
- The circumferential bottom head transition ring to bottom head welds.
- The nozzle to shell welds and nozzle inner radius regions.
- The vent nozzle and QuickLoc instrument nozzle full penetration welds
- Nozzle to safe end welds.

2. Reference 20A.42 does not constitute the Inspection Plan as required by 10 CFR 50.55a. The Inspection Plan remains to be issued at a later date, subsequent to regulatory Generic Design Acceptance.

- Studs, nuts and washers.
- IHP support lug welds.
- Core support lugs.
- The vessel interior.
- Removable core support structures.
- CRDM housing welds.

Reference 20A.43 identifies Code requirements for each of the above locations and takes into account the relevant code cases. Inspection methods and access arrangements are described to ensure effective ISI at each of the identified RV welds and components. For example, CH penetration welds are inspected from both the outer and inner surfaces by a combination of eddy-current and UT methods, and volumetric inspection, where demanded, is performed by sensitive UT methods.

20A.2.4.1.2 Qualified Inspection of HSS Welds Provides High Reliability ISI

Table 20A-1 identifies the Structural Integrity Classification for the RV components. For those components identified as HSS it is accepted good practice that qualified inspections are deployed as supporting evidence to demonstrate that there are no defects of concern in HSS components.

The reliability of the ISI for HSS welds in the RV is to be qualified by applying the principles of the ENIQ Methodology as contained in Reference 20A.33.

Adherence to the ENIQ Inspection Qualification methodology provides evidence of good practise for ISI of HSS locations. Reference 20A.32 identifies how inspection requirements and performance objectives are laid down in an inspection specification and provides a method for Inspection Qualification based on technical justification of the inspection method and practical trials on simplified or representative test pieces resembling the component to be inspected.

20A.2.4.1.3 ISI Provides Data to Judge In-service Defect Formation and Growth by Comparison with 'Finger-print' PSI Data

In Section 20A.2.1.6 qualified PSI of HSS components is described. The resulting data constitutes a "finger-print" against which ISI results can be compared. Comparison of ISI data with the PSI fingerprint is used to confirm the absence of significant degradation or that build defects are stable i.e. defects detected during ISI must have started life as no greater than the PSI validation defect size. PSI will be performed using the same equipment that is likely to be used for the periodic ISI.

20A.2.4.1.4 A 'Design for Inspectability' Philosophy Facilitates Effective ISI

For effective ISI, the RV design should accommodate requirements for inspection equipment and personnel access in accordance with current inspection technology and strategies. Reference 20A.32 describes how the RV design has been developed with the goal of maximising inspectability.

The AP1000 RV design accommodates current best-practice ISI techniques and, so far as is practicable, allows for newly emergent inspection technologies to be employed. Reference 20A.32 provides a summary of ISI requirements for each location of the RV and RV Head. Design for Inspectability is demonstrated by consideration of the following aspects:

- Access for personnel and equipment conducting either manual deployed or mechanically deployed techniques.
- Surface finish requirements.
- Access either side of the welds to facilitate UT of the full section, where necessary, with angle beams of up to 60°.

Reference 20A.32 establishes that provisions for inspectability are consistent with current best practice. An assessment is provided to demonstrate that design and access arrangements are provided to satisfy the requirements set out in NCA-3200 of the ASME Code Section III, IWA-1400 and IWA-1500 of the ASME Code Section XI and 10 CFR 50.55a(g)(3)(i) and 10 CFR 50.55a(g)(3)(ii).

An additional assessment of the RV Head penetrations is provided to ensure adequate design and access provisions to demonstrate compliance with ASME Code Section XI Code Case N-729-1, EPRI-MRP Letter 2003-013 (Reference 20A.54) and WesDyne Letter WDI-LTR-RVH-05-2 (Reference 20A.55). ISI of the RV head to ASME CC N-729-1 and 10 CFR 50.55a includes inspection for indications of leakage and boric acid accumulation.

20A.2.4.1.5 Diverse Systems are Provided to Detect, Locate and Monitor Reactor Coolant Leakage from the RV

In order to demonstrate that leaks from the RCPB will be detected before they result in a safety issue, the following arguments are presented.

20A.2.4.1.6 Leak Detection of the RCPB Provides Warning of Reactor Coolant Leakage from the RV

ISI is the preferred method of demonstrating forewarning of failure. The primary arguments for ISI are enumerated in this section. Whilst leak detection and monitoring provide forewarning of failure, this safety argument does not seek to establish a quantitative case for excluding the gross failure of the RV as a result of this forewarning. The leak detection measures described in this section are provided as qualitative evidence of defence in depth in support of this leg of the safety argument. Leak detection provides warning of unforeseen or unexpected loss of coolant from the RV, and monitoring provides a means to confirm that any leakage of the coolant is kept within the limits specified in the technical specifications (Reference 20A.50).

The RCPB is monitored for leaks by a variety of components located in multiple systems. The leak detection system provides information that will prompt plant operators to take corrective action if any detected leakage exceeds technical specifications.

Identified leakage from the RV is collected in the reactor coolant drain tank. The RV flange and head flange are sealed by two concentric seals. Seal leakage is detected by two leak-off connections: one between the inner and outer seal, and one outside the outer seal. These lines are combined in a header before being routed to the reactor coolant drain tank. An isolation

valve is installed in the common line. During normal plant operation, the leak-off valves are aligned so that leakage across the inner seal drains to the reactor coolant drain tank. A surface-mounted resistance temperature detector installed on the bottom of the common RV seal leak pipe provides an indication and high temperature alarm signal in the main control room indicating the possibility of an RV head seal leak. The temperature detector and drain line downstream of the isolation valve are part of the liquid radwaste system.

Diverse methods are provided to detect, quantify, and assist in locating unidentified leakage from the RV. It is possible for unidentified leakage to originate from the RV head or the RV head vent connections, which are flanged. During normal operation, variations in airborne radioactivity, containment pressure, temperature, or specific humidity above the normal level signify a possible increase in unidentified leakage rates and alert the plant operators that corrective action may be required. Similarly, increases in containment sump level signify an increase in unidentified leakage. Section 20.6.4.3.2 outlines the methods used to collect and monitor unidentified leakage.

Intersystem leakage through the RV is not possible, as no system interconnections exist within the jurisdictional boundaries of the RV.

20A.2.4.2 In Service Material Surveillance Provide Forewarning of Unanticipated Damage Behaviour

In-service materials surveillance programme will provide forewarning of unanticipated damage.

20A.2.4.2.1 Materials Surveillance Programme

The RV in-service materials surveillance programme provides plant specific data which confirms that irradiation shift predictions used in the RV defect tolerance assessment and in the derivation of P/T limits remain conservative for the current period of operation and also provides forewarning of unanticipated material behaviour which could lead to non-conservative shift predictions later in plant life. The evaluation of radiation damage is based on comparison of pre-irradiation testing of Charpy V-notch, 1/2-T CT and tensile specimens and post-irradiation testing of Charpy V-notch, tensile, and 1/2-T CT fracture mechanics test specimens.

The surveillance programme conforms to ASTM E185 (Reference 20A.28) and 10 CFR 50, Appendix H (Reference 20A.44). The RV surveillance programme incorporates eight specimen capsules. The capsules are located in guide baskets welded to the outside of the core barrel as shown in Figure 20A-7 and positioned directly opposite the centre portion of the core. The capsules can be removed when the vessel head is removed. In order to meet the guidelines of ASTM E185, the placement of the specimens should yield lead factors between 1.0 and 3.0 to facilitate closely mirroring the history of the RV. In order to meet this recommendation, the specimen guide baskets are located azimuthally near the lowest fluence locations at 135, 225, and 315 degrees. The 45 degree location is also a low fluence azimuthal location; however, there is a Roto-Lock insert for the internals lifting rig, which would prevent access for removal of the capsules from the baskets. Therefore, there are no guide baskets at the 45 degree location.

Eight specimen capsules are provided by including three guide baskets at the 135 and 315 degree azimuthal locations and two baskets at the 225 degree location. The capsules contain RV weld metal, base metal, and heat-affected zone metal specimens. The base metal specimens are oriented both parallel and normal (longitudinal and transverse) to the principal

rolling direction of the limiting base material located in the core region of the RV. The 8 capsules contain 72 tensile specimens, 480 Charpy V-notch specimens, and 196 CT specimens.

Dosimeters are placed in filler blocks drilled to contain them. The dosimeters permit evaluation of the flux seen by the specimens and the vessel wall. In addition, thermal monitors made of low melting point alloys are included to monitor the maximum temperature of the specimens. The specimens are enclosed in a tight-fitting stainless steel sheath to prevent corrosion and ensure good thermal conductivity. The complete capsule is helium leak tested. As part of the surveillance programme, a report of the residual elements in weight percent to the nearest 0.01 percent is made for surveillance material and as deposited weld metal.

The fast neutron exposure of the specimens occurs at a faster rate than that experienced by the vessel wall, with the specimens being located between the core and the vessel. Since these specimens experience accelerated exposure and are actual samples from the materials used in the vessel, the transition temperature shift measurements are representative of the vessel at a later time in life. The lead factors for the eight specimen capsule locations based on the Reference neutron flux distribution (flux distribution that results in the maximum fluence on the RV inner surface) vary between approximately 1.8 and 2.3. These lead factors will change over the life of the plant due to changes in core design and operating parameters. Data from CT fracture toughness specimens are expected to provide additional information for use in determining allowable stresses for irradiated material.

The recommended programme schedule for removal of the capsules for post-irradiation testing conforms to ASTM E185 for the first 4 removals, whilst the 5th removal is an additional recommendation. The following is the recommended withdrawal schedule.

Capsule Withdrawal Time

- 1st When the accumulated neutron fluence of the capsule is 5×10^{18} n/cm^2.
- 2nd When the accumulated neutron fluence of the capsule corresponds to the approximate end of life fluence at the RV 1/4T location.
- 3rd When the accumulated neutron fluence of the capsule corresponds to the approximate end of life fluence at the RV inner wall location.
- 4th When the accumulated neutron fluence of the capsule corresponds to a fluence not less than once or greater than twice the peak end of vessel life fluence.
- 5th End of plant design objective of 60 years (not required by ASTM E185).

Plant-Specific Calculations

The location, selection, and evaluation of neutron dosimetry and the associated radiometric monitors, as well as fast (E > 1.0 MeV) neutron fluence assessments of the AP1000 reactor pressure vessel, are conducted in accordance with the guidelines that are specified in Regulatory Guide 1.190 (Reference 20A.45). Specific details of the calculation procedures for evaluating the integrated flux and dosimetry procedures are presented in Reference 20A.18. These consider the effect of the differences between the plant material and surveillance capsule material conditions i.e. differences in the flux, temperature profile, power cycling, and knowledge of strain ageing, thermal ageing.

Material Archiving

Material will be archived and retained for delivery to the end customer for use as required to support future operation. The material will be traceable to the original source and have documentation of processing and heat treatment. The material will have had a similar thermal treatment and fabrication as the final material condition of the associated RV material. The material will include the following archive samples (where T is the nominal thickness) as detailed in the Design Specification (Reference 20A.2).

- Vessel Flange Shell: Nozzle cutout x 1 pc
- Outlet Nozzle: 89 mm (3.5 inches) x Tmm x 457 mm (18 inches) circ x 2 pcs
- Inlet Nozzle: 89 mm (3.5 inches) x Tmm x 457 mm (18 inches) circ x 4 pcs
- DVI Nozzle: 89 mm (3.5 inches) x Tmm x 152.4 mm (6 inches) circ x 2 pcs
- Outlet Nozzle Safe End: 89 mm (3.5 inches) x Tmm x 457 mm (18 inches) circ x 2 pcs
- Inlet Nozzle Safe End: 89 mm (3.5 inches) x Tmm x 457 mm (18 inches) circ x 4 pcs
- DVI Nozzle Safe End: 89 mm (3.5 inches) x Tmm x 152.4 mm (6 inches) circ x 2 pcs
- Lower Shell: 203 mm (8 inches) x 203 mm (8 inches) x 1,016 mm (40 inches) circ(1) x 1 pc
- Transition Ring: 203 mm (8 inches) x 203 mm (8 inches) x 1,016 mm (40 inches) circ x 1 pc
- Closure Head: 51 mm (2 inches) thk x 127 mm (5 inches) x 1,016 mm (40 inches) circ x 1 pc
- Bottom Head Dome: 152 mm (6 inches) thk x 127 mm (5") x 1,016 mm (40 inches) circ x 1 pc
- CRDM Penetration: 203 mm (8 inches) per heat of tube material
- Vent Tube: 203 mm (8 inches) x 1 pc
- QuickLoc Nozzle: 203 mm (8 inches) per heat of tube material

20A.3 Strength of the Safety Case

20A.3.1 Objective

SFRs for the RV are developed from the structural integrity safety design bases, as identified in Section 20A.1.9. This report provides a safety argument which identifies evidence to substantiate that the SFRs of the RV will be maintained for all conditions within the design basis.

The availability and reliability of the safety measures identified to deliver a component's SFRs should demonstrably be commensurate with the significance of the radiological hazards to be controlled. This is achieved by a process of component structural integrity classification

which, for the safety justification of each class of component, establishes the degree of rigour to be applied commensurate with the potential radiological consequences of any postulated gross failure mode.

The process of structural integrity classification is discussed in Section 20.5 and detailed in Reference 20A.4, where gross failure of the RV is assessed to potentially lead to the most severe and therefore intolerable offsite consequences against which there is no claimed protection. As identified in Section 20A.1.10, the RV is classified as a highest safety significance component[3]. HSS-classification necessitates substantiation of a tolerable failure frequency where the probability of gross structural failure of the RV is so low it can be discounted.

20A.3.2 **Evidence**

To substantiate the claim that gross structural failure of the RV can be discounted, a safety argument is presented in Section 20A.1.8. Various elements of sound engineering practice are identified which provide evidence that there is defence in depth against structural failure within the RV arrangement and design. A defence in depth justification usually involves the provision of multiple layers of protection and defence is provided through diversity, redundancy and segregation to provide a robust design. For single components without multiple protection layers, the defence in depth principle is retained by demonstrating that the likelihood of failure is so low that it can be considered as not credible. The safety argument comprises four conceptually different legs, within each of which multiple subordinate arguments are supported by diverse sources of substantiating evidence. Robustness is achieved by considering the combined contribution from the four legs, a philosophy generally known as conceptual defence in depth. In combination the four legs provide sufficient confidence that gross failure of the RV with unacceptable consequences will not occur during normal operation, during design basis transient or during fault conditions. The combined strength of the claims, arguments and evidence presented in Section 20A.2 is discussed in this section.

The safety argument is founded upon a high standard of manufacture sufficient to achieve an appropriately high level of structural integrity. Design and fabrication of the RV is to be in accordance with ASME Code, Section III, Class 1 requirements as a minimum. Supplemental requirements are identified that enhance the quality of RV design and fabrication beyond ASME Class 1 standards. These are detailed in Section 20A.2.1, where multiple arguments and supporting evidence to substantiate achievement of RV integrity are presented. Section 20A.2.1 includes claims, arguments and evidence to address the following aspects:

- The design is well founded and in accordance with internationally recognised standards. The design of PWR RVs is well established and Westinghouse has an established track record. The AP1000 RV benefits from this historical experience which is embodied in the codes and standards applied in design and fabrication.

- Procurement of materials is specified and controlled to ensure that well proven materials are chosen, that the materials have good resistance to fracture and are of suitable chemical composition to limit the effect of irradiation embrittlement and other through-life degradation mechanisms. AP1000 RV materials comply with the corresponding material specification permitted by the ASME Code, Section III,

3. The HSS classification does not apply to every component of the RV or to every postulated failure mode and defect orientation, since certain failure modes will not lead to the most severe off site consequences. Classification of each component of the RV is detailed in Section 20A.1.10.

Division 1. For certain RV materials, supplementary requirements are specified which exceed the requirements specified in ASME code. Materials testing is specified to confirm that material properties comply with the relevant specifications.

- Very high standards have been applied that control RV fabrication. RV components will be manufactured by experienced suppliers and evidence to confirm the suitability of the chosen manufacturer will form part of the Site Specific Justification. Compliance with ASME III and the experience embodied within the code provides high confidence in manufacturing quality. Supplemental requirements have been identified which enhance the standards applied in fabrication beyond ASME requirements. Approved welding procedures and qualified operators are used. Stringent Quality Assurance arrangements control manufacturing procedures and records are maintained to provide a clear auditable trail that will confirm this. There are procedural controls to limit deviations from the design intent and all repairs and deviations will be recorded to confirm acceptability.

- Manufacturing inspections and PSI with appropriate levels of redundancy and diversity confirm the absence of defects which have the potential for causing, or developing into a failure mode. This judgement is based on definition of allowable SoL defect sizes. Where appropriate the inspections are subject to independent validation and in the case of HSS components of the RV, a programme of qualified PSI is specified. In the unlikely event that defects are found, they will be repaired in accordance with accepted techniques.

The diverse evidence summarised above demonstrates that the RV will be designed and fabricated against well established and appropriate deterministic engineering rules, verified by application of rigorous PSI. The various elements identified establish defence in depth for preventing failure of RV structural integrity. Functional hydrostatic testing to demonstrate that the RV meets the design intent, as described in Section 20A.2.2, supplements the arguments to demonstrate achievement of RV integrity, ensuring that the RV enters service fit for purpose and free of safety-significant defects.

The measures established to ensure good design and construction are supplemented with additional claims and evidence to demonstrate continued structural integrity throughout the planned RV lifetime. Careful control of operating conditions enables the RV to fulfil its safety function for its projected lifetime. Plant Operation and Maintenance is clearly defined in accordance with recognised procedures as described in Section 20A.2.1. Design and operating parameters used in the design evaluation are robustly determined using established and conservative procedures, as detailed in Section 20A.2.1. The evidence provided to this effect ensures the validity of stress analysis and fracture analysis to substantiate claims based on ASME Code compliance.

Section 20A.2.3 and Section 20A.2.4 provide evidence to substantiate RV integrity under all design basis conditions by demonstrating that any defect which may have gone undetected during manufacture will not cause failure during the lifetime of the plant. The elements that substantiate this claim are as follows:

- Stress Analysis – The AP1000 RV is designed in accordance with the ASME Code, Section III, Division 1. Consideration of Levels A to D and Test conditions encompass the design basis for the purposes of the analysis. Stress analysis to the ASME code supports demonstrating fitness-for-purpose and also provides a basis for subsequent fracture analysis.

- Fracture Analysis – LEFM analysis, as prescribed in Appendix G of ASME Section III, has been supplemented by elastic-plastic fracture mechanics procedures specified in the R6 Defect Assessment code. These fracture analyses demonstrate that the sizes of defect which are of safety concern are large in relation to those which could remain undetected in the component following qualified inspection.

- In-Service Inspection – The RV is designed to facilitate effective ISI, which provides assurance that defects will be detected long before growing to a size that could threaten structural integrity of the RV. Qualified inspection of HSS locations establishes the sizes of defects that can be reliably detected and the associated sizing uncertainty. Qualification is to be achieved through a combination of Technical Justification of inspection procedures and equipment, supported by trials. ISI data enables judgement of in-service defect formation and growth by comparison with PSI data.

- Materials Surveillance – The RV in-service materials surveillance programme provides plant specific data which confirms that irradiation shift predictions used in the RV defect tolerance assessment and in the derivation of P/T limits remain conservative for the current period of operation and also provides forewarning of unanticipated material behaviour which could lead to non-conservative shift predictions later in plant life.

- Leakage Monitoring – Diverse systems are provided to detect, locate and monitor reactor coolant leakage from the RV. Alarm and indication of reactor coolant leakage from the RV in excess of specified limits provides diverse means to detect failure.

The summary and review of the safety argument in this section provides the basis for the conclusions of this report which are presented in Section 20A.5.

20A.4 Review of Open Issues

There are no open issues that affect the basis of the RV safety case arguments presented in support of GDA.

20A.5 Conclusions

This CSR for the UK AP1000 RV presents a safety argument to establish that the structural reliability of the RV is commensurate with the consequences of gross failure. SFRs have been identified for the RV, based on structural integrity safety design bases. These requirements are to be maintained for the lifetime of the plant to ensure plant nuclear and radiological safety. For the RV, assurance that these SFRs will be maintained is provided by substantiating structural integrity against appropriate reliability targets.

Structural reliability targets have been identified for the RV that are based on a procedure of structural integrity classification. Based on this, the RV has been classified as a HSS component. The structural reliability target associated with HSS classification is to substantiate a tolerable failure frequency that is so low that gross failure can be discounted.

The safety argument is presented in a four legged format that is well established in the UK for the safety justification of nuclear plant components similar to the RV that share similar structural reliability targets. The safety argument identifies diverse defence in depth measures to substantiate the structural reliability claimed for the RV:

- The intent and principles that govern the design, future manufacture and operation of the RV in the UK are identified to substantiate fitness for purpose within a pre-construction

safety case. The safety argument demonstrates how modern and well established good practice has been or will be implemented in RV design, manufacture, defect tolerance assessment, and in the provision for through-life inspection.

- The RV design benefits from the long operating history of PWR RVs and incorporates design measures to minimise frequency of failure based on that experience. To minimise the potential for a LOCA by leakage from the RV that would result in the core being uncovered, there are no penetrations in the RV below the core. In addition the core is positioned low in the RV to minimise re-flood time in accident conditions. The RV design facilitates effective inspection which supports a programme of qualified inspection to ensure timely forewarning of failure.

- Structural integrity of the RV is secured largely by passive means and is not significantly reliant on control systems, active safety systems or human intervention. As such, the diverse defence in depth measures identified focus on prevention of failure through conservative, robust design. Surveillance, inspection and leakage monitoring provide secondary defence in depth measures to detect and provide forewarning of failure.

- RV structural integrity is established based on extensive quality assurance measures in design, manufacture, materials, testing and qualified inspection. The strength of the safety case is based on achievement of integrity and the RV has been deterministically justified in accordance with ASME Code Class 1 requirements. Additional arguments provide robust evidence to demonstrate that the RV is defect tolerant and this is supported by qualified manufacturing inspection. Numerous other defence in depth measures are identified.

In combination these elements constitute a cogent argument to substantiate structural reliability commensurate with the HSS structural integrity classification of the RV.

20A.6 Index of Technical Reports

Table 20A-17 provides a list of technical references supporting the safety case and summarises the function of each document within the safety case.

Location	Postulated Defect Orientation or Failure Mode	Classification	Supporting Comment
4. CH penetration welds			
a) CH penetration J groove buttering and attachment welds (CRDM penetration, head vent pipe)	All	Class 1	Axial circumferential failure assessed as Class 1. Failure of weld would not result in tube ejection and would not result in CH failure.
b) CRDM latch housing to penetration bi-metallic weld	All	Class 1	Defect propagation from latch housing to CH forging not considered credible.
5. Welded support pads/blocks			
5.1 Vessel support pad attachment welds	All	Class 1	Support pads and lugs will be inspected in accordance with ASME III requirements and are assessed as Class 1.
5.2 Core support block attachment welds	All	Class 1	As above
5.3 IHP support lug	All	Class 1	As above
5.4 CH lift lugs	All	Class 1	As above
FORGING REGIONS			
6. Main forging regions			
6.1 Nozzle inner/outer crotch corners Inlet Nozzle, Outlet Nozzle, DVI Nozzle	All	HSS	(1)
6.2 Core support ledge radius	All	HSS	(1)
6.3 Main RV and CH forgings: CH, upper shell, lower shell, transition ring.	All	HSS	(1)
6.4 Seal Ledges	All	HSS	(1)
6.5 Clad/underclad defects in beltline region	All	HSS	(1)

Table 20A-1. Structural Integrity Classification of Reactor Vessel Components (cont.)

Location	Postulated Defect Orientation or Failure Mode	Classification	Supporting Comment
OTHER RV REGIONS			
7. RV Bolting			
7.1 Studs	All	Class 1	Failure of a single stud will not lead to loss of RV head. LOCA protectable and standard Class 1.
7.2 Nuts	All	Class 1	Bounded by bolt failure.
7.3 Washers	All	Class 1	Bounded by bolt failure.
8. RPV sealing arrangements			
8.1 Failure of Inner and Outer O ring seals	Leakage arising from seal failure	Class 1	Failure of a seal will not lead to loss of RV head. LOCA protectable and standard Class 1.
9. Latch Housings/CRDM extensions			
9.1 CRDM extension	R All	Class 1	Failure of CRDM extension tube would not affect pressure boundary integrity.
9.2 CRDM extension funnel	All	Class 1	Failure of CRDM extension funnel would not affect pressure boundary integrity.
9.3 Latch housing Assembly	All	Class 1	Defect propagation from latch housing to CH forging not considered credible.
10. Instrument Nozzles/Monitor Tubes			
QuickLoc Instrument Nozzle Flange Adaptor	All	Class 1	Leakage from instrument nozzles/monitor tubes is a protectable LOCA, hence Class 1.
QuickLoc Nozzle	All	Class 1	As above
Outer Monitor Tube	All	Class 1	As above
Inner Monitor Tube	All	Class 1	As above

Notes:

1. Individual failure modes assessed as HSS are bounded by the component level classification presented for the RV in Reference 20A.4.

Table 20A-2. Not Used

Table 20A-3. Reactor Coolant Water Chemistry Specifications

Electrical conductivity	Determined by the concentration of boric acid and alkali present. Expected range is <1 to 40 μmhos/cm at 25°C.
Solution pH	Determined by the concentration of boric acid and alkali present. Expected values range between 4.2 (high boric acid concentration) and 10.5 (low boric acid concentration) at 25°C. Values will be 5.0 or greater at normal operating temperatures.
Oxygen(1)	0.1 ppm, maximum
Chloride(2)	0.15 ppm, maximum
Fluoride(2)	0.15 ppm, maximum
Hydrogen(3)	25 to 50 cm^3 (STP)/kg H_2O
Suspended solids(4)	0.2 ppm, maximum
pH control agent (Li7OH)(5)	Lithium is coordinated with boron per fuel warranty contract.
Boric acid	Variable from 0 to 4000 ppm as boron
Silica(6)	1.0 ppm, maximum
Aluminium(6)	0.05 ppm, maximum
Calcium(6) + magnesium	0.05 ppm, maximum
Magnesium(6)	0.025 ppm, maximum
Zinc(7)	0.04 ppm, maximum

Notes:

1. Oxygen concentration must be controlled to less than 0.1 ppm in the reactor coolant by scavenging with hydrazine prior to plant operation above 93.33°C (200°F). During power operation with the specified hydrogen concentration maintained in the coolant, the residual oxygen concentration will not exceed 0.005 ppm.
2. Halogen concentrations must be maintained below the specified values regardless of system temperature.
3. Hydrogen must be maintained in the reactor coolant for plant operations with nuclear power above 1 MW. The normal operating range should be 25-35 cm^3 (STP) H2/kg H_2O.
4. Solids concentration determined by filtration through filter having 0.45-μm pore size.
5. The specified lithium concentrations must be established for start-up testing prior to heatup beyond 65.56°C (150°F). During cold hydrostatic testing and hot functional testing in the absence of boric acid, the reactor coolant limits for lithium hydroxide must be maintained to inhibit halogen stress corrosion cracking.
6. These limits are included in the table of reactor coolant specifications as recommended standards for monitoring coolant purity. Establishing coolant purity within the limits shown for these species is judged desirable with the current data base to minimise fuel clad crud deposition, which affects the corrosion resistance and heat transfer of the clad.
7. Specification is applicable during power operation when zinc is being injected. The zinc concentration is maintained at the lower of 0.04 ppm or that specified in the reload safety analyses.

Table 20A-4. Reactor Vessel External Environment

Environmental Parameter	Design Conditions		Abnormal Condition
	Max.	Min.	
Pressure, MPa (psig)	0.007 (1.0)	-0.01 (-0.2)	0[(1)] - 0.124 (18)[(2)]
Temperature, °C (°F) Vessel Closure Head	 57 (135) 49 (120)[(3)]	 10 (50)	 66 (150)[(1)] – 121 (250)[(2)]
Relative Humidity, (%)	100	1	100
Radiation Level, R-hr $^{-1}$	3.63 x 10^4	–	3.63 x 10^4

Notes:

1. Group 1: 66°C (150°F) Events
   Loss of nonsafety Heating Ventilation and Air Conditioning/Loss of a fan cooler
   Loss of all AC for up to 2 hours
   Pressuriser safety valve open/close during RCS transient
2. Group 2: 121°C (250°F) Events
   Spurious automatic depressurisation system (ADS) actuation
   Passive residual heat removal (PRHR) system use (long-term)
   RCS depressurisation via pressuriser safety valve
   Small LOCA
3. The maximum normal environmental operating temperature around the RV closure head (refuelling cavity) is 49°C (120°F).

(a) RT – Radiographic
UT – Ultrasonic
PT – Dye penetrant
MT – Magnetic particle

(b) Dye Penetrant (PT) examination may be used in lieu of Magnetic Particle (MT) examination in accordance with ASME Code Section III, NB-2541(a) when the inspection surface and surrounding geometry do not permit effective use of magnetic particle examination equipment.

Table 20A-8. Maximum Limits for Elements of the Reactor Vessel

Element	Beltline Forging (percent)	As Deposited Weld Metal (percent)
Copper	0.06	0.06
Phosphorus	0.01	0.01
Vanadium	0.05	0.05
Sulphur	0.01	0.01
Nickel	0.85	0.85

Table 20A-9. End-Of-Life RT_{NDT} and Upper Shelf Energy Projections

	Unirradiated		End-of-life (54 EFPY)	
	RT_{NDT} (°C / °F)	USE (J / ft-lb)	USE (J / ft-lb) 1/4T	RT_{PTS} (°C / °F)
Beltline Forging	-23.3 / -10	> 101.7 / 75[1]	> 67.79 / 50	< 132.2 / 270[2]
Head	10	N/A	N/A	N/A
Flange	10	N/A	N/A	N/A
Weld	10	N/A	N/A	N/A
Beltline Weld	-55.5 / -68	> 101.7 / 75	> 67.79 / 50	< 148.9 / 300[2]

Notes:

1. The minimum unirradiated upper shelf energy for beltline base metal is for the transverse direction.
2. End-of-Life RT_{PTS} requirements shown. End-of-Life RT_{PTS} (also equals RT_{NDT}) will be determined for as-built material. The preliminary RT_{PTS} for the AP1000 RV beltline forging and beltline weld are 34.4°C (94°F) and 37.8°C (100°F), respectively.

Table 20A-10. Not Used

Table 20A-11. ASME Code Stress Limits for Other than Bolts

Condition	Code Subsection	Criteria
Design	NB-3200	$P_m \leq S_m$
		$P_L \leq 1.5\ S_m$
		$P_L + P_b \leq 1.5\ S_m$
Normal (Level A)		$P_L + P_b + Q \leq 3\ S_m$
Upset (Level B)		$P_m \leq 1.1\ (S_m)$
		$P_L \leq 1.1\ (1.5\ S_m)$
		$P_L + P_b \leq 1.1\ (1.5\ S_m)$
		$P_L + P_b + Q \leq 3\ S_m$
Thermal Ratchet		Thermal Ratchet Ratio ≤ 1.0
Fatigue		FUF ≤ 1.0
Emergency (Level C)		$P_m \leq$ Greater of $1.2\ S_m$ or S_y
		$P_L \leq 1.5 \times P_m$ limit
		$P_L + P_b \leq 1.5 \times P_m$ limit
Faulted (Level D)	F	$P_m \leq$ Minimum $(2.4\ S_m, 0.7\ S_U)$, $0.7 S_U$ for ferritic
		$P_L \leq 1.5 \times P_m$ limit
		$P_L + P_b \leq 1.5 \times P_m$ limit
Test	NB-3200	$P_m \leq 0.9\ S_y$ at test temperature
		For $P_m \leq 0.67\ S_y$ $P_m + P_b \leq 1.35\ S_y$
		$P_m + P_b \leq (2.15\ Sy - 1.2\ P_m)$
Tri-Axial Stress		$\sigma 1 + \sigma 2 + \sigma 3 \leq 4.0\ S_m$

	Core Support Block	Ax – In			1.00	
	Inlet Nozzle	Ax – In			1.00	
	Outlet Nozzle	Ax – In			0.98	
	DVI Nozzle	Ax – In			1.00	

Notes:

1. Flaw orientation: Circ = Circumferential, Ax = Axial/Meridional, In = ID flaw, Out = OD flaw.
2. Closure studs are not required to be evaluated to Level A/B or Test conditions as they require impact tests. See G-4000 of the ASME Code, Section III, Division 1, Appendix G, 1998 Edition through 2000 Addenda.
3. Per G-2120 of the ASME Code, Section III, Division 1, Appendix G, 1998 Edition through 2001 Addenda, flaw sizes smaller than 0.25T may be considered on an individual case basis if detection of the smaller flaw can be ensured. Thus, for flaw sizes smaller than0.25T that result in $K_I > K_{IR}$, a reduced, detectible flaw size was calculated assuming $K_I = K_{IR}$.
4. Per Section 7.C of the Welding Research Council Bulletin Number 175, for bolts over 3 inches in diameter, the recommended toughness requirement equates to a fracture toughness value of 142.8 MPa$\sqrt{}$m and is not dependent on temperature.
5. Per Paragraph 6.2.7 of the Reactor Vessel design specification, the minimum Hydrostatic Test temperature is 21.1°C. Larger flaw sizes can be determined if the Test temperature is raised to a more realistic value (i.e. 43.3°C).

APPENDIX 20B
PRESSURISER COMPONENT SAFETY REPORT

20B.1 Introduction

This is the component safety report (CSR) for the pressuriser (PZR) as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the PZR to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentary evidence outlined in Section 20B.7 regarding the quality of design, manufacture, installation and operation of the PZR.

20B.1.1 Scope

This CSR presents arguments to support the claim that the nuclear and radiological risks potentially arising from gross structural failure of the PZR are tolerably low for the lifetime objective of 60 years. Conventional hazards to personnel safety are outside the scope of this Appendix 20B.

20B.1.2 Objectives

This report supports the nuclear safety claim that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. This claim is substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: maintaining these at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the PZR are identified in Section 20B.2.1.

20B.1.3 Interface with Other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data and analyses. These are listed in the Technical Index (Section 20B.7) and each is specifically identified in the relevant section of the structured safety argument.

20B.1.4 Description

The PZR is a vertical, cylindrical vessel having hemispherical top and bottom heads constructed of low alloy steel. Internal surfaces exposed to the reactor coolant are clad using corrosion resistant materials. Material specifications for the PZR are provided in Table 20B-1.

The AP1000 PZR is approximately 13.78 m (542.4") long and has an inner diameter of approximately 2.54 m (100"). The nominal free internal volume for the PZR is 59.47 m^3 (2,100 cubic feet). The upper head of the vessel is penetrated by one (1) spray nozzle, two (2) safety relief nozzles, four (4) instrumentation nozzles and one (1) temperature nozzle. One (1) manway, four (4) instrumentation nozzles, one (1) sampling nozzle and one (1) temperature nozzle are located in the cylindrical shell. The lower head is penetrated by one (1) surge nozzle and seventy eight (78) heater assemblies, which are inserted from the bottom head through heater sleeve assemblies.

The general configuration of the PZR is shown in Figure 20B-1. The design data for the PZR are given in Table 20B-2 and Table 20B-4.

The PZR is designed to meet the requirements of the American Society of Mechanical Engineers (ASME) Boiler & Pressure Vessel Code (Code), Section III, subsection NB, 1998 Edition with Addenda up through and including 2000. Other applicable codes, standards and regulations are summarised in section 20B.3.1.1.3.

The surge nozzle design is such that it is integrally forged with the bottom head and the safety/relief nozzle and spray nozzle are both integrally forged with the upper head to limit the number of welds required. The surge nozzle safe-end will be spaced sufficiently below the lowest heater sleeve to facilitate field welding to the surge line. Thermal sleeves are included in the surge nozzle and the spray nozzle to limit thermal stresses during surge and spray transients. The spray line nozzles and the automatic depressurisation and safety valve connections are located in the top head of the PZR vessel.

The safety relief nozzle (DN 350, NPS 14), surge nozzle (DN 100, NPS 4) and temperature and instrumentation nozzles terminate in stainless steel material to facilitate compatibility with the interfacing material. The spray nozzle terminates in Alloy 690 material. The safe ends are of sufficient length to prevent damage to the transition weld on the nozzle during field welding. The surge, safety relief and ferritic nozzle weld end preparations are buttered prior to final post weld heat treatment (PWHT). After final PWHT, the safe ends are welded to the buttered nozzles. The internal upper head spray nozzle region, to which the spray nozzle nipple is welded, are first be buttered and then stress relieved prior to welding the spray nozzle nipple. The weld metal for buttering and the weld to join the safe end to the nozzle is detailed in section 20B.3.1.4.2. The compatibility of the materials is detailed in section 20B.3.1.4.4.

A retaining screen above the surge nozzle prevents passage of any foreign matter from the PZR to the reactor coolant system (RCS). Baffles in the lower section of the PZR prevent an in-surge of cold water from flowing directly to the steam/water interface. The baffles also assist in mixing the incoming water with the water in the PZR. The retaining screen and baffles also act as a diffuser and support the heaters to limit vibration.

Electric direct-immersion heaters are installed in vertically oriented heater wells penetrating the PZR bottom head. The heater sleeves are welded to the bottom head and form part of the pressure boundary. The heaters can be removed for maintenance or replacement. They are manufactured from austenitic stainless steel. Nickel-chromium-iron alloys are not used for the heaters.

The PZR is fitted with mirror-type insulation, which contains easy locking joints for quick removal and reinstallation. A manway in the upper shell provides access to the internal space of the PZR in order to inspect or maintain the spray nozzle. The manway closure is a gasketed cover held in place with threaded fasteners.

Brackets on the upper shell attach the structure (a ring girder) of the PZR safety and relief valve (PSARV) module. The PSARV module includes the safety valves and the first three stages of the automatic depressurisation system (ADS) valves. The support brackets on the PZR represent the primary vertical load path to the building structure. Sway struts between the ring girder and PZR compartment walls also provide lateral support to the upper portion of the PZR.

Support arrangement for the PZR is shown in Figure 20B-6. Four steel columns attach to pads on the lower head to provide vertical support for the vessel. Lateral support for the lower

portion of the vessel is provided by sway struts between the columns and compartment walls. As part of the lower support system, four support pads will be forged in the PZR lower head. The upper support system provides lateral/seismic support and consists of eight sway struts that attach to a ring girder which in turn attaches to eight pairs of support brackets on the shell. The other ends of the struts attach to the corners of the PZR compartment. The supports will be constructed in accordance with Subsection NF of the ASME Code. The support brackets are also used to support the ADS module that is located above the PZR. The support brackets will be constructed in accordance with Subsection NB of the ASME Code.

20B.1.5 Function

The PZR will perform the following functions:

- Provide a point in the RCS where liquid and vapour can be maintained in equilibrium under saturated conditions for pressure control purposes.
- Provide a barrier to the release of reactor coolant and other radioactive materials to the containment atmosphere.
- Provide a controlled volume from which level can be measured.
- Contain the water volume that is used as an initial source to maintain RCS volume in the event of a minor system leak.

The PZR is designed to accommodate positive and negative surges through the surge line connecting the bottom head to a hot leg. During normal transient events, the pressure increases caused by insurges are controlled/mitigated by the PZR spray, such that the high pressure reactor trip setpoint is not reached. During pressure decreases (outsurges), water-to-steam flashing and automatic heater operation keep the pressure above the low pressure reactor trip setpoint. The heaters are also energised on high water level during insurges to heat the sub-cooled surge water entering the PZR from the reactor coolant loop. A screen at the surge line nozzle, as well as baffles in the lower section of the PZR, prevent cold insurge water from flowing directly to the steam/water interface. The screen and baffles also assist in mixing. Because of the relatively low flow rate of the insurges and outsurges associated with normal PZR transients, the PZR may experience thermal stratification. This is taken account of in the design. During plant heat up and cool down, when the potential for thermal stratification is the greatest, the PZR may be operated with a continuous outflow of water to minimise the possibility of PZR thermal transients resulting from insurges (in addition to operation in Modes 1 and 2[1]).

The PZR volume and level setpoints are selected to prevent water relief through the safety valves following any normal or upset event (Condition I or II) without the benefit of the rod control and steam dump systems. Conservation of inventory during normal and upset events is a safety-related function. The RCS and PZR will perform this function in accordance with all of the applicable safety related criteria discussed in Section 20B.2.

1. Mode 1 – Feedwater Cycling, Slug Flow every 2 hours; Mode 2 – Feedwater Cycling, Slug Flow every 24 minutes.

On a best estimate basis, with normal plant conditions, the combination of the normal PZR liquid and vapour volumes is sufficient to support the following performance requirements:

- Maintain pressure response to programmed system volume changes within appropriate limits.
- Prevent uncovering of the heaters following a step load decrease.
- Accept a 100% load rejection without actuating a reactor trip in conjunction with automatic reactor control and steam dump to the condenser.
- Prevent letdown isolation on low PZR water level following a reactor trip.
- Avoid generation of a low PZR pressure safety injection signal (core makeup tank (CMT)/passive core cooling system (PXS) actuation) following reactor trip, assuming normal operation of control systems.
- Prevent safety valve actuation for any normal or upset event.

The PZR contains electrical heaters installed through the bottom head of the vessel. These heaters are removable for maintenance or replacement. The total heater capacity is selected to provide sufficient heat up of the PZR during start up operation to meet the RCS heat up requirements.

The heaters are configured into 5 groups. A control group is sized to accommodate steady state heat losses. The control group operates continuously during normal operation and is controlled by a proportional controller. Four backup groups of heaters are also installed. Two smaller backup groups can be manually loaded onto diesel generators. Backup heater capacity is based on producing the minimum heat required to maintain sub-cooled RCS pressure during standby operations to support natural circulation through the steam generators (SGs) (this assumes a loss of off-site power). The remaining heater capacity is arranged in two larger backup groups not normally loaded, but being capable of being loaded, onto the diesels. The backup heaters operate in a full on/full off mode, and are actuated during transient events to increase pressure in the RCS. A backup group(s) may be energised temporarily to promote mixing of the boron concentration between the RCS loop piping and the PZR. Energising a heater group(s) creates a demand for PZR spray and promotes mixing. The capacity of the control and backup groups is defined in Table 20B-3.

20B.1.6 Instrumentation

Instrument connections are provided in the PZR shell to measure important parameters. Eight (8) level taps are provided for four (4) channels of level measurement. Level taps are also used for connection to the pressure measurement instrumentation. Two (2) temperature taps monitor water/steam temperature. A sample tap connection is provided for connection to the sampling system to monitor coolant chemistry. The instrument and sample taps are constructed of austenitic stainless steel and designed for a socket weld of the connecting lines to the taps. The sample and instrument taps incorporate an integral flow restrictor to limit loss of coolant to within the capacity of the makeup system in the event of a failure.

All instrumentation nozzles are welded to the weld build up on the cladding on the inside wall of the vessel in accordance with the ASME Code, Section II, Subsection NB for partial penetration welds.

20B.1.7 Pressuriser Spray

Two separate, automatically controlled spray valves with remote manual overrides are used to initiate PZR spray.

In parallel with each spray valve is a manual throttle valve. The throttle permits a small, continuous flow through both spray lines to reduce thermal stresses and thermal shock when the spray valves open. Flow through this valve helps to maintain uniform water chemistry and temperature in the PZR. Temperature sensors with low temperature alarms are located in each spray line to alert the operator to insufficient bypass flow.

The layout of the common spray line piping routed to the PZR forms a water seal that prevents steam build up back to the control valves. The design spray rate is selected to prevent the PZR pressure from reaching the reactor trip setpoint during a step reduction in power level of 10% of full load.

The PZR spray lines and valves are large enough to provide the required spray flow rate under the driving force of the differential pressure between the surge line connection in the hot leg and the spray line connection in the cold leg. The spray line inlet connections extend into the cold leg piping in the form of a scoop in order to use the velocity head of the reactor coolant loop flow to add to the spray driving force. The spray line also assists in equalising the boron concentration between the reactor coolant loops and the PZR.

A flow path from the chemical and volume control system (CVS) to the PZR spray line is also provided. This path provides auxiliary spray to the vapour space of the PZR during cool down, hot standby, and hot shutdown when the reactor coolant pumps are not operating. The PZR spray connection and the spray piping can withstand the thermal stresses resulting from the introduction of cold spray water.

20B.1.8 Boundaries

The equipment boundary of ASME Code jurisdiction includes all components in Figure 20B-2 to Figure 20B-5. The welds at safe end/piping interface or nozzle/piping interface are considered as part of the RCS piping system. These figures show the end of the nozzle or safe end as the equipment boundary and also show the boundaries for the support interfaces.

The manway cover and attachment hardware are included within the equipment boundary.

20B.2 SAFETY CASE REQUIREMENTS

This CSR supports the substantiation of these claims by establishing that the structural integrity of the PZR is commensurate with the consequences of gross failure by means of a structured safety argument, supported by suitable and sufficient evidence. The safety argument is presented according to an established four legged structure as detailed in the Demonstration of Incredibility of Failure in Structural Integrity Safety Cases (Reference 20B.3), to demonstrate an appropriate level of defence in depth by identifying evidence to satisfy safety claims and objectives identified within each leg of the argument, as follows:

Leg 1	**Interpolation/Extrapolation of Experience – 'Good Design and Manufacture' (Section 20B.3.1)**
Objective	Provides evidence of good design and manufacture based upon a proven track record. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with the objectives of achieving good quality of build, high integrity (HI) and the avoidance of defects.
Claim	High quality is achieved through good design and manufacture.
Leg 2	**Functional Testing (Section 20B.3.2)**
Objective	Incorporates the build experience as embodied in design codes and provides some diversity and redundancy to the pre-service inspection.
Claim	Components are shown to be fit for purpose through effective functional testing.
Leg 3	**Failure Analysis (Section 20B.3.3)**
Objective	Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval. Goes beyond design code requirements to provide a further demonstration of integrity. Recognises that flaws may be present and shows tolerance to them. Supplements the Leg 1 aim of avoidance of defects to provide a safety case with both defect avoidance and tolerance.
Claim	Components are tolerant to through life degradation over the design life of the plant.
Leg 4	**Forewarning of Failure (Section 20B.3.4)**
Objective	Confirms the absence of a degradation mechanism or that a known degradation mechanism is not significant enough to threaten integrity or will have limited consequences. Provides contingency for the unexpected.
Claim	Effective systems are in place to provide forewarning of failure.

20B.2.1 Safety Functional Requirements

Chapter 20 identifies performance and safety design bases for the AP1000 SSCs. These are requirements of plant systems, some duty, some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. Identification of the SFRs (also listed in Table 20-1) for the PZR follows from the performance and safety design bases as follows:

SFR	Description
20.2.1	The PZR is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation and under design basis faulted conditions for the design life of the plant.
20.2.2	The PZR is required to provide the point in the RCS where system pressure is controlled during steady state operations and transients, to ensure minimum pressure requirements associated with core coolant boiling and departure from nucleate boiling limits are maintained.

SFR	Description
20.2.3	The PZR is required to provide the controlled volume from which the level of reactor coolant can be measured.
20.2.4	The PZR is required to contain the water volume which is used to maintain RCS volume in the event of a minor system leak for a reasonable time without replenishment.

Postulated failure modes, which result in a loss of these SFRs lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20B.2.2. The safety argument in Section 20B.3 is provided to establish that structural integrity of the PZR will be maintained for all conditions within the design basis and thus demonstrate that all of the above SFRs will be maintained at all times.

20B.2.2 Pressuriser Structural Integrity Classification

Key to the PZR structural integrity safety case is the clear understanding of the potential radiological consequences of any postulated gross failure mode. Based upon this understanding, a structured and systematic basis can be established for setting the level of rigour applied during the design assessment, material procurement, fabrication, in-manufacture inspection, testing and in-service testing, maintenance, inspection and safety case assessment of the component. Details of the approach for developing the AP1000 component structural integrity safety cases are given in the United Kingdom (UK) AP1000 Structural Integrity Classification (Reference 20B.4).

The approach to structural integrity classification is discussed in Section 20.5 and is consistent with the overall AP1000 safety classification scheme as detailed in Chapter 5. Reference 20B.4 details the approach taken whereby a more detailed assessment of selected individual components is made to establish the consequences of gross failure, due to both direct consequences, such as a loss-of-coolant accident (LOCA), and indirect consequences, such as the effect of missiles, jet loading or pipe whip on essential safety systems. Based on this assessment, and in accordance with the scheme identified in Table 20-2, components are ascribed one of the five structural integrity classifications described in Section 20.5.2.

For the PZR, a detailed assessment of the failure consequences is documented in Reference 20B.4. The results of this assessment are tabulated in Table 20-7. This concludes that postulated gross failure of the PZR has the potential for the most severe off-site consequences and hence a Highest Safety Significance (HSS) Classification is appropriate.

The HSS classification does not, however, apply to each and every component of the PZR or to every postulated failure mode and defect orientation, since certain failure modes will not lead to the most severe consequences. Since the identification of HSS locations is most important to the safety case arguments at each individual location, as well as establishing the inspection and defect tolerance requirements for individual welds, it is important to consider each location in turn. This is presented in Table 20B-5.

20B.3 SAFETY ARGUMENT

This section provides a structured safety argument to demonstrate that the PZR is fit for purpose for the required component lifetime of 60 years. The safety argument is presented according to the four legged structure outlined in Section 20B.2.

Consistency with the appropriate ASME rules for design, manufacture and inspection forms the basis to substantiate fitness-for-purpose for PZR components with Standard Class 1 classification.

Compliance with the relevant rules of the ASME Code is generally inferred as providing substantiation for a component's reliability. In the case of the PZR, where gross failure is postulated to lead to severe off-site consequences, it is necessary to substantiate a lower frequency of failure such that the probability of gross failure is so low that it can be discounted. This is achieved by identifying supplementary measures to ensure high quality and by demonstrating tolerance to manufacturing defects above qualified detection limits. Additional qualitative arguments are presented in Section 20B.3.2 and Section 20B.3.4 to demonstrate evidence of defence in depth and substantiate component reliability commensurate with the structural classification of the PZR.

20B.3.1 Leg 1: Interpolation/Extrapolation of Experience – Good Design and Manufacture

The objective of Leg 1 is to provide evidence to support the claim that the quality of design and manufacture is commensurate with the classification of each component of the PZR. This supports the structural reliability targets associated with the classification of each PZR component.

Reference 20B.1 establishes the basis for the materials, design, operability, manufacture, inspection, and testing of the AP1000 PZRs. This provides the basis to demonstrate that the design and construction of the PZR conforms to the ASME Code, Section III, Rules for the Construction of nuclear power plant (NPP) components and the applicable Code Cases and Addenda for Class 1 and Class 2 vessels. The ASME Section III Rules embody extensive international industry-wide operating experience and compliance with these rules provides a keystone for a demonstration of high structural reliability. A number of elements are built up to support this claim.

- The design is well founded, designed in accordance with internationally recognised standards and takes into account operating experience (Section 20B.3.1.1).
- Loading, temperatures and environment have been well defined (Section 20B.3.1.2).
- The AP1000 PZR design has been assessed against relevant design code requirements (Section 20B.3.1.3).
- Components are manufactured using a good choice of materials (Section 20B.3.1.4).
- Good manufacturing (Section 20B.3.1.5).
- Manufacturing inspection (Section 20B.3.1.6).
- Plant operation and maintenance (Section 20B.3.1.7).

Together, these provide an important keystone for a demonstration that the PZR is well designed, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the PZR.

20B.3.1.1 The Pressuriser Design is Well Founded, Designed in Accordance with Internationally Recognised Standards and Takes into Account Operating Experience

In order to demonstrate that the design is well founded, designed in accordance with internationally recognised standards and takes into account historical experience, evidence to substantiate the following arguments is provided.

- The Westinghouse design of the PZRs is well founded and supported by an excellent safety record.
- The design of the PZR takes account of in-service experience and known age related degradation mechanisms.
- Design and manufacture in accordance with established codes, standards and regulations provides assurance of high reliability.
- Novel features of design are avoided or adequately justified.
- The use of forgings is maximised to limit the number of welds.

20B.3.1.1.1 Westinghouse Design of Pressurisers is Well Founded and Supported by an Excellent Safety Record

The design of the AP1000 PZR is supported by decades of successful plant operating experience which have accumulated many operating years without significant issue. Westinghouse has substantial proven experience, knowledge, and capability to design, manufacture and furnish technical assistance for the installation, start-up and service of NPPs.

The AP1000 PZR is of similar design to that of the earlier Westinghouse designs, and also to typical pressurised water reactor (PWR) PZR design, which use similar proven materials and manufacturing processes. The design has been the subject of regulatory scrutiny overseas: the United States (US) Nuclear Regulatory Commission (NRC) approved the final design certification for the AP1000 in December 2005 following the earlier approval of the AP600 design certification in 1999.

Whilst the substantial record of safe operating experience alone does not fully support reliability claims commensurate with a HSS component, it provides confidence that there is a thorough understanding of the in-service performance of these vessels, the management and mitigation of through-life degradation issues and in the avoidance of issues at the design and manufacturing stage that can affect the through-life performance.

20B.3.1.1.2 The Design of the Pressuriser Takes Account of In-service Experience and Known Age Related Degradation Mechanisms

NUREG-1801 (Reference 20B.6), issued in 2005, presents a comprehensive review of the ageing effects including PWR PZRs, as covered by generic ageing management programmes. During the design of the AP1000 PZR, consideration has been given to the susceptibility of the AP1000 PZR design to known in-service degradation mechanisms. The main conclusions from this review of each of the major in-service issues are summarised below.

Degradation Mechanism	Component	AP1000 Mitigation
Fatigue Cracking	• Reactor coolant pressure boundary components • Piping, piping components and piping elements • Flanges • Nozzles and safe-ends • Vessel shell, heads and welds • Heater sheaths and sleeves • Thermal sleeves • Penetrations • Integral support	Selection of materials. Good design & manufacture. AP1000 components are evaluated against a design life of 60 years and fatigue usage factors (FUFs) will be below unity for the life of each component. In-service inspection (ISI).
Stress corrosion cracking	• Spray head • Heater sheaths and sleeves • Heater bundle diaphragm plate • Instrumentation penetrations • Manways • Flanges	Selection of appropriate materials. The use of material susceptible to Primary Water Stress Corrosion Cracking (PWSCC) is forbidden by the PZR Design Specification. The concentration of chlorides, fluorides, sulphates, lithium, and dissolved oxygen and hydrogen are monitored and kept below the recommended levels. ISI.
Primary water stress corrosion cracking	• Spray head • Instrumentation penetrations • Heater sheaths and sleeves • Heater bundle diaphragm plate • Manways • Flanges • Surge and steam space nozzles • Welds	Selection of appropriate materials. The use of material susceptible to PWSCC is forbidden by the PZR Design Specification. The concentration of chlorides, fluorides, sulphates, lithium, and dissolved oxygen and hydrogen are monitored and kept below the recommended levels. ISI.

Recent UK PWR experience has highlighted concerns relating to the integrity of the PZR heater sheath material. Based on Westinghouse own knowledge of PZR design and worldwide operating experience, there are known issues associated with hardening and sensitisation of the heater sheath material as a result of coldworking during the fabrication process and the lack of a subsequent annealing heat treatment, which eventually lead to stress

corrosion cracking of the heater sheaths. In the AP1000 PZR design, an improved PZR heater sheath is produced in accordance with the ASME SA-213 material specification and with certain supplementary technical requirements, as detailed in Reference 20B.22. These include heat treatment and surface treatment procedures and supplementary material testing in accordance with ASTM A262 (Reference 20B.36).

Design and manufacture in accordance with established codes, standards and regulations provides assurance of high reliability.

The PZR is designed to meet all applicable regulations and standards defined in Reference 20B.1 as summarised below. Complying with such proven and established codes, standards and regulations minimises the level of design and manufacturing uncertainty. Compliance with the ASME Code provides assurance over a wide range of issues from material procurement, component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination (NDE), testing, installation and pre-service inspection (PSI) and ISI requirements. The extensive body of experience that is embodied within the ASME Code and the successful operation of a significant number of pressure vessels (both nuclear and non-nuclear), mean that compliance with the code provides assurance that the vessel reliability will remain high for the design life of the component. However, in order to substantiate a reliability claim commensurate with a component classified (as per Reference 20B.4) as HSS, i.e., where gross failure can be discounted, or HI it is necessary to demonstrate that measures have been taken over and above the minimum requirements specified by ASME. This is discussed in Section 20B.4. Evidence of compliance with ASME requirements will come from the ASME certificate number for the PZR.

20B.3.1.1.3 **Novel Features of Design are Avoided or Adequately Justified**

The PZR is sized to have sufficient volume to accomplish the functional requirements without power operated relief valves. The PZR has approximately 40% more volume than the PZRs for previous plants with similar power levels. This increased volume provides plant operating flexibility and minimises challenges to the safety relief valves.

In other regards, the AP1000 PZR design and materials selection is broadly similar to that typical of PWR PZRs and is consistent with accepted industry practice.

20B.3.1.1.4 **The Use of Forgings is Maximised to Limit the Number of Welds**

To minimise welds and reduce ISI, the PZR cylindrical sections (upper, middle and lower) will be forged shell sections, thereby eliminating the need for longitudinal seam welds. The safety relief nozzle and the spray nozzle of the upper head region and the support pads and the surge nozzle of the lower head region are integrally forged, again to minimise welds present at these regions.

20B.3.1.2 Loading, Temperatures and Environment have been Well Defined

In order to demonstrate that the loading, temperature and environment have been well defined, evidence to substantiate the following arguments is provided.

- Design and operating parameters used in the design evaluation have been determined using established and conservative procedures and capture all normal and design basis conditions.
- The PZR is designed to operate in the specified environmental conditions.

20B.3.1.2.1 **Design and Operating Parameters used in the Design Evaluation have been Determined using Established and Conservative Procedures and Capture all Normal and Design Basis Conditions**

The PZR is designed, fabricated, examined and tested in accordance with Reference 20B.1 and the ASME Code, Section III and all applicable Code Cases and Addenda for Class 1 Vessels. To substantiate claims based on ASME Code compliance, evidence is provided here to demonstrate that design and operating parameters used in the design evaluation have been determined using established conservative procedures. Section III Subsection NB of the code requires assessment against design, service and test conditions, and that the stresses within the vessel are shown to comply with specified allowable stress limits appropriate to the material of construction. The design conditions include those pressure, temperature and

mechanical loadings selected as the basis for the design. Service conditions cover those normal operating conditions, anticipated transients and accident conditions expected or postulated to occur during operation. The evaluation of service and testing conditions includes an evaluation of fatigue due to cyclic stresses.

The design and service conditions for the PZR are shown in Table 20B-2. The following five categories of operating condition, as defined in ASME Code, Section III, have been evaluated as part of the design substantiation for the PZR. These encompass all operating conditions within the design basis, as summarised in Table 20-22 along with the number of occurrences of each transient over the design life of the plant.

- Level A Service Conditions – Normal Conditions.
- Level B Service Conditions – Upset Conditions, Incidents of Moderate Frequency
- Level C Service Conditions – Emergency Conditions, Infrequent Incidents
- Level D Service Conditions – Faulted Conditions, Limiting Faults
- Testing Conditions – Include primary and secondary hydrostatic tests and SG tube leak tests specified.

The specific transients to be considered for equipment fatigue analyses are based upon PWR plant operating experience along with engineering judgment. The plant condition categorisation defined in ANS/ANSI N51.1 (Reference 20B.7), which categorises transients on the basis of expected frequency, are also part of the process to define transients and which service condition applies for a given transient. The transients for each of these service conditions are summarised in Table 20-22 and are further specified in Reference 20B.1.

The transients selected are a conservative representation of transients that, used as a basis for component fatigue evaluation, provide confidence that the component is appropriate for its application for the 60-year design objective. These transients are described by pertinent variations in pressure, fluid temperature, and fluid flow. The frequency of these transients, in some cases, is greater than the maximum frequency that defines the plant condition in Reference 20B.7. The design transients and the number of events of each that are normally used for fatigue evaluations of components are presented in Table 20-22, as specified in Reference 20.3.

Section 6.4.16 of Reference 20B.1 provides a description of the seismic requirements. The seismic loading is based upon that defined in the AP1000 Seismic Design Criteria (Reference 20B.11) and considers 20 safe shutdown earthquake (SSE) cycles (or alternatively 315 cycles of 1/3 SSE). The analysis also considers the hydraulic interaction between the coolant (gas or liquid) and the system structural elements. For dynamic analysis either equivalent static analysis or response spectrum analysis methods may be used.

The peak ground acceleration of the SSE has been established as 0.30 g for the AP1000 design. The vertical peak ground acceleration is conservatively assumed to equal the horizontal value of 0.30 g. Both horizontal and vertical design response spectra are based on the Regulatory Guide 1.60 (Reference 20B.34) spectra augmented at the higher frequencies. In Chapter 12, these spectra are compared to the UK generic design basis Principia Mechanica Limited spectra, which are based on a 0.25 g zero period acceleration event.

20B.3.1.2.2 **The Pressuriser is Designed to Operate in the Specified Environmental Conditions**

The PZR is designed to maintain performance and structural integrity when operating with specific environmental conditions. The interior of the PZR will be exposed to the primary coolant. Bounding conditions for operational chemistry control of primary fluids in contact with primary system materials and nuclear fuel are presented in Table 20A-3, which reflects well established EPRI guidelines for PWR primary chemistry (Reference 20B.12). The exterior will be exposed to the atmospheric conditions prevailing in the reactor containment defined in Table 20B-7. The internal and external environmental conditions are used in conjunction with the design transients of Table 20-22. The design accounts for the effects of the radiation fields in which the PZR operates. Applicable radiation environmental conditions are given in Reference 20B.1.

Table 20B-15 specifies the operating environment inside containment during group 1 and 2 abnormal events.

20B.3.1.3 The AP1000 Pressuriser Design has been Assessed Against Relevant Design Code Requirements

In order to demonstrate that the PZR design has been assessed against the relevant design code requirements, evidence to substantiate the following arguments is provided.

- The PZR design complies with the allowable stress limits and sizing limits as specified in ASME III for a Class 1 component.

- The end of life FUFs are below the 1.0 fatigue limit.

20B.3.1.3.1 **The Pressuriser Design Assessment Against Relevant Stress Limits and End of Life Fatigue Usage Factors are Below Unity**

The PZR is designed in accordance with the relevant and recognised design codes, discussed in Section 20B.3.1.1.3. The following regions of the PZR are included in the scope of the stress analysis:

- Upper Head and Shell
- Spray nozzle
- Surge Nozzle
- Safety Relief Nozzle
- Instrument Nozzle
- Manway
- Trunnion and Shell Build-up
- Bracket
- Lower Head/Support Pad
- Heater/Heater Support plate
- Heater/Heater Sleeve
- Heater Sheath

The PZR Design Report (Reference 20B.13) summarises results of detailed analyses to substantiate the design of the PZR. The scope of the analyses includes all locations identified above and all of the required loading conditions specified in Reference 20B.1.

The PZR is designed in accordance with the requirements of the ASME Boiler and Pressure Vessel Code, Section III, 1998 Edition with addenda up through and including 2000 as stated in the Design Specification (Reference 20B.1). The PZR Design Report (Reference 20B.13) consolidates the results of detailed analyses demonstrating the adequacy of the structural design to sustain and meet ASME Code requirements.

The components of the PZR forming part of the reactor coolant pressure boundary, including all openings in the vessel shell and upper and lower head, has been shown to meet the minimum thickness and reinforcement requirements for internal pressure in accordance with ASME Code, Section III. Detailed results for each component are presented in Reference 20B.13. Also reported in Reference 20B.13 are the calculated ratios of the stress intensities to the allowable stress limits and the calculated fatigue usage factors for each of the main locations on the PZR. The results demonstrate that all requirements of the Design Specification and of the ASME Code are met.

20B.3.1.4 Components are Manufactured Using Good Choice of Materials

In order to demonstrate that the AP1000 PZR components are manufactured using a good choice of materials, evidence to substantiate the following arguments is provided.

- AP1000 PZR materials have a proven service performance.
- Material specifications meet or exceed ASME specifications.
- Tight control on chemical composition is specified.
- Materials are compatible with each other and with the environment and are resistant to environmental degradation over the life of the plant. Degradation characteristics are known and understood.
- Nozzle and safe-end materials have been optimised for design and fabrication.
- Materials testing is sufficient to demonstrate that the material properties are compliant with the relevant specifications.

20B.3.1.4.1 AP1000 Pressuriser Materials have a Proven Service Performance

The selection of the AP1000 PZR materials reflects international experience in PWR design, manufacture and operation and the lessons learned. The upper, middle and lower shells, lower head, upper head and nozzles and support pads will be manufactured from ASME SA-508 Grade 3 Class 2 (same chemical composition as Grade 3 Class 1, used in the reactor vessel (RV), but has a higher specified strength of approximately 12%). There is extensive experience with this material in the nuclear industry.

Regulatory Observation, RO-AP1000-21, as detailed in the Step 3 Structural Integrity Assessment of the AP1000 (Reference 20B.14), was raised in regard to the choice of material for the pressuriser. UK precedent has been to use the UK modified specification of ASME SA-508 Class 3 (now Grade 3 Class 1) for the RV, PZR and SG (primary and secondary side) shells. A full response was provided to these concerns.

As is standard for PWR ferritic components, which are in contact with primary coolant, wetted surfaces are clad with austenitic stainless steel or equivalent corrosion-resistant material; the AP1000 cladding is Type 309L austenitic stainless steel followed by Type 308L weld material for weld overlay cladding. The use of Alloy 600 and associated weld metals is prohibited, which reflects lessons learned from the in-service issues relating to PWSCC of these nickel based alloys under PWR conditions.

20B.3.1.4.2 **Material Specifications Meet or Exceed ASME Specifications**

Materials comply with the applicable requirements of the design and construction codes and standards of the ASME Code, Section III. The approved materials used for the PZR assembly are as identified in Table 20B-1.

To support this argument, a QA compliant certified material test report as per the ASME Code will be provided with shipment of the forgings. This will include the material test results and information on:

- Chemical analyses: heat and product
- Mechanical properties: tensile stress-strain, Charpy V-Notch, drop weight, nil-ductility transition temperature (T_{NDT}) and reference nil-ductility transition temperature (RT_{NDT})
- Heat treatments
- Information on archive/weldment material
- Sketches or drawings with dimensions
- A statement certifying that no weld repairs had been made (where applicable)
- Start-of-life inspection results

The following Supplementary Requirements of SA-508 apply.

- S1 Simulated PWHT of Mechanical Test Samples
- S2 UT Reference Block Calibration
- S3 Charpy Impact Transition Curve
- S4 Additional Charpy Data
- S9 Restrictive Chemistry
- S10 Alternative Fracture Toughness Requirements
- S15 Product Analysis

The attachment of the safe ends to vessel nozzle ends for the PZR use buttering. The weld metal for this buttering and the weld to join the safe end to the nozzle is one or more of the following ASME Section II Part C specifications:

- SFA-5.11 ENiCrFe-7 (Alloy 152).
- SFA-5.14 ERNiCrFe-7 (Alloy 52).
- SFA-5.14 ERNiCrFe-7A (Alloy 54 – chemical specification as for Alloy 52, but with Cobalt (0.12%), Boron (0.005% max) and Zirconium (0.02% max).

20B.3.1.4.3 **Tight Control on Chemical Composition is Specified**

The chemical composition of the PZR shell forgings is specified in the Material Specification for SA-508/SA-508 M Grade 3 Class 2 Forgings (Reference 20B.15). A supplementary ASME Code Section II requirement for SA-508 Grade 3 Class 2 material (S9 – Restrictive Chemistry) includes additional restrictions on chemical composition. These are listed below.

- Phosphorus will be 0.015% maximum for heat analysis and 0.018% maximum for product analysis; sulphur will be 0.005% maximum for heat analysis and product analysis; copper will be 0.15% maximum for heat and product analysis.

- Chromium content for heat and product analyses will be greater than 0.10%.

Samples for product analysis will be taken from material adjacent to each tensile specimen, or may be taken from the ends of broken tensile specimens. The certified material test report will identify, by location, which product analysis corresponds to which reported tensile test results.

If the steel is vacuum-carbon deoxidised, the silicon content will be 0.10% maximum both by heat and product analyses. The test report will indicate that the steel was vacuum-carbon deoxidised.

20B.3.1.4.4 **Materials are Compatible with Each Other and with the Environment and are Resistant to Environmental Degradation over the Life of the Plant. Degradation Characteristics are Known and Understood**

The materials selected for use in the PZR will be compatible with the full range of internal and external environmental conditions, which may be encountered over the plant life and are predicted not to degrade in that time. These environmental conditions include temperature, humidity, radiation, chemistry of fluid or materials in contact, and other external conditions which may affect the suitability of a material.

To prevent corrosion of low alloy steel component in contact with primary coolant, all principal pressure-retaining components made from such materials, including the PZR, have corrosion-resistant cladding on surfaces exposed to the reactor coolant. Clad surfaces will be "L" grade austenitic stainless steel and welds and buttering will be "L" grade austenitic stainless steel or Ni-Cr-Fe Alloy. The stainless steel cladding surfaces will meet all of the requirements of the Material Test Specification for Austenitic Stainless Steel Cladding (Reference 20B.16). For multiple layer stainless steel cladding, the stainless steel cladding will be Type 308L austenitic stainless steel weld metal with Type 309L austenitic stainless steel weld metal used for the first layer. The corrosion resistance of the cladding material is at least equivalent to the corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy, martensitic stainless steel, and precipitation-hardened stainless steel.

20B.3.1.4.5 **Nozzle and Safe-end Materials have been Optimised for Design and Fabrication**

The safety relief, surge temperature and instrumentation nozzles will all terminate in Type 316LN austenitic stainless steel material for compatibility with the interfacing piping material, thus avoiding the requirement for field transition welds. The spray nozzle terminates in UNS N06690 (Alloy 690) material. The safe ends will be of sufficient length to prevent damage to the transition weld on the nozzle during field welding.

The surge, safety relief, and spray ferric nozzle weld end preparations will be buttered prior to final PWHT. After final PWHT, the safe ends will be welded to the buttered nozzles.

The internal upper head spray nozzle region to which the spray nozzle nipple is welded will be first buttered and then stress relieved prior to welding the spray nozzle nipple.

The instrument and temperature nozzle weld build up pads on the inside vessel wall will be first made with SFA 5.4 or SFA 5.9 Type 309L (first layer only) followed by Type 308L weld material and then be stress relieved prior to welding these nozzles.

The heater sleeve weld buildup pads on the inside vessel wall will be stress relieved prior to welding the nozzles.

The use of Nickel alloy weld and buttering consumables reduces the thermal mis-match stresses in the nozzles.

20B.3.1.4.6 **Materials Testing is Sufficient to Demonstrate that the Material Properties are Compliant with the Relevant Specifications**

The materials testing requirements for each material are contained within the relevant material specifications as identified in the PZR Design Specification. For the PZR main forgings the mechanical property tests will consist of Tensile Tests, Drop Weight Tests and Charpy V-Notch Impact Tests. Test methods, location and orientation of specimens will be in accordance with ASME Code, Section III, Subsection NB-2000.

Tests will be performed at the upper and lower head forgings, upper, middle and lower shell forgings, trunnions, manway pads and forgings exceeding 454 kg (1,000 lbs.) (prior to quenching and tempering treatment) and small forgings not exceeding 454 kg (1,000 lbs.) (prior to quench and tempering treatment).

Subsequent to quenching and tempering, mechanical property test specimens will be given a simulated PWHT as follows; place coupons in a furnace at not over 425°C (800°F), heat at no more than 56°C/hr. (100°F/hr.) to the range 595°C-621°C (1,100°F-1,150°F) and hold for 48 hours, then cool at not more than 56°C/hr. (100°F/hr.) to below 425°C (800°F).

Sufficient drop weight tests will be run to determine the actual nil-ductility transition temperature (NDTT) or nil-ductility temperature for each forging. Specimens from two locations on a given forging may be intermixed to determine the NDTT. However, one specimen from each of the two locations will show no-break at the lowest no-break temperature used to define the NDTT. The NDTT will not be higher than -12.2°C (10°F). T_{NDT} as defined by ASME Code will be considered as the actual NDTT determined by drop weight tests.

Charpy V-Notch tests and drop weight fracture toughness tests are required. Orientation of test specimens will be per the ASME Code, Section III, Subsection NB-2000. For each test location the RT_{NDT} will not be higher than -12.2°C (10°F). Charpy V-Notch tests (sets of three specimens) will be performed for each location at a temperature not higher than the T_{NDT} temperature plus 33°C (60°F). Three sets of data are required for weld material and heat-affected-zone (Reference 20B.15). Additional data, if necessary, will be obtained by testing of production material for the shell or head and incorporated into this specification. The supplier is responsible for providing these data.

Supplementary fracture toughness testing, which is described in Reference 20B.39, will be performed to underpin the values assumed in the Reference 20B.27 and 20B.38 defect tolerance assessments.

20B.3.1.5 Good Manufacturing

In order to demonstrate that good manufacturing processes will be used, evidence to substantiate the following arguments is provided.

- PZR components will be manufactured by experienced suppliers with a track record for producing similar components.
- High confidence in PZR manufacturing quality can be taken from compliance with ASME III and the experience embodied within the code.
- Approved welding procedures and qualified operators are used to minimise defect occurrence.
- Repairs and deviations from the design intent will be recorded. Approval for deviations from the design intent will be appropriate with justification where necessary.
- Manufacturing and procedural controls ensure quality of forging material.
- Manufacturing records and procedures.
- Quality Assurance.

20B.3.1.5.1 Pressuriser Components will be Manufactured by Experienced Suppliers with a Track Record for Producing Similar Components

In selecting the manufacturer for the heavy pressure vessels, a detailed technical evaluation of the suppliers ability to comply with Reference 20B.1 and quality assurance requirements will be undertaken, giving particular attention to the suppliers ability with regard to achievement of the material compositional requirements including minimum fracture toughness requirements, the methods for the qualification of weld procedures and the ability to carry out the required range of inspections during manufacture. The evidence to support this argument forms part of a site specific justification by the utility company.

The PZR components will be joined by welding, using the single or multiple wire submerged arc and the shielded metal arc processes or other established techniques. Gas metal arc welding and plasma arc welding are acceptable methods of applying buttering for dissimilar metal welds. The use of severely sensitised stainless steel as a pressure boundary material is prohibited and is eliminated by either a select choice of material or by programming the method of assembly. At locations in the PZR where austenitic stainless steel and

nickel-chromium-iron alloy are joined, the final joining beads are nickel-chromium-iron alloy weld metal in order to prevent cracking. The location of full penetration weld seams in the upper closure head and vessel bottom head are restricted to areas that permit accessibility during ISI. The austenitic stainless steel clad surfaces are sampled to demonstrate that composition requirements are met.

20B.3.1.5.2 **High Confidence in Pressuriser Manufacturing Quality can be Taken from Compliance with ASME III and the Experience Embodied within the Code**

Design and fabrication of the PZR is carried out in accordance with ASME Code, Section III, Class 1 requirements and manufactured using well established procedures. Details of manufacturing codes and standards are provided in Reference 20B.1 with certain more stringent requirements defined in the AP1000 Supplemental Fabrication and Inspection Requirements (Reference 20B.17). Compliance with the code and the experience embodied within the code provides a high degree of confidence that high quality has been achieved and also that the vessel will be tolerant to minor variations in material properties and minor imperfections in fabrication.

20B.3.1.5.3 **Approved Welding Procedures and Qualified Operators are used to Minimise Defect Occurrence**

As detailed in Reference 20B.1, welding of all materials will be done in accordance with welding procedures, using certified welders who have been qualified according to the rules of Sections III and IX of the ASME Code as well as the additional requirements identified in Reference 20B.1 and the supplemental requirements detailed in Reference 20B.17. Control of welding variables (as well as examination and testing) during procedure qualification and production welding is performed according to ASME Code requirements. Specific details of welding processes, selection and control of welding consumables, welding procedure qualification, pre-heat, interpass temperatures and post heating requirements and specific control for cladding and buttering are provided in Reference 20B.17.

20B.3.1.5.4 **Repairs and Deviations from the Design Intent will be Recorded. Approval for Deviations from the Design Intent will be Appropriate with Justification where Necessary**

The requirement to record major/minor repairs and deviations from the design intent is stated within Reference 20B.1. Deviation reports or deviation notices will be prepared by the manufacturer for all conditions that do not meet requirements of the Design Specification, the ASME Code or Westinghouse-approved Supplier procedures and drawings and cannot be corrected using previously approved repair procedures. Deviations/defects that are identified during processing/fabrication, which will not affect the final fit-up/function (e.g., weld defects) of the final component and which may be repaired by previously approved repair procedures, will not need to be submitted for Westinghouse approval as a deviation notice. However, these will be recorded for future reference. The requirements placed on the manufacturer include the reporting criteria and the conditions under which formal review and approval by Westinghouse will be required. The following should be noted:

- All major repairs to base material and pressure boundary welds will be subjected to formal review by Westinghouse before approval to proceeding with the repair is granted.

- All arc strikes on pressure boundary and accessible non-pressure boundary materials will be removed and the areas grounded to a smooth contour with a 4:1 taper. Any arc strike

that exceeds a depth of 2.54 mm (0.10 inches) will be documented and reviewed by Westinghouse for approval.

- Repairs by welding will be cleared by the same NDE technique/procedure by which the indications were found.

- The location of these repairs will be identified on the as-built weld seam drawing for permanent record and may be required to be permanently marked on the vessel or head when so indicated in the deviation notice disposition.

20B.3.1.5.5 **Manufacturing and Procedural Controls Ensure Quality of Forging Material**

The PZR upper, middle and lower shells, upper and lower heads and nozzles will be manufactured from high quality forgings supplied by an experienced forge master, working to approved procedures to meet relevant product specifications, which are compliant with ASME Code requirements. Individual material specifications for SA-508 Grade 3 Class 2 forgings and stainless steel forgings are provided in the relevant material specifications as listed in the technical index. These provide specific details of controls on chemical composition, microstructures, heat treatment, materials testing, grain size evaluation and ultrasonic examination to ensure that the final product has the desired through thickness properties and is free from unacceptable forging defects.

20B.3.1.5.6 **Manufacturing Records and Procedures**

To ensure that there is a high degree of control over the achievement of high quality during manufacture, the following controls on the manufacturing records and procedures are specified as part of the component design specification.

Weld Procedures

To ensure that weld procedures are acceptable, all procedures for weld and weld repair and base metal repair will be approved prior to use in fabrication.

All welding procedure specifications to be used in the fabrication of the PZR will be prepared in accordance with a general welding procedure specification and the requirements of Section III of the ASME Code.

Heat Treatment

Heat treatment specifications will be approved prior to manufacture and will include the following (where applicable).

- Holding times for austenitising and tempering
- Rates of heating
- Temperature control
- Temperatures for the austenitising and tempering operations during heating/holding
- Time from the furnace to the quench tank
- Quenching medium
- Cooling method

Material Records

All material ordering specifications (including heat treatment and base metal repair procedures) will be approved prior to material procurement. This includes all welding consumables. Each chemical analysis including both ladle and check, physical and mechanical mill test data sheets, supplier test data sheets, weld material certifications, and inspection reports for materials required by the Design Specification and applicable references will also be provided. The certified chemical and mechanical properties of the weld metal used for full penetration pressure boundary welds in the vessel will be provided, any weld repairs to these welds, and all base metal weld repairs.

Manufacturing Inspections

Each NDE examination report will be made available to Westinghouse for review after the completion of each examination. Defects will be recorded and defect tolerance studies will be carried out by Westinghouse to ensure that recorded indications do not present a concern over the design life of the plant.

Dimensional Checks

The dimensional profile document will be used to record vessel as-built dimensions to demonstrate that the as-built dimensions satisfy the design specification.

Cleaning and Contamination Protection Procedures

Materials used in the fabrication, installation, and testing of nuclear steam supply components and systems are handled, protected, stored, and cleaned according to recognised, accepted methods designed to minimise contamination that could lead to cracking.

20B.3.1.5.7 **Quality Assurance**

Activities affecting the quality of items and services for the AP1000 project during design, procurement, fabrication, inspection, and/or testing are performed in accordance with the quality plan described in the Westinghouse Electric Company Quality Management System, (Reference 20B.18) to satisfy the requirements of 10 CFR 50 Appendix B. The following requirements are identified in Reference 20B.1.

The reliability of the equipment identified in the design specification is dependent upon the design, together with the control of quality during fabrication of the equipment. The quality will be in accordance with the following requirements (Reference 20B.1):

- US Nuclear Regulatory Commission, Regulatory Guide 1.28, "Quality Assurance Program Requirements (Design and Construction)," Revision 3, August 1985.
- This item/service is nuclear safety-related; 10 CFR 21 "Reporting of Defects and Noncompliance" applies.
- 10 CFR 50 Appendix B – "Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants."
- ASME NQA-1-1994, "Quality Assurance Requirements for Nuclear Facility Applications" applies.

- ASME Code, Section III, "Rules for Construction of Nuclear Power Plant Components," 1998 Edition with addenda up through and including 2000.

20B.3.1.6 Manufacturing Inspection

Materials and fabrication processes are well designed in order to demonstrate that the AP1000 PZR enters service free of significant defects, which will be confirmed by an effective manufacturing 20B-24 non-destructive testing (NDT) inspection programme. Evidence to substantiate the following arguments is provided.

- Manufacturing inspections meet or exceed the requirements of ASME.
- Reliability of NDT is assured through a "Design for Inspection" philosophy.
- NDT performed at key stages of manufacture assures the high quality of the completed PZR and its components.
- Qualified inspection performed on HSS components demonstrates a good safety margin.
- Qualified inspection of HSS components confirms the plant is free of defects meeting ASME Section XI criteria.

20B.3.1.6.1 Manufacturing Inspections Meet or Exceed the Requirements of ASME

A diverse range of effective NDT methods and techniques are deployed at various manufacturing stages to ensure that steel forgings, plate, welds and cladding in the PZR enter service free of significant manufacturing defects. The scope of the manufacturing NDT and the techniques applied either meet or exceed the requirements of ASME Section III, as summarised in Table 20B-17.

All repairs made as a result of NDT findings are subsequently inspected using the same NDT method(s) that originally detected the defect leading to the repair.

20B.3.1.6.2 Reliability of Nondestructive Testing is Assured through a "Design for Inspection" Philosophy

The AP1000 incorporates a "Design for Inspectability" philosophy, as detailed in the AP1000 Design for Inspectability Program: ISI Requirements for Class 1 Components (Reference 20B.19), in which the PZR welds and surrounding areas are designed to facilitate NDT by:

- Ensuring a good surface finish for deploying the range of techniques.
- Enabling good access for NDT personnel and equipment.
- Providing sufficient access for deploying angle beam ultrasonic testing to give full volumetric coverage.
- Providing as many inspection surfaces/scanning directions as possible.

20B.3.1.6.3 **Nondestructive Testing is Performed at Key Stages of Manufacture Assures the High Quality of the Completed Pressuriser and its Components**

Experience shows that materials and manufacturing processes similar to those chosen for the AP1000 lead to a low frequency of defect occurrence. However, sensitive volumetric and surface NDT methods are applied at points in the manufacturing programme that ensure any necessary repairs are undertaken at the earliest possible stage.

Inspections are carried out at various stages of manufacture, at increments during weld fill and following completion of major welds, to identify any degradation resulting from processes such as PWHT and hydrotest.

20B.3.1.6.4 **Qualified Inspection Performed on Highest Safety Significant Components Demonstrates a Good Safety Margin**

Qualified ultrasonic volumetric inspections are performed on HSS locations, identified in Section 20B.2.2, after the final post-weld heat treatment to provide a very high level of confidence that the PZR enters service free of any defect that could threaten the structural integrity. Target sizes for manufacturing defects for HSS welds have been established from elastic-plastic fracture mechanics by calculating the end-of-life limiting defect sizes and fatigue crack growth in accordance with the R6 methodology. Inspection of non-HSS welds in the PZR will be qualified in accordance with the requirements of ASME V. A procedure for the manufacturing NDT qualification process has been outlined and this will form the basis for the qualification procedure.

For HSS welds, NDT will be performed using currently available tried and tested ultrasonic techniques and will be shown to provide a detect and reject capability that demonstrates a defect size margin (DSM) of 2 or greater. The basis for this is discussed in Section 20B.3.3.1. High reliability for these inspections will be demonstrated through qualifying the inspection system (procedure, equipment, and personnel) using the principles specified in the European Network for Inspection and Qualification (ENIQ) document, European Methodology for Qualification of Non-Destructive Testing, (Reference 20B.20). For selected HSS welds, a manufacturing inspection plan has been produced which provides the physical reasoning underpinning the claimed inspection capability. Details of manufacturing inspection plans for the selected PZR welds are discussed in Section 20B.3.3.1.3. The manufacturing inspection plans were developed following a process (Reference 20B.37) which is based on the preparation of technical justifications described in ENIQ methodology. A process will be developed in due course to address parent material associated with HSS locations.

A rigorous approach to classification based on failure modes and consequences has identified the following pressure boundary welds as HSS (as identified in Table 20B-5).

1. PZR Vessel Shell Welds (Locations 1.1, 1.2, 1.3, 1.4, 1.5)
2. PZR Nozzle Welds (Locations 2.1, 2.2, 2.3, 2.4, 2.5)
3. PZR Vessel Shell Forgings (Locations 3.1, 3.2, 3.3)

20B.3.1.6.5 Qualified Inspection of Highest Safety Significant Components Confirms the Plant is Free of Defects Meeting ASME Section XI Criteria

The final stage of NDT for HSS welds is the application of qualified mechanised ultrasonic inspection systems to confirm the welds are free of any defects that exceed the specified acceptance criteria. These inspections have two purposes:

- They provide additional high reliability inspections at the end of all manufacturing stages.
- They generate a "fingerprint" set of data against which future ISI results can be compared. By establishing that acceptable indications found during ISI were also present at PSI fabrication, potential unnecessary repairs are avoided.

Supplemental inspections, additional to those specified by ASME Section III, are performed that match the PSI and ISI acceptance criteria of ASME Section XI. Here the objective is to reconcile the difference in acceptance standards between ASME III and ASME XI and ensure that the PSI does not report rejectable defects that were not identified as such during the standard manufacturing NDT (Reference 20B.1).

20B.3.1.7 Plant Operation and Maintenance

In order to demonstrate that the plant will be properly operated and maintained, evidence to support the following arguments is provided.

- The AP1000 RCS chemistry specification is clearly defined and measures are in place to control corrosion.
- Records of operation and maintenance will be maintained to confirm compliance with procedural requirements.
- Incidents involving transgressions of set limits will be investigated.
- Procedures are in place to control maintenance activities.
- ISI will detect defects before they compromise structural integrity.

In order for the operators to safely operate and maintain the AP1000, operating and maintenance manuals that are fully compliant with the technical specifications will be produced by the utility companies. Regarding the PZR, the following issues are considered the most pertinent at this stage in terms of providing assurances that the plant will be properly operated and maintained in such that through-life degradation is minimised.

20B.3.1.7.1 **The AP1000 Reactor Coolant System Chemistry Specification is Clearly Defined and Measures are in Place to Control Corrosion**

The RCS chemistry specifications, the control of chemistry, and the compatibility of primary coolant boundary materials with the RCS chemistry are detailed in section 21.5.5. In summary, the RCS water chemistry is selected to minimise corrosion and routinely scheduled analyses of the coolant chemical composition are performed to verify that the reactor coolant chemistry continues to meet the specifications. Other additions, such as those to reduce activity transport and deposition, may be added to the system. The RCS chemistry specifications conform to the recommendation of Regulatory Guide 1.44 (Reference 20B.35).

The CVS provides a means for adding chemicals to the RCS. The chemicals perform the following functions:

- Control the pH of the coolant during pre-start-up testing and subsequent operation.
- Scavenge oxygen from the coolant during heatup.
- Control radiolysis reactions involving hydrogen, oxygen, and nitrogen during power operations following start-up.

The values presented in Table 20A-3 are bounding for chemistry operational control of primary fluids that are in contact with primary system materials and nuclear fuel. The operational chemistry program may apply stricter limits as deemed appropriate.

20B.3.1.7.2 **Records of Operation and Maintenance will be Maintained to Confirm Compliance with Procedural Requirements**

Details of the quality assurance requirements during the operational phase are discussed in Section 3.4, and will be considered as part of the Site Specific Justification.

20B.3.1.7.3 **Incidents Involving Transgressions of Set Limits will be Investigated**

Operating limits for the UK AP1000 plant are specified within the generic technical specifications (Reference 20B.32). Limiting conditions for operation (LCOs) specify minimum requirements for ensuring safe operation of the plant. The following LCOs are relevant to the pressure/temperature (P/T) limits.

- LCO 3.4.3, “RCS pressure and temperature (P/T) Limits”
- LCO 3.4.14, “Low temperature overpressure protection (LTOP) System”
- LCO 3.4.2, “RCS Minimum Temperature for Criticality”

The consequence of violating the LCO limits is that the RCS has been operated under conditions that can result in brittle failure of the reactor coolant pressure boundary (RCPB), possibly leading to a non-isolable leak or LOCA. In the event these limits are exceeded, an evaluation must be performed to determine the effect on the structural integrity of the RCPB components. ASME Code, Section XI, Appendix E (Reference 20B.21) provides a recommended methodology for evaluating an operating event that causes an excursion outside the limits.

20B.3.1.7.4 **Procedures are in Place to Control Maintenance Activities**

As specified in Reference 20B.1, the PZR Instruction manual, provided by Westinghouse, will contain detailed instructions for the maintenance and repair of the PZR equipment. This will need to be developed further as part of the site specific safety case.

20B.3.2 **Leg 2: Functional Testing**

The objective of the functional testing leg of the safety case is to confirm that the good standards applied in PZR design, fabrication and installation identified in Section 20B.3.1 result in an installed component that is fit for purpose. Hydrostatic pressure tests are conducted to verify that the PZR is proofed against its design pressure, and similar tests are periodically carried out to affirm that reactor coolant pressure boundary integrity will be maintained at the design pressure throughout the component lifetime. Two elements are built up to support this claim. These are:

- The PZR is subject to Proof Testing.
- Testing is carried out to confirm PZR functionality.

These provide evidence that functional testing of the PZR will be conducted to ensure fitness for purpose at start of life (SoL) and continued integrity of the pressure boundary for the design life.

20B.3.2.1 The Pressuriser is Subject to Proof Testing

In order to demonstrate that the PZR will be subject to proof testing, evidence to support the following arguments is provided.

- The PZR is subject to hydrostatic pressure testing to verify pressure boundary integrity at design pressure prior to operation.

- Testing is carried out to confirm PZR functionality.

20B.3.2.1.1 **The Pressuriser is Subject to Hydrostatic Pressure Testing to Verify Pressure Boundary Integrity at Design Pressure Prior to Operation**

The hydrostatic pressure test contributes to the safety case in a number of ways but principally it provides assurance regarding the basic strength of the assembled vessel, the absence of gross manufacturing defects and evidence of out of specification material properties. It is recognised that the hydrostatic pressure test provides less strength to the safety case at locations where defect tolerance may be dominated by thermal stresses. At such locations, assurance is provided by inspection to confirm the absence of structurally significant defects supported by defect tolerance assessments.

Details of the PZR hydrostatic pressure testing requirements are specified in Section 7.1.1 of the AP1000 PZR Fabrication Specification (Reference 20B.22). The PZR will be hydrostatically tested in accordance with the ASME Code, Section III, Class 1 requirements.

A hydrostatic test will be performed at elevated pressure and a test temperature established by the Supplier. A hydrostatic test will be performed at a temperature not lower than RT_{NDT} plus 33°C (60°F), in accordance with ASME Section III, G-2400. The vessel will be capable of a subsequent field hydrostatic test as deemed necessary.

Reference 20B.22 describes NDEs which are required following the vessel hydrostatic test. These include magnetic particle testing (MT), visual and dimensional, liquid penetrant, ultrasonic and radiographic examinations.

As specified in Table 20-22, the RCS is conservatively designed for 10 cycles of hydrostatic pressure tests throughout the design lifetime of 60 years. Each RCS hydrostatic test is conducted at a water temperature compatible with reactor material ductility requirements.

20B.3.2.1.2 **Testing is Carried out to Confirm Pressuriser Functionality**

Section 7.5 describes a commissioning programme for AP1000 plant. The overall objective of the programme is to demonstrate that the plant has been constructed as designed, that systems perform consistent with the plant design, and that activities culminating in operation at full licensed power including initial fuel load, initial criticality, and power ascension are performed in a controlled and safe manner.

Pre-operational tests for all systems with safety related functions are specified to confirm that these functions will be maintained in operation. Pre-operational testing [2] of the RCS is specified in section 7.5.6. Prerequisites to the pre-operational testing are identified; these include completion of the hydrostatic proof testing of the PZR as described in section 20B.3.2.1.

Pre-operational testing of the RCS including the PZR is conducted to verify that the as-installed RCS will fulfil the following functions:

- Provide RCS pressure boundary integrity.
- Provide core cooling and boration in conjunction with the PXS.
- Measure process parameters required for safety-related actuations and safe shutdown.
- Measure selected process parameters required for post-accident monitoring.
- Vent the RV head.

Pre-operational testing of the RCS is also performed to verify that the system fulfils the following defence in depth functions:

- Provide forced circulation cooling of the reactor core in conjunction with heat removal by the SG(s).

- Provide core cooling by natural circulation of coolant in conjunction with heat removal by the SG(s).

- In conjunction with the SG(s) and the normal residual heat removal system, provide the capability to remove core decay heat and cool the reactor coolant to permit the reactor to be refuelled and started up in a controlled manner.

- Provide PZR pressure control during normal operation.

2. N.b. Pre-operational tests at elevated pressure and temperature are referred to as hot functional tests.

- Provide PZR level control in conjunction with the CVS.
- Provide PZR spray.

Pre-operational testing includes measures to confirm the integrity and leak tightness of the RCS and the high-pressure portions associated systems. The PZR is included within the scope of these tests. Structural integrity is verified by performing a cold hydrostatic pressure test in conformance with Section III of the ASME Code. Leakage monitoring during hot functional testing is conducted to confirm that any RCS leakage is within limits specified in the Technical Specifications.

A series of start-up test procedures are specified in Section 7.5. The start-up test procedures are to confirm safe and controlled operation during activities culminating in operation at full licensed power. As is the case for pre-operational testing, these start-up tests are applicable to systems rather than individual components such as the PZR.

20B.3.3 Leg 3: Failure Analysis

Leg 3 of the safety case provides an assessment of the effects of through-life degradation mechanisms on potential manufacturing defects to show that such mechanisms will not threaten vessel integrity over the plant design lifetime. This goes beyond design code requirements to provide a further demonstration of integrity, specifically by recognising that flaws may be present following manufacture and showing tolerance to them. The arguments supplement the Leg 1 aim of avoidance of defects to provide a safety case with both defect avoidance and defect tolerance.

20B.3.3.1 Pressuriser Components are Tolerant to Manufacturing Defects for the Design Life of the Plant

This section describes the scope of the analyses undertaken as part of the generic design assessment (GDA) process to demonstrate that the PZR is tolerant to potential defects that could remain undetected after manufacturing inspection. In order to demonstrate that the AP1000 PZR and its components are defect tolerant, evidence to support the following arguments is provided.

- Established methods are used to evaluate defect tolerance.
- The determination of crack growth rates and through-life crack sizes is conservative.
- Demonstration of adequate margins between allowable SoL defect sizes and defect sizes based on suitably qualified inspections.

20B.3.3.1.1 Established Methods are used to Evaluate Defect Tolerance

As discussed in section 20.6.4.2, the following sections describe the results of the R6 assessment for the PZR and present a summary of the existing LEFM assessment carried out in accordance with ASME Code, Section III, Appendix G.

Assessment using the R6 Methodology

In combination with the use of rigorous manufacturing controls and inspection qualification, the defect tolerance assessment provides the necessary understanding to support the claim, to an appropriate degree of confidence, that the vessel will enter service free from defects that

could be of concern at the throughout the PZR's designed life. The approach to determination of the limiting defect size in a particular orientation and location and the maximum allowable SoL defect size is discussed in section 20.6.4.2. As has been stated in Reference 20B.14 the regulatory expectation is that a defect size margin of 2 will be achieved.

Phase 1: Weld Defect Tolerance and NDE Ranking

A detailed evaluation of selected, limiting weld locations has been made available to provide confidence that there are no regions of the PZR where either low defect tolerance or low NDT inspectability would preclude the PZR design from being able to satisfy regulatory expectations and support the safety case claim for the PZR. To evaluate which locations present the greatest risk of entering service with a defect of structural significance, a ranking exercise was undertaken to consider, on a relative basis, the defect tolerance and the NDT inspectability at each of the PZR weld locations. The details of this evaluation and the rationale behind the selection of the limiting locations are reported in the results of weld ranking process (References 20B.24 and 20B.25). The final selection of the locations for R6 assessment are listed in Table 20B-19 of this report and summarised below.

a) Upper head to upper shell weld
b) Upper shell to middle shell weld
c) Manway to shell weld
d) Surge nozzle to safe end-weld

Phase 2: Assessment of Bounding Locations

Table 20B-19 details the locations selected for detailed evaluation during the GDA. The scope of the locations that were directly assessed, or have been shown to be bounded by other locations is indicated in Table 20B-19. For each of the selected locations, the R6 defect assessment methodology has been used to determine the limiting SoL defect size. Details of the assessment methodology are provided in Reference 20B.26. The results of this analysis for the pressuriser are presented in References 20B.27 and 20B.38 and are discussed in Section 20B3.3.1.1.

Phase 3: Assessment of Remaining Locations

The full defect tolerance assessment of the remaining HSS locations, including the selected locations in the parent material, will be carried out in due course. Once completed, the R6 assessment work for the PZR will provide assurance that the qualified examination defect size (QEDS) is based on a robust assessment of the maximum allowable SoL defect size with appropriate consideration of materials ageing and degradation and through life crack growth.

ASME Code, Section III, Appendix G Linear-Elastic Fracture Mechanics Assessment

The results of the ASME Code, Section III, Appendix G fracture assessment are described in Reference 20B.13. The procedure assumes a postulated defect having a depth of one-quarter of the section thickness (with a minimum value of 25.4 mm (1 in) and a length-to-depth ratio of 6.0. For the Service Level A and B and Test conditions, the calculated crack tip stress intensity must be less than the value of K_{IR}. K_{IR} is the reference stress intensity factor. For the Service Level C and D conditions, the calculated crack tip stress intensity must be less than the value of K_{IC}. K_{IC} is applied as an allowable fracture toughness and is the lower bound static initiation critical crack tip stress intensity. It is given in Section XI of the ASME Boiler and Pressure Vessel Code (Reference 20B.21). For limiting locations where the assumed quarter thickness flaw produces a stress intensity factor K_I greater than the reference or

allowable fracture toughness, the methods of WRCB-175 (Reference 20B.33) are used to determine the critical crack size.

20B.3.3.1.2 **The Determination of Crack Growth Rates and Through-life Crack Sizes is Conservative**

As part of the R6 assessment the through life crack growth has been calculated for selected locations in accordance with the R6 procedure. This includes the use of suitably conservative crack growth rates appropriate to the reactor coolant environment. As discussed in Reference 20B.26, these are based on the ASME upper bound FCG curves. These are considered to be conservative for modern steels with low sulphur content. The upper bound nature of these curves is supported by extensive testing worldwide.

20B.3.3.1.3 **Demonstration of Adequate Margins between Allowable Start of Life Defect Sizes and Defect Sizes Based on Suitably Qualified Inspections**

The results of the R6 defect tolerance assessments for three of the four PZR welds identified in Section 20B.3.3.1.1 are reported in Reference 20B.27. The results of the R6 defect tolerance assessment for the fourth PZR weld are reported in Reference 20B.38. A limiting QEDS, i.e., that leading to a DSM equal or larger than 2, has been calculated for one of two different defect aspect ratios according to flaw orientation. For flaws perpendicular to the weld axis, the QEDS is established for a defect aspect ratio of 2, since the potential length of flaws with that orientation is naturally limited by the weld width. For flaws oriented parallel to the weld axis, it is recognised that flaws with higher aspect ratios may potentially occur, and a defect aspect ratio of 6 is additionally considered in determining the QEDS. In addition to those used to calculate the limiting QEDS, an aspect ratio of 10 is also considered to demonstrate that “cliff-edge” effects do not occur.

Reference 20B.27 reports the calculated limiting QEDS (i.e., leading to a DSM equal or larger than 2) for select PZR welds as follows:

Weld	Limiting QEDS (mm)
Upper head to upper shell weld	11.5
Upper shell to middle shell weld	12.8
Manway to shell weld	10

Reference 20B.38 reports the calculated limiting QEDS (i.e., leading to a DSM equal or larger than 2) for the PZR surge nozzle to safe end weld as follows:

Weld	Limiting QEDS (mm)
Surge nozzle to safe end-weld	5

Based on these QEDS values, References 20B.27 and 20B.38 report that the calculated values of end of life limiting defect size (ELLDS) and lifetime fatigue crack growth (LFCG)

establish a DSM larger than 2 in all cases for the welds covered by each document. The demonstration of the capability for qualified inspection of these pressuriser welds is summarised below.

Reference 20B.30 provides the technical basis for an array of inspection techniques applied on the PZR outer surface at the upper head to upper shell weld, upper shell to middle shell weld and manway to shell weld to support detection and characterisation of surface-breaking and near-surface breaking planar defects having a height of 10 mm (0.39 in), and embedded planar defects of 20 mm (0.79 in). This basis included previous works associated with the Sizewell B qualified manufacturing NDT inspections, the United Kingdom Atomic Energy Authority defect detection trials (DDT), qualified inspections used in the US, and common industry approaches. This technical basis was reviewed by an independent qualification body (inspection validation centre (IVC)) and the inspection techniques were deemed to be capable of formal qualification.

Reference 20B.31 provides the technical basis for an array of inspection techniques applied on the surge nozzle/safe end inner diameter, outside diameter, and end face surfaces to support detection and characterisation of both surface-breaking and near-surface breaking planar defects having a height of 5 mm (0.20 in). This basis included previous works associated with the Sizewell B manufacturing NDT inspections, qualified inspections used in Sweden and the US, and common industry approaches. This technical basis was reviewed by an IVC and the inspection techniques were deemed to be capable of formal qualification.

Taken together with the QEDS discussed above, the results of the analyses provide assurance that there is a very low probability that the PZR will enter service containing defects that could challenge integrity over the lifetime of the component.

20B.3.4 Leg 4: Forewarning of Failure

The objective of the forewarning of failure leg of the safety case is to confirm the absence of a degradation mechanism through plant inspection or that, where a known degradation mechanism exists, uncertainty in the material behaviour is not significant to integrity or will have limited consequences. Three elements are built up to support this claim. These are:

- Appropriate ISI is carried out to provide forewarning of failure.
- Diverse systems are provided to detect, locate and monitor reactor coolant leakage from the PZR.
- In-service material surveillance provides forewarning of unanticipated degradation.
- The arguments presented provide contingency for the unexpected.

20B.3.4.1 Appropriate In-Service Inspection is Carried Out to Provide Forewarning of Failure

In order to provide assurances that defects will be detected prior to becoming a threat to the structural integrity of the AP1000 PZR, evidence to substantiate the following arguments is provided.

- An extensive programme of ISI identifies any degradation long before failure.
- Qualified inspection of HSS welds provides very high reliability ISI.

- ISI data enables judgment of in-service defect formation and growth by comparison with 'finger-print' PSI data.

- A 'Design for Inspectability' philosophy facilitates effective ISI.

20B.3.4.1.1 **An Extensive Programme of In-service Inspection Identifies any Degradation Long Before Failure**

ISI is the preferred method of demonstrating forewarning of failure. The role of an effective ISI programme is to confirm the absence of any unknown degradation mechanisms and that known degradation mechanisms are not significant to integrity.

ISI is used to confirm the absence of defects that could eventually lead to failure when the maximum tolerable defect size, as determined from fracture mechanics in Section 20B.3.3, is combined with a conservative assessment of in-service defect growth throughout the inspection interval.

In order to be effective, ISI requirements should be identified according to established good practice relevant to the characteristics of each inspection location. Evidence to substantiate this for planned PZR ISI is provided below, noting that the final ISI requirements are to be specified the operating utility company.

The anticipated ISI programme includes the PZR components and welds of importance to nuclear safety. ISI for the following welds and components of the PZR are identified in the AP1000 Component ISI Inspectability Assessment: Pressurizer (Reference 20B.28).

- Lower Shell to Lower Head Circumferential Weld
- Upper Shell to Upper Head Circumferential Weld
- Surge Nozzle Inside Radius Section
- Safety Relief Nozzle Inside Radius Section
- Spray Nozzle Inside Radius Section
- Surge Nozzle to Safe End Butt Weld
- Spray Nozzle to Safe End Butt Weld
- Safety/Relief Nozzle to Safe End Weld
- Studs and Nuts
- Welded Attachments (Support Bracket Pairs)
- Pressure Retaining Boundary

Reference 20B.28 identifies Code requirements for each of the above locations and takes into account the relevant code cases as approved by NRC. Inspection methods and access arrangements are described to ensure effective ISI at each of the identified PZR welds and components.

20B.3.4.1.2 **Qualified Inspection of Highest Safety Significant Welds Provides Very High Reliability In-service Inspection**

Section 20B.2.2 identifies the Structural Integrity Classification for the PZR components. For those components identified as HSS, it is accepted good practice that qualified inspections are deployed as supporting evidence to demonstrate that there are no defects of concern in HSS components.

The reliability of the ISI for HSS welds in the PZR is to be qualified by applying the principles of the ENIQ Methodology as contained in Reference 20B.20.

Adherence to the ENIQ Inspection Qualification methodology provides evidence of good practice for ISI of HSS locations. Reference 20B.20 identifies how inspection requirements and performance objectives are laid down in an inspection specification and provides a method for Inspection Qualification based on technical justification of the inspection method and practical trials on simplified or representative test pieces resembling the component to be inspected.

20B.3.4.1.3 **In-service Inspection Provides Data to Judge In-service Defect Formation and Growth by Comparison with 'Finger-print' Pre-service Inspection Data**

In Section 20B.3.1.6 qualified PSI of HSS components is described. The resulting data constitutes a "fingerprint" against which ISI results can be compared. Comparison of ISI data with the PSI finger-print is used to confirm the absence of significant degradation or that build defects are stable i.e., defects detected during ISI must have started life as no greater than the PSI validation defect size. PSI will be performed using the same equipment that is likely to be used for the periodic ISI.

20B.3.4.1.4 **A 'Design for Inspectability' Philosophy Facilitates Effective In-service Inspection**

For effective ISI, the PZR Design Specification includes the requirement to accommodate inspection equipment and personnel access in accordance with current inspection technology and strategies. Reference 20B.19 describes how the PZR design has been developed with the goal of maximising inspectability.

The AP1000 PZR design accommodates current best-practice ISI techniques and, so far as is practicable, allows for newly emergent inspection technologies to be employed. Reference 20B.19 provides a summary of ISI requirements for each location of the PZR. Design for Inspectability is demonstrated by consideration of the following aspects:

- Access for personnel and equipment conducting either manually deployed or mechanically deployed techniques.

- Surface finish requirements.

Reference 20B.19 establishes that provisions for inspectability are consistent with current best practice. An assessment is provided to demonstrate that design and access arrangements are provided to satisfy the requirements set out in NCA-3200 of the ASME Code, Section III, IWA-1400 and IWA-1500 of the ASME Code, Section XI and 10CFR50.55a. The following issues are identified in Reference 20B.19 that will be addressed to ensure that the AP1000 PZR satisfies the "Design for Inspectability" philosophy (Reference 20B.19) and the assessment defined in Reference 20B.28. These include:

- Recording as-built information
- Surface conditions and flatness specifications
- Nozzle blend radii
- Minimum safe-end length
- Qualification of PSI

20B.3.4.2 Diverse Systems are Provided to Detect, Locate and Monitor Reactor Coolant Leakage from the Pressuriser

In order to demonstrate that leaks from the reactor coolant pressure boundary will be detected before they result in a safety issue, evidence to substantiate the following argument is provided.

- Leak detection of the QEDS provides warning of reactor coolant leakage from the PZR.

20B.3.4.2.1 Leak Detection of the Reactor Coolant Pressure Boundary Provides Warning of Reactor Coolant Leakage from the Pressuriser

ISI represents the preferred method of demonstrating forewarning of failure and the primary element of Section 20B.3.4. Whilst leak detection and monitoring provide forewarning of failure, this safety argument does not seek to establish a quantitative case for excluding the gross failure of the PZR as a result of this forewarning. The leak detection measures described in section 20.6.4.3.2 are provided as qualitative evidence of defence in depth in support of this leg of the safety argument. Leak detection provides warning of unforeseen or unexpected loss of coolant from the PZR, and monitoring provides a means to confirm that any leakage of the coolant is kept within the limits specified in the generic technical specifications (Reference 20B.32).

Temperature is sensed downstream of each PZR safety relief valve and each ADS valve mounted on the PZR by a resistance temperature detector on the discharge piping just downstream of each globe valve. High temperature indications (alarms in the main control room) identify a reduction of coolant inventory as a result of seat leakage through one of the valves. These detectors are part of the RCS. This leakage is drained to the reactor coolant drain tank during normal plant operation and vented to containment atmosphere or the in-containment refuelling water storage tank during accident conditions. This identified leakage is measured by the change in level of the reactor coolant drain tank.

The primary sampling system takes suction from the PZR liquid space for chemistry control purposes. A flow restrictor is incorporated into the nozzle for this line, demarking the RCPB. A normally closed, fail closed isolation valve is provided in the primary sampling system (PSS) suction line inside containment in addition to the two normally closed containment isolation valves in series. Leakage from this connection would be measured by the change in level of the reactor coolant drain tank as unidentified leakage.

The connections on the PZR safety valves are flanged. During normal operation, variations in airborne radioactivity, containment pressure, temperature, or specific humidity above the normal level, or increases in containment sump level signify a possible increase in unidentified leakage and alert the plant operators that corrective action may be required. Unidentified leakage through the remaining jurisdictional boundaries of the PZR forming part of the RCPB is detected by the diverse methods described in section 20.6.4.3.2.

20B.4 Strength of the Safety Case

The availability and reliability of the safety measures identified to deliver a component's SFRs should demonstrably be commensurate with the significance of the radiological hazards to be controlled. This is achieved by a process of component structural integrity classification, which, for the safety justification of each class of component, establishes the degree of rigour to be applied commensurate with the potential radiological consequences of any postulated gross failure mode.

The process of structural integrity classification is detailed in Reference 20B.4, where gross failure of the PZR is assessed to potentially lead to the most severe and therefore intolerable offsite consequences against which there is no claimed protection. As identified in Section 20B.2.2, the PZR is classified as a HSS component[3]. HSS classification necessitates substantiation of a tolerable failure frequency where the probability of gross structural failure of the PZR is so low it can be discounted.

To substantiate the claim that gross structural failure of the PZR can be discounted, a safety argument is presented in Section 20B.2. Various elements of sound engineering practice are identified, which provide evidence that there is defence in depth against structural failure within the PZR arrangement and design. A defence in depth justification usually involves the provision of multiple layers of protection and defence is provided through diversity, redundancy and segregation to provide a robust design. For single components without multiple protection layers, the defence in depth principle is retained by demonstrating that the likelihood of failure is so low that it can be considered as not credible. The safety argument comprises four conceptually different legs, within each of which multiple subordinate arguments are supported by diverse sources of substantiating evidence. Robustness is achieved by considering the combined contribution from the four legs, a philosophy generally known as conceptual defence in depth. In combination the four legs provide sufficient confidence that gross failure of the PZR with unacceptable consequences will not occur during normal operation, during design basis transients or during fault conditions. The combined strength of the claims, arguments and evidence is discussed below.

The safety argument is founded upon a high standard of manufacture sufficient to achieve an appropriately high level of structural integrity. Design and fabrication of the PZR is to be in accordance with ASME Code, Section III, Class 1 requirements as a minimum. Supplemental requirements are identified that enhance the quality of PZR design and fabrication beyond ASME Class 1 standards. These are detailed in Section 20B.3.1, where multiple arguments and supporting evidence to substantiate achievement of PZR integrity are presented. Section 20B.3.1 includes claims, arguments and evidence to address the following aspects:

- The design is well founded and in accordance with internationally recognised standards. Design of PWR PZR vessels is long established and Westinghouse has an established track record. The AP1000 PZR benefits from this historical experience which is embodied in the codes and standards applied in design and fabrication.

- Procurement of materials is specified and controlled to ensure that well proven materials are chosen, that the materials have good resistance to fracture and other through-life degradation mechanisms. AP1000 PZR materials comply with the corresponding material specification permitted by the ASME Code, Section III, Division 1. For certain PZR materials, supplementary requirements are specified, which exceed the requirements specified in ASME code. Material testing is specified to confirm that material properties comply with the relevant specifications.

- Very high standards have been specified to control PZR fabrication. PZR components will be manufactured by experienced suppliers and evidence to confirm the suitability of the chosen manufacturer will form part of the Site Specific Justification. Compliance with ASME III and the experience embodied within the code provides high confidence in manufacturing quality. Supplemental requirements have been identified, which

3. The HSS classification does not apply to every component of the PZR or to every postulated failure mode and defect orientation, since certain failure modes will not lead to the most severe off site consequences. Classification of each component of the PZR is detailed in Section 20B.2.2.

enhance the standards applied in fabrication beyond ASME requirements. Approved welding procedures and qualified operators are used. Stringent Quality Assurance arrangements control manufacturing procedures and records are maintained to provide a clear auditable trail that will confirm this. There are procedural controls to limit deviations from the design intent and all repairs and deviations will be recorded to confirm acceptability.

- Manufacturing inspections and PSI with appropriate levels of redundancy and diversity confirm the absence of defects, which have the potential for causing, or developing into a failure mode. This judgement is based on definition of allowable SoL defect sizes. Where appropriate the inspections are subject to independent validation and in the case of HSS components of the PZR, a programme of qualified PSI is specified. In the unlikely event that defects are found, they will be repaired in accordance with accepted techniques.

The diverse evidence summarised above demonstrates that the PZR will be designed and fabricated against well established and appropriate deterministic engineering rules, verified by application of rigorous inspection. The various elements identified establish defence in depth for preventing failure of the PZR. Functional hydrostatic testing to demonstrate that the PZR meets the design intent, as described in Section 20B.3.2, supplements the arguments to demonstrate achievement of PZR integrity, ensuring that the PZR enters service fit for purpose and free of safety-significant defects.

The measures established to ensure good design and construction are supplemented with additional claims and evidence to demonstrate continued structural integrity throughout the planned PZR lifetime. Careful control of operating conditions enables the PZR to fulfil its safety function for its projected lifetime. Plant operation and maintenance will be defined in accordance with recognised procedures as described in Section 20B.3.1. Design and operating parameters used in the design evaluation are robustly determined using established and conservative procedures, as detailed in Section 20B.3.1. The evidence provided to this effect ensures the validity of stress analysis and fracture analysis to substantiate claims based on ASME Code compliance.

Section 20B.3.3 and Section 20B.3.4 provide evidence to substantiate PZR integrity under all design basis conditions by demonstrating that any defect, which may have gone undetected during manufacture, will not cause failure during the lifetime of the plant. The elements that substantiate this claim are as follows:

- Stress Analysis – The AP1000 PZR is designed in accordance with the ASME Code, Section III, Division 1. Consideration of Levels A to D and Test conditions encompass the design basis for the purposes of the analysis. Stress analysis to the ASME Code supports demonstrating fitness-for-purpose and also provides a basis for subsequent fracture analysis.

- Fracture Analysis – linear elastic fracture mechanics analysis, as prescribed in Appendix G of ASME Section III and XI, is to be supplemented by elastic-plastic fracture mechanics procedures specified in the R6 Defect Assessment code. The fracture analysis has demonstrated that the sizes of defect which are of safety concern are larger than those which could be present in the component following qualified manufacturing NDT. Qualified inspection of HSS locations establishes the sizes of defects that can be reliably detected and the associated sizing uncertainty. Qualification is to be achieved through a combination of Technical Justification of inspection procedures and equipment, supported by trials.

- ISI – The PZR is designed to facilitate effective ISI, which provides assurance that defects will be detected long before growing to a size that could threaten structural integrity of the PZR. ISI data enables judgment of in-service defect formation and growth by comparison with PSI data.

- Leakage Monitoring – Diverse systems are provided to detect, locate and monitor reactor coolant leakage from the PZR. Alarm and indication of reactor coolant leakage from the PZR in excess of specified limits provide diverse means to detect failure.

20B.5 Review of Open Issues

There are no open issues for the PZR that affect the basis of the safety case arguments.

20B.6 Conclusions

This CSR for the UK AP1000 PZR presents a safety argument to establish that the structural reliability of the PZR is commensurate with the consequences of gross failure. SFRs have been identified for the PZR, based on structural integrity safety design bases. These requirements are to be maintained to ensure plant nuclear and radiological safety. For the PZR, assurance that these SFRs will be maintained for the design life of the component is provided by substantiating structural integrity against appropriate reliability targets.

Structural reliability targets have been identified for the PZR that are based on a procedure of structural integrity classification (Reference 20B.4). Based on this, the PZR has been classified as a HSS component. The structural reliability target associated with HSS classification is to substantiate a failure frequency where the probability of gross structural failure of the PZR that is so low it can be discounted. The safety argument is presented in a four legged format that is well established in the UK for the safety justification of nuclear plant components similar to the PZR that share similar structural reliability targets. The safety argument identifies diverse defence in depth measures to substantiate the structural reliability claimed for the PZR:

- The intent and principles that govern the design, future manufacture and operation of the PZR in the UK are identified to substantiate fitness for purpose within a pre-construction safety case. The safety argument demonstrates how modern and well established good practice is to be implemented in PZR design, manufacture, defect tolerance assessment, and in the provision for through-life inspection.

- The PZR design benefits from the long operating history of PWR PZRs and incorporates design measures to minimise frequency of failure, which are based on this experience. The PZR design facilitates effective inspection, which supports a programme of qualified inspection to ensure timely forewarning of failure.

- Structural integrity of the PZR is secured largely by passive means and is not significantly reliant on control systems, active safety systems or human intervention. As such, the diverse defence in depth measures identified focus on prevention of failure through conservative, robust design. Surveillance, inspection and leakage monitoring provide secondary defence in depth measures to detect and provide forewarning of failure.

- PZR structural integrity is established based on extensive quality assurance measures in design, manufacture, materials, testing and qualified inspection. The strength of the safety case is based on achievement of integrity and the PZR has been deterministically justified in accordance with ASME Code Class 1 requirements. Additional arguments provide robust evidence to demonstrate that the PZR is defect tolerant and this is supported by qualified inspection. Numerous other defence in depth measures are identified.

In combination, these elements constitute a cogent argument to substantiate structural reliability commensurate with the HSS structural integrity classification of the PZR.

20B.7 Index of Technical Reports

Table 20B-20 provides a list of technical references supporting the safety case and summarises the function of each document within the safety case.

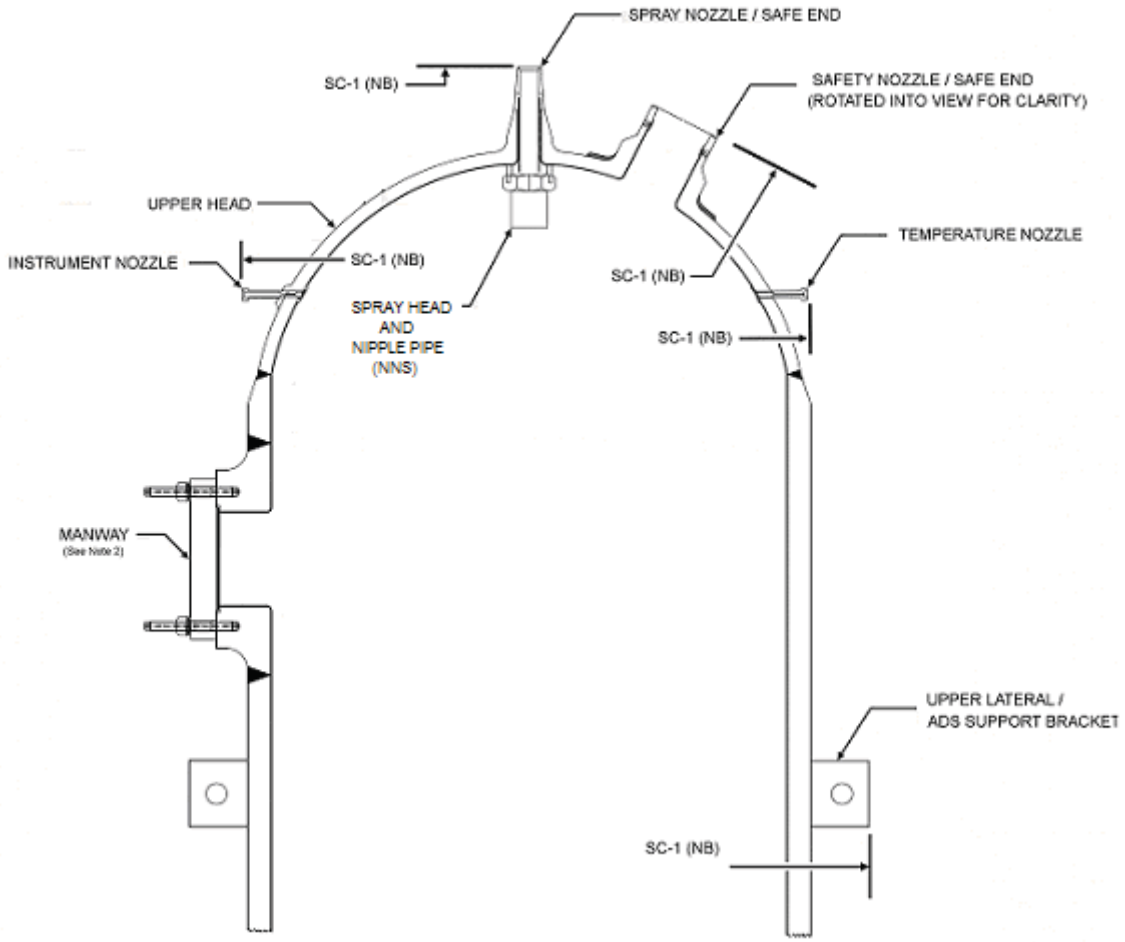

Figure 20B-2. AP1000 Pressuriser Jurisdictional Boundaries (Upper Section)

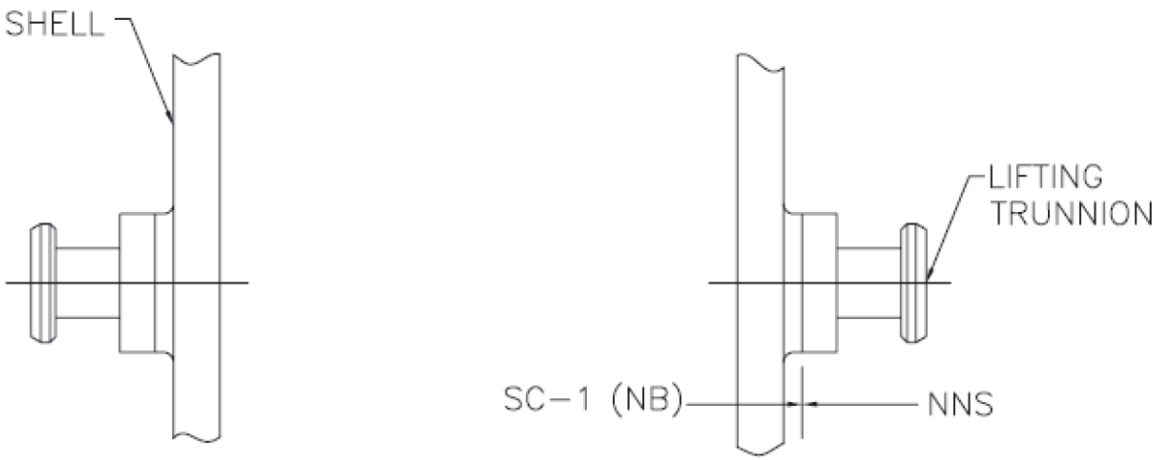

Figure 20B-3. AP1000 Pressuriser Jurisdictional Boundaries (Mid-Section)

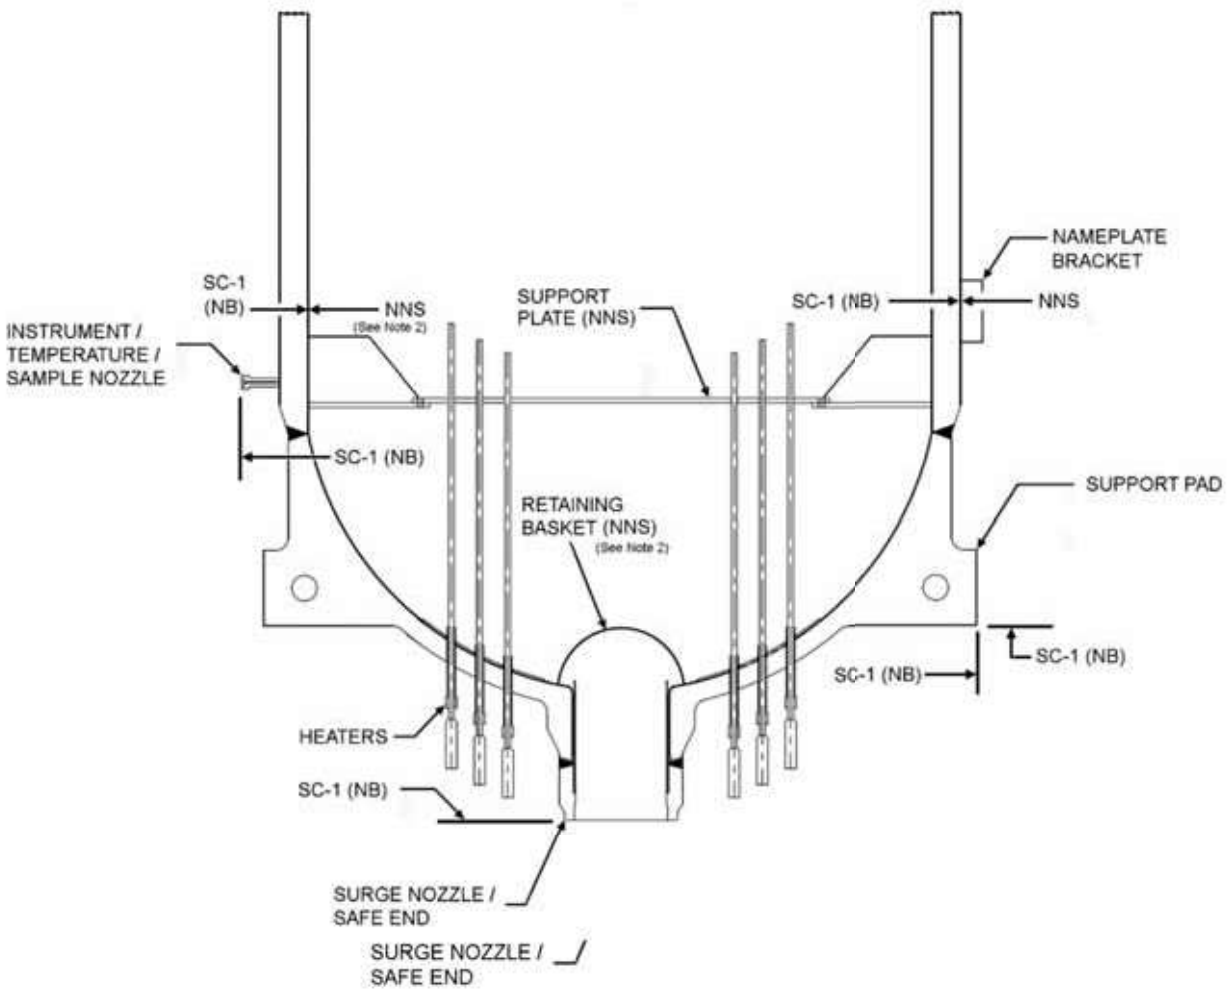

Figure 20B-4. AP1000 Pressuriser Jurisdictional Boundaries (Lower Section)

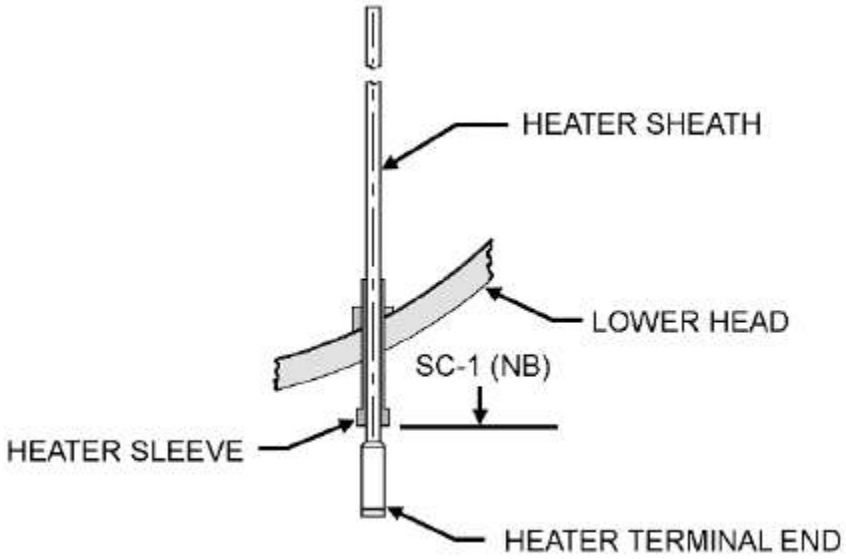

Figure 20B-5. AP1000 Pressuriser Jurisdictional Boundaries (Heaters)

Figure 20B-2 to Figure 20B-5 Notes:

1. The PZR assembly including nozzles and their safe ends, the ADS support lugs, lower head support lugs, and trunnion attachment pads are defined to be within the ASME Section III, Subsection NB jurisdictional boundary. The ADS lugs are considered structural attachments to the pressure boundary, and all attachments of internals to the pressure boundary are considered non-structural attachments.

2. Items outside of the ASME Section III NB Code jurisdiction are the heater support plate lug and attaching weld, heater support plates and attaching bolts, bolt-on trunnions and attaching bolts, surge line nozzle retaining screen and attachment weld, thermal sleeves, manway gasket, insert and seal plate, spray nipple pipe and attachment weld, spray nipple forging, and spray head.

3. The heaters are considered to be a part as they are welded into place prior to completion and stamping of the PZR. The attaching weld between the heater sleeve and the heater sheath will be evaluated in the PZR design report. The heater (including the heater connectors, seals and cables) jurisdictional boundary is defined in the heater design specification.

4. The connecting piping and its weld to the nozzles will be considered as part of the attached piping design.

APPENDIX 20C
STEAM GENERATOR COMPONENT SAFETY REPORT

20C.1 Introduction

This is the Component Safety Report (CSR) for the steam generator (SG) as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the SG to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentary evidence outlined in Section 20C.7, including aspects of design assessment, material procurement, fabrication, manufacturing inspection, testing and in-service testing, maintenance and inspection.

20C.1.1 Scope

Arguments are presented herein to substantiate the claim that the nuclear and radiological hazards potentially arising from gross structural failure of the SG remain tolerably low for the design lifetime. Conventional hazards to personnel safety are outside the scope of this Appendix 20C.

Reliability targets are to be substantiated for the entire design lifetime objective of 60 years, as established in Section 6.1.1 of the Design Specification (Reference 20C.1). The 60 year design basis is used to determine corrosion allowance, for calculating cycle fatigue, and determining wear of components which are used to establish inspection and maintenance requirements needed to achieve the 60 year component lifetime.

This assessment considers all pressure, temperature, and mechanical loadings within the design basis. This includes normal operating conditions, anticipated transients, postulated accident conditions and test conditions. Design basis load parameters and transient definitions for the 60 year period of operation are described in Section 20C.3.1.2. Accident transients within the design basis are assessed in Chapter 9.

The AP1000 steam generator system (SGS) includes two SGs. The primary side components of the SGs form part of the reactor coolant system (RCS) pressure boundary. The scope of this assessment is limited to the structural reliability of the SGs only and does not include other components of the SGS, RCS or any other systems. A description of the SGs is provided in Section 20C.1.5 and the physical boundaries of the SGs are identified in Section 20C.1.6.

20C.1.2 Objectives

Safety functional requirements (SFRs) for a range of AP1000 components, including the SGs, are identified in Table 20-1. These correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. Demonstrating that these SFRs will be maintained across the operational, process and lifecycle scope of the safety case supports the claim that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime.

The SFRs applicable to the SGs are identified in Section 20C.2.1. This CSR demonstrates that the structural reliability of the SGs is commensurate with the consequences of failure; in the case of the SGs this necessitates a demonstration that the probability of gross failure of

certain components[1] of the SGs is so low that it can be discounted for the required 60 year period of operation. Establishing this level of structural reliability will demonstrate that the SGs maintain the capability to fulfil their SFRs in all design basis conditions.

20C.1.3 Strategy

Component classification forms the basis for identification of criteria against which the acceptability of the safety argument is to be judged. Substantiating structural reliability claims against these criteria provides an appropriate degree of assurance that the SFRs allocated to the SG will be maintained under all conditions within the design basis.

A safety argument is presented in Section 20C.3 according to a four-legged structure that is both consistent with established good practice in the United Kingdom (UK) nuclear industry and appropriate to SG component classification. For SG components with the highest level of component classification the safety argument will seek to demonstrate that the probability of gross failure of the SG is so low that it can be discounted for the required 60 year period of operation. For SG components that are allocated less onerous classifications, compliance with appropriate codes and standards forms the basis of the safety justification as identified within the appropriate elements of the safety argument.

The structure and philosophy of the safety argument are established in Section 20C.2. SFRs are identified in Section 20C.2.1 and SG component classification is established in Section 20C.2.2.

20C.1.4 Interface with other Safety Case Documents

The safety argument is supported by evidence to substantiate structural reliability claims, as identified in the relevant sections of the structured safety argument and tabulated in the technical index (Section 20C.7).

20C.1.5 Steam Generator Description

The AP1000 RCS consists of two heat transfer loops, each with a SG, two reactor coolant pumps, a single hot leg and two cold legs for circulating reactor coolant. All RCS equipment is located in the reactor containment. An isometric view of the AP1000 reactor coolant loops is shown in Figure 20F-2.

During normal plant operation, the reactor coolant pumps (RCPs) circulate pressurised reactor coolant through the reactor vessel then the SGs. The SGs serve as heat exchangers by converting secondary water into steam from heat produced in the reactor vessel. Reactor coolant flowing through tubes in the SG boils secondary water on the shell side to produce steam in the secondary loop that is delivered to the turbines. The steam is subsequently condensed via cooled water from the tertiary loop and returned to the SG to be heated once again. The reactor coolant is returned to the reactor vessel by the pumps to repeat the process.

The design specification (Reference 20C.1) gives a detailed description of the SGs, and provides the basis for demonstrating that the design and construction of the SGs conform to the rules set forth in the American Society of Mechanical Engineers (ASME) Boiler & Pressure Vessel Code (Code), Section III. Evidence to demonstrate accordance with established codes and standards provides evidence to substantiate claims regarding SG

1. These components are identified in Section 20C.2.2.

reliability by ensuring a high quality of design and manufacture. This evidence forms part of the safety argument in Section 20C.3 where a diverse range of relevant aspects is addressed.

The components of the steam generator forming part of the reactor coolant pressure boundary are AP1000 Equipment Class A components; and are designed to ASME Code, Section III, Class 1 requirements. The components of the steam generator forming the secondary side pressure boundary are AP1000 Equipment Class B components. Strict interpretation of the ASME Code requirements would dictate these components be designed to ASME Code, Section III, Class 2 requirements. However, for conservatism, all pressure retaining components on the secondary side of the steam generator are designed to ASME Code, Section III, Class 1 requirements.

Details regarding SG materials are given in Section 20C.3.1.4 and the controls to ensure quality of manufacture are identified in Section 20C.3.1.5. A simplified physical description of the SGs is provided in Section 20C.1.5.1 and a basic functional description is given in Section 20C.1.5.2.

20C.1.5.1 Physical Description

Two SGs are used in the AP1000 plant. The design of the SG is generally similar to earlier Westinghouse design SGs and also to typical pressurised water reactor (PWR) SG design. The design of PWR SGs has evolved over time and the SG for the AP1000 plant incorporates a number of safety-related design enhancements that are described in Section 20C.3.1.1.2.

The SG, shown in Figure 20C-2, is a vertical shell and U-tube evaporator with integral moisture separating equipment. Critical dimensions and volumes are identified in Table 20C-1 and the recommended materials of construction are identified in Table 20C-2.

The outer body of the SG is known as the shell, comprised of a primary (RCS) side and a secondary (feedwater) side containing moisture-separating internals, as described in the following sub-sections. SG interfaces, including supports, nozzles, access ports and instrumentation taps are described in the following sub-sections and listed in Table 20C-3.

20C.1.5.1.1 SG Shell

As illustrated in Figure 20C-3, the SG shell is comprised of a transition cone, shell barrels, Tubesheet, channel head, primary side inlet nozzle, primary side outlet nozzle, passive residual heat removal (PRHR) nozzle, main and start-up feedwater nozzles, trunnions, manways and elliptical head.

Nominal design parameters for the SG are provided in Table 20C-1. The SG measures approximately 22.5 m (73.8 ft) from steam outlet nozzle at its top to the flat, exterior portion of the channel head at its lower end. The inner diameter (ID) of the upper shell is approximately 5.33 m (17.5 ft), and that of the lower shell is approximately 4.19 m (13.7 ft). The maximum outside diameter (OD) of the SG is approximately 5.576 m (18.3 ft). All parts of the SG shell are low-alloy steel forgings. The ring forgings of the SG shell are connected by girth welds, and all welds on the surfaces of the shell, including nozzle attachments, are ground to remove discontinuities and stress risers as well as to facilitate examinations and inspections.

The Channel Head forms the lower part of the SG. A single primary inlet nozzle connects to the hot leg RCS pipe. The Channel Head is divided into inlet (hot leg) and outlet (cold leg) primary chambers by a vertical divider plate that extends from the centre of the channel head to the Tubesheet. The lower portion of these chambers is spherical and merges into a

cylindrical portion, which mates to the Tubesheet. Reactor coolant flow exits the SG through two pump suction nozzles in the Channel Head. Two RCP casings are directly connected to and supported by the SG Channel Head at the pump suction nozzles. This weld will be a nickel-chromium-iron (Alloy 690) weld made to nickel-chromium-iron alloy (Alloy 690) buttered ends of the SG channel head and RCP inlet nozzles. The buttering removes the need for field post-weld heat treatment (PWHT) of the closure weld. The interior surfaces of the Channel Head, primary nozzles, and primary manways are clad with weld deposited austenitic stainless steel with a finished nominal thickness of 5.9 mm (0.23 in).

A PRHR nozzle attaches near the bottom of the Channel Head of the loop 1 SG on the cold leg portion of the head. This nozzle provides recirculated flow from the PRHR heat exchanger to cool the primary side under certain accident conditions. A separate nozzle on the loop 1 SG Channel Head is connected to a line from the chemical and volume control system (CVS). This nozzle provides for purification flow and makeup flow from the chemical and volume control system to the RCS. The design of the loop 2 SG does not include these PRHR and CVS nozzles.

The Channel Head incorporates provisions to drain the head without operator action. To minimise deposits of radioactive corrosion products on the Channel Head surfaces and to enhance the decontamination of these surfaces, the Channel Head cladding is machined or electropolished for a smooth surface. Two primary manways in each Channel Head are provided for access to the primary chamber.

The upper surface of the Channel Head is connected to the Tubesheet. The Tubesheet has a base metal (low alloy steel) thickness of approximately 791 mm (31.1 in) and is clad with Alloy 690 of finished nominal clad thickness 6.60 mm (0.25 in). In order to achieve optimal secondary side crevice depths, the primary face of the Tubesheet is machine faced to a flatness of within 0.25 mm (0.01 in) on the primary side face and 0.13 mm (0.005 in) on the secondary side face. The secondary side face is parallel to the primary clad face to within 0.38 mm (0.015 in).

The upper surface of the Tubesheet is welded to the lower shell, which is comprised of three forged barrels. A blowdown nozzle is provided on the secondary side of the SG in the lower shell on the Tubesheet. Its function is to remove non-volatile, dissolved impurities and particulate matter from the secondary side water. Four hand-holes are provided to facilitate inspection and maintenance of the lower tube bundle assembly described in Section 20C.1.5.1.2. All secondary side handholes, inspection ports, and manways are gasketed closures using studs and nuts. These gaskets are of graphite wound construction or equivalent.

The lower shell connects to the larger diameter upper shell via a transition cone, which incorporates 2 U-bend inspection ports and a maintenance recirculation access port. The transition cone has a downstand on the small end and an upstand on the large end to locate the girth welds to lower stress regions.

A feedwater nozzle in the SG upper shell connects to the secondary feedwater pipework and a start-up feedwater nozzle is also located in the upper shell to supplement main feedwater during certain operating conditions and transient events. The start-up feedwater nozzle is located at approximately the same elevation as the feedwater nozzle, and is provided with an upward-sloping sparger assembly inside the upper shell. The feedwater and startup feedwater nozzles are clad on the inner surface.

To limit the motion of the end of the feedwater pipe under a postulated circumferential pipe break, a pipe whip restraint is provided and attached to the SG with two welded lugs located on the upper shell.

Secondary side access for repair and replacement of internal components such as moisture separator vanes is provided through two secondary manways, located in the upper shell of the SG. The SG upper shell also incorporates sludge collector piping (located internal to the SG close to a secondary manway).

The upper shell connects to the elliptical head knuckle and elliptical head. The elliptical head has an integral forged steam outlet nozzle. The steam outlet nozzle is NiCrFe clad around the ID on the exit of the nozzle by weld deposit. The steam outlet nozzle incorporates seven flow limiting venturi at the steam outlet nozzle interface. The flow-limiting venturi are designed to limit the pressure drop in the SG during steam line break so as not to exceed allowable loads on the internals and to limit the rate of mass and energy release into containment.

Instrument Taps

Four channels of narrow-range water level indication and four channels of wide-range water level indication are provided for each SG by the inclusion of level tap penetrations on the secondary side of the SG shell.

Both the wide-range and narrow-range taps are located circumferentially in the same horizontal plane on the SG shell to maximise separation between each channel and all other narrow-range channels. There are four DN 25 (NPS 1) tap connections in the lower shell for wide-range sensors, four DN 25 (NPS 1) tap connections in the transition cone for narrow-range sensors, and in the SG upper shell there are four DN 25 (NPS 1) tap connections that are shared for wide-range and narrow-range sensors. In addition there are three DN 25 (NPS 1) tap connections for steam flow differential pressure sensors.

Level tap locations on the upper shell of the SG are selected to prevent impulse line termination in high velocity flow areas. At any loading condition between 0 and 100 percent of full thermal load, the SG level is determined by measuring the differential pressure between the level taps.

SG Shell Supports

The SG shell is externally supported both vertically and laterally, as illustrated in Figure 20C-4. The vertical support consists of a single vertical column extending from the SG compartment floor to the bottom of each SG Channel Head. The column is constructed of a heavy wide flange section, and is pinned at both ends to permit thermal movement of each SG during plant heatup and cooldown. The column is located so that it allows full access to the SG for maintenance activities.

Lateral support is provided at lower, intermediate and upper levels. The lower lateral support is located at the bottom of the Channel Head. It consists of a tension/compression link bar and extension bar oriented approximately perpendicular to the hot leg. The link bar/extension bar is pinned at both the wall bracket and the SG Channel Head to permit movement of the SG during plant heatup and cooldown.

The intermediate SG lateral support is oriented normal to the hot leg and located on the lower shell just below the transition cone. It consists of two rigid struts that are mounted on the SG compartment wall at the elevation of the operating deck. The SG loads are transferred to the struts through trunnions on the SG lower shell “C” barrel. The upper lateral support is

oriented in the direction of the hot leg and located on the upper shell just above the transition cone. It consists of two large hydraulic snubbers oriented parallel with the hot leg centreline. One snubber is mounted on each side of the generator on top of the SG compartment wall. The hydraulic snubbers are valved to permit relatively unrestricted SG movement during thermal transient conditions, and to "lock up" and act as a rigid strut under dynamic loads.

20C.1.5.1.2 **SG Primary Side**

The principal SG primary side components include the Channel Head, Tubesheet, and tube bundle. The Channel Head, Tubesheet, and tube bundle form part of the RCS pressure boundary, which provides a barrier against the release of radioactivity generated within the reactor. The Channel Head and Tubesheet form part of the SG shell and are described in the previous sub-section.

10,025 heat-transfer U-tubes are provided per SG and are welded to the Tubesheet inside the SG shell. The SG tubing is approximately 17.48 mm (0.688 in) outside diameter and 1.02 mm (0.041 in) nominal wall thickness. The nominal minimum U-bend radius is 82.55 mm (3.25 in). The tubes are fabricated of nickel-chromium-iron Alloy 690 and undergo thermal treatment following tube-forming operations. The tubes are tack-expanded, welded, and are expanded over the full thickness of the Tubesheet to minimise secondary water access to the tube-to-tube-sheet crevice. The method by which the tubes are expanded into the Tubesheet is determined based on consideration of the residual stresses and the resultant susceptibility of the tube to degradation. Residual stresses (and the expanded tube's susceptibility to degradation) are limited, in part, through tight control of the pre-expansion clearance between the tube and Tubesheet hole.

20C.1.5.1.3 **SG Secondary Side**

The secondary side of the SG shell, consisting of the lower shell, transition cone, upper shell, feedwater nozzles, elliptical head knuckle, elliptical head and steam outlet nozzle, is the pressure boundary for the secondary side steam/water mixture[2]. These are described in Section 20C.1.5.1.1.

Within the SG shell, the principal secondary side components include the feedwater ring, moisture separating equipment and tube supports. Support of the tubes is provided by ferritic stainless steel tube support plates. Holes in the tube support plates are broached with a hole geometry to promote flow along the tube and to provide an appropriate interface between the tube support plate and the tube. Anti-vibration bars are installed in the U-bend region of the tube bundle. The tube bundle is surrounded by a wrapper, forming an annulus for secondary side feedwater between the wrapper and the shell of the SG. The wrapper is supported by lugs attached to the inside of the SG Shell.

Secondary side feedwater enters the SG at an elevation above the top of the U-tubes through the feedwater nozzle in the SG shell. A welded thermal sleeve connection connects the nozzle to a feedwater ring fitted with debris filtering nozzles and located in the SG upper shell. The feedring is elevated above the feedwater nozzle to minimise feedwater thermal stratification at the nozzle location. The debris filtering nozzles feature perforated outlets above the feedwater ring with 7.3 mm (0.29 in) nominal diameter holes to help prevent loose parts ingress into the SG.

2. The SG upper shell, feedwater nozzles, elliptical head knuckle, elliptical head and steam outlet nozzle are collectively referred to as the steam barrel.

Feedwater then flows down the annulus between the tube bundle wrapper and the SG shell, passes through a gap between the wrapper and the Tubesheet and flows up past the U-tubes where it boils and arrives in the SG upper shell as a mixture of saturated liquid and steam. This saturated mixture passes through moisture separators. Moisture is removed and re-circulated in the SG, while dried steam exits the SG via the steam nozzle and venturi flow restrictors. The primary moisture separators comprise 33 swirl vane riser columns that induce centrifugal separation. The secondary separator contains eight banks of hook-and-pocket vanes that subject the flow to multiple changes in direction.

20C.1.5.2 Functional Description

The basic function of the SG is to transfer heat from the single-phase reactor coolant water through the U-shaped heat exchanger tubes to the boiling, two-phase steam mixture in the secondary side. The SG separates dry and saturated steam from the boiling mixture, and delivers the steam to a nozzle from which it flows to the turbine. Water from the feedwater system continuously replenishes the SG water inventory, entering the SG through the feedwater nozzle and feedring. In addition to its steady-state heat transfer function, the SG secondary side provides a water inventory which is available as a heat sink to mitigate primary side high temperature transients and to accommodate accident conditions.

20C.1.5.2.1 Primary Side – Reactor Coolant Flow

On the primary side, the reactor coolant flow enters the primary chamber of the Channel Head via the hot leg nozzle and enters inverted U-tubes via the Tubesheet, transferring heat to the secondary side during its traverse of the tubes. During its approximately 21.3 m (69.9 ft) traverse of the tubes, the primary water is cooled from approximately 322°C to 279°C (612°F to 534°F). The reactor coolant flow then returns to the cold leg side of the primary chamber via the Tubesheet. The primary coolant flow exits the SG via two cold leg nozzles to which the RCPs are directly attached.

20C.1.5.2.2 Secondary Side – Feedwater Flow

Secondary side feedwater enters the SG via the feedwater nozzle and passes through a feedring fitted with spray nozzles, located in the SG upper shell. The incoming secondary side feedwater mixes with saturated water that has been separated from the steam outlet flow. The result is subcooled water in the SG downcomer region. This water flows down the annulus between the tube bundle wrapper and shell and enters the tube bundle region via a 304.8 mm (12 in) diameter opening at the bottom of the wrapper just above the Tubesheet. The direction of flow then turns and is directed upward along the tube bundle U-tubes.

As it flows upward, the fluid on the secondary side is heated by the primary side fluid via heat transfer through the U-tube walls. The secondary side fluid boils and becomes a mixture of saturated liquid and steam. This saturated mixture continues to flow upward into the moisture separator assembly in the SG upper shell.

The two phase flow leaving the tube bundle enters the primary moisture separator assembly with integral swirl vanes. The swirl vanes impart a centrifugal acceleration to the flow, causing the heavier liquid droplets to collect along the inner surface of the riser pipe. This liquid flow, along with some steam (carry under), is returned to the SG downcomer plenum through openings in the riser pipes and at the outlet of the riser.

Additional separation takes place by gravity as the relatively low velocity flow travels upward to the entrance of the single tier secondary separator. The secondary separator

contains banks of hook-and-pocket vanes that subject the flow to multiple changes in direction. These changes in flow direction produce flow accelerations that act to separate out the remaining liquid in the steam-water mixture. The liquid then flows down the vanes to collection troughs that return it to the downcomer plenum via the drain manifold system. The steam flow exits the secondary separator then leaves the SG through the steam outlet nozzle. The moisture carryover limit of the exiting flow is 0.25% as measured by tracer technique and the design goal moisture carryover of the exiting flow is 0.10% or less.

All saturated water separated out from the steam-water mixture is returned to the SG upper downcomer plenum. Here it mixes with incoming subcooled feedwater, completing the recirculating loop.

20C.1.6 Boundaries

As identified in Reference 20C.1, the physical boundaries of the SG are illustrated in Figure 20C-5 to Figure 20C-9. Interfaces, which form part of a pressure boundary, are at the first circumferential weld joint joining the piping or pump casing to the SG nozzles. The connecting weld between the SG outlet nozzle and the RCP casing is considered a pressure boundary weld per the ASME Code. These physical limits are identified to specify the scope of this report and also represent the limit of applicability of the ASME Code, Section III to the SG.

20C.2 Safety Case Requirements

This key objective of this CSR is to establish that the structural reliability of the SG is commensurate with the consequences of gross failure. This is achieved by means of a structured safety argument, supported by suitable and sufficient evidence. The safety argument is presented in Section 20C.3 according to an established four legged structure (Reference 20C.3), to demonstrate an appropriate level and diversity of defence in depth by identifying evidence to satisfy safety claims and objectives identified within each leg of the argument, as follows:

Leg 1	**Interpolation/Extrapolation of Experience – 'Good' Design and Manufacture**
Objective:	To provide evidence of good design and manufacture based on a proven track record. This forms a keystone for a demonstration of high reliability and embodies the code and plant operating experience with objective of achieving quality of build, high integrity (HI) and the avoidance of defects.
Claim:	High quality is achieved through good design and manufacture.
Leg 2:	**Functional Testing**
Objective:	To incorporate build experience as embodied in design codes, and provides some diversity and redundancy to the pre-service inspection (PSI).
Claim:	Components are shown to be fit for purpose through effective functional testing.

Leg 3: **Failure Analysis**

Objective: By means of an assessment of through-life degradation mechanisms, to show that such mechanisms will not threaten integrity over a specific interval. This goes beyond design code requirements to provide a further demonstration of integrity. This leg acknowledges that flaws may be present and demonstrates tolerance to them. This supplements the Leg 1 aim of avoidance of defects to provide a safety case with both defect avoidance and defect tolerance.

Claim: Components are tolerant to through life degradation over the design life of the plant.

Leg 4 **Forewarning of Failure**

Objective: To confirm the absence of a degradation mechanism or that a known degradation mechanism is not significant to integrity or will have limited consequences. This provides a means of safely controlling any anticipated component degradation and also a contingency for the unexpected.

Claim: Effective systems are in place to provide forewarning of failure

The four legged safety argument will substantiate specific SFRs for the SG and these support nuclear safety claims made for AP1000 plant. The SG SFRs are identified in Section 20C.2.1.

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure. Classification of the SG and its component parts is established in Section 20C.2.2.

The four legged safety argument is provided in Section 20C.3 and the strength of the argument is discussed in Section 20C.4.

20C.2.1 Safety Functional Requirements

The SG is allocated the following SFRs, reiterated here from Table 20-1:

- **SFR 20.3.1** The SG pressure boundary is required to maintain the integrity of the primary and secondary coolant boundaries during standby, normal operation and under design basis faulted conditions for the design life of the plant.

- **SFR 20.3.2** The SG secondary side is required to provide a heat sink for the RCS during power operations and anticipated transients and under natural circulation conditions in accordance with component performance requirements (not required to provide safe shutdown of the plant).

Postulated failure modes which result in a loss of these SFRs lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20C.2.2. The safety argument in Section 20C.3 is provided to substantiate that these structural reliability targets will be achieved and thus demonstrate that the above SFRs will be maintained at all times.

20C.2.2 Structural Integrity Classification

A clear understanding of the potential radiological consequences of any postulated gross failure mode is a key starting point for the SG structural integrity safety argument. This forms a structured and systematic basis to establish an appropriate level of rigour to be applied in the design assessment, material procurement, fabrication, in-manufacture inspection, testing and in-service testing, maintenance, inspection and safety case assessment of the SG. Details of the approach for developing AP1000 component structural integrity safety cases are given in Reference 20C.4.

The approach to structural integrity classification is discussed in Section 20.5 and is consistent with the overall AP1000 safety classification scheme as detailed in Chapter 5. Reference 20C.4 details the approach taken whereby a more detailed assessment of selected individual components is made to establish the consequences of gross failure, due to both direct consequences such as a loss-of-coolant accident (LOCA), and indirect consequences, such as the effect of missiles, jet loading or pipe whip on essential safety systems. Based on this assessment, and in accordance with the scheme identified in Chapter 5, components are allocated one of the five structural integrity classifications described in Section 20.5.2:

The tolerable failure frequency, available mitigation and consequences associated with these classifications is summarised in Table 20-2. There are three regions of the SG where gross failure has been assessed in Reference 20C.4 as having the potential to lead to the most severe off-site consequences against which there is no claimed protection. These are the Secondary Shell, Channel Head, and Tubesheet; all three of which have been allocated a classification of Highest Safety Significance (HSS). Table 20-4 to Table 20-6 respectively, reproduced from Reference 20C.4, identify the basis for the classification of these three regions.

Other components of the SG are allocated a classification of Standard Class 1, since gross failure at other SG locations has been assessed as not having the potential to lead to the most severe and unprotectable off-site consequences. The classification of all individual SG components is presented in Table 20C-4.

20C.3 Safety Argument

This section provides a structured safety argument to demonstrate that the SG is fit for purpose for the required component lifetime of 60 years. The safety argument is presented according to a four-legged structure articulated in section 20C.2.

Consistency with the appropriate ASME rules for design, manufacture and inspection forms the basis to substantiate fitness-for-purpose for SG components with Standard Class 1 classification. Evidence to demonstrate appropriate code compliance for these components is presented in Sections 20C.3.1 (design & manufacture) and 20C.3.4 (in-service inspection).

Compliance with the relevant rules of the ASME Code is generally inferred as providing substantiation of satisfactory reliability for a component classified as Standard Class 1. In the case of the HSS components, i.e., the Channel Head, Tubesheet and Secondary Shell, it is necessary to substantiate a lower frequency of failure, such that the probability of gross failure is so low that it can be discounted. This is achieved by identifying supplementary measures to ensure high quality and by demonstrating the tolerance to manufacturing defects above qualified detection limits. In addition to evidence presented to demonstrate compliance with ASME rules given in Section 20C.3.1, further qualitative arguments are presented in Sections 20C.3.2, 20C.3.3 and 20C.3.4 to demonstrate evidence of defence in depth and

substantiate a level of structural reliability commensurate with HSS classification for the relevant SG components.

20C.3.1 Leg 1: Interpolation/Extrapolation of Experience – Good Design and Manufacture

The principal claim for Leg 1 of the safety argument is that the quality of design and manufacture is commensurate with the classification of each component of the SG. This supports the structural reliability targets associated with the classification of each SG component. Structural reliability targets, expressed in terms of tolerable frequencies of failure, are identified for each level of component classification in Table 20.2.

The Design Specification (Reference 20C.1) provides a diverse range of evidence to ensure the quality of design and manufacture, as identified within this leg of the safety argument. Reference 20C.1 establishes the basis for the materials, design, operability, regulatory requirements, manufacture, inspection, testing, packaging and preparation for shipment of the AP1000 SGs. This provides the basis to demonstrate that the design and construction of the SG conforms to the ASME Code, Section III, Rules for the Construction of Nuclear Power Plant Components and the applicable Code Cases and Addenda for Class 1 and Class 2 vessels. The ASME Section III Rules embody extensive international industry-wide operating experience and compliance with these rules provides a keystone for a demonstration of high structural reliability.

A series of subordinate safety arguments are established to substantiate appropriate quality of SG design and manufacture as follows:

- **Section 20C.3.1.1** SG design is well founded.
- **Section 20C.3.1.2** SG design parameters are suitably well defined.
- **Section 20C.3.1.3** Compliance with relevant design code requirements supports SG structural reliability claims.
- **Section 20C.3.1.4** SG components are manufactured from suitable materials.
- **Section 20C.3.1.5** Suitable controls ensure SG manufacturing quality.
- **Section 20C.3.1.6** Manufacturing and Pre-Service inspections confirm quality of manufacture.
- **Section 20C.3.1.7** Definition and control of plant operation and maintenance ensure continued fitness-for-purpose.

Collectively these arguments identify evidence to demonstrate that the SG is well designed, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a safety-significant deleterious effect on SG structural reliability.

20C.3.1.1 SG Design is Well Founded

To demonstrate that SG design is well founded, evidence to substantiate the following arguments is provided:

- SG design is well established.

- SG design takes due account of relevant experience.
- Appropriate codes, standards & regulations are specified to control the quality of design and manufacture.

20C.3.1.1.1 **SG Design is Well Established**

The design of the SG is fundamentally similar to previous well established designs and thus supported by a substantial record of safe operating experience. This leads to a comprehensive understanding of the in-service performance of SGs and the management and mitigation of through-life degradation. This understanding has influenced SG design and manufacture to eliminate, minimise and control issues that can adversely affect through-life structural integrity.

Westinghouse has substantial proven experience, knowledge, and capability to design and manufacture SGs. Westinghouse has more than fifty years' experience of nuclear power plant (NPP) design, development and manufacture, and has designed and delivered more than 100 commercial NPPs worldwide including Sizewell B in the UK. The SG design is, therefore, supported by unparalleled experience in design and manufacture, benefitting from substantial operating experience that demonstrates an excellent record of safe operation.

Two SGs are used in the AP1000 plant. The design of the AP1000 SG is similar to earlier Westinghouse design SGs, and also to typical PWR SG design with similar proven materials and manufacturing processes. The design has been the subject of regulatory scrutiny overseas: the Nuclear Regulatory Commission (NRC) of the United States (US) approved the AP1000 design in December 2005 following the earlier approval of AP600 NPP design certification in 1999.

The design of the AP1000 SG is based on standard Westinghouse Model-F technology. There are some 75 Model F-type units in commercial operation, with the highest level of reliability achieved by any SG worldwide. The high reliability of similar SG designs is well proven; examples of currently operating NPP that employ similar SG design include the Delta-75 replacement SGs for V.C. Summer and other plants; Delta-94 replacement SG for South Texas plant; replacement SGs for Arkansas and Waterford.

The SG design is based on well proven preceding designs and therefore novel design features are largely avoided. The design is not, however, identical to earlier designs but has evolved to include a number of enhancements to improve safety and reliability, as described in Section 20C.3.1.1.2 below.

20C.3.1.1.2 **SG Design Takes Due Account of Relevant Experience**

The design of the AP1000 SG benefits from lessons learned over many years of safe operation. This experience has led to design enhancements that improve the structural reliability of the SG. The general arrangement of the SG shell is designed to maximise structural reliability and is comprised of a series of forgings to minimise the number of circumferential welds and eliminate longitudinal welds. The SG design includes several enhancements to improve safety and reliability by mitigating against various issues relating to SG degradation experienced in similar NPP. These enhancements include the following:

- Full-depth hydraulic expansion of the heat transfer tubes in the Tubesheet to minimise secondary water access to the tube-to-Tubesheet crevice,

- Thermally treated Inconel 690 (I-690) heat transfer tubing provides enhanced resistance to tube degradation,

- Modified triangular pitch of heat transfer tubes provides enhanced resistance to tube degradation,

- Broached tube support plates and modified anti-vibration bars (AVBs) to minimise tube degradation due to vibration,

- Upgraded (more robust) primary and secondary moisture separators,

- Enhanced access arrangements for maintenance and inspection, including a modified Channel Head design that facilitates access for robotic tooling.

The SG design includes measures to minimise degradation due to water hammer, stratification, and striping. SG bubble collapse water hammer has occurred in certain early pressurised water reactor SG designs having feedrings equipped with bottom discharge holes. Prevention and mitigation of feedline-related water hammer has been accomplished through an improved design and operation of the feedwater delivery system. The AP1000 SG and feedwater system incorporate features designed to eliminate the conditions linked to the occurrence of SG water hammer. The SG features include introducing feedwater into the SG at an elevation above the top of the tube bundle and below the normal water level by a top discharge feedring. The top discharge of the feedring helps to reduce the potential for vapour formation in the feedring. This minimises the potential for conditions that can result in water hammer in the feedwater piping. The feedwater system features designed to prevent and mitigate water hammer include a short, horizontal or downward sloping feedwater pipe at SG inlet. These features minimise the potential for trapping pockets of steam which could lead to water hammer events.

Stratification and striping are reduced by an upturning elbow inside the SG which raises the feedring relative to the feedwater nozzle. The elevated feedring reduces the potential for stratified flow by allowing the cooler, denser feedwater to fill the nozzle/elbow arrangement before rising into the feedring.

The potential for water hammer, stratification, and striping is further reduced by the use of a separate start-up feedwater nozzle. The start-up feedwater nozzle is located at the same elevation as the main feedwater nozzle and is rotated circumferentially away from the main feedwater nozzle. A start-up feedwater spray system independent of the main feedwater feedring is used to introduce start-up feedwater into the SG. The layout of the start-up feedwater piping includes the same features as the main feedwater line to minimise the potential for waterhammer. The feedwater and startup feedwater nozzles are clad on the inner surface, as described in Section 20C.1.5.1.1, to minimise the potential for corrosion-related degradation.

The SG steam outlet nozzle incorporates flow-limiting venturi designed to limit the pressure drop in the SG during steam line break so as not to exceed allowable loads on the internals and to limit the rate of mass and energy release into containment.

The SG is designed for a component lifetime of 60 years, and the design accommodates facilities for maintenance activities over this period including provision for repair and replacement if necessary. The arrangement of the Channel Head primary chamber provides enhanced access to all tubes, including those at the periphery of the bundle, with robotic equipment. This enhances the ability to inspect, replace and repair portions of the AP1000

unit compared to the more spherical primary chamber of earlier designs. All heat transfer tubes in the SG are accessible for sleeving, if necessary.

Additional measures to control the quality of design and manufacture, based on industry-wide experience, are embodied in the codes, standards and regulations identified below in Section 20C.3.1.1.3.

20C.3.1.1.3 Appropriate Codes, Standards & Regulations are Specified to Control the Quality of Design and Manufacture

Compliance with relevant and internationally well established codes, standards and regulations to control the quality of SG design and manufacture provides assurance that an appropriate level of structural reliability will be achieved. Compliance with the ASME Code provides assurance over a diverse range of relevant aspects including material procurement, component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination (NDE), testing, installation and pre-service and in-service inspection requirements.

The SG is designed, fabricated and installed in accordance with the codes, standards, guidelines and regulations identified in Table 20C-5. These include elements of the ASME Code and Code Cases, American National Standards Institute and ASME Standards, US Code of Federal Regulations, US NRC Regulatory Guides, Electric Power Research Institute (EPRI) Guidelines, and miscellaneous standards and recommended practises.

The applicability of the codes, standards and regulations identified in Table 20C-5 to a particular component of the SG is primarily based on the AP1000 equipment classification of the component. Table 20C-6 identifies the AP1000 equipment classification for the subcomponents of the SG, as well as the corresponding American Nuclear Standards Institute (ANSI) safety class and seismic classification. Class A, B and C components are designed to nuclear codes and standards, such as the ASME Code. AP1000 Equipment Class A components are designed to ASME Code, Section III, Class 1 requirements. For conservatism, all pressure retaining components on the secondary side of the steam generator are also designed to ASME Code, Section III, Class 1 requirements. Class D or E components are designed to meet the design, material, fabrication, inspection and testing requirements of industry codes and standards.

The AP1000 NPP design originates in the US. As such, many of the specified codes, standards and regulations originate in that country. These codes represent internationally established good practice and as such are considered to be applicable in the UK. Where additional or alternative requirements or procedures specifically applicable to the UK are warranted, such as those associated with inspection and defect tolerance, this is identified within the appropriate section of this safety argument.

The codes, standards and regulations that are specified to control quality of SG design and manufacture embody extensive experience relevant to the SG. This experience helps to ensure a structurally robust design and provides a means to prevent, minimise and control component degradation at the design stage. Compliance with the codes, standards and regulations, therefore, provides a foundation for assuring that SG structural integrity will be maintained for the design lifetime.

Evidence of compliance with ASME requirements is provided by ASME certification of the SG at the construction stage of AP1000 NPP development, supported by an assessment to

demonstrate compliance with relevant design code requirements as described in Section 20C.3.1.3.

20C.3.1.2 SG Design Parameters are Suitably Well Defined

To substantiate claims based on ASME Code compliance and also to demonstrate that a safe plant operating envelope is clearly established, SG design parameters must be suitably well defined. Evidence is provided to substantiate the following claims:

- Specification of design load parameters is suitably comprehensive.
- Specification of environmental conditions is suitably comprehensive.

20C.3.1.2.1 Specification of Design Load Parameters is Suitably Comprehensive

Section III Subsection NB of the ASME Code requires that the SG design is evaluated against design, service, and test conditions and that the stresses within the SG are shown to comply with specified allowable stress limits appropriate to the material of construction. The assessment to demonstrate compliance with these requirements is described in Section 20C.3.1.3.

Design conditions include those pressure, temperature, and mechanical loadings selected as the basis for the design. Service conditions cover those normal operating conditions, anticipated transients, and postulated accident conditions expected or postulated to occur during operation. The evaluation of the service and testing conditions includes an evaluation of fatigue due to cyclic stresses. References that establish transient specification are identified in the index of technical reports (see Table 20C-7).

The following five categories of operating condition, as defined in ASME Code, Section III, encompass all operating conditions within the design basis of the SG:

- Level A Service Conditions – Normal Conditions.
- Level B Service Conditions – Upset Conditions, Incidents of Moderate Frequency
- Level C Service Conditions – Emergency Conditions, Infrequent Incidents
- Level D Service Conditions – Faulted Conditions, Limiting Faults
- Testing Conditions

The load parameters used in the design evaluation are summarised below to demonstrate that these have been determined using well established and conservative procedures and capture all conditions within the design basis.

The design basis of the SG is specified in Reference 20C.1. The structural design of the SG is based upon the following maximum steady state internal conditions:

Primary Chamber Components:	
Primary Side Design Temperature:	343.3°C (650°F)
Primary Side Design Pressure:	17.24 MPa (2500 psi)
Secondary Chamber Components:	
Secondary Side Design Temperature:	315.6°C (600°F)
Secondary Side Design Pressure:	8.27 MPa (1200 psi)

Primary-to-Secondary Chamber Components (both sides pressurised concurrently):

Maximum Temperature:	343.3°C (650°F)
Maximum primary-to-secondary differential pressure:	11.38 MPa (1650 psi)
Maximum secondary-to-primary differential pressure:	4.62 MPa (670 psi)

Design thermal-hydraulic conditions and transients are specified in Reference 20C.1, where load combinations for Design, Level A, Level B, Level C, Level D and Test conditions are identified. The load combinations for the SG stress analyses are listed in Table 20C-8. The load combinations are expressed in terms of the nomenclature identified in Table 20C-9.

As identified in Reference 20C.1, the load combinations listed in Table 20C-8 are documented in the interface control document (ICD) (Reference 20C.6). The design analysis includes the RCS pressure, temperature, and flow transients, as specified in Reference 20C.7. SG thermal-hydraulic conditions are determined under the design basis transient conditions specified in Reference 20C.7, with respect to secondary side pressures, temperatures, and heat transfer coefficients throughout the SG. Primary side condition inputs and loadings on SG internals are also determined based on the conditions specified in Reference 20C.7. Additionally, for SG No. 1 only, the scope of the design stress analysis includes consideration of the CVS and PRHR nozzles based on transients defined in the ICD. For the purpose of SG design evaluation, the number of transient occurrences is based on a plant design life of 60 years. In addition to the summary of load combinations listed in Table 20C-8, Reference 20C.1 details load levels and combinations at the following locations:

- SG primary inlet and primary outlet nozzle load combinations
- Support System and Support Loads
- SG Inlet Piping Loads
- SG/RCP Loads
- SG/PRHR Pipe Loads
- SG/Feedwater Pipe Loads
- SG/Steam Line Pipe Loads
- SG/Blowdown Pipe Loads
- SG Level/Pressure Tap Connection Loads
- SG Start-Up Feedwater Nozzle Connection Loads
- SG CVS Nozzle Connection Loads
- Support and Piping Stiffness Values

Cyclic loads, such as those introduced by normal power changes, reactor trips, startup and shutdown operations, are identified as part of the Level A and Level B service loads and are included in the design base transients for fatigue evaluation. Twenty safe shutdown earthquake (SSE) transients are included as Level B loads in the fatigue analysis. The transient conditions selected for equipment fatigue evaluation are based on a conservative estimate of the magnitude and frequency of the temperature and pressure transients that may occur during plant operation.

The AP1000 plant design assessment includes consideration of a postulated circumferential break of the feedwater pipe at the junction of the feedwater nozzle and the 90º, downturning, pipe elbow connecting to the feedwater nozzle. To limit the motion of the end of the feedwater pipe under such a postulated pipe break, a pipe whip restraint is provided at an elevation approximately equal to the bottom end of the 90º pipe elbow. The pipe whip restraint is attached to the SG with two welded lugs, and pipe break loads are reacted through the pipe whip restraint back to the SG shell lugs and upper shell. The loads are provided in Reference 20C.6.

The AP1000 plant design assessment (Section 20C.3.1.3) includes consideration of seismic loading, based on the SSE transient, as part of the assessment of the Level D Service Conditions. The reports describing seismic analysis of the SG are identified in the index of technical reports (see Table 20C-11). The peak ground acceleration of the SSE has been established as 0.30g for the AP1000 design. The vertical peak ground acceleration is conservatively assumed to equal the horizontal value of 0.30g. Both horizontal and vertical design response spectra are based on the Regulatory Guide 1.60 spectra augmented at the higher frequencies. In Chapter 12, a comparison is made between these spectra and the UK generic design basis Principia Mechanica Limited (PML)[3] spectra, which are based on a 0.25g event. SSE seismic response spectra are provided in Reference 20C.1, these are the upper envelope of all reactor coolant loop (including the SG) support locations.

20C.3.1.2.2 **Environmental Specification is Clearly Defined**

The materials selected for use in the SG are selected to be compatible with the full range of internal and external environmental conditions which may be encountered over the plant life. These environmental conditions include temperature humidity, radiation, chemistry of fluid and materials in contact with the SG, and other external conditions which may affect the suitability of a material for its intended service.

During start-up, normal operation, wet layup, and heatup conditions, the SG primary and secondary sides will be exposed to a range of fluid chemistry conditions. Time dependent evaluations in the design analysis are based on adherence to controls on the internal environment of both the primary side (as specified in Table 20-22) and secondary side of the SG, which are based on the well established guidelines of References 20C.8 and 20C.9, respectively. The values presented in Table 20-22 are bounding for chemistry operational control of primary fluids that are in contact with primary system materials and nuclear fuel. The operational chemistry program may apply stricter limits as deemed appropriate. Chapter 21 provides a detailed description of water chemistry.

During hydrostatic testing, the primary and secondary sides of the SG are exposed to a test water internal environment. The quality of the test water is specified in Reference 20C.1.

The SGs will be operating in a containment building and the external environment will vary in terms of temperature, pressure, humidity, and radiation levels depending upon plant conditions. The range of environmental conditions to which external surfaces of SG will be exposed are specified in Reference 20C.1. These include all normal and abnormal operating conditions and accident conditions that are within the design basis.

3. PML spectra were developed for use as broad band spectra for use in design of UK critical facilities. They are based on the anticipated peak ground acceleration at the site and the site ground conditions.

20C.3.1.3 Compliance of SG Design with Relevant Code Requirements will Support SG Structural Reliability Claims

Section III of the ASME Code provides a well established methodology for stress analysis to provide assurance of structural integrity before a component enters service. The SG design will be assessed to confirm that stress, sizing and fatigue limits specified in Section III of the code are met.

To demonstrate that SG design will be assessed against relevant design requirements, and that future operation will be dependent upon satisfying the stress, sizing and fatigue limits specified in Section III of the ASME Code, the following analyses are discussed:

- SG design assessment against relevant stress limits.
- SG design assessment of end-of-life fatigue usage factors (FUFs).

20C.3.1.3.1 SG Design Assessment Against Relevant Stress Limits

Section III of the ASME Code establishes stress limits for design, operational, accident and testing conditions. Reference 20C.1 specifies the requirements for the design stress report that demonstrates that these stress limits are met. Analysis of the following regions of the SG is included in the scope of the SG stress analysis:

- Primary Chamber (Channel Head, Tubesheet, and Support Pad)
- Divider Plate
- Upper Shell, Transition Cone, and Lower Shell
- Steam Nozzle and Upper Head
- Heat Transfer Tubes
- Feedwater Nozzle and Thermal Sleeve
- Feedring, Feedring Supports, and Spray Nozzles
- Recirculation Port (for Maintenance Recirculation)
- Start-up Feedwater Nozzle
- Tube-to-Tubesheet Weld
- Hand Hole
- Inspection Port
- Support Trunnion
- Snubber Support Pad
- Wrapper and Support
- Tube Support Plates, Anti-Vibration Bars and Stay Rods (Lower Internals)
- Minor Nozzles (Blowdown Nozzle, Instrumentation Tap)
- Separator Region (Upper Internals)
- Secondary Manway
- Primary Manway
- Primary Nozzles

Definition of the loading conditions associated with all ASME service and testing conditions is discussed in Section 20C.3.1.2.1. The material strength properties from the ASME Code Section II are used in the design stress report. Materials used in the fabrication process will have material strength properties that meet or exceed the material strength properties used in the design basis for the design stress report as discussed in Section 20C.3.1.4.2.

The ASME stress limits are identified for each of the Level A to D Service Conditions and Testing Conditions included in the code. These form the acceptance criteria for the design

assessment, and SG components classified as HSS and Standard Class 1 are required to meet criteria specified in Section III of the ASME Code for Class 1 components. The SG design report (Reference 20C.10) provides the evidence that these criteria are satisfied. Consistency with the appropriate ASME rules provides the basic demonstration of fitness-for-purpose. The results of stress and fatigue analysis, therefore, form an important element in substantiating the structural reliability of SG components classified as HSS and Standard Class 1.

The AP1000 SG Design Report (Reference 20C.10) summarises the results of detailed analyses against the requirements of ASME Code, Section III. The scope of the analyses includes all locations identified above and all of the required loading conditions specified in Reference 20C.1. The report concludes that the results of the analyses demonstrate that all locations satisfy the structural requirements of Section III of the ASME Code.

The SG supports are described in Section 20C.1.5.1.1. The adequacy of each member of the supports is verified by solving the stress and interaction equations of ASME Code, Section III, Subsection NF and Appendix F.

Section 20.6.1 addresses the design code requirements applicable to ASME Code Class 1 components.

20C.3.1.3.2 SG Design Assessment of End-of-Life Fatigue Usage Factors

The SG is designed to meet the fatigue design criteria as defined in the ASME Code, Section III without compromising other aspects of the design. The FUFs are determined as:

- Membrane plus bending plus peak component at each location (end points of each cut).
- A combination of the total components for all thermal cases, resulting in alternating stress intensity ranges in decreasing order until all usage cycles are exhausted.
- A partial usage factor is determined by computing the ratio of the number of cycles applicable to the alternating stress range, divided by the allowable number of cycles for the same alternating stress range, as defined in the applicable ASME fatigue curve.
- A cumulative FUF is determined by summing the partial usage factors. The cumulative FUF at end of design basis component lifetime must be less than 1.0.

Critical SG design features, as identified in the previous section for stress analysis, are analysed to demonstrate that the fatigue design criteria are met. The SG Design Report (Reference 20C.10) provides evidence that the end-of-life FUFs at all locations analysed are below unity.

20C.3.1.4 SG Components are Manufactured from Suitable Materials

The recommended materials for SG fabrication are specified in Reference 20C.1 and listed in Table 20C-2 of this report. To demonstrate that suitable materials have been chosen for the fabrication of SG components, evidence to substantiate the following arguments is provided.

- AP1000 SG materials have a proven service performance.
- Material specifications meet or exceed the specifications of ASME.
- Chemical composition of materials is well controlled.
- Materials are compatible with each other and with the environment.

- Mechanical testing demonstrates compliance with relevant material specifications.

20C.3.1.4.1 **AP1000 Steam Generator Materials have a Proven Service Performance**

The selection of the AP1000 SG materials reflects international experience in PWR design, manufacture and operation to minimise the effects of through-life degradation.

The material of the Channel Head, Tubesheet and all components of the secondary shell is SA-508 Grade 3 Class 2. UK practice for PWR SGs has been to use SA-508 Grade 3 Class 1 for these components. SA-508 Grade 3 Class 2 has higher strength than SA-508 Grade 3 Class 1. This is achieved during manufacture by SA-508 Grade 3 Class 2 being tempered at a lower temperature than SA-508 Grade 3 Class 1: the nominal chemical compositions being the same. All components of the SG shell are ring forgings, this reduces the number of welds and eliminates axial shell welds.

The hot leg inlet nozzle weld and the PRHR nozzle weld incorporate safe ends, of SA-336 CL F 316LN SS and SB-564 UNS N06690 material, respectively. These are well established in the nuclear industry for application in nozzle welds.

The surfaces of the primary shell that are designed to be in contact with primary coolant are clad with austenitic stainless steel or equivalent corrosion-resistant material; the cladding is Type 308L/309L welded overlay.

Wrought Alloy 600 and its weld metals (Alloy 182 and Alloy 82) were previously used in PWRs due to the materials' inherent resistance to general corrosion in a number of aggressive environments and because of a coefficient of thermal expansion that is closer to that of low alloy and carbon steel. Primary water stress corrosion cracking has been observed in numerous Alloy 600 component items and associated welds in PWR plant, sometimes after relatively long incubation times. Alloy 600 is not used. The use of nickel-chromium-iron alloys in the SG is limited to Alloy 690 and its compatible weld metals (Alloy 152 and Alloy 52). Alloy 690 and its associated weld materials have been shown to be highly resistant to primary water system stress corrosion cracking (PWSCC). A buttering layer of Alloy 690 may be applied to the outlet nozzle and to the RCP casing in order to avoid field PWHT of the outlet nozzle to RCP casing weld.

20C.3.1.4.2 **Material Specifications Meet or Exceed ASME Specifications**

The material recommended for the SG assembly is identified in Table 20C-2. As part of the quality assurance (QA) programme, certified material test reports are to be provided to demonstrate compliance of SG materials with relevant requirements of the ASME Code Section II, where applicable. The material specification requirements include limitations on manufacturing techniques, the use of weld repairs, heat treatment, chemical composition, mechanical testing, inspection and QA. The certified material test report (CMTR) will include material test results and information on the following:

- Chemical analyses: heat and product
- Mechanical properties: tensile stress-strain, Charpy, drop weight, temperature for nil ductility transition (T_{NDT}) and reference temperature for nil ductility transition (RT_{NDT}).
- Heat treatments
- Information on archive/weldment material

- Sketches or drawings with dimensions
- A statement certifying that no weld repairs had been made (where applicable)
- Start-of-life inspection results

Supplementary Requirements are specified for SG shell components (both the primary and secondary shell) which exceed the requirements specified in ASME Section II. The Supplementary Requirements, as detailed in Reference 20C.11, are as follows:

- S1 Simulated PWHT of mechanical test samples
- S2 Ultrasonic Testing (UT) Reference Block Calibration
- S4 Additional Charpy Data
- S9 Additional restrictions on chemical composition
- S10 Alternative Fracture Toughness Requirements to establish a valid T0 fracture toughness reference temperature
- S15 Product Analysis

The heat transfer tubing is subject to heat treatment which exceeds the requirements of ASME Section II, as specified in Reference 20C.12.

Additional Supplementary Requirements are specified for SG nozzle safe-ends which exceed the requirements specified in ASME Section II. The Additional Supplementary Requirements, as detailed in Reference 20C.26, are as follows:

- Fracture Toughness of SA-336/SA-376 Type 316LN and Stainless Steel Weld Material of Nozzle Safe-Ends
- Minimum Yield Strength of SA-336/SA-376 Type 316LN and Stainless Steel Weld Material of Nozzle Safe-Ends
- Minimum Yield Strength of Inconel 52/152 (N06690) Material Associated with Nozzle Safe-Ends

Supplementary fracture toughness testing will be performed to underpin the values assumed in the defect tolerance assessment as described in Reference 20C.37.

20C.3.1.4.3 Chemical Composition is Well Controlled

The chemical composition of SG materials is controlled to minimise the content of elements that could have a detrimental effect of structural integrity. The CMTR will provide evidence to demonstrate that the composition of the materials of construction for the SG comply with the requirements of ASME Code, Section II.

SG material specification is summarised in Reference 20C.1, which provides a point of reference for detailed specification for particular materials. The cobalt content of materials in contact with the primary coolant is restricted to a maximum of 0.05% by weight. All austenitic stainless steel are solution-annealed to ensure an unsensitised condition. All

nickel-chromium-iron alloy base materials are supplied in a thermally treated condition. As identified on Reference 20C.1, the chemical composition of stainless steel and nickel-alloy materials is controlled according to requirements specified in Reference 20C.13.

References 20C.11 and 20C.12 provide detailed specification of the chemical composition of SG shell material and heat transfer tube material, respectively. The cobalt content of the tubing is limited as specified in Reference 20C.12. The chemical composition of the SG shell material is controlled to minimise the potential for material degradation. In addition, chromium content for the SG shell material is required to be greater than 0.10%.

20C.3.1.4.4 **Materials are Compatible with Each Other and with the Environment**

SG materials are selected to be compatible with each other and with the environment on the basis of proven service performance as discussed in Section 20C.3.1.4.1. The environmental characteristics both outside and within the SG are well defined as established in Section 20C.3.1.2.2, and the effect of these environments on SG materials is well understood based on the experience embodied in the codes and standards that control SG design (described in Section 20C.3.1.1.3). This ensures that the materials are resistant to age-related degradation and that material degradation characteristics are known and understood. Key aspects of design materials that help to minimise degradation in the SG environment are summarised below.

Stainless steel cladding on surfaces of the SG primary shell that are in contact with reactor coolant minimises the potential for corrosion-related degradation. The feedwater and startup feedwater nozzles are also clad on the inner surface, as described in Section 20C.1.5.1.1, to minimise the potential for corrosion-related degradation. Details of the SG insulation are specified in Reference 20C.6. In the event of coolant leakage, the ferritic materials are likely to corrode at an increased rate. Ferritic materials potentially exposed to primary coolant leakage can be readily observed as part of the in-service visual and/or nondestructive inspection programme to confirm the integrity of the component for subsequent service.

Austenitic stainless steel materials, such as those used on the nozzle safe ends, and nickel-chromium-iron alloy base materials, such the Alloy 690 heat transfer tubes, are used in the solution-annealed or thermally treated conditions. Sensitised stainless steel is not used in the SG.

High margins against PWSCC over the range of anticipated operating environments exist due to the specification of thermally treated Alloy 690 for the heat transfer tubes. Materials with a low resistance to PWSCC, such as alloy 600, are not used in the SG.

The chemical composition of all stainless steel and Ni-Cr-Fe Alloy materials is controlled, as described in Section 20C.3.1.4.3, to ensure ductility of these materials by minimising the content of low melting-point elements, their alloys and compounds. The use of low melting point elements and other contaminants in expendable materials, such as adhesives, NDE penetrant materials, rust preventatives, marking paints, tapes, ultrasonic testing couplings etc., is restricted according to limits specified in Reference 20C.1.

20C.3.1.4.5 Mechanical Testing Demonstrates Compliance with Relevant Material Specifications

SG material properties are confirmed to comply with relevant design specifications by a test programme summarised in this section. Reference 20C.1 specifies archive material that is to be retained to permit further mechanical testing of SG materials throughout plant life if required.

The mechanical testing requirements for each material are contained within the relevant material specifications as identified in Reference 20C.1. For the SG shell main forgings, the mechanical property tests will consist of Tensile Tests, Drop Weight Tests and Charpy V-Notch Impact Tests. These will be carried out in accordance with ASME Section III Section NB-2000. Mechanical property test specimens are subject to simulated PWHT following quenching and tempering. Orientation of test specimens will be as described in the ASME Code Section III, NB-2322 except that the material is not considered to be subjected to high neutron irradiation.

Charpy V-notch and dropweight fracture toughness tests will be performed on pressure boundary materials in accordance with ASME Code Section III, NB-2320 requirements.

As established by the drop weight tests, a reference temperature for nil ductility transition (RT_{NDT}) of -20.6°C (-5°F) maximum, is required of all ferritic pressure retaining material (except bolting materials). The RT_{NDT} value of -20.6°C represents a design requirement, and an RT_{NDT} of -12.2°C (10°F) is conservatively adopted in the design analyses for many of the SG forgings, with the exception of the Tubesheet and transition cone which require -20.6°C. An RT_{NDT} of -28.9°C (-20°F) maximum, is required of the main feedwater nozzle and startup feedwater nozzle materials.

On pressure boundaries, material for bolting and other fasteners with nominal diameters exceeding 25.4 mm (1 in) will meet the minimum requirements of 25 mils lateral expansion and 61 Nm in terms of Charpy V-notch tests conducted at the lesser of 0°C, the lowest service temperature or the preload temperature.

20C.3.1.5 Suitable Controls Ensure SG Manufacturing Quality

The processes used to manufacture the SG are controlled by well established codes and standards to ensure a quality of manufacture commensurate with structural reliability targets. Procedural controls of manufacturing processes are identified in the index of technical reports (Section 20C.7) and the codes, standards and regulations applied to ensure manufacturing quality are identified in Table 20C-5. The evidence to demonstrate suitable control of manufacturing quality is summarised in this section as follows:

- The SG manufacturer will be suitably experienced.
- SG manufacturing quality will comply with ASME Section III requirements as a minimum.
- Welding will be conducted by suitably qualified and experienced operators in accordance with suitable and well-established procedures.
- Repairs and deviations from the design intent are controlled and will be recorded.
- Manufacturing and procedural controls ensure quality of forging material.
- SG manufacture is supported by a robust QA programme.

20C.3.1.5.1 The SG Manufacturer will be Suitably Experienced

The supplier for the SG has not yet been selected and a technical evaluation of the suppliers' ability to comply with the Design Specification (Reference 20C.1) will form part of site specific justification following generic design assessment (GDA). The Design Specification identifies a range of documentation to be provided by the supplier to demonstrate compliance with the specification and to demonstrate that all responsibilities defined in ASME Code, Section III for the "Manufacturer" have been fulfilled.

QA requirements are specified, giving particular attention to the suppliers' ability with regard to achievement of the material compositional requirements including minimum fracture toughness requirements, the methods for the qualification of weld procedures and the ability to carry out the required range of inspections during manufacture. QA arrangements are discussed in Section 20C.3.1.5.6; these include requirements for the supplier to provide detailed fabrication and inspection plans for Westinghouse review and approval. The plans are subject to Westinghouse approval prior to commencement of manufacturing activities, and will define hold or witness points throughout the manufacturing process to provide an additional means of monitoring the quality of manufacture.

20C.3.1.5.2 SG Manufacturing Quality will Comply with ASME Section III Requirements as a Minimum

Design and fabrication of the SG is carried out in accordance with ASME Code, Section III. The pressure-retaining parts of the SG, including the primary and secondary pressure boundaries, are designed to satisfy the relevant criteria of the ASME Code. Compliance with the code and the experience embodied within the code provides a high degree of confidence that high quality will be achieved and also that the SG will be to tolerant to minor variations in material properties and minor imperfections in fabrication. Supplementary requirements that are more stringent than those in the ASME Code provide additional assurance of the quality of SG design and manufacture and further support to structural integrity claims.

The Design Specification (Reference 20C.1) provides the basis to establish how the design and construction of the SG is to conform to the rules set forth in the ASME Code, as described throughout Leg 1 of this safety argument. The manufacturer will provide a certificate of compliance or equivalent document as evidence that the SG is in conformance with all standards, specifications, codes and procedures specified in Reference 20C.1. Sections 20C.3.1.4.2 and 20C.3.1.6.1 identify supplementary requirements, more stringent than those specified in the ASME Code, relating to SG material specification and manufacturing inspection, respectively.

20C.3.1.5.3 Welding will be Conducted by Suitably Qualified and Experienced Operators in Accordance with Suitable and Well-established Procedures

All SG pressure boundary welding procedures and welder qualifications will be in accordance with ASME Sections IX and III Subsection NB, and all non-pressure boundary welding procedures and welder qualifications will be in accordance with ASME Section IX or equivalent pre-approved standards. Supplementary codes and standards to control welding procedures and welder qualification are identified in Table 20C-5. Specification of weld materials, together with controls on weld procedures and qualification are identified in the index of technical reports (see Table 20C-11).

Fracture toughness testing of weld qualification samples and weld filler metal will be in accordance with ASME Section III and the supplementary requirements identified in

Section 20C.3.1.4.2. The manufacturer is required to provide plans describing welding procedures, along with PWHT procedures, for Westinghouse approval prior to initiating any welding. Welder qualification records are to be retained by the manufacturer.

20C.3.1.5.4 **Repairs and Deviations from the Design Intent are Controlled and will be Recorded**

A requirement to record major/minor repairs and deviations for the design intent is identified in the SG Design Specification (Reference 20C.1). Reporting of defects and noncompliance is carried out in accordance with United States Code of Federal Regulations 10 CFR 21, as identified in Table 20C-5. Deviation notices and nonconformance reports provide the manufacturer with a procedure to record all conditions that do not meet design requirements.

All major repairs to base material and pressure boundary welds will be subjected to formal review by Westinghouse before approval to proceeding with the repair is granted. As specified in Reference 20C.11, weld repairs to the SG shell are not permitted.

The manufacturer is required to provide a certificate of compliance or equivalent document to confirm that the SG conforms with all standards, specifications, codes and procedures identified in the Design Specification (Reference 20C.1) with the exception of any referenced approved deviation notices. Westinghouse will provide a Certificate of Conformance to confirm the acceptability of the certificate of compliance as part of the QA records described in Section 20C.3.1.5.6. These documents are to provide safety justification of any repairs and deviations from the design intent for site specific AP1000 safety cases following the GDA.

20C.3.1.5.5 **Manufacturing and Procedural Controls Ensure Quality of Forging Material**

Reference 20C.11 provides the material specification for the SG forgings that are of SA-508 Grade 3 Class 2 and details aspects including control of chemical composition, microstructure, heat treatment, materials testing, grain size evaluation and NDE. These represent a range controls to ensure that the forging material complies with the requirements of the ASME Code, Section III, Subsection NB for Code Class 1 components. Reference 20C.11 also specifies certain requirements more stringent than and/or supplemental to those in the Code, as identified in Section 20C.3.1.4.2.

20C.3.1.5.6 **SG Manufacture is Supported by a Suitable Quality Assurance Programme**

Quality assurance for the design, procurement, fabrication, inspection, and testing of the SG is performed in accordance with the quality plan described in Westinghouse Electric Corporation Quality Management System (QMS) (Reference 20C.14) to, as a minimum, satisfy the requirements of References 20C.15 to 20C.17. In addition, for all SG pressure boundary components and services, the QA programme will be in compliance with the requirements of Reference 20C.18. Supplementary QA requirements are also identified in Table 20C-5.

The QA programme is to be supported by a clear auditable trail of records that are to be maintained as part of the manufacturing process. These are to be provided during the construction stage of the AP1000 plant to provide evidence that the manufacturing programme is compliant with QA requirements and the codes and standards applied in SG design and manufacture. The Design Specification identifies requirements for records to be maintained by the manufacturer that are to identify details of the following aspects:

- Weld procedures
- Heat treatment

- Material Records including CMTRs
- A certificate of compliance with Reference 20C.1, including deviation notices and non-conformance reports (NCRs)
- Manufacturing Inspections
- Dimensional checks
- Cleaning and contamination protection procedures

20C.3.1.6 Manufacturing and Pre-Service Inspections Confirm Quality of Manufacture

Manufacturing inspections and PSI includes NDE that are conducted to confirm the absence of structurally significant defects. These examinations are carried out according to well established and suitably rigorous techniques that provide a capability for detection of structurally significant defects that is commensurate with the structural reliability claimed for the SG component to which they are to be applied. Evidence to substantiate this claim is provided in Sections 20C.3.1.6.1 to 20C.3.1.6.3 as follows:

- Manufacturing and Pre-Service inspections meet or exceed the requirements of the ASME Code.

- NDE Qualification for HSS Components Ensures Suitably Rigorous Inspection.

- SG design facilitates effective NDE.

20C.3.1.6.1 Manufacturing and Pre-Service Inspections Meet or Exceed the Requirements of the ASME Code

As identified in Section 20C.3.1.4, experience shows that the materials used in the manufacture of the SG lead to a low frequency of defect occurrence. NDE applied at key stages in the manufacturing programme provide further evidence to demonstrate a low frequency of significant defects in forgings and welds.

The manufacturing inspection and PSI programme for the SG will include a diverse range of methods for NDE. A NDE programme is to be produced by the manufacturer to identify how the requirements of the ASME Code and the Design Specification (Reference 20C.1) will be satisfied. The plan will list components and weldments versus the type of NDE to be made. The manufacturer will provide a NDE Inspection Report for each required examination and will include the following in addition to the information required by ASME Code Section III, Section V, and Section XI:

- Fabricator's name
- Purchase order number
- Name of part and part identification number
- Method and procedure used
- Records of Examination Calibrations
- Results of examination
- Personnel qualifications

Any repairs made as a result of NDE findings are subsequently inspected using the same NDE method(s) that originally detected the defect leading to the repair.

NDE will be carried out only by personnel qualified and certified in accordance with the following:

- "Recommended Practice No. SNT-TC-1A, Non-Destructive Testing, American Society for Non-destructive Testing"

- ANSI/ASNT CP-189 "ASNT Standard for Qualification and Certification of Non-destructive Testing Personnel, as amended by ASME Section XI, IWA 2300 and ASME Section III, NB-5500."

NDE results will be interpreted only by personnel certified as Level II, IIa (ET only), or III.

Each of the heat transfer tubes, prior to installation, is to be subjected to a hydrostatic test in accordance with the requirements of ASME Section II SB-163, except that the hydrostatic test pressure will be in accordance with Reference 20C.12. All tubes exhibiting leakage will be rejected.

A gas leak test will be performed to confirm the integrity of the tube-to-Tubesheet welds. The tube-to-Tubesheet helium gas leak test is to be performed after tack expansion and tube welding but before liquid penetrant testing of the tube-to-Tubesheet weld and hydraulic expansion of the tubes.

Sensitive volumetric and surface NDE methods are applied at specified points in the manufacturing programme to ensure any necessary repairs are undertaken at the earliest possible stage and that any degradation resulting from processes such as PWHT is identified. Supplemental inspections, additional to those specified by ASME Section III, are performed that match the pre-service inspection and in-service acceptance criteria of ASME Section XI. Here the objective is to reconcile the difference in acceptance standards between ASME Section III and ASME Section XI and ensure that the PSI does not report rejectable defects that were not identified during the standard manufacturing NDE. The codes, standards and other requirements applied to the diverse range of NDE techniques for manufacturing inspection and PSI are summarised below:

Ultrasonic Testing (UT)

UT examination will be performed in accordance with the following requirements and the codes referenced in the Design Specification:

- Materials – ASME Section III, NB-2000

- Cladding – ASME Section III, NB-5000

- Welds – ASME Section III, NB-5000

- Thickness – ASME Section V, Article 5

- Pre-service Inspection – ASME Section III and ASME Section XI, IWA 2000, IWB 2000, IWC 2000

UT examination of the SG heat-transfer tubes is specified in Reference 20C.12. Cladding on surfaces of the Channel Head bowl, nozzles, manways, and the Tubesheet primary flat face will be UT inspected for 100% of the volume for bond, defects, and thickness by the straight beam method where accessible. Cladding on the steam outlet nozzle for venturi attachment will be UT inspected for bond and defects by the straight beam method. Clad thickness will be measured in accordance with a procedure that will be submitted to the designer for review

and approval. After welding of the divider plate to the Channel Head, the cladding beneath the divider plate will be inspected for lack of bond.

Magnetic Particle Inspection (MT)

MT will be conducted in accordance with ASME Code Section V, Article 7 and to the applicable sub-articles of Section III, Subsection NB-5000 of the ASME Code. In addition to ASME Code requirements, magnetic particle inspection is specified for the following components:

- Tubesheet forging
- Channel Head forging
- Nozzle forgings
- Nozzle to shell (if not integral) weldment
- Support bracket weldments
- Instrument connections (secondary) weldments
- Temporary attachment, after removal, weldments
- Accessible pressure-retaining welds after hydrostatic test

Eddy Current Test (ECT)

Each straight finished heat-transfer tube will be tested during manufacture but before bending in accordance with ASME Section III and Reference 20C.12. ECT of each finished U-bend tube will be examined along the entire tube length using the guidelines of ASME Section XI and Reference 20C.12. After expanding the tubes in the Tubesheet, a 100% inspection will be conducted to measure the inside diameter of each expanded tube throughout the entire thickness of the Tubesheet in order to assess the quality of the expansion operation. Periodic ECT of SG tubes during service is described in section 20C.3.4.2.

Radiography

Radiographic inspection and acceptance will be in accordance with ASME Code Section V, Article 2, except as modified by the requirements of ASME Code Section III, Subsection NB-5000 and as follows:

- Compliance with radiographic density limitations will be determined using calibrated densitometers and density strips.

- Fluorescent screens are not permitted.

- All production radiographs are to be reviewed and approved by the manufacturer.

- Film processing and storage practice will be identified in the radiographic procedure. Storage will be in accordance with the requirements of ANSI N45.2.9.

Liquid Penetrant Test

Liquid penetrant inspection of pressure boundary components will be performed in accordance with ASME Code Section V, Article 6 and to the applicable sub-articles of Section III, Subsection NB-5000 of the ASME Code. Liquid penetrant inspection of non-pressure boundary components will be performed in accordance with ASME Code Section V, Article 6 and to the applicable sub-article of Section III Subsection NB-5000 or NG-5000 of the Code. Liquid penetrant examination will be performed whenever radiography or UT examination of nonmagnetic material is required or when accessibility limitations prohibit the use of MT equipment in magnetic materials. In addition to ASME Code requirements, liquid penetrant examination is required for the following components:

- Weld deposited Tubesheet cladding
- Channel Head cladding
- Divider plate-to-Tubesheet weldment
- Divider plate-to-Channel Head weldment
- Weld deposit cladding

Visual Examination of Welds

Visual examinations will be in accordance with ASME Code Section III and the supplemental requirements and acceptance criteria specified in Reference 20C.1.

Pre-Service Testing

Upon completion of the ASME Section III hydrostatic pressure test (Section 20C.3.2.1) and prior to shipment of the SG assemblies, a baseline Pre-Service NDE programme is to be conducted. This will include volumetric UT and surface examinations of all welds requiring in-service inspection (ISI) as defined by Section XI of the ASME Code. The Design Specification defines the Weld Surface Requirements to facilitate these inspections.

20C.3.1.6.2 **NDE Qualification for HSS Components Ensures Suitably Rigorous Inspection**

HSS welds and forgings are identified in Table 20C-4. Qualified UT volumetric inspections are to be conducted on the HSS locations to provide a very high level of confidence that the SG enters service free of any structurally significant defects. The qualified inspections provide additional high reliability inspections at the end of all manufacturing stages and also generate a “finger-print” set of data against which future ISI results can be compared.

The requirement for qualified inspection of HSS locations is specific to the UK AP1000 Safety Justification and supplements the requirements of the design specification (Reference 20C.1). As described in Section 20C.3.3, target sizes for manufacturing defects for selected HSS welds have been derived from elastic-plastic fracture mechanics by calculating the end-of-life limiting defect sizes and fatigue crack growth in accordance with the R6 methodology.

NDE performed with well established UT techniques will provide a “detect and reject” capability that demonstrates a defect size margin (DSM) of 2 or greater. The basis for this is discussed in Section 20C.3.3. High reliability for these inspections will be demonstrated through qualifying aspects of the inspection system, including procedure, equipment, and personnel, using the principles specified in the European Network for Inspection and Qualification (ENIQ) methodology for qualification of nondestructive tests (Reference 20C.20). For each of the selected HSS locations, a manufacturing inspection plan

has been produced which provide the physical reasoning underpinning the claimed inspection capability. These are discussed in Section 20C.3.3.1.3 below. The manufacturing inspection plans were developed following a process (Reference 20C.36) which is based on the preparation of technical justifications described in ENIQ methodology. A process will be developed in due course to address parent material associated with HSS locations.

20C.3.1.6.3 SG Design Facilitates Effective NDE

The SG design has been assessed to satisfy ASME Code Section III requirements for inspectability, as reported in Reference 20C.19. The design of the SG includes enhancements to facilitate inspection, as described in Section 20C.3.1.1.2. Aspects of SG design to facilitate inspection include access arrangements for personnel and equipment, access for deploying angle beam UT to give full volumetric coverage and provision for access to as many inspection surfaces/scanning directions as possible. Requirements specifying the quality of surface finish to facilitate inspection are specified in Reference 20C.1.

The SGs permit access to tubes for inspection, repair, or plugging, if necessary. Tooling to install mechanical and welded plugs, tube repair sleeves, or effect other repair processes remotely can be delivered robotically. In addition, the SG includes features to enhance robotics inspection of SG tubes without manned entry of the channel head. These include a cylindrical section of the channel head, primary manways, and provisions to facilitate the remote installation of nozzle dams.

20C.3.1.7 Plant Operation and Maintenance

Detailed specification of the control of plant operation and maintenance is to be defined at the nuclear site licencing stage. Issues of safety with respect to generic design and design measures identified in this section demonstrate that well defined and conservative operating parameters will be established. These measures provide a foundation for subsequent definition of site-specific operating rules and maintenance controls. The SG design includes engineered protection against transgression of operating rules. The following aspects are addressed:

- Procedural Control of Thermal and Hydraulic Operating Parameters
- Control of water chemistry to minimise SG corrosion.
- Overpressure Protection.

Plant operating and maintenance procedures, records of operation and maintenance to confirm compliance with procedural controls, and the record and investigation of any transgression of operating parameters will form part of the site-specific QA programme to be specified subsequent to the GDA.

20C.3.1.7.1 Procedural Control of Thermal and Hydraulic Operating Parameters

Procedural controls of thermal and hydraulic operating parameters are defined to identify a safe operating envelope for the SG. Operating within these limits of pressure and temperature minimises the possibility of brittle fracture.

Pressure and temperature (P/T) limits for primary coolant are to be determined for each fluence period in a pressure and temperature limits report. Further details of the P/T limits for the RCS are provided in section 20A.2.1.7.1, and their derivation has been carried out in accordance with an approach defined in Reference 20C.21. Limiting conditions for operation

(LCOs) specify minimum requirements for ensuring safe operation of the plant. The following LCOs are relevant to the control of primary side P/T limits.

- LCO 3.4.3, "RCS P/T Limits"
- LCO 3.4.14, "Low Temperature Overpressure Protection (LTOP) System"
- LCO 3.4.2, "RCS Minimum Temperature for Criticality"

Operation within the LCOs ensures the plant is operated under analysed conditions and brittle failure of the reactor coolant pressure boundary (RCPB) is unlikely. In the event that these limits are exceeded, an evaluation must be performed to determine the effect on the structural integrity of the RCPB components. ASME Code, Section XI, Appendix E provides a recommended methodology for evaluating an operating event that causes an excursion outside the limits.

A Thermal-Hydraulic Design Data Report is produced at the manufacturing stage to describe expected performance of the SG at steady state from 0 to 100% power in design basis and best-estimate conditions.

20C.3.1.7.2 Control of Water Chemistry to Minimise SG Corrosion

Specification of primary coolant and feedwater chemistry is identified in Section 20C.3.1.2.2. The CVS provides a means for adding chemicals to the reactor coolant water and the SG Channel Head incorporates a CVS nozzle to facilitate chemical dosing of primary coolant. The chemicals perform the following functions:

- Control the pH of the coolant during pre-startup testing and subsequent operation
- Scavenge oxygen from the coolant during heatup
- Control radiolysis reactions involving hydrogen, oxygen, and nitrogen during power operations following startup

These functions serve to minimise the potential for degradation due to corrosion of SG primary side internal surfaces that are exposed to primary coolant. Details of the secondary chemistry are presented in Chapter 21.

20C.3.1.7.3 SG Design Includes Protection Against Over Pressurisation

Transgression of the procedural control of thermal and hydraulic operating parameters discussed in Section 20C.3.1.7.1 could potentially result in over pressurisation of the SG. The SG design includes engineered safeguards to provide diversity of protection against over pressurisation.

Reference 20C.1 specifies that relief devices are to be provided to limit the maximum primary and secondary side pressure to 110% of the design pressure. The relief devices, if necessary, may be located outside of the SG jurisdictional boundary so that the overpressure protection requirements of the SG are fully complied with and the safety relieving devices cannot be isolated from the SG during operation. The primary side overpressure protection will comply with ASME Code, Section III rules for Class 1 components and the secondary side overpressure protection with the equivalent rules for Class 2 components.

20C.3.2 Leg 2: Functional Testing

Functional testing provides confirmation that the high standards applied in SG design, fabrication and installation identified in Section 20C.3.1 result in an installed component that is fit for purpose. Evidence of planned pre-service testing, to demonstrate that the SG will enter service fit-for-purpose, is identified as follows:

- **Section 20C.3.2.1** Hydrostatic pressure tests are specified to verify that the SG is proofed against its design pressure.
- **Section 20C.3.2.2** An initial plant testing programme confirms functionality of the SG.

20C.3.2.1 Hydrostatic Pressure Tests are Specified to Verify that the SG is Proofed Against its Design Pressure

Pressure testing is specified to verify integrity of SG pressure boundaries at design pressure prior to operation. Hydrostatic pressure testing of both the primary and secondary sides provides assurance regarding the basic strength of the assembled SG, confirms the absence of gross manufacturing defects and provides early warning of any out of specification material properties. Details of the SG hydrostatic pressure testing requirements are specified in Reference 20C.1; these include testing of the heat transfer tubes, the primary side pressure boundary and the secondary side pressure boundary. At locations where defect tolerance may be dominated by thermal stresses additional assurance of structural reliability is provided by manufacturing and pre-service inspections to confirm the absence of structurally significant defects at start of component life (section 20C.3.1.6.1). In the case of the HSS components of the SG, these are qualified inspections supported by defect tolerance justifications (section 20C.3.3.1). The programme of hydrostatic testing specified for the SG is summarised below.

Hydrostatic pressure testing is planned for both the primary and secondary sides of the SG both at the end of the manufacturing process and following installation, before entering service. These are known as shop and field tests, respectively. For design purposes it is conservatively assumed that the SG will experience 10 cycles of these tests and these hydrostatic test cycles are included in the stress and fatigue analyses. Additional, lower-pressure primary side hydrostatic tests may be performed to meet the in-service inspection requirements of ASME Code, Section XI, Sub article IWB-5200. Four such tests are expected over the design lifetime. The increase in the FUF caused by these tests is covered by the primary-side leakage tests that are considered for design.

The manufacturer is required to conduct hydrostatic tests of the primary and secondary sides of the SGs in accordance with ASME Section III, Subsection NB of the ASME Code. Compliance with these well established rules for the proof testing of pressure vessels against design pressure provides a demonstration of structural reliability before the SG enters service.

The required hydrostatic test pressure of 1.25 times the design pressure for both primary and secondary sides will be applied for a minimum of 10 minutes. The pressure will then be reduced to the design pressure and held for at least four hours while the primary side or secondary side is examined for leaks. No tubes will be plugged before hydrostatic testing without prior written approval by the appropriate authority (normally the buyer).

The primary side hydrostatic test pressure is to be applied at metal and water temperatures high enough to ensure that the metal is at least 33°C above its nil-ductility transition

temperature. The nil-ductility transition temperature (T_{NDT}) is determined as an outcome of the material properties testing described in Section 20C.3.1.4.2. In no case will the hydrostatic test temperature be less than 21.1°C (70°F). The maximum primary side hydrostatic test temperature is 121.1°C (250°F). The temperature for the secondary side hydrostatic test will not exceed 82.2°C (180°F).

Controls on the chemistry of water used for hydrostatic tests and final equipment flushes are detailed in Reference 20C.1. A report will be provided by the manufacturer to confirm that the results of the hydrostatic test of the SG conform to the requirements of the ASME Code Section III.

Section 20C.3.1.6 describes the NDE to be conducted following the SG hydrostatic pressure tests. These are to ensure that the ASME Section XI pre-service examination acceptance criteria can be satisfied and confirm that the SG has sustained no significant damage as a result of the hydrostatic testing.

20C.3.2.2 An Initial Plant Testing Programme Confirms Functionality of the SG

Section 7.5 identifies an initial testing programme for AP1000 plant. The overall objective of the programme is to demonstrate that the plant has been constructed as designed, that systems perform consistent with the plant design, and that activities culminating in operation at full licensed power including initial fuel load, initial criticality, and power ascension are performed in a controlled and safe manner.

The pre-operational tests are applied to entire systems, rather than specific components. A series of start-up test procedures are also specified to confirm safe and controlled operation during activities culminating in operation at full licensed power. As is the case for pre-operational testing, these start-up tests are applicable to systems rather than individual components such as the SG.

The purpose of the RCS pre-operational testing is to verify that the as-installed RCS properly performs the following safety-related functions:

- Provide RCS pressure boundary integrity.
- Provide core cooling and boration in conjunction with the passive core cooling system.
- Measure process parameters required for safety-related actuations and safe shutdown.
- Measure selected process parameters required for post-accident monitoring.
- Vent the reactor vessel head.

Pre-operational testing of the RCS is also performed to verify that the system properly performs the following defence in depth functions:

- Provide forced circulation cooling of the reactor core in conjunction with heat removal by the SGs.

- Provide core cooling by natural circulation of coolant in conjunction with heat removal by the SG(s).

- In conjunction with the SG(s) and normal residual heat removal system, provide the capability to remove core decay heat and cool the reactor coolant to permit the reactor to be refuelled and started up in a controlled manner.

- Provide pressuriser pressure control during normal operation.

- Provide pressuriser level control in conjunction with the CVS.
- Provide pressuriser spray.

The purpose of the SGS pre-operational testing is to verify that the as-installed components properly perform the following safety-related functions:

- Provide SG isolation, including isolation of the main steam lines, feedwater lines, and blowdown lines.
- Remove heat from the RCS and provide secondary side overpressure protection.
- Measure process parameters required for safety-related actuations.
- Measure process parameters required for post-accident monitoring.

SGS pre-operational testing is also to verify that the as-installed components properly perform the following defence in depth functions:

- Provide heat removal from the RCS
- Provide overpressure protection for the SGs to minimise required actuations of spring-loaded safety valves
- Measure process parameters and provide actuation signals for the diverse actuation system

20C.3.3 Leg 3: Failure Analysis

Leg 3 of the safety case provides an assessment of the effects of through-life degradation mechanisms on potential manufacturing defects to show that such mechanisms will not threaten vessel integrity over the plant design lifetime. This goes beyond ASME design code requirements to provide a further demonstration of integrity for HSS components of the SG, specifically by recognising that flaws may be present following manufacture and demonstrating tolerance to them over the design lifetime of 60 years. The arguments supplement the Leg 1 aim of avoidance of defects, by the stringent control of quality of design and manufacture, to provide a safety case with both defect avoidance and defect tolerance.

20C.3.3.1 HSS Components of the SG are Tolerant to Manufacturing Defects for the Design Life of the Plant

This section describes the scope of the analyses undertaken as part of the GDA process to demonstrate that the SG is tolerant to potential defects that could remain undetected after manufacturing inspection. Evidence to demonstrate that the analyses substantiate the claimed defect tolerance of the HSS components is provided in this section as follows:

- The methods planned for defect tolerance assessment are well established.
- The defect tolerance assessments will adequately address through-life crack growth
- Defect tolerance assessments establish allowable start of life (SoL) defect sizes that are to be judged against the qualified examination defect size (QEDS).

20C.3.3.1.1 The Methods Planned for Defect Tolerance Assessment are Well Established

As discussed in section 20.6.4.2, the following sections describe the results of the R6 assessment for the SG and present a summary of the existing linear elastic fracture mechanics (LEFM) assessment carried out in accordance with ASME Code, Section III, Appendix G.

Assessment using the R6 Methodology

In combination with the use of rigorous manufacturing controls and inspection qualification, the defect tolerance assessment provides the necessary understanding to support the claim, to an appropriate degree of confidence, that the SG will enter service free from defects that could be of concern throughout the designed life. The approach to determination of the limiting defect size in a particular orientation and location and the maximum allowable SoL defect size is discussed in section 20.6.4.2. As has been stated in Reference 20C.23, the regulatory expectation is that a defect size margin of 2 will be achieved.

Phase 1: Weld Defect Tolerance and NDE Ranking

A detailed evaluation of selected, limiting weld locations has been made available to provide confidence that there are no regions of the SG where either low defect tolerance or low NDE inspectability would preclude the SG design from being able to satisfy regulatory expectations and support the safety claims for the SG. To evaluate those locations with the greatest risk of entering service with defect of structural significance, either as a result of small allowable SoL defect sizes or a large QEDS, a ranking exercise has been undertaken to consider, on a relative basis, the defect tolerance and the NDE inspectability at each of the AP1000 SG weld locations. The details of this evaluation are reported in Reference 20C.24 and provide the justification for selection of the following SG welds for assessment in Phase 2:

- Lower Shell Barrel A to Tubesheet
- SG Main Feedwater Nozzle to Shell
- Inlet Nozzle to Safe-End

Phase 2: Assessment of Bounding Locations

A limited number of locations were selected for more detailed evaluation in Phase 1. By examination of the primary and secondary loading, it is possible to present quantitative arguments to show that other regions are bounded by the locations that have been assessed. The justification that these locations bound other SG locations classified as HSS is established in Reference 20C.24.

For each of the selected locations, the R6 methodology (Reference 20C.22) was used to determine the defect size margin, which is the margin between the QEDS and the allowable SoL defect size. The allowable defect size is determined using the end of life limiting defect size (ELLDS) and the lifetime fatigue crack growth (LFCG). Details of the assessment methodology are provided in Reference 20C.26. Assessments have been carried out for defects both parallel and transverse to the weld. Material fracture toughness properties reflect the end of life and the supplementary testing described in Reference 20C.37 will be performed to underpin the values assumed. LFCG) was evaluated using appropriate upper bound crack growth laws.

As discussed in Section 20C.3.3.1.3, the results of the defect tolerance assessment can be used to inform an evaluation of the adequacy of the NDE capability at each of the highest ranked locations.

Phase 3: Assessment of Remaining Locations

The full defect tolerance assessment of the remaining HSS locations, including the selected locations in the parent material, will be carried out as part of subsequent assessments. Once completed, the R6 assessment work for the SG will provide assurance that the QEDS is based on a robust assessment of the maximum allowable SoL defect size with appropriate consideration of materials ageing and degradation and through life crack growth.

ASME Code, Section I III, Appendix G Linear Elastic Fracture Mechanics Assessment

The ASME Code, Section III, Appendix G, "Protection against Non-ductile Failure", presents a method for obtaining the allowable loadings to protect against non-ductile failure for ferritic pressure-retaining materials in Class 1 components. Although this approach is not considered sufficient in a UK regulatory context, the results of the assessment nonetheless provide a conservative assessment of defect tolerance which is recognised internationally.

The method given in Appendix G of the ASME Code, Section III is based on the principles of LEFM. At each evaluated location, a postulated defect is assumed. Typically, this is conservatively based on a quarter wall defect; although at certain locations, ASME permits smaller defects to be used. At each location, the mode-I stress intensity factor, K_I, produced by each of the specified loadings is calculated. Then, the summation of the K_I values due to primary and secondary stresses resulting from mechanical and thermal loading during normal, upset, and test conditions is compared to a referenced stress intensity factor, K_{IR}. This reference K_{IR} is the highest critical value of K_I allowed for the material and the temperature involved. An Appendix G assessment is specified in Reference 20C.1. The results of the Appendix G non-ductile failure evaluation are provided in Reference 20C.10. This confirms that the ASME requirements are satisfied.

20C.3.3.1.2 The Defect Tolerance Assessments will Adequately Address Through-life Crack Growth

As part of the R6 assessment the through life crack growth has been calculated in accordance with the procedures specified in the R6 procedure. This includes the use of suitable conservative crack growth rates appropriate to the reactor coolant environment. As discussed in Reference 20C.26, these are based on the ASME upper bound fatigue crack growth curves. These are considered to be conservative for modern steels with low sulphur content. The upper bound nature of these curves is supported by extensive testing worldwide.

20C.3.3.1.3 Defect Tolerance Assessments Establish Allowable SoL Defect Sizes that are to be Judged Against the Qualified Examination Defect Size

The results of the R6 defect tolerance assessments for the three limiting SG welds identified in Section 20C.3.3.1.1 are reported in Reference 20C.29. A limiting QEDS, i.e., that leading to a DSM equal or larger than 2, is calculated for one of two different defect aspect ratios according to flaw orientation. For flaws perpendicular to the weld axis, the QEDS is established for a defect aspect ratio of 2, since the potential length of flaws with that orientation is naturally limited by the weld width. For flaws oriented parallel to the weld axis, it is recognised that flaws with higher aspect ratios may potentially occur, and a defect aspect ratio of 6 is additionally considered in determining QEDS.

Reference 20C.29 reports the calculated limiting QEDS for the SG welds as follows:

Weld	Limiting QEDS (mm)	
	Aspect Ratio = 2	Aspect Ratio = 6
SG Primary Inlet Nozzle to Safe End	6	6
SG Lower Barrel A to Tubesheet	15	15
SG Main Feedwater Nozzle to Shell	15	10

Demonstrating the capability for qualified inspection of these SG welds is considered bounded by the inspection techniques defined and assessed for other AP1000 HSS welds as summarised below:

- Inspection qualification of the SG primary inlet nozzle to safe end weld is considered bounded by the inspection plan for the reactor pressure vessel (RPV) inlet nozzle to safe end weld (Reference 20C.30) where a QEDS surface/near surface defect height of 6mm (approximately 0.24 in) is technically justified. Both are dissimilar metal welds with a coarse-grained austenitic structure and both welds allow inspection access to both the inner and outer surfaces as well as the safe-end end face.

- Inspection qualification of the SG lower barrel A to Tubesheet weld is considered bounded by the inspection plan for the pressuriser (PZR) surge nozzle to safe end weld (Reference 20C.31) where a QEDS surface/near surface defect height of 5mm (approximately 0.2 in) is technically justified. The lower barrel A to Tubesheet weld is a ferritic weld joint between two ferritic forgings with no austenitic stainless steel cladding and good access to both the inner and outer surfaces for inspection techniques. The PZR surge nozzle to safe end weld is a dissimilar metal weld and difficult to effectively inspect. Inspection techniques can be applied in line with previous work associated with the Sizewell B manufacturing non-destructive test (NDT) inspections, the United Kingdom Atomic Energy Agency defect detection trials (DDT), qualified inspections used in Sweden and the US, and common industry approaches.

- Inspection qualification of the SG main feedwater nozzle to shell weld is considered bounded by the inspection plan for the PZR upper head to upper shell weld (Reference 20C.32) where a QEDS surface/near surface height of 10mm (approximately 0.4 in) is technically justified. Both welds are ferritic steel, however the main feedwater nozzle to shell weld does not have stainless steel cladding and benefits from greater accessibility for applying the inspection techniques.

The inspection plans identified above are considered to demonstrate that the capability exists to develop and justify suitable inspection techniques for the SG HSS welds, each to be qualified against a limiting QEDS, as determined by defect tolerance assessment, such that a satisfactory DSM (DSM $\geq$ 2) can be justified. Specific inspection plans for the SG HSS welds will be developed and validated as part of the future safety case development.

20C.3.4 Leg 4: Forewarning of Failure

Legs 1 to 3 of the safety argument identify measures aimed at the avoidance of defects at start of service and throughout component lifetime. Leg 4 provides additional assurance that structural integrity will be maintained by identifying measures to provide timely warning of any structurally significant defects that, in spite of the diverse measures identified in Legs 1 to 3, may be present at SoL or develop during service. The measures identified to provide forewarning of failure are intended to reveal component degradation before any defect could grow to an extent that may threaten the structural integrity of the SG, and thus enable corrective action to be taken to ensure that plant safety is maintained. ISI and detection of leakage provide forewarning of structural failure of the SG, as described below.

20C.3.4.1 Planned In-Service Inspection will Provide Forewarning of Failure

In order to provide assurance that any defects will be detected prior to becoming a threat to the structural integrity of the SG, a programme of ISI is planned. This provides a means of detecting degradation due to anticipated damage mechanisms, provides a means of monitoring any growth of known defects to provide assurance that these remain of a tolerable size, and also provide a contingency measure to detect defects that may unexpectedly arise as a result of unanticipated degradation mechanisms. Qualified techniques and operators are planned for inspection of the most safety-significant (HSS) locations of the SG to ensure that the measures to provide forewarning of failure at these locations are highly reliable. The aspects of the ISI programme described below provide evidence of effective arrangements to provide forewarning of failure:

- An extensive programme of ISI will identify any degradation long before failure.
- Qualified inspection of HSS welds provides highly reliable ISI.
- ISI provides data to monitor and judge in-service defect formation and growth.
- Planned locations for ISI are accessible and inspectable.

20C.3.4.1.1 An Extensive Programme of ISI will Identify any Degradation Long Before Failure

ISI is the preferred method for provision of forewarning of failure. The role of an effective ISI programme is twofold: firstly to detect and monitor anticipated degradation, and secondly to confirm the absence of any unanticipated degradation. ISI is used to confirm the absence of defects that could give rise to gross structural failure: such judgements are based on a comparison of the size of detected defects with a maximum tolerable defect size, as determined by fracture analyses (Section 20C.3.3), combined with a conservative assessment of in-service defect growth throughout the inspection interval.

To be effective, ISI requirements should be identified according to established good practice relevant to the characteristics of each inspection location. Evidence to substantiate that this is the case for the SG is provided in References 20C.27 and 20C.28, where, the proposed ISI arrangements for SG components are outlined to address the requirements of IWA-1400(b) and IWA-1500 of the ASME Code Section XI, supplemented where applicable by 10 CFR 50.55a. Reference 20C.27 identifies inspection requirements for ASME Class 1 components, and Reference 20C.28 identifies requirements for ASME Class 2 and

3 components. These references provide a statement of the inspection techniques, inspectability and access arrangements applicable to ISI for AP1000 NPP and do not constitute a fully developed Inspection Plan: this is to be developed by the utilities as part of the site-specific safety case following GDA.

Reference 20C.27 identifies inspection requirements for primary side SG locations based on those prescribed in ASME Code Section XI for Class 1 pressure retaining components, including the various types of welds, bolting, and heat-transfer tubing. Reference 20C.28 identifies inspection requirements for secondary side SG locations based on those prescribed in ASME Code Section XI for Class 2 components, including shell and nozzle welds.

The planned ISI programme includes the SG components and welds of importance to nuclear safety. A summary of the examination requirements for the SG, as identified in Reference 20C.19, is shown in Table 20C-10. ASME Code Section XI requirements are identified for each location, and relevant code cases are taken into account.

20C.3.4.1.2 Qualified Inspection of HSS Welds Provides Highly Reliable ISI

The ISI arrangements described in section 20C.3.4.1.1 are generic to AP1000 plant worldwide. This section describes supplementary or alternative ISI arrangements planned specifically for the AP1000 SG in the UK.

The Structural Integrity Classification for the SG components is shown in Table 20C-4. For the SG welds classified as HSS, qualified in-service-inspections are to be specified. This requirement, additional to the ISI described in the previous section, is specifically applicable to UK AP1000 plant only and represents a more onerous inspection regime than is applied elsewhere.

Qualified inspection is specified for the most safety-significant regions of the SG to provide the most robust demonstration that there are no defects of concern in these HSS components. The reliability of the ISI for HSS welds of the SG is to be qualified by applying the principles of the ENIQ Methodology as contained in Reference 20C.20.

Adherence to the ENIQ Inspection Qualification methodology provides evidence of good practice for ISI of HSS locations. Reference 20C.20 identifies how inspection requirements and performance objectives are laid down in an inspection specification and provides a method for Inspection Qualification based on technical justification of the inspection method and practical trials on simplified or representative test pieces resembling the component to be inspected. For each of the HSS locations, a qualified inspection plan will be produced which will provide justification for the claimed inspection capability. The qualified inspection plans, for both PSI and ISI, are to be developed following GDA.

20C.3.4.1.3 ISI Provides Data to Monitor and Judge In-service Defect Formation and Growth

In Section 20C.3.1.6.2 qualified manufacturing inspections of HSS welds are described. The resulting data constitute a “finger-print” against which ISI results can be compared. Comparison of ISI data with the manufacturing inspection fingerprint is used to confirm the absence of significant degradation or that build defects are stable i.e., defects detected during ISI must have started life as no greater than the manufacturing inspection validation defect size. Manufacturing inspections are to be performed using the same equipment that is likely to be used for the periodic ISI.

20C.3.4.1.4 Planned Locations for ISI are Accessible and Inspectable

For effective ISI, the SG design should accommodate requirements for inspection equipment and personnel access in accordance with current inspection technology and strategies. Aspects of SG design intended to facilitate effective pre-service and in-service inspection are discussed in Section 20C.3.1.6.3 and an inspectability assessment is provided in Reference 20C.19.

Reference 20C.19 establishes that provisions for inspectability are consistent with good practice, based on compliance with requirements set out in established codes and regulations including NCA-3200(r) of the ASME Code Section III, IWA-1400 and IWA-1500 of the ASME Code Section XI and 10CFR50.55a(g)(3)(i) and 10CFR50.55a(g)(3)(ii). Compatibility with the requirements of these elements of the ASME Code and Federal Regulations provides assurance that the ISI planned for the SG will be effective.

The inspectability assessment is based, in part, on ASME Code, inspectability and access requirements for ISI identified in References 20C.27 and 20C.28. These references address the inspection of SG pressure retaining welds, full penetration nozzle welds, pressure retaining dissimilar metal welds, pressure retaining bolting, pressure retaining welds in pump casings attached to the SG outlet nozzle and SG heat-transfer tubing. ISI requirements are identified as follows:

- Preferred or prescribed inspection technique(s).
- Surface finish requirements.
- Access for personnel and equipment for manual and/or mechanical inspection techniques.
- Access to welds to facilitate UT inspection of the full section.

20C.3.4.2 Diverse Systems are Provided to Detect, Locate and Monitor Leakage from the SG

ISI, as described in section 20C.3.4.1, is the preferred method of demonstrating forewarning of failure. Whilst leak detection and monitoring provide forewarning of failure, this safety argument does not seek to establish a quantitative case for excluding the gross failure of the SG as a result of this forewarning. The leak detection measures described in this section are provided as qualitative evidence of defence in depth in support of this leg of the safety argument. Leak detection provides warning of unforeseen or unexpected loss of coolant from the SG, and monitoring provides a means to confirm that any leakage of the coolant is kept within the limits specified in the technical specifications. To demonstrate that leaks of reactor coolant from the SG will be detected before they compromise plant safety, the following arguments are presented.

- Diverse systems are provided to detect leakage of primary coolant from the SG heat transfer tubes.

- Leak detection of the RCPB provides warning of reactor coolant leakage from the SG.

- SG design includes provision for in-service heat transfer tube monitoring and leakage tests.

20C.3.4.2.1 **Diverse Systems are Provided to Detect Leakage of Primary Coolant from the SG Heat Transfer Tubes**

An important potential identified leakage path for reactor coolant is through the SG heat transfer tubes into the secondary side of the SG. Identified leakage from the SG primary side will be detected by one, or a combination, of the following:

- High condenser air removal discharge radioactivity, as monitored and alarmed by the turbine island vent discharge radiation monitor.
- SG secondary side radioactivity, as monitored and alarmed by the SG blowdown radiation monitor.
- Secondary side radioactivity, as monitored and alarmed by the main steam line radiation monitors.
- Radioactivity, boric acid, or conductivity in condensate as indicated by laboratory analysis.

20C.3.4.2.2 **RCPB Leak Detection Provides Warning of Reactor Coolant Leakage from the SG**

The RCPB is monitored for leaks from the reactor coolant and associated systems as described in section 20.6.4.3.2. The leak detection system provides a means to detect and, to a limited extent, identify the source of the RCPB leakage and provides warning of leakage from all components of the RCS, including the SGs.

20C.3.4.2.3 **SG Design Includes Provision for In-service Heat Transfer Tube Monitoring and Leakage Tests**

The SG design includes provision for tests to detect tube leakage and tube-to-Tubesheet leakage. These tube leakage tests are to be carried out if necessary while the plant is in a cold shutdown state.

Steam generator tubing is subject to a variety of degradation mechanisms. Steam generator tubes may experience tube degradation related to corrosion phenomena, such as wastage, pitting, intergranular attack, and stress corrosion cracking, along with other mechanically induced phenomena such as denting and wear. These degradation mechanisms can impair tube integrity if they are not managed effectively.

Technical specification 3.4.18 of the generic Technical Specifications (Reference 20C.34) includes provisions for steam generator heat transfer tube integrity. Technical Specification 3.4.7 also imposes limits applicable to SG tube integrity. A SG Programme will be developed by the Licensee in accordance with Technical Specification 5.5.4 to manage steam generator integrity. Technical Specification 5.5.4 includes prescriptive criteria to ensure tube integrity that incorporate the good practice of NEI 97-06 and its referenced EPRI Guidelines (References 20C.35 and 20C.33).

Use of the SG Programme ensures that the inspection is appropriate and consistent with accepted industry practices. The SG Programme determines the scope of the inspection and the methods used to determine whether the tubes contain flaws satisfying the tube repair criteria. Inspection scope (i.e., which tubes or areas of tubing within the SG are to be inspected) is a function of existing and potential degradation locations. The SG Programme also specifies the inspection methods to be used to find potential degradation. Inspection

methods are a function of degradation morphology, NDE technique capabilities, and inspection locations.

The steam generators permit access to tubes for inspection, repair, or plugging, if necessary, per the requirements of the SG Programme.

A secondary side leakage test is performed after each opening of the secondary system to check closures for leakage. For design purposes, it is assumed that the steam generator secondary side is pressurised to just below its design pressure to prevent the safety valves from lifting. So that a secondary-side to primary-side pressure differential of 4.62 MPa (670 psi) is not exceeded, the primary side must also be pressurised. The 4.62 MPa differential is the steam generator design differential pressure for secondary-to-primary pressure. The primary system must be above the minimum temperature imposed by reactor vessel material ductility requirements (that is, between 120°F and 250°F (48.8°C and 121.1°C)). It is assumed that this test is performed 80 times for design purposes.

It may become necessary to check the steam generator for tube leakage and tube-to-Tubesheet leakage. This is done by inspecting the underside (channel-head side) of the Tubesheet for water leakage whilst the secondary side is pressurised. This would be done while the plant is shut down.

For this test, the secondary side of the SG is pressurised with water, initially at a relatively low pressure, and the primary system remains depressurised. The underside of the Tubesheet is examined for leaks. If any are observed, the secondary side is depressurised and the leaking tube is plugged. The secondary side is then re-pressurised (to a higher pressure), and the underside of the Tubesheet is again checked for leaks. This process is repeated until the leaks are repaired. The maximum secondary-side test pressure reached is approximately 5.792 MPa (840 psi) gauge.

During these tests, both the primary and the secondary sides of the SGs are at ambient temperatures. Neither the primary-side nor secondary-side design pressure is exceeded. The expected secondary-to-primary pressure differential exceeds the design value of 4.62 MPa (670 psi) for some of the test cycles. The following is a breakdown of the anticipated number of occurrences at each secondary side test pressure:

Test Pressure MPa gauge (psi)	Number of Occurrences
1.379 (200)	400
2.758 (400)	200
4.137 (600)	120
5.792 (840)	80

The total number of tube leakage test cycles is defined as 800 for design purposes. These tests are also accounted for in the design transients for ASME qualification of the RCPB components reflected in Table 20-22.

20C.4 Strength of the Safety Case

20C.4.1 Objective

SFRs for the SG, as given in Table 20-1, are identified in Section 20C.2.1. This report provides a safety argument which identifies evidence to substantiate that the SFRs of the SG will be maintained for all conditions within the design basis. This is achieved by demonstrating that the structural integrity of the SG will be maintained for all conditions within the design basis for a 60-year component lifetime.

The availability and reliability of the SFRs should demonstrably be commensurate with the significance of the radiological hazards to be controlled. This demonstration is achieved by a process of component structural integrity classification which, for the safety justification of each class of component, establishes the degree of rigour to be applied commensurate with the potential radiological consequences of any postulated gross failure mode.

As described in Section 20C.2.2, structural integrity classification of the components of the SG is identified in Table 20C-4; these have been determined according to a process detailed in Reference 20C.4. All welds and forgings of the SG shell, including both the primary and secondary sides, are classified as HSS components. As established in Reference 20C.4, this classification necessitates substantiation of a higher level structural reliability such that the probability of gross structural failure of these SG components is so low it can be discounted.

The structural integrity classification of all SG components, other than the shell welds and forgings, is Standard Class 1. A summary of the evidence presented in the safety argument to substantiate the structural reliability claims for the HSS and Standard Class 1 SG components is given in Section 20C.4.2. This summary and review of the safety argument provides the basis for the conclusions of this report which are presented in Section 20C.6.

20C.4.2 Evidence

It is necessary that the structural integrity of HSS components of the SG is substantiated to a higher degree of rigour than that required for the Standard Class 1 components. The four legged safety argument provides diverse evidence to substantiate the very high structural reliability claimed for HSS components; this evidence is summarised in section 20C.4.2.1. The evidence to substantiate the structural reliability claimed for Standard Class 1 components is effectively a sub-set of that presented in the four legs of the safety argument, as identified in section 20C.4.2.2.

20C.4.2.1 HSS Components

To substantiate the claim that gross structural failure of the HSS components of the SG can be discounted, a safety argument is presented in Section 20C.3. Various elements of sound engineering practice are identified which provide evidence that there is defence in depth against structural failure within the SG arrangement and design. The safety argument comprises four conceptually different legs, within each of which multiple subordinate arguments are supported by diverse sources of substantiating evidence. Robustness is achieved by considering the combined contribution from the four legs. In combination the four legs provide sufficient confidence that gross failure of the HSS components will not occur during normal operation, during design basis transient or fault conditions. The combined strength of the claims, arguments and evidence presented in Section 20C.3 is discussed in this section.

The safety argument is founded upon a high standard of manufacture sufficient to achieve an appropriately high level of structural integrity. Design and fabrication of the SG HSS components is to be in accordance with ASME Code, Section III, Class 1 requirements as a minimum. Supplemental requirements are identified that enhance the quality of SG design and fabrication beyond ASME Class 1 standards. These are detailed in Section 20C.3.1, where multiple arguments and supporting evidence to substantiate achievement of SG integrity are presented. Section 20C.3.1 includes claims, arguments and evidence to address the following aspects:

- The design is well founded and in accordance with internationally recognised standards. Design of PWR SGs is long established and Westinghouse has an established track record. The AP1000 SGs benefit from this historical experience which is embodied in the codes, standards and regulations applied in design and fabrication.

- Procurement of materials is specified and controlled to ensure that well proven materials are chosen, that the materials have good resistance to fracture and are of suitable chemical composition to limit the effect of through-life degradation mechanisms. SG materials comply with the corresponding material specification permitted by the ASME Code, Section II. Supplementary requirements are specified for the HSS forgings which exceed the requirements specified in the ASME Code. Materials testing is specified to confirm that material properties comply with the relevant specifications.

- Very high standards have been applied that control the quality of SG manufacture. HSS components will be manufactured by experienced suppliers and evidence to confirm the suitability of the chosen manufacturer will form part of the Site Specific Justification. Compliance with ASME III Class 1 requirements and the experience embodied within the Code provides high confidence in manufacturing quality. Supplemental requirements have been identified which enhance the standards applied in fabrication beyond those prescribed in the ASME Code. Approved welding procedures and qualified operators are used. Stringent QA arrangements control manufacturing procedures and records are maintained to provide a clear auditable trail that will confirm this. There are procedural controls to limit deviations from the design intent and all repairs and deviations will be recorded to confirm acceptability.

- The HSS components are designed in accordance with the requirements of the ASME Code, Section III for Class 1 components[4]. Consideration of Levels A to D and Test conditions encompass the design basis for the purposes of the analysis. The parameters used in the design evaluation are robustly determined using established and conservative procedures, as detailed in section 20C.3.1.2. Section 20C.3.1.3 describes the analyses that demonstrate compliance with stress and fatigue limits prescribed by the Code, and thus demonstrate fitness-for-purpose for the HSS components at SoL.

- Manufacturing inspections and PSI with appropriate levels of redundancy and diversity will confirm the absence of defects which have the potential for causing, or developing into a failure mode. This will be based on the calculated allowable SoL defect sizes determined using the R6 methodology. Where appropriate, the inspections are subject to independent validation and in the case of HSS components of the SG, a programme of

4. N.b. Secondary side components of the shell, including the Feedwater and Steam Outlet Nozzles, are assigned Class B AP1000 Equipment Classifications, which would normally correspond to ASME III Class 2. The construction of these components is, however, specified in accordance with the requirements applicable to ASME Class 1 components for conservatism.

qualified PSI is specified. These requirements exceed those prescribed by the ASME Code. In the unlikely event that defects are found, they will be repaired in accordance with accepted techniques.

The diverse evidence summarised above demonstrates that the HSS components will be designed and fabricated against well established and appropriate deterministic engineering rules, verified by application of rigorous inspections. The various elements identified establish defence in depth for preventing failure of structural integrity. Functional hydrostatic testing to demonstrate that the HSS components meet the design intent, as described in Section 20C.3.2, supplements the arguments to demonstrate achievement of SG integrity, ensuring that the SG enters service fit for purpose and free of safety-significant defects.

The measures established to ensure good design and construction are supplemented with additional claims and evidence to demonstrate continued structural integrity throughout the planned SG lifetime. Careful control of operating conditions enables the SG to fulfil its safety function for its projected lifetime. The controls that will govern plant operation and maintenance, in accordance with well established procedures, are described in section 20C.3.1.7. Section 20C.3.3 and Section 20C.3.4 provide evidence to substantiate SG integrity under all design basis conditions by demonstrating that any defect which may have gone undetected during manufacture will not cause failure during the lifetime of the plant. The elements that substantiate this claim are as follows:

- Fracture Analyses – The fracture analyses, comprising LEFM analyses, as per in Appendix G of ASME Section III, supplemented by elastic-plastic fracture mechanics procedures specified in the R6 Defect Assessment code, are described in section 20C.3.3.1. The fracture analysis demonstrates that the sizes of defect which are of safety concern are large in relation to those which could be present in the component following qualified NDT.

- Pre-Service and In-Service Inspection – The SG is designed to facilitate effective PSI and ISI, which provide assurance that defects will be detected long before growing to a size that could threaten structural integrity of the SG. Qualification of inspection methods for HSS locations establishes the sizes of defects that can be reliably detected, and provides more robust control of the efficacy of PSI and ISI than the requirements of ASME Section XI. Qualification is to be achieved through a combination of Technical Justification of inspection procedures and equipment, supported by trials. ISI data enables judgement of in-service defect formation and growth by comparison with PSI data.

- Leakage Monitoring – Diverse systems are provided to detect, locate and monitor leakage of reactor coolant from the SG, including leakage via the heat transfer tubes to the secondary side of the SG. Alarm and indication of reactor coolant leakage from the SG in excess of specified limits provides diverse means to detect failure. Periodic tests are planned to confirm the integrity of the primary and secondary side pressure boundaries.

20C.4.2.2 Standard Components

As asserted in Reference 20C.4, the failure statistics for industrial pressure vessels and piping that are built to according to the good practice embodied in modern codes and standards supports a failure rate to be inferred that is in accordance with the structural reliability target for Standard Class 1 (or lower classification) components. Substantiation of the structural reliability of the SG Standard Class 1 components is therefore largely based on demonstrating

compliance with relevant aspects of the ASME Code and with additional regulations as applicable.

General principles that ensure the quality of construction for all SG components are discussed in Section 20C.3.1. These are reinforced by a demonstration of adherence to the requirements of the ASME Code which establishes rules of safety governing the design, fabrication, and inspection of boilers and pressure vessels that are internationally recognised and well established. As identified in section 20C.3.1.1.3, the following sections of the ASME Code establish requirements governing aspects of SG design:

- Section II – Materials
- Section III – Rules for construction.
- Section XI – ISI

Materials of manufacture are discussed in section 20C.3.1.4, where it is established that all materials used in Standard Class 1 components are specified to be in accordance with the requirements of Section II of the ASME Code. In addition, the heat treatment specified for the heat transfer tubing exceeds the requirements of ASME Section II.

The requirements of ASME Code, Section III are identified on the basis of the ASME safety classification of a particular structure, system, or component. The components of the SG forming the reactor coolant pressure boundary are designed in accordance with the rules applicable to ASME Code, Section III, Class 1 components. The subcomponents of the SG performing ASME Class 2 functions are also designed in accordance with the rules applicable to ASME Code, Section III, Class 1 components, for conservatism. AP1000 Class D and AP1000 Class E components of the SG will be designed and manufactured to industry codes and standards. The applicable standards will be specified as part of the site-specific safety justification.

The integrity of the SG pressure boundaries, including the Standard Class 1 components that have a pressure-retaining function, is confirmed by the hydrostatic testing described in section 20C.3.2.1. Gas leak testing is conducted during manufacture to confirm the integrity of the tube-to-Tubesheet welds as described in section 20C.3.2.2.

The ISI requirements for the SG are described in section 20C.3.4.1.1. For the Standard Class 1 components included within the ISI programme, this will be in accordance with the requirements of ASME Code Section XI, IWB-2500 and IWC-2500, and supplemented by requirements specified in 10 CFR 50.55a. A SG programme described in section 20C.3.4.2.3 will dictate the periodicity of examinations for characterisation of tube wear, which will identify degradation and allow implementation of corrective action as needed while the plant is in a safe state. In addition to the planned ISI for Standard Class 1 components, forewarning of failure is also provided by leak monitoring, in particular to detect leakage of primary coolant from the SG heat transfer tubes (section 20C.3.4.2.1). In the event leakage at the heat transfer tubes or Tubesheet is suspected, a tube leakage test can provide indication of failed tubes or leaking tube-to-Tubesheet welds.

20C.5 Review of Open Issues

There are no open issues for the SG that may affect the basis of the safety case arguments.

20C.6 Conclusions

This CSR for the UK AP1000 SG design presents a safety argument to establish that the structural reliability of the SG is commensurate with the consequences of gross failure. SFRs have been identified for the SG. These are to be maintained to ensure plant nuclear and radiological safety. For the SG, assurance that SFRs will be maintained for the design life of the component is provided by substantiating structural integrity against appropriate reliability targets.

Structural reliability targets have been identified for the SG that are based on a procedure of structural integrity classification. Several components of the SG have been ascribed a classification of HSS, for which the highest level of structural reliability must be demonstrated. Other SG components are Standard Class 1, a classification that requires a somewhat less stringent and extensive substantiation of structural reliability.

The components of both the primary and secondary sides of the SG shell have been classified as HSS. The structural reliability target associated with HSS classification is to substantiate a probability of gross structural failure that is so low it can be discounted. The safety argument for the HSS components is presented in a four legged format that is well established in the UK for the safety justification of nuclear plant components similar to the SG that share similar structural reliability targets. The safety argument identifies diverse defence in depth measures to substantiate the structural reliability claimed for the HSS components of the SG:

- The intent and principles that govern the design, future manufacture and operation of the SG in the UK are identified to substantiate fitness for purpose within a pre-construction safety case. The safety argument demonstrates how modern and well established good practice is to be implemented in SG design, manufacture, defect tolerance assessment, and in the provision for through-life inspection.

- The SG design benefits from the long operating history and good safety record of similar components. The design incorporates measures to minimise frequency of failure which are based on substantial operating experience, and this has influenced the design for the SG, for example in terms of the materials selected, the choice of inspection techniques and selection of locations to be inspected. Much of this experience is embodied in the codes, standards and regulations that have been specified to ensure the quality of manufacture.

- Structural integrity of the HSS components is secured largely by passive means and is not significantly reliant on control systems, active safety systems or human intervention. As such, the diverse defence in depth measures identified focus on prevention of failure through conservative, robust design. Surveillance, inspection, leakage monitoring and periodic testing provide secondary defence in depth measures to detect and provide forewarning of structural failure. The SG design facilitates effective inspection which supports a programme of qualified inspection for the HSS components.

- Extensive QA measures covering aspects of design, manufacture, material specification, materials testing and inspection ensure a level of structural reliability that is commensurate with the consequences of gross structural failure of the HSS components. The strength of the safety case is founded on the achievement of integrity. Analyses are specified to deterministically justify the structural integrity of the HSS components of the SG in accordance with ASME Code Section III requirements for Class 1 components. Additional arguments specify robust analyses to provide evidence that

these components are tolerant to structurally significant defects, and this is supported by the qualified inspections.

The structural integrity classification of all other SG components has been determined to be Standard Class 1. The structural reliability target associated with this classification is less onerous than that for HSS components. Failure statistics for industrial pressure vessels and piping built in accordance with the good practice embodied in modern codes and standards are judged to support inference of a failure rate that is commensurate with the structural reliability target for Standard Class 1 components. Substantiation of the structural reliability of the SG Standard Class 1 components is thus based on demonstrating compliance with relevant aspects of the ASME Code. Evidence is presented within various elements of the four-legged safety argument to show that, as a minimum, the Standard Class 1 components of the SG comply with the relevant requirements of the ASME Code.

It is concluded that the safety argument presented in Section 20C.3 identifies a suitable and sufficient diversity of evidence to substantiate the structural reliability claimed for both the HSS and Standard Class 1 components of the SG.

20C.7 Index of Technical Reports

Table 20C-11 provides a list of technical references supporting the safety case and summarises the function of each document within the safety case. Codes, standards and regulations that will be applied to the design, manufacture and operation of the SG are identified separately in Table 20C-5.

Table 20C-1. AP1000 Steam Generator Nominal Design Parameters(3)

Type	Vertical U-tube Feedring
Number of tubes per SG	10,025
Heat Transfer Surface area per SG	11,477 m^2
Tube OD	17.48 mm
Tube wall thickness	1.02 mm
Tube ID	15.42 mm
Tube pitch	24.89 mm
Overall length of SG shell	22.45 m(1)
Upper shell I.D	5.33 m
Lower shell I.D	4.19 m
Channel Head thickness (base metal wall thickness)	254 mm
Tubesheet thickness (base metal vertical thickness)	791.4 mm
Primary side design pressure	17.24 MPa
Primary side design temperature	343.3°C
Secondary side design temperature	315.6°C
Secondary side design pressure	8.27 MPa
Primary to secondary maximum differential pressure	11.38 MPa
Secondary to primary maximum differential pressure	4.62 MPa
No Load Temperature	291.7°C
Primary water volume per SG	58.8 m^3
Water volume in plena	16.7 m^3
Water volume in tubes	42.2 m^3
Secondary water volume per SG(2)	103.2 m^3
Secondary steam volume per SG(2)	147.9 m^3
Secondary liquid mass per SG(2)	79,722 kg

Notes:

1. Measured from steam outlet nozzle to the flat, exterior portion of the Channel Head.
2. At full power design conditions. Actual volumes and masses are dependent on final design and operating conditions.
3. All dimensions are nominal. Construction tolerances apply.

Table 20C-2. AP1000 Steam Generator Material Recommendation

SG Sub-Component	Material
Heat Transfer Tubes(1)	SB-163 UNS N06690 Special Thermally Treated
Tubesheet	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Channel Head and Nozzles	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Transition Cone and Secondary Shell	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
AVBs	SA-479 Type 405 with SB-166 UNS N06690 end caps
Tube Bundle Wrapper	SA-516 Grade 70
Feedwater, Start-up Feedwater, and Steam Outlet Nozzles	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Blowdown/Drain Nozzle and Instrumentation Nozzles	SA-508 GR. 1A plus supplementary requirements S1, S2, S4, S10, S15
Tubesheet Cladding	SFA-5.11/SFA-5.14 Weld Metal, (ENiCrFe-7/ ERNiCrFe-7) (Primary Surface), and SFA-5.4/SFA-5.9 Stainless Steel (E308L, ER308L, E309L, ER309L) (Upstand region)
Access Opening Covers	SA-533 Type B Class 2
Channel Head Divider Plate	SB-168 UNS N06690
Stay Rods	SA-739 Grade B22
Feedwater Spray Nozzles	SB-167 UNS N06690
Feedwater Ring Assembly	SA-335 Grade P11 , SA-234 Grade WP11, SB-167 UNS N06690, SB-564 UNS N06690, SB-168 UNS N06690
Primary Moisture Separator Assembly	SA-516, Grade 70, ASTM A517/A514 Grade B, SA-36, SA-106 Grade B, SA-105
Secondary Moisture Separator Assembly	ASTM A36, ASTM A106 Gr. B, ASTM A234 Gr. WPB, ASTM 285 Gr. C, ASTM A516 Gr. 70
Steam Outlet Nozzle Flow Limiting Venturi (at Steam Outlet Nozzle Interface)	SB-564 UNS N06690 Forging
External Bolting (Bolts and Nuts)	SA-193 Grade B7 (Studs and/or Studs Bolts), SA-194 Grade 7 (Nuts)
Primary Inlet Nozzle Safe Ends	SA-336 Class F 316LN
PRHR Nozzle Safe End	SB-564 UNS N06690

Table 20C-2. AP1000 Steam Generator Material Recommendation (cont.)

SG Sub-Component	Material
Upper Elliptical Head	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Sludge Collector	SA-516 Grade 70, SA-36, SA-105, SA-106 Grade B
Upper Lateral Support	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Lower Shell Trunnion	SA-508 GR. 3 CL. 2 plus supplementary requirements S1, S2, S4, S9, S10, S15
Channel Head Cladding	Austenitic stainless weld deposited with SFA-5.9, ER309L/ER308L and SFA-5.4, E309L/E308L.
Pipe Whip Restraint	SA-533 Type B Class 2

Notes:

1. Heat transfer tubing will meet all of the requirements of Reference 20C.12.

Table 20C-3. AP1000 Steam Generator Interfaces

Table 20C-6. SG Equipment Classification#1 (Reference 20C.1)

Major Assembly or Part Description	AP1000 Equipment[1] Classification	ANSI Safety Class[3]	Seismic Design
Primary Side Pressure Boundary	Class A	SC-1	Cat. I
Tube-to-Tubesheet Weld	Class A	SC-1	Cat. I
Primary Channel Head Divider Plate	Class B	SC-2	Cat. I
Secondary Side[4] Pressure Boundary	Class B	SC-2	Cat. I
Tube Bundle Support Assembly	Class C	SC-3	Cat. I
Feedwater Nozzle[4]	Class B	SC-2	Cat. I
Instrumentation Tap[4]	Class B	SC-2	Cat. I
Steam Outlet Nozzle[4]	Class B	SC-2	Cat. I
Flow Limiting Venturi	Class B	SC-2	Cat. I
Primary & Secondary Separator Assemblies and Supports	Class D	NNS	Cat. II
Feedwater Ring Pressure Boundary Interface	Class B	SC-2	Cat. I
Feedwater Distribution Ring Assembly & Supports (Except Pressure Boundary Interface)	Class C	SC-3	Cat. I
Nozzle Dam Support Feature	Class C	SC-3	Cat. I
Lifting & Handling Lugs	Class E	NNS	N/A
Pipe Whip Restraint	Class B	SC-2	Cat. I
Anti-Vibration Bars	Class C	SC-3	Cat. I
AVB End Caps, AVB Retaining Rings, and AVB Retaining Bars	Class D	NNS	Cat. II
All Other Assemblies	Class E	NNS	N/A

Notes:

1. For those items designated with Equipment Classification as Class D&E (Non-Nuclear Safety) the design, material, fabrication, inspection and testing will be to industry codes and standards.
2. Not used.
3. The safety classification is based on ANSI-51.1. Compliance with safety classification requirements is demonstrated if the assembly or part meets the same level of Code classification or a more stringent level.
4. The secondary side is classified as Class B. However, all pressure retaining components on secondary side will be designed to ASME Code, Section III, Class 1 (AP1000 Equipment Classification – Class A) requirements.

Table 20C-7 SG Equipment Classification#2 (Ref. 20C.1)

AP1000 Code Letter[1]	ANS Equipment Safety Class[2]	RG 1.29 Seismic Design Requirements	ASME Code, Sec. III Class[3]	IEEE Requirements	RG 1.26 NRC Quality Group[4]	10 CFR 50 Appendix B[5]	Inspection & Testing Requirements	Required Test & Maintenance
A	SC-1	I	1	NA	GROUP A	YES	YES[6]	See Note 7
B	SC-2	I	2	NA	GROUP B	YES	YES[6]	See Note 7
C	SC-3	I	3	1E	GROUP C	YES	YES[6]	See Note 7
D	NNS[2]	N/A	N/A	N/A	GROUP D	NO	YES[8]	See Note 8
E	NNS[2]	N/A	N/A	N/A	N/A	N/A	N/A	N/A
N/A – Not Applicable								

Notes:

1. A single letter equipment classification identifies the safety class, quality group, and other classifications for AP1000.
2. AP1000 safety classification is an adaptation of that defined in ANSI 51.1. The NNS defined in the ANSI 51.1 standard is divided into several AP1000 equipment classifications namely, Classes D, E, F, L, P, R, and W.
3. ASME Code, Section III defines various classes of structures, systems and components (SSCs) for NPPs. It defines criteria and requirements based on the classification.
4. The quality group classification corresponds to those provided in Regulatory Guide 1.26.
5. "Yes" means QA programme is required according to 10 CFR 50 Appendix B. "No" means QA programme is not required according to 10 CFR 50 Appendix B.
6. Class A, B, and C structures, systems, and components built to ASME Code, Section III, are inspected to ASME Code, Section XI requirements.
7. Class A, B, and C structures, systems, and components that are required to function to mitigate design base accidents have some testing requirements included in the plant technical specifications. In addition to the requirements in the technical specifications, testing and maintenance requirements are included in an administratively controlled reliability assurance plan.
8. Class D SSCs determined to be risk important have selected technical requirements programme requirements and procedures to assure defence in depth availability. Class D SSCs not identified as risk important have select reliability assurance programmes and procedures to ensure reliability where needed. These programmes are administratively controlled programmes and may be included in the technical requirements manual or general availability controls manual, as appropriate.

Table 20C-8 Design Loading Combinations Applicable For Steam Generator

Condition	Design Loading Combinations[10]	Notes
Design	P + DW + DML + XL[11]	DML may include normal vibration loading/bldg settlement. XL contains max thermal for service levels A.
Level A Service	PMAX[1] + DW + XL[3]	Normal 100% power operating condition pressure and thermal (XL).
	PMAX + DW + DN + XL[6]	Max level A loadings of coincident pressure, thermal (XL) and normal dynamic
Level B Service	PMAX + DW + DU + XL[6]	DU is service level B dynamic (if applicable)
Level C Service	PMAX + DW + DE + XL[6]	DE is service level C dynamic (if applicable)
	PMAX + DW + DY + HYDSP + XL[7]	DY, HYDSP, and XL (thermal) are loads associated with ADS sparger discharge
Level D Service	PMAX + DW + DF + XL[6]	DF is some other dynamic level D event (other than SSE or DBPB) with corresponding level D thermal (XL) If no other level D dynamic then evaluate thermal faulted without dynamic
	PMAX + DW + SRSS((SSE + SSES) + DBPB)[5] + XL[3]	This case uses normal operation thermal for XL
	PMAX + DW + RVOS + SRSS(SSE + SSES)[5]+ XL[9]	This case uses thermal loads for XL associated with RVOS condition
	PMAX + DW + DYS + DBPBS + SRSS((SSE+ SSES)[5] + DY + HYDSP) + XL[7][8]	XL for this case corresponds to thermal associated with the long term steady state pipe break condition

Table 20C-8 Design Loading Combinations Applicable For Steam Generator (cont.)

Condition	Design Loading Combinations(10)	Notes
Test	P + DW + DML	DML may include normal vibration loading/bldg settlement.

Notes:

1. The values of PMAX in the load combinations may be different for different levels of service conditions as provided in the design transients. For earthquake loadings PMAX is equal to normal operating pressure at 100% power.
2. Not used.
3. In combining loads, the timing and causal relationships that exist between PMAX, and XL, are considered for determination of the appropriate load combinations.
4. Not used.
5. For components that behave as anchors to the piping system, such as equipment nozzles, SSE and SSES are combined by absolute sum. For other components, such as straight pipe, tees, and valves, SSE and SSES are combined by SRSS method.
6. In combining loads, the timing and causal relationships that exist between PMAX, DN, DU, DE, DF, and XL, are considered for determination of the appropriate load combinations.
7. In combining loads, the timing and causal relationships that exist between PMAX, DY, HYDSP, and XL, are considered for determination of the appropriate load combinations.
8. In combining loads, the timing and causal relationships that exist between PMAX, DY, and XL, are considered for determination of the appropriate load combinations.
9. In combining loads, the timing and causal relationships that exist between PMAX, RVOS, and XL, are considered for determination of the appropriate load combinations.
10. 10% SSE is used as the allowable load for the unknown loads defined for each service level (DML, DN, DU, DE, DY + HYDSP, DF, RVOS, and DYS + SRSS(DY+HYDSP) loads). For the Level A and B conditions, 10% SSE is assumed to have an infinite number of cycles.
11. Thermal loads are combined with Design Condition loads for inside the limit of reinforcement, as specified in subsection NB of the ASME Code.

Table 20C-9 Load Nomenclature

Load	Description
P	Internal design pressure.
PMAX	Peak pressure.
DW	Dead weight.
DML	Design Mechanical Loads (other than DW). This includes Service Level A loads and RVOS loads that are Service Level B.
XL	External mechanical loads, such as the nozzle reactions associated with piping systems, will be combined with other loads in the loading combination expressions.
SSE	SSE (inertia portion).
FV	Fast valve closure.
RVC	Relief/safety valve – closed system (transient).
RVOS	Relief/safety valve – open system (sustained).
RVOT	Relief/safety valve – open system (transient).
DY	Dynamic load associated with various service conditions including FV, RVC, and RVOT is applicable (transient).
DN	Dynamic load associated with Level A (Normal) service conditions including FV, RVC, and RVOT as applicable (transient).
DU	Dynamic load associated with Level B (Upset) service conditions including FV, RVC, and RVOT as applicable (transient).
DE	Dynamic load associated with Level C (Emergency) service conditions including FV, RVC, and RVOT as applicable (transient).
DF	Dynamic load associated with Level D (Faulted) service conditions during which, or following which, the piping system being evaluated must remain intact including FV, RVC, and RVOT as applicable. This includes postulated pipe rupture events (transient).
DYS	Dynamic load associated with various service conditions (sustained).
SSES	Seismic anchor motion portion of SSE.
ES	Seismic anchor motion of earthquake smaller than SSE.
DBPB	Design basis pipe break, includes LOCA and non-LOCA (transient).
HYDSP	Building structure motions due to automatic depressurisation system sparger discharge.
DBPBS	Design basis pipe break, includes LOCA and non-LOCA (sustained).
SRSS	Square root of the sum of the squares (mathematical operator).

Table 20C-10 Summary of Examination Requirements for the Steam Generator

Description	Examination Method		
	Volumetric	Surface	Visual
Primary Side			
Tubesheet to Channel Head weld	X	–	–
Inlet nozzle inside radius section	See Note 1	–	See Note 1
Outlet nozzle inside radius section	See Note 1	–	See Note 1
PRHR nozzle inside radius section	See Note 1	–	See Note 1
Inlet nozzle to safe end butt weld	X	X	–
Outlet nozzle to RCP casing butt weld	X	X	–
PRHR nozzle to safe end butt weld	X	X	–
Studs and nuts	–	–	X
CVS nozzle to Channel Head weld	–	X	–
Pressure retaining boundary	–	–	X
SG heat transfer tubing	X	–	-
Secondary Side			
Elliptical head knuckle to upper shell weld	X	–	–
Tubesheet to lower shell weld	X	–	–
Start-up feedwater nozzle to shell weld	X	X	–
Start-up feedwater nozzle inside radius section	See Note 3	–	–
Main feedwater nozzle to shell weld	X	X	–
Main feedwater nozzle inside radius section	X	–	–
Steam outlet nozzle inside radius section	See Note 2	–	–
Welded attachments(4)	–	X	–

Notes:

1. Inspection requirements allow for substitution of volumetric examination with enhanced magnification visual examination.
2. The main steam outlet nozzle is not considered to have an inside radius section. It is integrally forged with elliptical head.
3. IWC-2500 excludes this examination; only applicable to nozzles having NPS > 12.
4. Associated with the full penetration welded intermediate and upper lateral support trunnions and support pads respectively.

APPENDIX 20D
MAIN STEAM LINE

20D.1 Introduction

This is the component safety report (CSR) for the AP1000 main steam line (MSL) as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the MSL to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by identification of a suite of documentary evidence outlined in Section 20D.5 regarding the quality of design, manufacture, installation and operation of the MSL.

20D.1.1 Scope

This report addresses all nuclear and radiological hazards potentially arising from gross structural failure of the MSL for the entire design lifetime objective of 60 years. Conventional hazards to personnel safety are outside the scope of this Appendix 20D.

This assessment is limited to the piping running from the steam generator (SG) steam outlet nozzle to the Line 11 anchor point on the Auxiliary Building wall where the piping is connected to the main steam system (MSS). The scope does not include any other components of the steam generator system (SGS), MSS or any other systems. The physical boundaries of the MSL are identified in Section 20D.1.6.

The scope of this report is restricted to consideration of those pressure, temperature, and mechanical loadings within the design basis. The design basis includes normal operating conditions, anticipated transients, and postulated accident conditions.

20D.1.2 Objectives

This CSR supports that the claim that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. For the purposes of the structural integrity assessment, this claim is substantiated by satisfying structural integrity safety design bases for all safety-significant systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for the MSL are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the MSL are identified in Section 20D.2.1.

20D.1.3 Interface with other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data, specifications and analyses. These are listed in the Technical Index (Section 20D.5).

20D.1.4 Main Steam Line Description

The MSL is part of the SGS, which supplies steam to the MSS and subsequently to the main turbine system (MTS) over a range of flows and pressures covering the entire operating range from system warmup to maximum calculated turbine conditions at full power operation. There are two MSLs in the AP1000 plant. Each MSL is routed from the top of its respective SG, dropping to a horizontal run below the containment operating deck. From there, the

MSLs separately penetrate the containment vessel (CV) and are each routed through their own physically separated main steam and feedwater isolation valve compartment in the auxiliary building to the pipe anchors located at the structural interface between the auxiliary building and the turbine building (Wall 11), where the MSL terminates into the MSS piping. Each MSL within the SGS has one main steam isolation valve (MSIV), six main steam safety valves, one power-operated relief valve (PORV), and one PORV block valve.

Key system pressures, temperatures and flowrates are given in Table 20D-1. A sectional elevation of the nuclear island is shown in Figure 20D-1, where the MSLs can be seen running from the top of the steam generators. A general arrangement of the nuclear island is provided in Reference 20D.1 which shows the MSL pipework running through the containment penetration in the containment vessel, and into the individual MSIV (main steam isolation valve) compartments. Isometric drawings of both MSLs are given in References 20D.2 to 20D.9. Figure 20D-2 shows a detailed view of the containment penetration. This includes bellows to minimise piping loads applied to the CV and a guardpipe to protect the bellows and to prevent over pressurisation of the containment annulus in a postulated pipe rupture event. Similar features are present on feedwater penetrations.

The MSL pipe is 965 mm (38") nominal outside pipe diameter with 44.2 mm (1.74") minimum wall thickness after American Society of Mechanical Engineers (ASME) allowable wall thickness is adjusted for bending. The MSL is manufactured from the ASME SA-335 Gr P11 seamless ferritic alloy-steel pipe for high temperature service. The MSL is fabricated from various pipe lengths using the tungsten inert gas (TIG) method (known as gas tungsten arc welding (GTAW)) in the US).

Codes and standards utilised in the design of the MSL are applied according to the AP1000 equipment class of the component. The MSL piping is designed in accordance with relevant requirements of the ASME Boiler & Pressure Vessel Code (Code), Section III, as discussed in Section 20D.3.2. Schematics of MSL Loops A and B are shown on the Steam Generator System piping and instrumentation diagram (P&ID) in Reference 20D.10 and 20D.11.

20D.1.5 Function

The SGS (and hence MSL) is required during start-up and operation at power, to remove the heat produced by the reactor core; and also in the initial phase of shutdown operation before the normal residual heat removal system can be connected, to remove the decay heat from the reactor core. The heat sinks are provided either by venting steam to the atmosphere or by the turbine bypass system dumping steam to the condenser. Each MSL passes through the containment boundary.

The system is provided with a MSIV and associated MSIV bypass valve on each MSL from its respective SG. These valves are located outside the containment boundary and provide the ability to isolate the secondary side of each SG to prevent the uncontrolled blowdown of more than one SG, and also to isolate downstream portions of the system. Also located in each MSIV compartment are the six (6) main steam safety valves; every one of these safety valves vents to atmosphere through two discharge pipes and vent paths. The safety valves are spring operated and are designed to ensure that the pressure limitations of the SG, and subsequently the MSL, are not exceeded. Downstream of the safety valves is the power-operated atmospheric relief valve, which vents to atmosphere through a vent pipe and silencer. The operation of the power-operated relief valves is automatically controlled by steam line pressure during plant operations: the power-operated relief valves automatically modulate open and exhaust to atmosphere whenever the steam line pressure exceeds a

predetermined set point; as steam line pressure decreases, the relief valves modulate closed. Their capacity is sufficient to exhaust the steam produced during any design basis initiating event before the pressure rise threatens the integrity of the steam generator or the MSLs. They also provide defence-in-depth safety by cooling down the SGs and the reactor coolant system (RCS) in conjunction with the power-operated atmospheric relief valves when the condenser is not available. Each MSL is anchored at the point where it passes through the wall between the auxiliary building and the turbine building; the section of it from the SG to the anchor has sufficient flexibility to accommodate thermal expansion. Beyond this wall the two MSLs are cross-connected into a common header, which itself subsequently branches into four lines to the turbine stop valves; the connections to the two moisture-separator reheaters, the gland sealing system and the turbine bypass are also in this common header.

A postulated gross failure of MSL piping has been considered to establish appropriate structural reliability targets. Such failure could also result in consequential damage to nearby SSCs, through pipe whip, explosion or missiles. The layout configuration and material of construction of the MSLs are designed to maintain low pipe stresses in these areas. Thus, pipe rupture restraints are not required, and the loop is analysed for pipe ruptures only for small auxiliary lines.

20D.1.6 Boundaries

The physical boundaries for safety case assessment of the MSL, are identified below:

- SG steam outlet nozzle safe end weld;
- Circumferential girth weld to MSS piping at Line 11.

20D.2 Safety Case Requirements

As identified in Section 20D.1.2, the principal objective of this CSR is to demonstrate that the SFRs allocated to the MSL piping, established in Section 20D.2.1, will be maintained for all conditions within the design basis. This objective is to be achieved by substantiating the structural reliability of each component of the MSL piping against targets that are commensurate with the consequences of gross failure of that component. These targets are determined by means of a United Kingdom (UK) AP1000 component structural integrity classification process as described in Section 20D.2.2, where structural reliability targets for all MSL piping components are identified. The safety argument presented in Section 20D.3 identifies evidence to support the following nuclear safety claims for the MSL piping.

Claim:	**High quality is achieved through good design and manufacture.**
Objective:	Provides evidence of good design and manufacture based on established design and manufacturing processes and use of proven materials. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with an objective of achieving quality of build and the avoidance of defects.
Claim:	**Good design is achieved through compliance with ASME.**
Objective:	Incorporates the build experience as embodied in the design codes.
Claim:	**Components are tolerant to through-life degradation over the design life of the plant**
Objective:	Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval.

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure.

The elements of the safety argument are provided in Section 20D.3 and the strength of the argument is discussed in Section 20D.4.

20D.2.1 Safety Functional Requirements

The pre-construction safety report (PCSR) identifies structural integrity safety design bases for AP1000 SSCs. These are requirements of plant systems, some duty, some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. As identified in Table 20-1, the MSL is allocated the following SFRs:

SFR 20.5.1 The MSL is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation and under design basis faulted conditions for the design life of the plant.

SFR 20.5.2 MSLs are required to exhibit leak behaviour in the event of a through wall defect developing (defence in depth).

SFR 20.5.3 The pipework in the vicinity of the containment penetrations is required to maintain the integrity of the pressure boundary during standby, normal operation and under design basis faulted conditions for the design life of the plant.

SFR 20.5.4 The pipework in the vicinity of the containment penetrations above 50 mm (2 in) is required to exhibit leak behaviour in the event of a through wall defect developing (defence in depth).

The associated MSL containment penetrations also form part of the CV and the following relevant SFR for the containment penetrations applies from the performance and safety design bases allocated to the CV, as follows:

SFR 20.9.1 The CV is required to provide a leak tight barrier against the uncontrolled release of radioactivity to the environment under postulated accident conditions for the design life of the plant and to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

Postulated failure modes which result in a loss of these SFRs lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20D.2.2. The safety argument in Section 20D.3 is provided to establish that structural integrity of the MSL and associated containment penetrations will be maintained for all conditions within the design basis and thus demonstrate that all of the above SFRs will be maintained at all times.

20D.2.2 Main Steam Line Structural Integrity Classification

Key to the MSL structural integrity safety case is the clear understanding of the potential radiological consequences of any postulated gross failure mode. Based on this understanding, a structured and systematic basis can be established for setting the level of rigour applied during the design assessment, material procurement, fabrication, in-manufacture inspection, testing and in-service testing, maintenance, inspection and safety case assessment of the component. Details of the approach for developing AP1000 component structural integrity safety cases are given in the 'UK AP1000 Structural Integrity Classification' report at Reference 20D.13.

The approach to structural integrity classification is consistent with the overall AP1000 safety classification scheme as detailed in Chapter 5. In this, three broad classifications for UK SSCs are defined, requiring judgment to be made with respect to the component's importance to safety, these are defined as Class 1, Class 2 and Class 3. In practice, for the MSL and other AP1000 components, this classification scheme is too coarse to determine component structural integrity requirements, since Class 1 covers a very broad range of initiating event frequencies and consequences and hence a commensurately broad range of structural reliability targets. Reference 20D.13 details the approach taken whereby a more detailed assessment of selected individual components is made to establish the consequences of gross failure, due to both direct consequences such as a loss-of-coolant accident (LOCA), and indirect consequences, such as the effect of missiles, jet loading or pipe whip on essential safety systems. Based on this, and in accordance with the scheme identified in Reference 20D.13, components are ascribed one of the following five structural integrity classifications:

- Highest safety significance (HSS)
- High integrity (HI)
- Standard Class 1
- Standard Class 2
- Standard Class 3

The unmitigated direct consequences of gross failure of the MSL have been assessed in Reference 20D.13 and gross failure of the MSL is analysed within the design basis main steam line break (MSLB) and is protectable without core damage and does not result in over-pressurisation of the containment. A failure of the MSL (MSLB) is analysed at hot zero power (section 9.1.5) and at full power (section 9.1.6) to demonstrate the event can be mitigated without core damage. The analysis of the peak containment pressure incurred due to a MSLB is provided in Section 9D.3. However, considering the possible indirect consequences, there is potential for pipe whip since pipe supports are not specifically designed to prevent this. A review based on detailed interrogation of 3D models indicated that damage to containment as a result of pipe whip is not credible. The potential for pipe whip of the casualty line to rupture the non-casualty MSL leading to a double MSLB was also evaluated. The double MSLB is outside the design basis and could lead to core damage and over-pressurisation of the containment, which consequently could lead to the most severe off-site consequences against which there is no claimed protection. However, evaluation of the potential for a double MSLB due to pipe whip determined the geometry does not allow for pipe whip of the casualty line to affect the non-casualty line. As such, the MSL inside containment is classified as a Standard Class 1 component.

Other parts of the MSL lie outside containment in the MSIV. Failure of the MSL is analysed within the design basis MSLB. Flow restrictors in the outlet nozzle on the SG serve to limit the magnitude of the resulting plant transient and hence the direct consequences of an MSLB

would not lead to unacceptable radiological consequences. The wall between the MSIV compartment and the main control room, and the floor slab between the MSIV compartment and the Class 1 electrical equipment room are evaluated for pipe whip and jet impingement loads for worst case breaks in either the MSL or the main feedwater line due to their proximity to the main control room and Class 1 electrical room. UK Class 1 equipment inside containment is protected against the indirect consequences of an MSLB that occurs outside containment. Indirect consequences from a gross failure of a main steam line have the potential to affect the equipment upper elevations of the auxiliary building. The loss of equipment in the upper elevations of the auxiliary building would not affect the passive system used to put the plant in a safe shutdown condition should an event occur. Additionally, supplemental deterministic design controls are required which include additional analysis, design criteria, fabrication and construction criteria, and in-service inspection criteria.

On the basis that unacceptable consequences would not occur, the MSL and feedwater line in the MSIV compartments outside containment are classified as Standard Class 1 components, but they are subject to supplemental deterministic design controls.

20D.3 Safety Argument

For a Standard Class 1 component, the primary safety argument is that design and manufacture in accordance with the ASME Code provides the basis against which adequate structural reliability can be claimed for a Standard Class 1 component. The basis of the safety case for the MSL is, therefore, the arguments and evidence to substantiate the following claims.

- Claim 1: High quality will be achieved during manufacture (Section 20D.3.1).
- Claim 2: Good design is achieved through compliance with ASME (Section 20D.3.2).
- Claim 3: In-Service Degradation is Avoided (Section 20D.3.3).

20D.3.1 High Quality is Achieved During Manufacture

The design, manufacture and inspection of the MSL piping and welds will accord with the appropriate requirements of relevant sections of the ASME Code. This demonstrates that the measures applied to achieve a high quality of build and the avoidance of defects are suitably robust and appropriate to the safety classification of the piping.

To ensure that there is a high degree of control over the achievement of high quality during manufacture, the following controls on the manufacturing records and procedures are specified in References 20D.15 (for shop fabricated piping) and 20D.14 (for field fabricated piping and installation) as part of the piping design specification.

Materials Specification

The materials specified for the different parts of the main steam piping from the SGs to the turbine stop valves is presented below.

Description of Main Steam Piping	
Segment	**Material Specification**
SG outlet to containment penetration	SA-335 Gr. P11 seamless pipe
Containment penetration to MSIV	SA-335 Gr. P11 seamless pipe
MSIV to auxiliary/turbine building wall	SA-335 Gr. P11 seamless pipe

The AP1000 MSL materials comply with the corresponding material specification permitted by the ASME Code, Section III, Division 1. All ASME III material will be manufactured in accordance with the ASME II material specifications included in the 1998 edition, 2000 Addendum of ASME II.

The mechanical testing requirements for each material are contained within the relevant material specifications. For the MSL these will be carried out in accordance with ASME III Section NC-2000.

Code Class 2 pressure retaining material, except as exempted by NC-2311, will be impact tested and accepted in accordance with NC-2300. Code Class 3 pressure retaining material, except as exempted by ND-2311, will be impact tested and accepted in accordance with ND-2300. The acceptance standards for both Class 2 and 3 piping tests will satisfy the applicable lowest service temperature requirements as per NC-2332 and ND-2332.

Materials for parts within the jurisdiction of the ASME Code will have certified material test reports clearly presenting the results of all ASME Code required testing. All other materials will be designed to be certified as required by the applicable material specifications, but as a minimum by a certificate of compliance.

Bending Procedures

Prior to bending any of the piping being undertaken copies of the manufacturer's bending procedures, including qualification test results for ASME III Piping for each material to be bent will be submitted to Westinghouse. Bending will not be started until the Contractor's bending procedures are approved.

Heat Treatment after Bending or Forming

Heat treatment procedure will be submitted for review by Westinghouse prior to the start of heat treatment. Carbon and low-alloy steel piping such as that used in the MSL does not require heat treatment if it has been bent or formed in the temperature range of 1,650°F to 2,000°F (899°C to 1,093°C) and cooled in still air.

Weld Procedures

As detailed in References 20D.14 and 20D.15, welding of all materials will be done in accordance with welding procedures and using certified welders that have been qualified according to the rules of Sections III and IX of the ASME Code and the supplemental requirements detailed in Reference 20D.18. Control of welding variables (as well as

examination and testing) during procedure qualification and production welding is performed according to ASME Code requirements. Specific details of welding processes, selection and control of welding consumables, welding procedure qualification, pre-heat, interpass temperatures and post heating requirements are provided in Reference 20D.18. All welding, welding procedure qualification, and welder qualification will be in accordance with the requirements of ASME III for Code Classes 1, 2, and 3 piping, and the additional requirements of Reference 20D.14.

Post Weld Heat Treatment

Post weld heat treatment (PWHT) procedures will be submitted to Westinghouse for review and approval prior to the start of heat treatment. For carbon and low-alloy steel piping such as that used in the MSL, PWHT is to be in accordance with ASME III, NB-4600, NC-4600, or ND-4600 as applicable.

Manufacturing Inspections

Reference 20D.15 and Reference 20D.14 specify the test and inspection requirements for shop fabricated pipework and field fabricated and installed pipework, respectively. A summary of the examinations and tests for pipework and fittings is provided. These include requirements for materials and welds. Supplemental inspection requirements are defined in Reference 20D.18.

All NDE for Code Classes 1, 2, and 3 piping welds will be performed in accordance with ASME III NB-5000, NC-5000, or ND-5000, as applicable. All personnel performing NDEs will be qualified and certified in accordance with SNT-TC-1A and ASME III NB-5500, NC-5500 or ND-5500, as applicable. The MSL welds are all to be subject to 100% volumetric ultrasonic manufacturing inspections from the outer diameter.

Mechanical Testing

In accordance with ASME II SA-335 a hydrostatic test of each length of pipe supplied will be carried out. Shop hydrostatic tests are also carried out on the MSL containment penetrations, and these are checked prior to their installation on plant.

After installation, Code Classes 1, 2 and 3 piping systems will be pressure tested in accordance with ASME III (Reference 20D.14). The requirements for hydrostatic testing are given in ASME III NC-6200. The test temperature is selected so that the possibility of brittle fracture is minimised. The test pressure is 1.25 times the design pressure, and is 10.343 MPa abs (1500 psia) for the MSL. The test is held at the design pressure and then reduced to the design pressure of 1200 psia (8.274 MPa abs) and examined for leaks.

Cleaning and Contamination Protection Procedures

Materials used in the fabrication, installation, and testing of nuclear steam supply components and systems are handled, protected, stored, and cleaned according to recognised, accepted methods designed to minimise contamination that could lead to deterioration.

20D.3.2 **Good Design is Achieved Through Compliance with ASME**

Compliance with relevant and internationally well-established codes, standards and regulations to control the quality of design and manufacture provides assurance that an appropriate level of structural reliability will be achieved. Compliance with the ASME Code provides assurance over a diverse range of relevant aspects including material procurement,

component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination (NDE), testing, installation and manufacturing, pre-service and in-service inspection requirements.

The codes, standards and regulations that are specified to control quality of MSL piping design and manufacture embody extensive relevant experience that helps to ensure a structurally robust design and provides a means to prevent, minimise and control component degradation at the design stage. Compliance with the codes, standards and regulations, therefore provides a foundation for assuring that MSL piping structural integrity will be maintained for the design lifetime.

The MSL is designed to meet the requirements of ASME Code, Section III class B (ASME III Code Class 2/Class MC), or class C (ASME III Code Class 3). The AP1000 Class 2, 3 Piping and B31.1 Extensions Design Specification report (Reference 20D.16) is the Westinghouse design specification for ASME Class 2 and 3 piping. This document specifies that ASME Class 2 and 3 piping, will be designed, analysed, fabricated, and constructed in accordance with the ASME Code, Section III, 1998 Edition with Addenda up to and including 2000 (Reference 20D.17) with specific conservative usage provisions concerning the application of subsections NC and ND as detailed in the piping design criteria for the AP1000 Plant (Reference 20D.19).

The AP1000 Specification for Field Fabricated Piping and Installation, ASME Code, Section III, Classes 1, 2, and 3 and ASME B31.1 (Reference 20D.16), in conjunction with the Piping Design Specification (Reference 20D.14), and the AP1000 Specification for Shop Fabricated Piping (Reference 20D.15) including references therein, constitute a complete ASME Code, Section III Design Specification and provides the complete basis for the design, fabrication, installation, testing, and Code certification of ASME Code, Section III piping systems.

Appendix 15A summarises the safety classification and categorisation of mechanical and fluid systems, structures, and components. The MSL containment penetrations at SGS-PY-C01A and SGS-PY-C01B respectively, are designed to ASME III, MC.

Evidence of compliance with ASME requirements is provided by ASME certification of the MSL piping at the construction stage of AP1000 NPP development, supported by an assessment to demonstrate compliance with relevant design code requirements.

Other codes, regulations and standards apply to the MSL pipework and are tabulated in References 20D.14, 20D.15 and 20D.16. These include American National Standards Institute (ANSI) and ASME standards, Westinghouse Documents, US Code of Federal Regulations (CFRs), and US Nuclear Regulatory Commission (NRC) Regulatory Guides.

20D.3.3 Mitigation and Management In-Service Degradation

To demonstrate that the design has taken account of in-service degradation mechanisms, evidence to substantiate the following argument is provided:

- A structured process has been applied to identify in-service degradation mechanisms.
- The design has been optimised to mitigate against the risk from in-service degradation mechanisms.

Forewarning of degradation is identified through in-service inspection.

20D.3.3.1 Identification of Degradation Mechanisms

Westinghouse has designed, developed, and manufactured nuclear facilities since the 1950s, beginning with the world's first large central station nuclear plant (Shippingport), which produced power beginning in 1957. Westinghouse has since designed and delivered more than 100 commercial nuclear power plants worldwide, including the design of Sizewell B in the UK, with a combined electrical generating capacity in excess of 90,000 MW. The design of the AP1000 MSL is, therefore, supported by decades of successful plant operating experience which has accumulated many operating years. Westinghouse has substantial proven experience, knowledge, and capability to design, manufacture and furnish technical assistance for the installation, start-up and service of nuclear power plants.

The substantial record of safe operating experience provides confidence that there is a thorough understanding of the in-service performance of the MSL, the management and mitigation of through-life degradation issues and in the avoidance of issues at the design and manufacturing stage that can affect the through life performance.

In high-energy piping, there are material degradation mechanisms that could adversely affect the integrity of the system. The following is a list of potential degradation mechanisms relevant to the MSL:

- Erosion-corrosion induced wall thinning
- Stress corrosion cracking (SCC)
- Water hammer
- Fatigue
- Thermal aging
- Thermal stratification
- Other mechanisms

Erosion-Corrosion Induced Wall Thinning

The MSLs in the AP1000 are fabricated from SA-335 Grade P11 Alloy steel. Erosion-corrosion induced wall thinning is not expected in the main steam line. Extensive work has been done investigating erosion-corrosion in carbon steel pipes. The main steam line has low susceptibility to erosion due to the pipe material composition, which has sufficient levels of chromium to preclude erosion-corrosion material loss. Susceptibility is also low due to the relatively high operating temperature and the high quality steam in the MSL.

Based on the above discussion, erosion-corrosion induced wall thinning does not have an adverse effect on the integrity of the MSL piping.

Stress Corrosion Cracking

The main steam piping is constructed from ferritic steel. SCC in ferritic steels commonly results from a caustic environment. A source of a caustic environment in the main steam piping would be moisture carryover from the SG. However, the secondary side water treatment utilises all-volatile treatment (AVT). AVT effectively precludes causticity in the SG bulk liquid environment. For some operating plants prior to implementing AVT, the phosphate water treatment caused a caustic chemical imbalance resulting in SCC of SG tubing. Under AVT water treatment conditions, there are no instances of caustic SCC on the

ferritic steam lines, indicating no significant caustic carryover. The operating secondary side chemistry precludes SCC on the ferritic main steam line.

Based on the above discussion, SCC does not have an adverse effect on the integrity of MSL piping.

Water Hammer

The steam lines are not subject to water hammer by the nature of the fluid transported. The following system design provisions address concerns regarding steam hammer within the MSL and identify the significant dynamic loads included in the main steam piping design.

Design features that prevent water slug formations are included in the system design and layout. In the MSL, these include the use of drain pots and the proper sloping of lines.

The operating and maintenance procedures that protect against a potential occurrence of steam hammer include system operating procedures that provide for slowly heating up (to avoid condensate formation from hotter steam on colder surfaces), operating procedures that caution against fast closing of the MSIVs except when necessary, and operating and maintenance procedures that emphasise proper draining.

The stress analyses for the MSL piping and components include the dynamic loads from rapid valve actuations, including actuation of the MSIVs and the safety valves.

Based on the above discussion, water hammer does not have an adverse effect on the integrity of MSL piping.

The MSL piping is designed to take account of the potential for damage due to steam-driven slugs of water, as outlined in NUREG-0371.

Fatigue

Low-cycle fatigue due to normal operation and anticipated transients is accounted for in the design of the piping system. The MSL piping complies with the stress range reduction factors of the ASME Code, Section III. Due to the nature of operating parameters, MSL piping is not subjected to any significant transients to cause low-cycle fatigue. Based on the above discussion, low-cycle fatigue is not a concern for the AP1000 MSLs.

To address high-cycle fatigue, a pre-operational test programme is implemented as required by NB-3622.3, NC-3622, and ND-3622 of the ASME Code, Section III to verify that the piping and piping restraints will withstand dynamic effects due to transients, such as pump trips and valve trips, and that piping vibrations are within acceptable levels. The piping systems to be tested include the MSL piping.

Thermal Aging

The main steam piping system does not have cast materials. The welding process used on these lines is GTAW. There are no thermal aging concerns for the carbon steel piping of the MSL and the alloy steel of the main feedwater piping. The material used for the main steam piping system is not susceptible to dynamic strain aging effects.

Thermal Stratification

The design of piping and component nozzles in the AP1000 includes provisions to minimise the potential for and the effects of thermal stratification, cycling, and striping, pursuant to actions requested in several NRC bulletins.

Thermal stratification occurs only in a pipe that has a susceptible geometry and low flow velocities. A temperature difference between the flowing fluid and stagnant fluid is also a prerequisite. The MSL piping is not subjected to thermal stratification by the nature of fluid transported.

Other Mechanisms

The MSL pipe does not operate at temperatures for which creep fatigue must be considered. Creep fatigue is a concern for ferritic steel piping operation at temperatures above 371.11°C (700°F).

Pipe degradation or failure by indirect causes such as fires, missiles, and component support failures is precluded by criteria for design, fabrication, inspection, and separation of potential hazards in the vicinity of the safety-related piping.

The material used in the MSL is highly ductile and resistant to cleavage type failure at operating temperatures. The resistance to failure has been demonstrated by material fracture toughness tests.

Overall Conclusion

Consideration of the above in-service experience and known age related degradation mechanisms confirms that these have been considered in the design process, and that the design of the MSL is not susceptible to them. In the case of fatigue caused by vibration, appropriate pre-operational tests will be carried out on the plant to confirm that this will not be a problem.

20D.3.3.2 In-Service Inspection

ISI provides forewarning of degradation mechanisms and this forms an important element of the safety case argument. The role of an effective in-service inspection (ISI) programme is twofold: firstly to detect and monitor anticipated degradation, and secondly to confirm the absence of any unanticipated degradation. ISI is used to confirm the absence of defects that could give rise to gross structural failure.

To be effective, ISI requirements should be identified according to established good practice relevant to the characteristics of each inspection location. Evidence to substantiate that this is the case for the MSL piping of ISI is provided in Reference 20D.12, where the planned ISI arrangements for MSL piping are outlined to address the requirements of IWA-1400(b) and IWA-1500 of the ASME Code Section XI, supplemented where applicable by 10CFR50.55a. Reference 20D.12 provides a statement of the inspection techniques, inspectability and access arrangements applicable to ISI for AP1000 plant although it does not constitute a fully developed Inspection Plan: this is to be developed and submitted for regulatory approval as part of the site-specific safety case following the generic design assessment (GDA). Inspection intervals are to be established for the Inspection Plan in accordance with Sub articles IWA-2400 and IWC-2400 of the ASME Code, Section XI.

Reference 20D.12 presents a summary of examination requirements for AP1000 Class 2 and 3 Components, including Class 2 and 3 piping.

20D.4 Strength of the Safety Case

All portions of the MSL have been classified as Standard Class 1 components. The safety argument in Section 20D.3 demonstrates how structural integrity of the MSL is established based on extensive quality assurance measures in design, manufacture, materials, testing, and qualified inspection. The strength of the safety case is based on achievement of integrity and that the MSL has been deterministically justified in accordance with ASME Code, Section III. The arguments presented are considered to provide a cogent basis to substantiate reliability claims commensurate with the Standard Class 1 classification of the MSL.

To substantiate this assertion this report provides a structured argument supported by suitable and sufficient evidence to achieve this, three key elements namely; Quality of Build, Good Design and Mitigation and Management In-service Degradation have shown how this will be achieved.

Quality of Build has been demonstrated by compliance with ASME Code, Section III. Material specification control has been achieved in accordance with Section II of ASME Code, NDE in accordance with ASME Code, Section III with adequate fracture toughness demonstrated by compliance with the ASME Code.

Good Design has been demonstrated by providing evidence that design transients including normal, upset, emergency and faulted conditions have been analysed and loadings shown to be within the allowable limits of ASME Code, Section III, Div 1 – 1998 Edition with Addenda up through and including 2000.

The approach to Mitigation and Management of In-service Degradation has been demonstrated by identifying all design characteristics, degradation mechanisms and potential hazards that could lead to injury, fatality or loss of operation of the MSL. ISI will also provide forewarning of degradation with inspection and maintenance carried out at appropriate intervals.

20D.5 Index of Technical Reports

A list of the main supporting documents that have been used in the preparation of this report are given in Table 20D-2, with a summary of their content.

20D.6 Review of Open Issues

There are no open issues that affect the basis of the MSL safety case arguments presented in support of GDA.

20D.7 Conclusions

A safety argument to establish that the structural reliability of the UK AP1000 MSL is commensurate with the consequences of gross failure has been presented. SFRs have been identified for the MSL, based on structural integrity safety design bases established in the PCSR. These requirements are to be maintained to ensure plant nuclear and radiological safety. For the MSL, assurance that these SFRs will be maintained for the design life of the plant is provided by substantiating structural integrity against appropriate reliability targets.

Structural reliability targets have been identified for the MSL based on the procedure of structural integrity classification discussed in Section 20.5 and in Reference 20D.13. All portions of the MSL have been classified as Standard Class 1 components.

The main element of the safety case argument is that the MSL has been designed in accordance with the high standards of the ASME Code as applicable to ASME Class 1 components. This includes tight controls on material properties, manufacturing processes, design, testing, inspection and installation such that there is a high level of confidence in the quality of the MSL and that it will enter service free from significant flaws that could affect the integrity of the MSL over its lifetime. Section 20D.5 identifies the detailed specifications and analyses that provide the evidence to support this argument.

Based on the arguments presented, together with the referenced supporting evidence, it is considered that the structural reliability of the MSL has been justified to a standard commensurate with the consequences of its gross failure.

APPENDIX 20E
REACTOR COOLANT LOOP PIPING COMPONENT SAFETY REPORT

20E.1 Introduction

This is the component safety report (CSR) for the reactor coolant loop (RCL) piping as introduced in Section 20.2.The safety argument herein substantiates the structural integrity of the RCL piping to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20E.4 that supports the design, manufacture, installation, and operation of the RCL piping.

20E.1.1 Scope

This report presents arguments to substantiate the claim that the nuclear and radiological risk potentially arising from gross structural failure of the RCL piping remains tolerably low for the 60 year design lifetime. Structural reliability targets are established on the basis of the nuclear and radiological risks associated with gross structural failure. Conventional (non-nuclear/radiological) hazards to safety are not addressed.

Reliability targets are to be substantiated for the entire design lifetime objective of 60 years. This duration of service is used to calculate fatigue usage, and to establish inspection and maintenance requirements based on anticipated degradation over the design lifetime.

The scope of the assessments includes consideration of all pressure, temperature, and mechanical loadings within the design basis. This includes normal operating conditions, anticipated transients, postulated accident conditions and test conditions.

The scope of the assessment is limited to the structural reliability of the RCL piping only and does not include other components of the reactor coolant system (RCS), of which the RCL is a part, or any other systems. A description of the RCL piping is provided in Section 20E.1.4, and physical boundaries are identified in section 20E.1.4.2 to establish the piping and welds included within the scope of this report.

20E.1.2 Objectives

Safety functional requirements (SFRs) for the safety-significant components of AP1000 nuclear power plant (NPP) are identified in Table 20-1. These SFRs must be maintained in order that AP1000 plant risk is maintained at a level that is both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. The SFRs applicable to the RCL piping are identified in Section 20E.2.1. The principal objective of this CSR is, therefore, to demonstrate that the SFRs will be maintained for all conditions within the design basis.

This strategy to achieve this objective is described in Section 20E.2 and substantiation of the claimed structural reliability is provided by a safety argument in Section 20E.3, where evidence to support the nuclear safety claims is identified.

20E.1.3 Interface with Other Safety Case Documents

The safety argument presented in Section 20E.3 is supported by a dossier of technical evidence. Specific references are identified in the relevant sections of a structured safety argument in Section 20E.3, applicable codes and standards are identified in section 20E.3.1.1, and Westinghouse documents that specify and control the design and manufacture of the RCL are listed in Section 20E.5.

20E.1.4 Reactor Coolant Loop Piping – Description

The RCS includes two (2) heat transfer loops, each of which contains a steam generator (SG). Attached to each SG are two (2) reactor coolant pumps (RCPs), a single hot leg, and two (2) cold legs for circulating reactor coolant between the reactor vessel (RV) and the SGs (Reference 20E.11). In addition, the RCS includes a pressuriser (PZR), interconnecting piping and valves, and instrumentation necessary for operational control and safeguards actuation. All reactor coolant system equipment is located in the reactor containment. Figure 20F-2 and Figure 20E-1 illustrate isometric and plan views of the RCS, respectively. The RCL piping forms part of the reactor coolant pressure boundary (RCPB), which provides a barrier against the release of radioactivity generated within the reactor and is designed to provide a high degree of integrity throughout operation of the plant.

The RCS piping that connects the RV to the SG, RCPs and PZR is known as the RCL and is comprised of the following:

- Two single piece, seamless, forged austenitic stainless steel (ASME SA-376) piping sections, known as hot legs. Each hot leg is connected at one end by a pipe to safe end weld to an outlet nozzle on the RV, and at the other end by a pipe to safe end weld to an inlet nozzle located in the channel head of each SG. The nominal wall thickness of the hot leg piping is 82.6 mm (3.25 in) and the inner diameter (ID) is approximately 787.4 mm (31 in).

- Four single seamless forged austenitic stainless steel (ASME SA-376) piping sections, known as cold legs. Each cold leg is welded at one end to the safe end weld of an inlet nozzle on the RV and at the other end to the casing of a RCP; the RCP casings are in turn connected at the upstream end to SG outlet nozzles. The nominal wall thickness of the cold leg piping is 65.0 mm (2.55 in) and the ID is approximately 558.8 mm (22 in).

- A single piece seamless forged austenitic stainless steel (ASME SA-312) surge line that connects one (1) hot leg (Loop 1) to the PZR. The surge line is welded at one end to a nozzle in one hot leg, and at the other end to the PZR outlet nozzle safe end. The surge line is DN 450 (nominal pipe size (NPS) 18), Schedule 160 piping.

The RCL piping includes nozzles that connect to auxiliary systems piping. The piping associated with these auxiliary systems is not included within the scope of this CSR, but is described here in order that the role of the RCL nozzles that connect to these systems can be understood. Figure 3-1 of Reference 20E.11 provides a simplified sketch of the RCS including depiction of the connecting auxiliary systems. The auxiliary systems are described in the AP1000 class 1 piping and non-class 1 extensions design specification (Reference 20E.2) and include the following:

- PZR safety relief subsystem

- RCS automatic depressurisation subsystem (ADS)

- RV head vent (RVHV) subsystem
- Passive core cooling system (PXS)
- Emergency core decay heat removal subsystem, consisting of one (1) Passive Residual Heat Removal Heat Exchanger (PRHR HX) and associated valves, piping, and instrumentation
- Chemical and volume control system (CVS)
- Normal residual heat removal system (RNS)

The connections of these systems to nozzles in the RCL piping are as follows:

- Two PZR spray line branch connections, welded to nozzles in Loop 1 cold legs. These lines are DN 100 (NPS 4) and merge into a single line that is welded to the PZR spray nozzle safe end.
- Branch connections from the RCL Loop 2 cold legs to the core makeup tanks (CMTs) (DN 200 (NPS 8)).
- Branch connection from the RCL Loop 1 hot leg to the PRHR HX and ADS (DN 450 (NPS 18)).
- Branch connection from the RCL Loop 2 hot leg to the ADS (DN 450 (NPS 18)).
- Branch connection from the Loop 2 hot leg to RNS line (DN 500 (NPS 20)).

20E.1.4.1 Functional Description

During operation, the RCPs circulate pressurised water through the RCL and primary components. The pressurised water, which serves as coolant, moderator, and solvent for boric acid is heated as it passes through the core in the RV. It next flows via the hot legs into the SGs where the heat is transferred to the SG secondary side water, and then is returned to the RV via the RCPs and cold legs to repeat the process. The surge line connects the RCL to the PZR to provide a means of controlling RCS pressure within specified limits. The functions of the auxiliary systems connected to the RCL piping are described in Reference 20E.2.

Figure 20E-2 provides a schematic illustration of the flow within the RCS and Table 20E-1 identifies the principal pressures, temperatures, and flow rates of the RCS piping at the locations identified in Figure 20E-2 under normal steady-state, full-power operating conditions. These parameters are based on the best-estimate flow at the pump discharge.

20E.1.4.2 Physical Boundaries

The physical boundaries of the RCL piping contribute to the definition of the scope of this report, as discussed in Section 20E.1.1. The boundaries are identified as follows:

- The boundaries of the ends of the two (2) RCL hot legs are, at one end, the pipe to safe end welds to outlet nozzles on the RV, and at the other end at the pipe to safe end welds that connect to the inlet nozzles at the channel head of each SG. The physical boundaries at the connections between the hot legs and ancillary systems are at the nozzle to pipe weld connecting to the ancillary piping.

- The boundaries of the ends of the four (4) RCL cold legs are, at one end, the safe end weld to RV inlet nozzles, and at the other end the weld to the RCP. The physical boundaries at the connections between the cold legs and ancillary systems are at the cold leg nozzle to pipe weld connecting to the ancillary piping.

- The boundaries of the surge line are at the circumferential weld connecting a nozzle on the hot leg (Loop 1) and at the other end at the surge line pipe to PZR outlet nozzle safe end weld.

The welds described above are considered as pressure boundary welds per the American Society of Mechanical Engineers (ASME) Code and are included within the scope of this report.

20E.2 Safety Case Requirements

As identified in Section 20E.1.2, the principal objective of this CSR is to demonstrate that the SFRs allocated to the RCL piping, established in Section 20E.2.1, will be maintained for all conditions within the design basis. This objective is to be achieved by substantiating the structural reliability of each component of the RCL piping against targets that are commensurate with the consequences of gross failure of that component. These targets are determined by means of a United Kingdom (UK) AP1000 component structural integrity classification process as described in Section 20E.2.2, where structural reliability targets for all RCL piping components are identified. The safety argument presented in Section 20E.3 identifies evidence to support the following nuclear safety claims for the RCL piping.

Claim 1: High quality is achieved through good design and manufacture

Objective: The safety argument will seek to establish that the design, manufacture and inspection of the RCL piping will be in accordance with the appropriate requirements of relevant sections of the ASME Boiler and Pressure Vessel Code (ASME Code). This code embodies considerable operating experience relevant to the RCL piping and adherence to the relevant code requirements and forms a keystone for demonstrating quality of build, high integrity and the avoidance of defects. Additional requirements for qualified manufacturing inspections of the most safety significant welds are identified.

Claim 2: Design assessment of the RCL will demonstrate compliance with relevant design code requirements

Objective: An assessment of the RCL piping design in accordance with the requirements of Section III of the ASME Code is specified, with the objective of demonstrating that the appropriate design limits for stress and fatigue for all relevant service conditions are satisfied.

Claim 3: Forewarning of failure is provided by in-service inspection

Objective: In-service inspection (ISI) represents the preferred method to provide forewarning of failure. It provides a means of monitoring and controlling anticipated degradation and also can confirm the absence of unanticipated degradation mechanisms. Evidence is provided to demonstrate that the ISI arrangements are sufficient to provide timely warning before structural failure of RCL piping could occur.

Claim 4: Leak behaviour provides further forewarning of gross structural failure of the reactor coolant loop

Objective: Leak monitoring adds defence in depth to the argument that effective forewarning of failure will be provided by ISI. Diverse means to warn of leakage from the RCS are identified.

The elements of the safety argument are provided in Section 20E.3 and the strength of the argument is discussed in Section 20E.4.

20E.2.1 Safety Functional Requirements

Table 20-1 identifies SFRs for AP1000 systems, structures, or components (SSCs). The following SFRs are applicable to the RCL piping:

- **20.4.1**: The pipework is required to maintain the integrity of the RCPB during standby, normal operation and under design basis faulted conditions for the design life of the plant.

- **20.4.2**: Leak behaviour provides forewarning of gross failure of the reactor coolant loop.

Postulated failure modes, which result in a loss of these SFRs, lead to the identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification, as described in Section 20E.2.2 below. The safety argument in Section 20E.3 is provided to substantiate that these structural reliability targets will be achieved and thus demonstrate that the SFRs will be maintained at all times.

20E.2.2 RCL Structural Integrity Classification

A structured and systematic approach has been applied to establish the appropriate level of rigour to be applied in the design assessment, material procurement, fabrication, in-manufacture inspection, testing and in-service testing, maintenance, inspection and safety case assessment of the RCL piping. This involves a process of structural integrity classification of the components, as described in Section 20.5 and detailed in the AP1000 UK structural integrity classification (Reference 20E.3). The classification process entails a detailed assessment of AP1000 components to establish the consequences of gross failure due to both direct consequences, such as a loss-of-coolant accident (LOCA), and indirect consequences, such as the effect of missiles, jet loading or pipe whip on essential safety systems.

The RCL piping components have been determined to have a structural integrity classification of Standard Class 1. The basis for the classification of the RCL to RV nozzle safe end welds, the RCL to SG/RCP welds, and the surge line are shown in Table 20-9, Table 20-10, and Table 20-19, respectively.

The Standard Class 1 classification of the RCL components is informed by the LOCA analysis reported in Section 9.6.4. Passive protection systems are identified in Table 20-9, Table 20-10 and Table 20-19 that mitigate the consequences of failure for a range of break sizes up to and including a guillotine break of the largest pipe. The classification is also supported by assessment of pipe whip, jet impingement, asymmetric and subcompartment pressurisation performed in support of Reference 20E.16. Additionally, core depressurisation forces following a loss of coolant accident were evaluated in Reference 20E.17.

As identified in Table 20-9, Table 20-10 and Table 20-19, the anticipated effects arising from a guillotine break of the large bore pipework is not anticipated to result in core damage.

20E.3 SAFETY ARGUMENT

The structural integrity classification for Standard Class 1 necessitates demonstration of compliance with the relevant rules of the ASME Code. The structure of this safety argument is based on substantiation of the nuclear safety claims identified in Section 20E.2. These claims are addressed in this safety argument as follows:

- **Section 20E.3.1** High quality is achieved through good design and manufacture.
- **Section 20E.3.2** Design assessment of the reactor coolant loop will demonstrate compliance with relevant design code requirements.
- **Section 20E.3.3** Forewarning of failure is provided by in-service inspection.
- **Section 20E.3.4** Leak behaviour provides further forewarning of gross structural failure of the reactor coolant loop.

Evidence is presented in Section 20E.3 to show that, as a minimum, all components of the RCL piping comply with the relevant requirements of Sections II (materials), III (construction) and XI (ISI) of the ASME Code.

20E.3.1 High Quality Is Achieved through Good Design and Manufacture

The design, manufacture and inspection of the RCL piping and welds will accord with the appropriate requirements of relevant sections of the ASME Code. This demonstrates that the measures applied to achieve a high quality of build and the avoidance of defects are suitably robust and appropriate to the safety classification of the piping. To demonstrate that high quality is achieved through good design and manufacture, evidence to support the following claims is provided:

- Appropriate codes, standards & regulations are specified to control the quality of design and manufacture.
- RCL design and operation minimises the potential for in-service degradation.
- Materials specifications comply with relevant ASME Code requirements.
- Specification of reactor coolant water chemistry minimises the potential for corrosion.
- Mechanical testing demonstrates compliance with relevant material specifications.

- Welding will be conducted by suitably qualified and experienced operators in accordance with suitable and well-established procedures.
- Manufacturing inspections confirm the absence of structurally significant defects.
- Hydrostatic pressure testing confirms RCPB integrity.

20E.3.1.1 Appropriate Codes, Standards & Regulations Are Specified to Control the Quality of Design and Manufacture

Compliance with relevant and internationally well established codes, standards and regulations to control the quality of design and manufacture provides assurance that an appropriate level of structural reliability will be achieved. Compliance with the ASME Code provides assurance over a diverse range of relevant aspects including material procurement, component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination (NDE), testing, installation and manufacturing, pre-service and in-service inspection requirements.

The RCL piping includes the hot leg and cold leg pipes with their integral branch connection nozzles, and the surge line. The design, manufacture and installation is to be undertaken in accordance with the codes, standards and regulations identified in the reactor coolant loop seamless forged and formed pipe fabrication specification (Reference 20E.4). These are summarised in Table 20E-2 and include elements of the ASME Code, ASME Code Cases, American National Standards Institute (ANSI) and ASME Standards, US Code of Federal Regulations (CFRs), United States (US) Nuclear Regulatory Commission (NRC) Regulatory Guides (RG) and a number of supplementary Westinghouse specifications and other documents. The applicable edition of the ASME Code is the 1998 Edition with addenda up through and including 2000 Addenda with an additional restriction for piping design. The restriction on piping design is that the treatment of dynamic loads, including seismic loads in pipe stress analysis, will satisfy the requirements of the ASME Code, Section III, Subarticles NB-3210, NB-3220, NB-3620, NB-3650, NC-3620, ND-3620, and ND-3650, 1989 Edition, 1989 Addenda.

The AP1000 NPP design originates in the US and as such, many of the specified codes, standards and regulations originate in that country. These are internationally well established and as such, are considered to be applicable in the UK.

The codes, standards and regulations that are specified to control quality of RCL piping design and manufacture embody extensive relevant experience that helps to ensure a structurally robust design and provides a means to prevent, minimise and control component degradation at the design stage. Compliance with the codes, standards and regulations, therefore provides a foundation for assuring that RCL piping structural integrity will be maintained for the design lifetime.

Evidence of compliance with ASME requirements is provided by ASME certification of the RCL piping at the construction stage of AP1000 NPP development, supported by an assessment to demonstrate compliance with relevant design code requirements as described in Section 20E.3.2.

20E.3.1.2 Reactor Coolant Loop Design and Operation Minimises the Potential for In-Service Degradation

The inclusion of integral branch connection nozzles within the design minimises the number of welds in the RCL piping, and thus reduces the potential for in-service degradation. Appendix B of Reference 20E.16 includes an assessment of degradation mechanisms that could adversely affect the structural integrity of AP1000 piping including the RCL. Appendix B of Reference 20E.16 identifies design measures and procedural controls that minimise in-service degradation and these aspects, where relevant to the RCL, are summarised below.

In high-energy piping, there are material degradation mechanisms that could adversely affect structural integrity and may also undermine the validity of a leak behaviour assessment. The following categories of degradation mechanism are addressed in Appendix B of Reference 20E.16:

- Resistance to wall thinning
- Stress corrosion cracking (SCC)
- Water hammer
- Fatigue
- Thermal ageing
- Thermal stratification
- Other mechanisms

These categories are discussed in turn below:

Resistance to Wall Thinning

Wall thinning by erosion and erosion-corrosion effects does not occur in the primary loop piping because Series 300 austenitic stainless steel material is highly resistant to these effects. The coolant velocity in the AP1000 primary loop is approximately 23 m/s (75 ft/s). This flow velocity is not expected to create erosion-corrosion effects, since stainless steels are considered to be virtually immune (Reference 20E.5). A review of erosion-corrosion in nuclear power systems (Reference 20E.6) reported that "stainless steels are increasingly being used due to their excellent resistance to erosion-corrosion, even at high water velocities, 40 m/s (130 ft/s)." The bend radii in the AP1000 hot and cold legs are greater than the bend radii used in the crossover legs of operating plants. There is no record of erosion-corrosion induced wall thinning in the primary loops of operating plants.

Based on the above, erosion-corrosion induced wall thinning will not adversely affect the structural integrity of RCL piping.

Stress Corrosion Cracking

SCC is not anticipated in RCL piping because the three conditions necessary for SCC to take place are not present. The three conditions are:

- There must be a corrosive environment.
- The material itself must be susceptible to SCC.
- Tensile stresses must be present in the material.

During plant operation, the reactor coolant water chemistry is monitored and maintained within specific limits (see section 20E.3.1.4). Contaminant concentrations are kept below the thresholds known to be conducive to SCC. The major water chemistry control standards are considered in the plant operating procedures.

The key to mitigation and management of a corrosive environment is control of oxygen. During normal power operation, oxygen concentration in the RCS is controlled to extremely low levels by controlling charging flow chemistry and maintaining a hydrogen overpressure in the reactor coolant at specified concentrations. Halogen concentration is controlled by maintaining concentrations of chlorides and fluorides within the specified limits and thus the likelihood of SCC in the RCL is very low. As described in Chapter 21 and in section 20E.3.1.4, periodic analysis of the coolant chemistry is performed to verify that the reactor coolant water quality meets specifications.

The elements of a water environment known to increase the susceptibility of austenitic stainless steel to stress corrosion are oxygen, fluorides, chlorides, hydroxides, hydrogen peroxide, and reduced forms of sulphur (for example, sulfides, sulfites, and thionates). Pipe cleaning minimises the potential for contamination and control of water chemistry prevents the occurrence of a corrosive environment during plant operation.

Series 300 stainless steel materials have been chosen for the RCL piping due to recorded operating experience in low-oxygen or no-oxygen environments with no significant safety-related incidents. The use of these materials in the AP1000 coolant environment is in accordance with the requirements of RG 1.44.

Design tensile stresses in the RCL are within the ASME Code, Section III allowable limits, as discussed in section 20E.3.2.2. Residual tensile stresses in RCL welds are not considered when designing in accordance with the ASME Code, Section III, since these are self-equilibrating and do not affect the failure loads. The residual stresses should not be more severe than for the operating Westinghouse pressurised water reactor plants (which have not experienced stress corrosion cracking in the primary loop).

The material used for buttering nozzles at stainless-to-carbon steel safe ends is a high nickel alloy. The nickel-chromium-iron alloy selected and qualified for this application is not susceptible to primary water SCC.

Water Hammer

The RCL is designed to operate at a pressure greater than the saturation pressure of the coolant, thus precluding the voiding conditions necessary for water hammer to occur. The RCS is designed for Level A, B, C, and D (normal, upset, emergency, and faulted) service condition transients. The design requirements are conservative relative to both the number of transients and their severity. Relief valve actuation and the associated hydraulic transients following valve opening have been considered in the system design. Other valve and pump actuations cause relatively slow transients with no significant effect on the system dynamic loads.

To provide dynamic system stability, reactor coolant operating parameters are controlled. Temperature during normal operation is maintained within a narrow range by control rod positioning. Pressure is controlled within a narrow range for steady-state conditions by PZR heaters and PZR spray. The flow characteristics of the system remain constant during a fuel cycle. The operating transients of the RCL piping are such that significant water hammer loads are not expected to occur.

Fatigue

Low-cycle fatigue due to normal operation and anticipated transients is accounted for in the design of the piping system. An assessment to demonstrate that the RCL piping complies with the fatigue usage requirements of the ASME Code, Section III is described in Section 20E.3.2.

High-cycle fatigue loads on the RCL piping and other RCPB components result primarily from pump vibrations. The steam generator is designed so that flow-induced vibrations in the tubes are avoided. The loads from RCP vibrations are minimised by criteria for pump shaft vibrations during hot functional testing and operation. During operation, an alarm signals when the reactor coolant pump vibration is greater than the limits. These measures minimise the potential for high-cycle fatigue in the RCL.

Thermal Aging

RCL piping materials are chosen in preference to cast material so that the potential for thermal ageing is minimised. The welds used in the assembly of the AP1000 plant are gas tungsten arc welds (GTAW). Due to the typically low ferrite content in GTAW, these are essentially as resistant to the effects of thermal ageing as the base metal materials.

Thermal Stratification

Thermal stratification occurs only in a pipe that has a susceptible geometry and low flow velocities. A temperature difference between the flowing fluid and stagnant fluid is also a prerequisite. The design of RCL piping includes provisions to minimise the potential for and the effects of thermal stratification, cycling, and striping as discussed below.

Thermal stratification in the RCL resulting from actuation of passive safety features is evaluated as a design transient. Stratification effects due to both Level B and Level D service conditions are considered. The criteria used in the evaluation of the stress in the loop piping due to stratification is the same as that applicable for other Level B and Level D service conditions. Section 20E.3.2 describes the design assessment which includes consideration of these design basis conditions.

The surge line has been specifically designed and instrumented to minimise the potential for thermal stratification that could increase cyclic stresses and fatigue usage. At the connection of the surge line to the hot leg, the surge line is sloped 24 degrees from the horizontal. The connection to the hot leg is in the portion of the loop piping that is at an angle with the horizontal and adjacent to the steam generator inlet nozzle. The run between the hot leg and PZR continuously slopes up. The surge line has an angle of at least 2.5 degrees to the horizontal. Changes of direction in the surge line are made using pipe bends instead of elbow fittings.

The surge line temperature is monitored for the indication of thermal stratification. The temperature is monitored at three locations using strap-on resistance temperature detectors. One location is on the vertical section of pipe directly under the PZR. The other two locations are on the top and bottom of the pipe at the same diameter on a more horizontal section of pipe near the PZR. Temperatures in the spray lines from the cold legs of one loop are measured and indicated. Alarms from these signals actuate to warn the operator of low spray water temperature or to indicate insufficient flow in the spray lines.

Hot functional testing requirements for the AP1000 plant will ensure that piping thermal deflections result in no adverse consequences. As part of the Westinghouse Owners Group

programme on surge line thermal stratification, Westinghouse collected surge line physical design and plant operational data for all domestic Westinghouse pressurised water reactors (PWRs). In addition, Westinghouse collected surge line monitoring data from approximately 30 plants. This experience was used in the development of the AP1000 thermal stratification loadings.

A monitoring programme will be implemented at the first AP1000 plant to record temperature distributions and thermal displacements of the surge line as well as pertinent plant parameters such as PZR temperature and level, hot leg temperature, and reactor coolant pump status. Monitoring will be performed during hot functional testing and during the first fuel cycle to provide evidence that the RCS is operating within specified limits of temperature and displacement.

Other Mechanisms

Creep fatigue is a concern for austenitic stainless steel piping operating at temperatures above 426°C (800°F). RCL piping does not operate at temperatures for which creep fatigue must be considered.

Pipe degradation or failure by indirect causes, such as fires, missiles, and component support failures, is precluded by criteria for design, fabrication, inspection, and separation of potential hazards in the vicinity of the safety-related piping. A deterministic justification of RCL piping against seismic event transients is provided in Reference 20E.18.

The potential for cleavage failure of RCL piping is precluded by the high ductility of the material at operating temperatures.

20E.3.1.3 Materials Specifications Comply with Relevant ASME Code Requirements

The RCL piping materials are specified in accordance with applicable requirements of the ASME Code Section II. This is confirmed following manufacture by certified material test reports (CMTRs). There is a full scale mockup test in place to confirm the material properties could be achieved (Reference 20E.7). A summary of the Section II requirements applicable to the RCL piping is provided in this section. The following elements of the ASME Code Section II are applicable to the RCL piping:

- SA-312, “Specification for Seamless and Welded Austenitic Stainless Steel Pipes.”
- SA-370, “Mechanical Testing of Steel Products.”
- SA-376, “Seamless Austenitic Steel Pipe for High-Temperature Central-Station Service.”
- SA-745, “Ultrasonic Examination of Austenitic Steel Forgings.”
- SFA-5.9, “Specification for Bare Stainless Steel Welding Electrodes and Rods.”

The RCL piping is made from austenitic stainless steels as identified in Section 20E.1.4. These are supplied in the final heat-treated condition required by the respective ASME Code, Section II materials specification for the particular type or grade of alloy. The use of sensitised stainless steels in the RCS is restricted in accordance with RG 1.44, and sensitised stainless steels are not used for the RCL piping. RCL piping is stress-relieved subsequent to bending or other fabrication operations which could result in significant residual stress in the pipe. Processes such as welding or heat treating, which apply heat to stainless steel, are controlled to minimise the potential for sensitisation of the stainless steel. During the latter stages of fabrication, the stainless steel piping is not heated above 426°C (800°F) other than locally by welding operations. The solution-annealed surge line material is subsequently formed by hot-bending followed by a solution-annealing heat treatment.

The hot and cold leg pipe material are specified in accordance with the applicable requirements of ASME Code, Section II, SA-376, TP316LN and all RCL forgings will comply with the requirements of ASME Code, Section III, Subsection NB, Article 2000. The surge line pipe material is specified in accordance with the applicable requirements of ASME Code, Section II, SA-312, TP316LN.

Reference 20E.4 identifies the following restrictions for material composition of the RCL piping. Limits are specified with regard to the concentration of elements including sulphur, phosphorous, carbon, copper, lead, tin, arsenic, and antimony. Any quantities detected will be recorded for information as part of the CMTR.

In Reference 20E.4 the grain size determination for the RCL piping is specified in accordance with ASTM E-112. The photomicrographs illustrating the microstructure (including identification, magnification, and etchant) will be provided in the CMTR. The flattening test will comply with the applicable requirements of ASME Code, Section II, SA-376, TP316LN.

Welding materials used for fabrication and installation of welds of austenitic stainless steel materials and components meet the requirements of Section III of the ASME Code. For applications using austenitic stainless steel welding material, the material conforms to ASME weld metal analysis A-8, Type 308, 308L, 309, 309L, 316, or 316L.

Austenitic stainless steel materials used in the fabrication, installation, and testing of nuclear steam supply components and systems are handled, protected, stored, and cleaned accordance with ASME NQA-1 and RG 1.37 to minimise the potential for contamination that could subsequently result in degradation of the piping.

20E.3.1.4 Specification of Reactor Coolant Water Chemistry Minimises the Potential for Corrosion

The RCS water chemistry is specified to minimise the potential for corrosion and the materials selected for RCL piping are well established for use in a PWR reactor coolant environment. Time dependant evaluations in the design analysis are based on adherence to controls on the internal environment, and Chapter 21 provides a detailed specification of water chemistry, the limits of which are summarised in Table 20A-3. The specification of reactor coolant is in accordance with the well established pressurised water reactor primary water chemistry guidelines (Reference 20E.8). The RCL piping will be exposed to a range of fluid chemistry conditions during start-up, normal operation, wet layup, and heatup conditions.

The CVS and sampling system provide an effective means to monitor and control reactor coolant water chemistry. Periodic analyses of the coolant chemistry are performed to verify that the reactor coolant water quality meets the specifications, and the CVS provides a means of chemical dosing to maintain water chemistry quality.

20E.3.1.5 Mechanical Testing Establishes Compliance with Relevant Material Specifications

RCL piping material properties are confirmed to comply with relevant design specifications by a test programme. Mechanical, metallographic, and hardness test requirements of hot leg and cold leg piping are specified in Reference 20E.4. Similar tests for the Surge Line are specified.

The mechanical testing programme for RCL piping is specified to be in accordance with ASME Code, Section II, SA-370, “Mechanical Testing of Steel Products”. A limit on the

hardness of the Type 316LN material in the final fabricated condition is specified and the procedure for hardness testing will be in accordance with SA-370 or ASTM A1038. Additional mechanical testing of RCL material is summarised below:

- Tensile testing at room temperature on finished, heat treated hot and cold leg forgings is specified in accordance with the ASME Code, Section II, SA-376.
- Grain size determination in accordance with ASTM E-112.
- Corrosion sensitisation tests in accordance with ASTM A262, Practice E.

Tensile testing of weld filler material is specified in Reference 20E.9. The results of all mechanical testing of RCL piping materials are to be included in the CTMRs to confirm that material specifications are satisfied.

20E.3.1.6 Welding Will be Conducted by Suitably Qualified and Experienced Operators in Accordance with Suitable and Well-Established Procedures

The RCL piping will use narrow gap tungsten inert gas (TIG) welding, a high quality process with low likelihood of flaw occurrence. As specified in Reference 20E.9, all welding of RCL piping is conducted in accordance with the rules of Sections III and IX of the ASME Code. Additional detailed requirements for welding processes and consumables are specified in the AP1000 supplemental fabrication and inspection requirements (Reference 20E.10). All welding is to be performed by operators who have been qualified in accordance with the ASME Code Sections III and IX. The practices for storing and handling welding electrodes and fluxes comply with ASME Code, Section III, Paragraphs NB-2400 and NB-4400.

The welding of austenitic stainless steel is controlled to mitigate the occurrence of microfissuring, or hot cracking, in the weld. Also, it has been well documented that delta ferrite is one of the mechanisms for reducing the susceptibility of stainless steel welds to hot cracking. The minimum delta ferrite level below which the material will be prone to hot cracking lies between 0 and 3% delta ferrite. Delta ferrite control is generally appropriate for welding processes used to join stainless steel parts in components designed, fabricated, or stamped according to the ASME Code, Section III, Classes 1 and 2, and core support components, except where no filler metal is used, or where such control is not applicable, such as the following: electron beam welding; autogenous gas shielded tungsten arc welding; explosive welding; welding using fully austenitic welding materials. The welding specifications also include the delta ferrite determinations for the austenitic stainless steel welding materials used for welding qualification testing and for production processing.

20E.3.1.7 Manufacturing Inspections Confirm the Absence of Structurally Significant Defects

The RCL piping is subject to manufacturing NDE in accordance with requirements established in the ASME Code and ASME NQA-1. The manufacturing inspection requirements for RCL piping are specified in Reference 20E.4. The requirements for manufacturing inspection applicable to all RCL piping are summarised, as follows.

Ultrasonic Examination

Ultrasonic examination (UT) examination is specified to be performed throughout 100% of the wall volume of each RCL pipe according to the applicable requirements of Section III of the ASME Code for RCL piping. The finished machined and heat treated forging (hot leg and cold leg piping) will be UT examined by both straight beam method in accordance with

NB-2540 and angle beam method in accordance with NB-2550 requirements. The examinations will be conducted over 100% of the accessible surfaces of the pipe wall volume.

The straight beam UT examination acceptance standard will meet NB-2540 requirements with the additional requirements per SA-745 for QL-1 for straight beam. The angle beam UT examination will be performed in two circumferential and two axial directions, where feasible.

The surge piping material will be UT examined per ASME Code Section III, NB-2550.

In the final configuration for the hot leg, cold leg, and surge line piping, the ends that will be attached to other piping will be examined using UT techniques comparable to those to be applied for ISI.

Liquid Penetrant Examination

Liquid penetrant examinations will be performed on accessible surfaces, including weld surfaces, of each finished RCL pipe and fitting according to the criteria of the ASME Code, Section III. Liquid penetrant examinations will be conducted on the pipe bends both before the bending operation and after the subsequent heat treatment. Liquid penetrant examinations will be performed on all accessible (outside and inside) surfaces of:

- Finished pipe
- Finished or machined branch connection nozzles
- Repair welds and weld overlays
- All machined weld end preparations intended for use in field welds
- Additional pre- and post-bending liquid penetrant examinations

Radiographic Examination

Radiographic examination (RT) examination, in accordance with ASME Code, Section III requirements, are specified for all RCL circumferential butt welds and branch connection nozzle welds exceeding DN 100 pipe size.

All weld repairs are to be approved prior to repair and will be recorded. The examination of any weld repair is to be repeated as required for the original weld. When the defect was originally detected by the liquid penetrant method and the repair cavity does not exceed the lesser of 9.7 mm or 10% of the thickness, it only needs to be re-examined by the liquid penetrant method.

20E.3.1.8 Hydrostatic Pressure Tests Confirm the Integrity of the Reactor Coolant Pressure Boundary

The RCS is subjected to a hydrostatic pressure test to proof the system against design pressure. The system hydrostatic test will be performed rather than a component hydrostatic test for the RCL piping. This is in accordance with the applicable requirements of ASME Code, Section II, SA-376, TP316LN.

The RCS hydrostatic pressure testing complies with IWA-5000 and IWB-5000 of the ASME Code, Section XI. Although it is planned only to conduct a single RCS hydrostatic test before the RCS enters service, ten hydrostatic test transients are included in the design for the evaluation of fatigue of RCS components due to cyclic loads.

The hydrostatic test confirms the integrity of the RCPB before operation of the plant. section 20E.3.4.2 provides details of detection of leakage from the RCS to provide warning of any significant loss of coolant throughout the period of operation.

20E.3.2 Design Assessment of the Reactor Coolant Loop Will Demonstrate Compliance with Relevant Design Code Requirements

Section III of the ASME Code provides a well established methodology for undertaking stress analysis to provide assurance of structural integrity before a component enters service. The RCL design has been assessed to confirm that stress, sizing and fatigue limits specified in Section III of the ASME Code are met.

To demonstrate that RCLs are designed to satisfy the stress, sizing, and fatigue limits specified in Section III of the ASME Code over the required period of service, the following aspects of the analyses are discussed:

- The scope of the ASME III design assessment is comprehensively specified.
- The RCL design assessment will demonstrate that relevant stress limits and end of life fatigue usage factors (FUFs) are satisfied.

20E.3.2.1 The Scope of the ASME III Design Assessment Is Comprehensively Specified

Section III Subsections NB and NC of the ASME Code require that the RCL piping design is evaluated against design, service, and test conditions and that the stresses within the RCL are shown to comply with specified allowable stress limits appropriate to the material of construction. The RCL piping design is to be justified against the requirements of the ASME Code, Section III for Class 1 components for all conditions within the design basis. The material strength properties from the ASME Code Section II (Section 2.3.1-A) are to be used in the design stress report. Materials used in the fabrication process will have material strength properties that meet or exceed the material strength properties used in the design basis for the design stress report as discussed in section 20E.3.1.3. Other parameters to be included within the scope of the design assessment are summarised in this section.

The design basis conditions are specified in terms of pressure, temperature, and mechanical loadings associated with all normal operating conditions, other anticipated transients, and postulated accident conditions. The evaluation of the service and testing conditions includes an evaluation of fatigue due to cyclic stresses. The following five categories of operating condition, as defined in ASME Code, Section III, encompass all operating conditions within the design basis of the RCL piping:

- Level A Service Conditions – Normal Conditions.
- Level B Service Conditions – Upset Conditions, Incidents of Moderate Frequency
- Level C Service Conditions – Emergency Conditions, Infrequent Incidents
- Level D Service Conditions – Faulted Conditions, Limiting Faults
- Testing Conditions

The RCL design transients are discussed in Section 20.6.1 and summarised in Table 20-22. Principal RCS pressures, temperatures, and flow rates are shown in Table 20E-1. The structural design of the RCL piping is based upon the following maximum steady state conditions:

Design Pressure	17.13 MPa (2485 psi)
Design Temperature	343°C (650°F)

The ASME stress limits, generally expressed as ratios of calculated stress vs. design allowable stress intensity (Sm), are identified for each of the Level A to D service conditions and testing conditions included in the Table 20-22. The ASME stress limits form the acceptance criteria for the design assessment, and the RCL piping meets the criteria specified in Section III of the ASME Code, Section III, subsection NB for Class 1 components.

The scope of the RCL design assessment will, as a minimum, include the loading combinations listed in Table 20E-3. These are described according to the nomenclature given in Table 20E-4. The RCL piping is to be analysed for the normal loads of weight, pressure, and temperature; mechanical transients of safe shutdown earthquake (SSE) and auxiliary line pipe ruptures; and pressure and temperature transients are outlined in Section 3.2 of Reference 20E.2

The transient conditions selected for ASME Code, Section III fatigue evaluation are based upon a conservative estimate of the magnitude and frequency of the temperature and pressure transients that may occur during plant operation. The design transients and the number of events used for the fatigue evaluation of RCS components, including the RCL piping, are presented in Table 20-22. Generally, only Level A and B service condition design transients are evaluated in the analysis of cyclic fatigue. Up to 25 stress cycles for Level C service conditions may be excluded from cyclic fatigue analysis in conformance with ASME Code, Section III criteria. Any Level C service conditions which are in excess of the 25-cycle limit are evaluated for the effect on cyclic fatigue using Level B criteria. For the evaluation of cyclic fatigue, the cycles included for seismic events are evaluated using Level B criteria and are not excluded from the fatigue evaluation regardless of the size of the stress range considered.

20E.3.2.2 The Reactor Coolant Loop Design Assessment Will Demonstrate that Relevant Stress Limits and End of Life Fatigue Usage Factors Are Satisfactory

The ASME Code, Section III establishes stress and fatigue limits for design, operational, accident and testing conditions. The ASME design report demonstrates that the requisite stress limits, as specified in the AP1000 Class 1 Piping Design Specification, are met for the RCL piping. This is presented in Reference 20E.14 and includes the assessment of support loads, nozzle loads and functional capability. Equivalent analyses for other sections of the RCS piping and branch lines are identified in Table 20E-6. The fatigue analysis is reported separately in Reference 20E.15.

The FUFs for the RCL piping have been evaluated using the 1998 Edition of the ASME Code (with addenda up through and including 2000 Addenda) fatigue design curves. Generic design assessment (GDA) Assessment Finding AF-AP1000-SI-39 has set the expectation that the future Licensee will undertake a fatigue design evaluation for locations in stainless steel and ferritic components that are in contact with the wetted environment to ensure that the effects of environment have been properly accounted for in the fatigue design analysis. GDA Assessment Finding AF-AP1000-SI-40 has also set the expectation that the future Licensee will review the changes to the design which would be required if the current version of the

ASME Code were used and either make these changes or justify why these changes are not practical.

20E.3.3 Forewarning of Failure Is Provided by In-Service Inspection

Effective ISI provides a well established means of monitoring and controlling anticipated degradation, confirms the absence of unanticipated degradation mechanisms and provides forewarning of failure. Evidence is provided to demonstrate that suitable ISI arrangements will effectively provide timely warning before structural failure of RCL piping could occur as follows:

- ISI of RCL piping is specified in accordance with established codes and standards.
- ISI provides data to monitor and judge in-service defect formation and growth.
- Arrangement for inspectability and access are specified to facilitate effective inspection.

Reference 20E.13 presents the component ISI assessment for the main loop and surge line piping. Leak monitoring adds defence in depth to the argument that effective forewarning of failure will be provided, and diverse means to warn of leakage from the RCS are identified, as described in section 20E.3.4.2.

20E.3.3.1 In-Service Inspection of Reactor Coolant Loop Piping Is Specified in Accordance with Established Codes and Standards

ISI is the preferred method for provision of forewarning of failure. The role of an effective ISI programme is twofold: firstly to detect and monitor anticipated degradation, and secondly to confirm the absence of any unanticipated degradation mechanisms. ISI is used to confirm the absence of defects that could give rise to gross structural failure.

To be effective, ISI requirements should be identified according to established good practice relevant to the characteristics of each inspection location. Evidence to substantiate that this is the case for the RCL piping of ISI is provided in the AP1000 design for inspectability programme: ISI requirements for class 1 components (Reference 20E.12), where the planned ISI arrangements for RCL piping are outlined to address the requirements of IWA-1400(b) and IWA-1500 of the ASME Code Section XI, supplemented where applicable by 10 CFR 50.55a. Reference 20E.12 provides a statement of the inspection techniques, inspectability and access arrangements applicable to ISI for AP1000 NPP and does not constitute a fully developed Inspection Plan, as required by 10 CFR 50.55a. A fully developed Inspection Plan is to be submitted for regulatory approval as part of the site-specific safety case following GDA. Inspection intervals are established for the Inspection Plan in accordance with Sub articles IWA-2400 and IWB-2400 of the ASME Code, Section XI and it is intended that in-service examinations be performed during normal plant outages, such as refuelling shutdowns or maintenance shutdowns occurring during the inspection interval.

Reference 20E.12 identifies inspection requirements for the RCL piping, based on those prescribed in ASME Code Section XI for Class 1 components.

The planned ISI programme includes the RCL components and welds of importance to nuclear safety. ASME Code Section XI requirements are identified for each location, and relevant code cases, as approved by NRC, are taken into account. The ISI requirements are summarised in Table 20E-5.

For the pressure retaining welds in piping DN 100 (NPS 4) or larger the ASME Code, Section XI examination category is B-J. The pipe to safe end welds, pump casing to pipe welds and pipe to pipe welds in the surge line are to be inspected by volumetric UT and liquid penetrant surface examinations. These are required over essentially 100% of the length of each weld during each inspection interval.

20E.3.3.2 In-Service Inspection Provides Data to Monitor and Judge In-Service Defect Formation and Growth in High Integrity Welds

Pre-service inspection will be undertaken in which the resulting data constitute a "fingerprint" against which ISI results can be compared. Comparison of ISI data with the manufacturing inspection fingerprint is used to confirm the absence of significant degradation or that build defects are stable i.e., defects detected during ISI must have started life as no greater than the manufacturing inspection validation defect size. Manufacturing inspections are to be performed using the same equipment that is likely to be used for the periodic ISI.

20E.3.3.3 Arrangement for Inspectability and Access Are Specified to Facilitate Effective Inspection

For effective ISI, the RCL design should accommodate requirements for inspection equipment and personnel access in accordance with current inspection technology and strategies. A design for inspectability programme for the UK AP1000 plant included an assessment for main loop and surge line piping welds. This assessment was, in part, based on the ISI Requirements Report for AP1000 Class 1 piping (Reference 20E.12), which identifies inspectability and access requirements for RCL locations. The following inspectability assessment for ISI of pressure retaining welds in RCL piping provides an evidence of the level of detail obtained from the inspectability programme.

Inspectability

- Pipe weld liquid penetrant examinations will be conducted on the outside diameter (OD) surface of the pipe. The examination area is defined as the area comprised of the weld plus approximately 12 mm (0.5 in) on each side of the weld. These inspections are performed manually.

- Pipe weld UT examinations are to be conducted on the OD surface of the pipe. The examination volume is defined as the volume comprised of the inner 1/3 thickness of the weld plus approximately 6 mm (0.25 in) on each side of the weld. Manual or mechanised contact equipment can be applied. Probes having 45° and 60° angles are typically applied, 45° is the predominant approach.

Access

- Application of the surface examination technique requires access to the examination surface plus approximately 150 mm (6 in) beyond to allow for sufficient space to use inspection equipment. Since the examination is performed manually, sufficient access and space must be provided for at least one operator to have hand contact and direct visual contact with the examination surface. At least 300 mm (12 in) of radial clearance from the component surface is required.

- Application of the volumetric examination techniques requires an OD examination surface free from obstructions for an axial distance on each side of the weld of (2 x thickness + 51 mm (2 in)). This includes thermal insulation adjacent to the OD surface, attachments and abrupt changes in the surface contour including counterbores and thickness changes in nozzles. The weld crown should be flush. It is noted that the required length of both sides of the weld may be reduced depending on the latest qualified techniques.

20E.3.4 Forewarning of Failure is Further Provided Through Leakage Detection

The RCPB is monitored for leaks from the reactor coolant and associated systems by a variety of components located in multiple systems as described in section 20.6.4.3.2. The leakage detection provisions forewarn of failure by providing timely warning of leakage before gross structural failure of the RCL piping would occur. Leak detection measures supplement the ISI arrangements (Section 20E.3.3) in providing forewarning of failure.

Unidentified leakage from through-wall cracks in the RCL piping would be released through the reflective insulation to the containment atmosphere. During normal operation, variations in airborne radioactivity, containment pressure, temperature, or specific humidity above the normal level signify a possible increase in unidentified leakage rates and alert the plant operators that corrective action may be required. Similarly, increases in containment sump level signify an increase in unidentified leakage.

20E.4 Strength of the Safety Case

20E.4.1 Objective

SFRs for the RCL piping are identified in Section 20E.2.1. This report provides a safety argument which identifies evidence to substantiate that the SFRs of the RCL piping will be maintained for all conditions within the design basis. This is achieved by demonstrating that the structural integrity of the RCL piping will be maintained for a 60 year component lifetime.

The availability and reliability of the SFRs should demonstrably be commensurate with the significance of the radiological hazards to be controlled. This demonstration is achieved by a process of component structural integrity classification which, for the safety justification of each class of component, establishes the degree of rigour to be applied commensurate with the potential radiological consequences of any postulated gross failure mode.

The structural integrity classifications of the components of the RCL piping are identified in Section 20E.2.2; these have been determined according to a process detailed in Reference 20E.3. The structural integrity classification of all components of the RCL piping is Standard Class 1.

A synthesis of the evidence presented in the safety argument to substantiate the structural reliability claims for the Standard Class 1 components of RCL piping is given in Section 20E.4.2, below. This summary and review of the safety argument provides the basis for the conclusions of this report which are presented in Section 20E.7.

20E.4.2 Evidence

The evidence to substantiate the structural reliability claimed for Standard Class 1 components, as identified in Sections 20E.3.1 to 20E.3.4, is based on a demonstration of compliance with relevant requirements of the ASME Code, supplemented by forewarning of failure to augment substantiation of the claimed structural reliability.

As asserted in Reference 20E.3, the failure statistics for industrial pressure vessels and piping that are built according to the good practice embodied in modern codes and standards supports inference of a failure rate that is in accordance with the structural reliability target for Standard Class 1 components. Substantiation of the structural reliability of the RCL components is, therefore, largely based on demonstrating compliance with relevant aspects of the ASME Code and with additional regulations as applicable.

The good practice that will control design and manufacture ensure quality of construction for all RCL components and these are described in Section 20E.3.1. The ASME Code prescribes rules of safety governing the design, fabrication, and inspection of boilers and pressure vessels that are internationally recognised and well established. As identified in section 20E.3.1.1, the following sections of the ASME Code establish requirements governing the following aspects of RCL design:

- Section II – Materials
- Section III, Rules for construction.
- Section XI: ISI

Procurement of materials is specified and controlled to ensure that well proven materials are chosen, that the materials have good resistance to fracture and are of suitable chemical composition to limit the effect of through-life degradation mechanisms. Materials of manufacture are discussed in section 20E.3.1.3, where it is established that all materials used in all RCL piping is specified to be in accordance with the requirements of Section II of the ASME Code.

All RCL components are designed and manufactured in accordance with the rules applicable to ASME Code, Section III for Class 1 components. Compliance with these requirements, and the experience embodied within the code, provides high confidence in manufacturing quality. Section 20E.3.1 identifies how various aspects of the Section III requirements are addressed for the RCL, these include mechanical testing to confirm material properties, welding procedures and welder qualification, manufacturing inspections to confirm the absence of defects, and hydrostatic pressure testing to confirm the integrity of the pressure boundary. Section 20E.3.2 describes assessments which deterministically justify the structural integrity of RCL piping against stress and fatigue limits established by the ASME Code, Section III for Class 1 components. The RCL design features integral branch nozzles connections that minimise the number of welds required in fabrication.

The planned programme of ISI for the RCL piping is described in Section 20E.3.3. This will be undertaken in accordance with the requirements of ASME Code Section XI and IWB-2500, and supplemented by requirements specified in 10 CFR 50.55a. In addition to the

planned ISI, forewarning of failure in RCL piping is also provided by leak monitoring for the RCS (section 20E.3.4.2).

20E.5 Index of Technical Reports

The Codes, Standards and other documents specified in Reference 20E.9 to control the quality of RCL design and manufacture are listed in Table 20E-2. Table 20E-6 lists design and analysis documents germane to the assessment of the RCL structural integrity safety case. A number of these Westinghouse reports are also specified in Reference 20E.9 and therefore are listed in both Table 20E-2 and Table 20E-6.

20E.6 Review of Open Issues

There are no open issues that affect the basis of the RCL piping safety case arguments presented in support of GDA.

20E.7 Conclusions

This CSR for the UK AP1000 RCL piping design presents a safety argument to establish that the structural reliability of the RCL piping is commensurate with the consequences of gross failure. SFRs have been identified for the RCL piping. These are to be maintained to ensure plant nuclear and radiological safety. For the RCL piping, assurance that SFRs will be maintained for the life of the component is provided by substantiating structural integrity against appropriate integrity targets.

Structural integrity targets have been identified for the RCL piping based on the procedure of structural integrity classification discussed in Section 20.5. All RCL components are classified as Standard Class 1, a classification that requires a less stringent and extensive substantiation of structural reliability than that of High Integrity or Highest Safety Significance.

The structural reliability target associated with a Standard Class 1 classification can be achieved through consideration of actuarial failure statistics. Industrial pressure vessels and piping built in accordance with the good practice embodied in modern codes and standards are judged to support inference of a tolerably low failure rate. Substantiation of the structural reliability of the RCL Standard Class 1 components is, thus, based on demonstrating compliance with relevant aspects of the ASME Code.

Evidence is presented within the structured safety argument to show that, as a minimum, all components of the RCL piping comply with the relevant requirements of Sections II (materials), III (construction) and XI (ISI) of the ASME Code for Class 1 components.

The scope of the code requirements provides a diversity of measures for the prevention of failure through conservative, robust design and stringent control of manufacture. ISI and leak detection monitoring provide further assurance of structural reliability by detecting and warning of any in-service degradation.

The evidence identified is judged to substantiate a tolerably low frequency of failure which is commensurate with the consequences of failure.

It is concluded that the safety argument presented in Section 20E.3 identifies a suitable and sufficient diversity of evidence to substantiate the structural reliability claimed for the

components of the RCL piping. The final results of the ASME III design analyses confirm that the RCL piping design satisfies the relevant stress and fatigue limits of the ASME Code.

Table 20E-3. ASME III Design Loading Combinations for RCL Piping

Condition	Design Loading Combinations[3]
Design	P + DW + DML + XL
Level A Service	PMAX[1] + DW + XL
	PMAX + DW + DN + XL
Level B Service	PMAX + DW + DU + XL
Level C Service	PMAX + DW + DE + XL
	PMAX + DW + DY + HYDSP + XL
Level D Service	PMAX + DW + DF + XL
	PMAX + DW + SRSS[2] ((SSE + SSES) + DBPB) + XL
	PMAX + DW + RVOS + SRSS (SSE + SSES) + XL
	PMAX + DW + DYS + DBPBS + SRSS ((SSE + SSES) + DY + HYDSP) + XL

Notes:

1. The values of PMAX in the load combinations may be different for different levels of service conditions as provided in the design transients. For earthquake loadings PMAX is equal to normal operating pressure at 100% power.
2. SRSS equals the square root of the sum of the squares.
3. See Table 20E-4 for description of loads.

Table 20E-4. Loading Nomenclature

Load	Description
P	Internal design pressure
PMAX	Peak pressure
DW	Dead weight
DML	Design Mechanical Loads (other than DW). This includes Service Level A loads and RVOS loads that are Service Level B.
XL	External mechanical loads, such as the nozzle reactions associated with piping systems, will be combined with other loads in the loading combination expressions.
SSE	Safe shutdown earthquake (inertia portion)
E	Earthquake smaller than SSE (inertia portion)
FV	Fast valve closure
RVC	Relief/safety valve – closed system (transient)
RVOS	Relief/safety valve – open system (sustained)
RVOT	Relief/safety valve – open system (transient)
DY	Dynamic load associated with various service conditions including FV, RVC, and RVOT as applicable (transient)
DN	Dynamic load associated with Level A (Normal) service conditions including FV, RVC, and RVOT as applicable (transient)
DU	Dynamic load associated with Level B (Upset) service conditions including FV, RVC, and RVOT as applicable (transient)
DE	Dynamic load associated with Level C (Emergency) service conditions including FV, RVC, and RVOT as applicable (transient)
DF	Dynamic load associated with Level D (Faulted) service conditions during which, or following which, the piping system being evaluated must remain intact including FV, RVC, and RVOT as applicable. This includes postulated pipe rupture events (transient)
DYS	Dynamic load associated with various service conditions (sustained)
SSES	Seismic anchor motion portion of SSE
ES	Seismic anchor motion of earthquake smaller than SSE
TH	Thermal loads for the various service conditions
TNU	Service Level A and B (normal and upset) plant condition thermal loads; including thermal stratification and thermal cycling
TN	Service Level A (normal) plant condition thermal loads
TU	Service Level B (upset) plant condition thermal loads
TE	Service Level C (emergency) plant condition thermal loads

Table 20E-4. Loading Nomenclature (cont.)

Load	Description
TF	Service Level D (faulted) plant condition thermal loads
SCVNU	Static displacement of steel containment vessel – normal and upset conditions
SCVE	Static displacement of steel containment vessel – emergency condition
SCVF	Static displacement of steel containment vessel – faulted condition
HTDW	Hydrostatic test dead weight
DBPB	Design basis pipe break, includes LOCA and non-LOCA (transient)
LOCA	Loss-of-coolant accident
HYDSP	Building structure motions due to automatic depressurisation system sparger discharge
DBPBS	Design basis pipe break, includes LOCA and non-LOCA (sustained)

APPENDIX 20F
REACTOR COOLANT PUMP COMPONENT SAFETY REPORT

20F.1 Introduction

This is the component safety report (CSR) for the reactor coolant pump (RCP) as introduced in Section 20.2.The safety arguments herein substantiate the structural integrity (SI) of the RCPs to a degree of rigour commensurate with the consequences of gross structural failure. The safety arguments are supported by a suite of documentation outlined in Section 20F.5 that supports the design, manufacture, installation and operation of the RCP.

20F.1.1 Scope

This CSR presents a structural integrity argument for the RCPs in relation to their pressure retention function; withstand to design basis internal and external hazards, including the effects of postulated flywheel disintegration and rotor locking. These arguments support the claim that the nuclear and radiological risks, potentially arising from gross structural failure of an RCP casing are tolerably low for the entire design lifetime objective of 60 years. The mechanical and electrical aspects of the RCP design are considered in sections 17.3.1 and 18, and are outside the scope of this appendix.

20F.1.2 Objectives

This CSR establishes arguments to support the claim that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. These claims are substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for the RCP are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the structural integrity aspects of the RCP are identified in Section 20F.2.

The approaches to achieving this objective are:

- To support the nuclear safety claims made for the AP1000 RCP design.
- To present arguments that support the claim that the structural reliability of the RCPs is commensurate with the consequences of failure and remains so throughout their design life. That is, where failure is intolerable, the probability of gross failure should be shown to be so low that such failure can be discounted, or where failure does not lead to intolerable consequences, the target reliability is linked to the consequences in accordance with the methodology in Reference 20F.1. This is discussed in Section 20F.2.2.

20F.1.3 Interface With Other Safety Case Documents

The RCP Final Research and Development (R&D) Report, Reference 20F.2, which details the proposed design solution, references a dossier of technical data and supporting analyses. In addition to this report, the Final Design Report (Reference 20F.12) summarises the supporting design process, including dedicated design reviews, the main conclusions and supporting and reference documentation, and updates to the design as part of the design finalisation process, especially in resolution to the open issues (chits) identified during the design reviews.

A full index of technical documentation is provided in the final design review package, which also includes a synopsis of the main design reviews and analyses. Table 20F-5 shows the reports, calculations, and analysis supporting the RCP design.

20F.1.4 Reactor Coolant Pumps Description

20F.1.4.1 Overview

Reference 20F.3 provides the AP1000 RCP design specification for the sealless, wet winding RCP, while Reference 20F.12 provides a review of the RCP design. This Final Design Review package provides a summary and synopsis of the design and design process. Its main reference is the technical report in Reference 20F.2, as updated in Reference 20F.12 to the design finalisation in support of the final design review, and in resolution of open items identified during previous intermediate design reviews. These two reports and the design specification, and the extensive supporting documentation therein referenced, provide the basis of the design for this CSR. Although these documents cover all aspect of the pump design, including the hydraulic characteristics and electrical performance, this CSR covers those aspects of the design relevant to structural integrity.

The RCPs are an integral part of the reactor coolant system (RCS) pressure boundary and are designed to circulate pressurised water to extract heat from the core delivering it to the steam generators (SGs) and then back to the core. The reactor coolant system consists of two heat transfer circuits, each with a single SG, two RCPs, and a single hot leg and two cold legs. Figure 20F-1 shows the schematic flow diagram for the AP1000 RCS; the principal pressures, temperatures and flow rates under normal steady-state, full-power operating conditions relating to the various numbered locations are presented in Table 20F-1. SG number 1 has RCP 1A and RCP 1B attached whilst SG number 2 has RCP 2A and RCP 2B attached. Figure 20F-2 is an isometric figure depicting the reactor coolant loops and the RCPs. Figure 20F-3 is an elevation figure showing the RCP configuration below one of the SGs.

The AP1000 RCPs are high-inertia, high-reliability, sealless pumps that circulate the reactor coolant through the reactor vessel, loop piping, and SGs. Each pump is a compact, vertical pump/motor unit, designed to fit into the SG compartment. The pump casings are welded to the channel head by the suction nozzle. The integration of the pump suction into the bottom of the SG channel head is a significant pressurised water reactor design development. By eliminating the coolant loop piping cross-over leg associated with traditional pump pairs, the loop pressure drop is reduced, reducing the pumping requirements and promoting passive circulation, the foundation and support system for the steam generator and associated piping is simplified, the overall plant footprint is reduced, and the potential for uncovering of the core is reduced by eliminating the need to clear the loop seal during a small loss-of-coolant accident (LOCA).

20F.1.4.2 Description

Each AP1000 RCP is a vertical, single-stage centrifugal pump designed to pump large volumes of main coolant at high pressures and temperatures. Owing to its sealless design, it is more tolerant of beyond design basis conditions that could adversely affect shaft seal designs. The main impeller attaches to the rotor shaft of the driving motor, which is an electric induction motor. Primary coolant circulates between the stator windings and along the rotor which obviates the need for a seal around the motor shaft. Additionally, the motor bearings are lubricated by primary coolant. The motor is, thus, an integral part of the pump. The basic pump design has been proven by many years of service in similar applications around the world and in other applications. Evidence to support this argument is presented in Reference 20F.2.

The pump motor size is minimised through the use of a variable frequency drive to provide speed control in order to reduce motor power requirements during pump startup from cold conditions. The variable frequency drive is used not only during heatup and cooldown, but also during all operational modes. To provide the rotating inertia needed for flow coast-down, a bi-metallic flywheel assembly is attached to the pump shaft. The flywheel ensures that, following a loss of electrical power supply to the main coolant flow, the resulting coastdown meets the requirements for the design basis analysis.

Pressure Boundary

The pressure boundary consists of three parts, the pump casing, heat barrier assembly, and motor casing assembly. These parts are clamped together by 24 high strength closure bolts. The reactor coolant pump casing is a single-piece forging, constructed of ferritic material (SA-508 Grade 3) and includes an austenitic cladding of the wetted surfaces. Cladding is applied using weld overlay consistent with the application process used for similar portions of the reactor coolant system. The use of SA-508 material offers high strength, greater ease of manufacture and compatibility with the SG channel head material thereby reducing the number of potential on dissimilar metal welds. Weld buttering or post weld heat treatment will be utilised on the remaining dissimilar metal welds to reduce the risk of welds failing. The specific method will be determined during the detailed design phase. The heat barrier and motor casing components are also single-piece forgings constructed of high-strength (Gr. F6NM) martensitic stainless steel material.

The pressure boundary components are designed to meet the requirements of the American Society of Mechanical Engineers (ASME) Boiler & Pressure Vessel Code (Code), Section III, Division 1, Class 1998 edition, including 2000 Addenda; and are designed and analysed according to the requirements in Subarticle NB-3400 of the Code. This is discussed further in Section 20F.3.2.

Impeller/Diffuser

The pump/motor unit consists of a pump hydraulic part, where a semi-axial impeller/diffuser combination is mounted in a flow-optimised, single-piece casing. The impeller/diffuser combination is of a very high hydraulic efficiency and is based on well proven designs that have been used by Westinghouse for more than 30 years.

Flywheel

The flywheel is located between the impeller and the motor, and consists of a single-piece forged stainless steel cylinder, with several smaller heavy metal cylinders inside. The inclusion of very high density materials such as tungsten alloy is required to minimise the

size of the flywheel, thereby, allowing incorporation within the pressure boundary as well as reducing the drag on the flywheel and associated heat production caused by the location of the flywheel within the pressure boundary. However, these high density materials do not have the required strength. Hence, a bi-metallic design has been selected, which has the following advantages over the alternatives:

- The forged stainless steel base can be selected to meet the operating conditions.
- It is possible to produce large stainless steel forgings without structurally significant flaws.
- The high density material is not relied upon structurally.
- The amount of material needed in order to provide the same inertia as a monolithic flywheel is considerably lower.

A short and rigid shaft, supported by a radial bearing, connects the impeller with the high-inertia flywheel. In order to avoid potentially high circumferential stress in the central bore, the flywheel is connected to both pump shaft and motor shaft via Hirth-type spline face adapters. In addition, no shrink fit to a shaft is needed to transmit the torque.

The flywheel is located inside the heat barrier, which forms part of the pressure boundary. A complex arrangement of cooling water circuits provides a homogeneous temperature distribution in and around the flywheel, minimises the friction losses of the flywheel, and protects the motor from hot coolant.

Motor/Electrical Components

The driving torque is transmitted by the motor shaft, which itself is supported by two radial bearings. A three-phase, high voltage squirrel cage induction motor generates the driving torque. The speed of the motor is variable by the variation of the output frequency of the variable frequency drive. The motor is mounted in a single-piece forged motor casing with a bolted cover at the lower end side. Due to the wet winding concept, it is possible to achieve an optimal cooling of the stator and avoid internal hotspots with positive effects regarding motor lifetime. The cooling water is forced through the stator windings and the gap between the rotor and stator by an auxiliary impeller. Furthermore, this wet winding motor concept is of very high efficiency as compared to a canned motor with its high eddy current losses.

Supports

The RCPs are supported entirely by the SGs; consequently, there are no RCP supports.

20F.1.5 Boundaries

The physical boundaries for safety case assessment of the RCP are as follows:

- RCP casing suction nozzle end. The weld of the suction nozzle to the SG is considered as part of the SG.
- RCP casing to discharge nozzle end. The weld of the discharge nozzle to the cold leg pipe is considered part of the RCS piping.
- Heat exchanger cooling water supply and return flanges.

- Flange for the RCP fill and drain line.

The RCP casing boundaries are indicated in Figure 20F-4.

20F.2 Safety Case Structure

The main focus of this CSR is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate the reliability appropriate to the classification of the RCP as a Standard Class 1 component, as outlined in Section 20F.2.2. To achieve this, the safety argument is presented as three key elements, as follows:

Claim 1:	Quality of Build: High quality will be achieved during manufacture.
Objective:	Provides evidence of good design and manufacture based on established practices and track record. It provides a keystone for a demonstration of appropriate reliability and embodies the code and plant operating experience with the objective of achieving a good quality of build and the avoidance of defects.
Claim 2:	Good Design: Good design is achieved through compliance with ASME.
Objective:	Incorporates the build experience as embodied in the design codes.
Claim 3:	Mitigation and Management of In-service Degradation: RCP pressure boundary components are tolerant to through-life degradation over the design life of the plant
Objective:	Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval. It is also established that potential degradation mechanisms are understood and that the inspection and maintenance programme will detect degradation before it affects the performance requirements.

The safety argument has been tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure.

The three elements of the safety argument are provided in Section 20F.3 and the strength of the argument is discussed in Section 20F.4.

20F.2.1 Safety Functional Requirements

The basis for the selection of the SFRs is discussed in Section 20.4. These are based on the safety design bases established for each component and include the duty functions and accident response requirements of plant systems, which must be maintained at all times or upon demand as appropriate to provide assurance of plant nuclear and radiological safety. Identification of the SFRs for the RCP follow from the performance and safety design bases allocated in Reference 20F.3, as follows:

- **SFR 20.11.1** The RCP is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation and under design basis faulted conditions for the design life of the plant.

- **SFR 20.11.2** The RCP is required to retain missile fragments arising from a disruptive failure of the RCP flywheel without gross failure of the RCS pressure boundary.

Postulated failure modes which result in a loss of these functional requirements lead to the identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20.5.

20F.2.2 Reactor Coolant Pump Structural Integrity Classification

For the United Kingdom (UK) AP1000 plant, a structural integrity classification methodology detailed in Reference 20F.1 and summarised in Section 20.5 has been applied to pressurised components with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct consequences and indirect consequences of gross failure. Direct consequences include the effect of LOCA or reactivity addition, indirect consequences include missile generation, pipe whip, blast and flood.

The assessment of the RCP pressure boundary and flywheel is presented in Table 20-8. This includes the conclusion that a gross failure of the RCP pressure boundary would lead to a large LOCA, bounded by the double-ended guillotine break (DEGB) of the primary loop. This is within the analysis presented in Chapter 9 and therefore mitigated by the Class 1 AP1000 passive systems. Considering the indirect consequences, the assessment of the potential for high energy missiles to be generated concluded that these missiles would be contained within the SG compartment without threatening the operability of the plant passive safety systems or containment boundary. Specific consideration was given to the potential for missile fragments from the RCP to lead to a disruptive failure of the SG channel head or secondary shell, which would in itself attract a highest safety significance (HSS) classification. The assumption of two consecutive disruptive failures is considered outside the methodology and hence was dismissed. Consideration was also given to the failure of the SG support column arising from missile damage. Analysis performed demonstrates that core cooling is maintained in the unlikely event that the vertical support should fail as a result of missile damage. Based on these arguments, the RCP pressure boundary has been assessed as a Standard Class 1 component. The basis for the safety case is presented in Section 20F.3.

The RCP to SG Channel Head weld has been assessed as highest safety significance. The justification for this weld is presented in Appendix 20C.

20F.3 Safety Case Arguments

For a Standard Class 1 component, the primary safety argument is that design and manufacture in accordance with the ASME Code provides the basis against which adequate structural reliability can be claimed for a Standard Class 1 component. Evidence to support this claim is provided by pressure vessel failure statistics, as indicated in the UK Technical Advisory Group on Structural Integrity (TAGSI) paper on the presentation of incredibility of failure safety cases (Reference 20F.4).

The basis of the safety case for the RCP is, therefore, the arguments and evidence to substantiate the following claims.

- Claim 1: High quality will be achieved during manufacture (Section 20F.3.1).
- Claim 2: Good design is achieved through compliance with ASME (Section 20F.3.2).

- Claim 3: In-Service Degradation is Avoided (Section 20F.3.3).

20F.3.1 High Quality Is Achieved During Manufacture

The reliability and integrity of the RCP pressure boundary is dependent upon the achievement of high quality during design, manufacture and installation. The design intent is translated into a manufacturing process which is controlled by a Quality Assurance Programme complying with rigorous design codes including the ASME Code. The RCP Design Specification (Reference 20F.3) provides the complete list of the industry codes, specification and standards which are to be complied with. These include:

- Westinghouse specifications and standards, including supplementary fabrication and inspection requirements.
- The ASME Code and applicable Code cases.
- American National Standards Institute (ANSI)/ASME Standards
- United States (US) Code of Federal Requirements
- US Nuclear Regulatory Committee (NRC) Regulatory Guides and NUREGS
- American Society for Testing and Materials (ASTM) Standards

Fabrication and manufacturing for the RCP will meet the specifications described in Reference 20F.3 to satisfy the requirements of ASME Code, Section III, Subsection NB, Article NB-4000. The following sections outline design requirements to assure the manufactured RCP is of high quality.

20F.3.1.1 Fabrication

The Class 1 parts of the RCP pressure boundary will be fabricated per the requirements of ASME Code, Section III, Subsection NB, Article NB-4000. The heat exchanger structural support will be fabricated to Subsection NF, Article NF-4000.

20F.3.1.2 Material Specifications

The pressure boundary materials for the AP1000 RCP will all comply with the material specifications of ASME Code, Section II. The RCP Design Specification (Reference 20F.3) specifies the requirements for the RCP pressure boundary materials including welding and bolting materials. Allowable pressure boundary materials are summarised in Table 20F-2. SA-508 Grade 3 was selected for the casing material as the selection of SA-508 Grade 3 material provides the following benefits:

- Existing world-wide manufacturing experience in forging large diameter, thick ring sections thus ensuring predictable through-thickness material properties.
- Extensive world-wide operating experience in light water reactor environments with no fatigue driven failures.
- Reduces the number of reactor coolant system pressure boundary materials.
- Minimises the reliance on dissimilar metal welds.

- Industry proven chemistry specification and mechanical property database
- Mechanical property balance between yield strength and thermal conductivity.
- Extensive welding and nondestructive examination (NDE) inspection experience related to heavy section forgings utilising established techniques.

To prevent corrosion of low alloy steel components in contact with primary coolant, the pump casing will have corrosion-resistant cladding on surfaces exposed to the reactor coolant. Clad surfaces will be austenitic stainless steel weld overlay. For multiple layer austenitic stainless steel cladding, the cladding will be Type 308L weld metal with Type 309L weld metal used for the first layer. The approach to cladding provides the following benefits:

- Extensive world-wide operating experience in light water reactor environments
- Corrosion resistance of cladding material equivalent to corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy, martensitic stainless steel, and precipitation-hardened stainless steel
- Equivalent inspectability to other clad application approaches

The heat barrier and motor casing are to be fabricated from Gr. F6NM forged high-strength martensitic stainless steel (Table 20F-3). Reference 20F.3 specifies the design requirements for martensitic stainless steel.

The materials used for the pressure boundary bolting will be examined and tested as per paragraph NB-2300 and NB-2500 of the ASME Code. Ferritic pressure boundary bolting materials will meet the minimum requirements of 0.63 mm (0.025 in) lateral expansion and 61J for Charpy V notch tests conducted at 10°C (50°F) maximum.

20F.3.1.3 Welding

External pressure boundary welds are limited to the interface to connecting components as the casing is a single forging. The pump casing, heat barrier assembly, and motor casing assembly components are manufactured as single-piece forgings; no fabrication welding is included.

Welding, welder qualifications and welding inspection will be in accordance with ASME III and Section IX as described in Reference 20F.3. The same standards apply to welds within the flywheel enclosure even though they are not external pressure boundary welds.

20F.3.1.4 Nondestructive Testing

As specified in Reference 20F.3, nondestructive testing will be carried out by personnel qualified and certified in accordance with the requirements of ASME III, NB-5000. The requirements with respect to testing and examination techniques are specified. The results of these tests on the pressure boundary components and the structural components of the flywheel will be documented.

Examination will be performed in accordance with the following requirements:

- Materials – ASME Section III, NB-2000.

- Cladding – ASME Section III, NB-5000.
- Welds – ASME Section III, NB-5000.
- Thickness – ASME Section V, Article 5.

Any ultrasonic testing weld examination zone includes the weld and heat affected zone. The weld heat affected zone will extend 12.7 mm (0.5 in) beyond the weld fusion line.

Radiographic inspection or magnetic particle inspection will be performed in accordance with ASME Section III, Subsection NB. Magnetic particle examination will be performed after any required post-weld heat treatment.

The final NDE of pressure boundary materials will be conducted in the stage of fabrication indicated in the ASME Section III, Subsection NB and the following:

- Low alloy materials will be magnetic particle inspected after quench and temper.
- Surfaces to be clad will be magnetic particle examined prior to cladding.

Liquid penetrant inspection will be performed in accordance with ASME Section III, Subsection NB.

The weld between the RCP and the SG channel head has been classified as a HSS weld. This weld has been considered as part of Appendix 20C and will be subjected to inspection qualified in accordance with the European Network on Inspection Qualification methodology and supported by elastic-plastic defect tolerance studies.

The flywheel structural components will be inspected prior to final assembly in conformance with Regulatory Guide 1.14 (Reference 20F.5). Inspection of the flywheel will be in accordance with the fabrication methods used and the procedures in ASME Section III, Article NB-2500. To ensure the integrity of the flywheel following final assembly, a penetrant test will be performed on the enclosure welds.

20F.3.1.5 Quality Control

The requirements of a quality control programme relevant to the RCPs is summarised in Reference 20F.3. A compliant programme will be produced for the fabrication and installation of the RCP.

20F.3.1.6 Hydrostatic Testing

ASME Code provides hydrostatic requirements which will be carried out for each RCP as specified in Reference 20F.3. A shop hydrostatic test will be performed at a test temperature established to be safe from brittle fracture. Reference 20F.3 recommends that the test temperature should not be lower than the reference temperature nil-ductility temperature (RT_{NDT}) plus 33°C.

20F.3.1.7 Prototype/Production Testing Requirements

Testing requirements relating to the pressure boundary are specified in Reference 20F.3. This includes a requirement for testing of a full sized first-of-a-kind pump. Reference 20F.12 and Reference 20F.2 summarise the design, fabrication and testing programme of a ½-scale prototype pump used to test and verify the response of the RCP components. The scaled pump testing was completed as part of the design refinement process and has been used to provide comparison between calculated performance data and measured data including temperature distributions and bearing performance.

Reference 20F.12 and Reference 20F.2 summarise the results of testing performed on a ½-scale flywheel with tungsten alloy inserts including balancing and overspeed testing. The maximum speed for the flywheel prototype was 2,437 rpm, which exceeds the 2,250 rpm required in the design specification for the full-sized flywheel (Reference 20F.3). Overspeed testing is required for the full size flywheel during factory acceptance testing.

Together these arguments provide a basis for a demonstration that each RCP will achieve a high quality during manufacture and will enter service free from significant structural defects. The outcome of the materials testing and NDE will provide supporting evidence on a case-by-case basis in due course.

20F.3.2 Good Design Is Achieved Through Compliance With ASME.

As stated in section 20F.1.4.2, the pressure boundary components have been designed to meet the design, analysis and testing requirements of the ASME Code, Section III, paragraph NB-3400.

Summaries of the calculations against these criteria are presented in Reference 20F.2. These summaries have been developed from the detailed design calculations.

Pressure Boundary Stress Analysis

The RCP Design Specification, Reference 20F.3, presents the loading combinations used to analyse and justify the RCP assembly: The resulting RCP pressure boundary stress intensities are not to exceed the limits specified in ASME III, NB-3400. The rules to be used for evaluation of the Level D conditions are defined in Appendix F of ASME Code, Section III.

Reference 20F.3 presents the allowable design nozzle loads for outlet and inlet nozzles. These loads are applied at the nozzle safe ends where applicable or at the nozzle-piping interface during the design of the RCP.

Reference 20F.2 summarises the results of the ASME sizing calculations and stress analyses for the pressure retaining parts, which provides evidence that the ASME sizing requirements have been satisfied. Reference 20F.12 also describes the results of the stress and fatigue analysis against the mechanical and thermal loads described above. The analysis, which was performed using the ANSYS Code, covers the following components:

- Pump Casing
- Lower Part of Motor Housing
- Thrust Bearing Housing
- Bearing Bracket
- Upper Part of Motor Housing
- Heat Barrier
- Main Closure Studs

The conclusion from this analysis is that all pressure retaining parts of the RCP comply with the rules and limits set forth in the ASME Code.

As stated in section 20F.1.4.2, the pump casing is ferritic material with austenitic stainless steel cladding. The existing ASME analysis for the pump casing was completed for a martensitic pump casing. Reference 20F.12 documents in detail the comparison of the different materials and justifies why it is not considered necessary to update the stress analysis at this stage. It is recognized that prior to shipment, the analysis is required to be

updated for the material change. The following arguments support the applicability of the existing ASME stress analyses to the current pump casing design:

Material Properties

Reference 20F.12 provides a summary of important parameters for three different microstructures of ASME Code compliant pressure boundary materials including the ferritic material chosen for the pump casing and two other materials – martensitic stainless steel (the material analysed in the ASME stress analysis referenced in Reference 20F.12) and austenitic stainless steel (for comparison). The impact of these parameters is discussed in the following reconciliation.

Evaluation and Reconciliation with Regard to Stress Analysis

The stress analysis performed for the martensitic casing material was reviewed with regard to changes that would be needed to reflect the ferritic pump casing material. Because the material strength of SA-508 is not as high as of the Grade F6NM material, the locations of stress classification lines (SCLs) and nodes with maximum stresses and usage factors were evaluated. The relevant positions are shown in Reference 20F.12.

The design and test conditions produced the maximum stresses. Service Levels A to D are covered by these conditions. The general maximum usage factor was found away from the discharge nozzle; however, the absolute value was so low that this area did not require any further consideration. A local usage factor needed to be evaluated for the area in and around the discharge nozzle, because the stress intensity range at this location needed special justification. The reconciliation therefore focused on the section through the discharge nozzle.

It is expected that a change in pump casing material will not lead to major changes in the stress analysis. The following facts have positive or supporting influence on the stress analysis:

1. Sizing Calculations (wall thickness, reinforcement) were re-performed for the ferritic material (Reference 20F.12). All requirements of ASME Code, Section III, Division 1, Subsection NB-3300 are fulfilled.

2. Ferritic material has a higher thermal conductivity than martensitic (Section 5.1.2 of Reference 20F.12). Therefore, the same thermal loads would result in lower stresses in a ferritic material of similar thickness during steady state and especially during transient conditions.

3. Since general usage factors are very low, even an increased alternating stress would be compared to the same fatigue curve and would not exceed the limits.

4. The ferritic casing design also includes a reinforced transition area per ASME Code.

5. The circumferential groove at the bottom of the casing in the analysed case was eliminated in the ferritic design, resulting in a thicker and more homogeneous casing bottom.

These factors combine to mitigate the effects of reduced material strength. Should these contributors turn out to be insufficient to meet ASME code requirements, the appropriate measure would be to reinforce the transition to the discharge nozzle further by adding material to the outside. In order to keep the required distance to the weld (for in-service inspection (ISI)), the nozzle length would have to be increased. This would also cause

changes in the raw part of the pump casing. However, the general design of the casing or the pump would not be affected. The ASME stress analysis using ferritic material will be performed during the detailed design phase of the RCP and acceptable results are necessary to meet the requirements specified in the design specification (Reference 20F.3).

20F.3.3 Seismic Operability Analysis

The RCP is classified as AP1000 Class A with Seismic Category I requirements (Reference 20F.6). The AP1000 design earthquake is referred to as the AP1000 certified seismic design response spectra (CSDRS). Figures 1 and 2 of Reference 20F.6 depict the horizontal and vertical design response spectra for the AP1000 plant, scaled to the safe shutdown earthquake at 0.3g. The design response spectra are applied at foundation level (87.96 m) in the free field at hard rock sites and at finished grade (100 m) in the free field at firm rock and soil sites. In addition to the CSDRS, the AP1000 design has been enhanced to meet hard rock high frequency seismic response associated with earthquakes representative of Central and Eastern United States rock sites.

The RCP is welded to the SG and will predominantly be driven by the seismic response of the SG through this support, which is justified in Appendix 20C. The RCP pressure boundary itself is a seismically rugged structure that will not be prone to failure due to the inertial forces. Nevertheless, a series of analyses have been undertaken to investigate the additional stresses due to a seismic event as summarised in Reference 20F.2. This discusses the results of analyses which provide the evidence that the RCP is seismically designed and qualified for the safe shutdown earthquake (SSE), that it can withstand the effect of specified earthquakes, that the pump will perform its safety shutdown functions during and after SSE and that it will maintain the safe shutdown condition.

Flywheel Integrity

The AP1000 plant is designed such that components important to safety are protected against the effects of missiles. The AP1000 RCP is therefore designed such that, in the event of a postulated worst-case flywheel assembly failure, the surrounding structure can contain the energy of the fragments without causing gross failure of the pressure boundary. In the design and fabrication of the flywheel, the intent of US NRC Regulatory Guide 1.14 (Reference 20F.5) is followed. The Final R&D Report (Reference 20F.2) provides a summary of the analysis undertaken using the energy absorption equations of Hagg and Sankey (Reference 20F.9). This analysis assumes that fracture of the flywheel has occurred and seeks to prove the energy of the fragments is insufficient to penetrate the pump pressure boundary walls. The analysis covers a range of fragment sizes. The results show that for the worst case fragment size, the fragments will be retained within the pressure boundary as they possess insufficient energy to perforate the RCP casing. This supports the argument that in the unlikely event of flywheel failure, any fragments will be contained within the pressure boundary.

Rotor Seizure

The design of the pump is such as to preclude the instantaneous stopping of any rotating component of the pump or motor. The rotating inertia would overcome interference between components for a period of time. To analyse the mechanical and structural effect of a rapid slowdown of the rotating assembly, a failure of the rotating assembly is postulated that results in deformation that causes an interference with the surrounding RCP components. For such interference, the pump and motor are postulated to come to a rapid stop. This bounds other postulated mechanisms involving a rapid slowdown of the pump.

For normal operating conditions, the connection of the pump with the steam generator and discharge piping is analysed for the vibration of the pump, hydraulic effects and the torque due to rapid slowdown of the rotating assembly. The stresses in the pump casing, motor housing, steam generator channel head, and piping are analysed using ASME Code, Section III, Service Level D limits for this condition. The evidence to support this is presented as part of the Final R&D Report (Reference 20F.2) which considers the deceleration from a normal operating rotational speed of n = 1,780 rpm to standstill during one revolution. The report discusses the results of the analysis undertaken using finite element methods. The conclusion in this report is that the stress intensities from the postulated locked rotor event are always lower than the allowable Service Level D stress limits. Therefore, the integrity of the pump is not jeopardised by such an event.

Flywheel Overspeed

Reference 20F.2 presents the results of an overspeed analysis of the flywheel considering both ductile and non-ductile failure. This analysis concludes that the maximum allowable stress intensity in the load carrying part of the flywheel would be reached at 3,640 rpm, considerably above the design speed (125% of nominal) of 2,250 rpm. Considering non-ductile failure, the stress intensity factor for an assumed crack with length equal to the minimum that can be detected by NDE is evaluated against a lower bound fracture toughness of 50 MPa√m. Based on this calculation, the limiting speed was determined to be 7,140 rpm, demonstrating a considerable margin against non-ductile failure of the flywheel.

Dynamic Analysis

The rotating components of the pump have been analysed for dynamic characteristics, including damped natural frequencies, stability, and forced responses to normal operational load (Service Level A), and upset conditions (Service Level B) associated with the rotating masses. A linear modal and stability analysis has been performed with the aid of the computer programme ANSYS. The linear modal and harmonic responses were performed for different pump speeds within the operating frequency range or at the natural frequencies of the housing. The computer code NIROD has been applied for non-linear rotating dynamic calculations. The results of this analysis are summarised in Reference 20F.2.

20F.3.4 Mitigation and Management of In-Service Degradation

The design of the AP1000 RCP takes account of potential through life degradation mechanisms which could threaten the integrity of the pressure boundary. Design and manufacture in accordance with established codes, standards and regulations provides assurance of high reliability, in addition to supplemental requirements based on Westinghouse's extensive experience with such mechanisms and practices for mitigation and management. The degradation mechanisms are summarised below.

Degradation Mechanism	AP1000 Mitigation
Material Defects	• Selection of appropriate material product types (forging vs. casting) • Good design and manufacture (ASME) • High degree of control of manufacturing processes • Material and manufacturing inspections (NDE) • Pressure testing
Corrosion/Erosion	• Selection of materials • Good design and manufacture (ASME)

Degradation Mechanism	AP1000 Mitigation
Fatigue Cracking	• Selection of materials • Good design and manufacture (ASME) • In-service inspection
Stress Corrosion Cracking	• Selection of materials • Detrimental material control during manufacturing • Control and limitation of material compositions • Identification (design) and control (operation) of plant fluid chemistry parameters
Primary Water Stress Corrosion Cracking (PWSCC)	• Selection of materials • Prohibiting use of materials susceptible to PWSCC
Underclad cracking	• Selection of materials • High degree of control of welding processes • Material and manufacturing inspections (NDE)
Irradiation embrittlement	The AP1000 RCP is located away from the Reactor Vessel such that the pump is not considered to be susceptible to irradiation effects.

These mechanisms are primarily mitigated and managed through design, manufacturing, and inspection requirements for the RCP:

- Use of forgings instead of castings to provide a higher quality of material and alleviate the potential for internal flaws and defects
- Experienced-based selection of corrosion/erosion resistant materials
- Design, analysis, manufacturing, inspection and testing in accordance with ASME Boiler and Pressure Vessel (B&PV) Code to promote inherent quality and good design
- Identification of bounding plant chemistry values within design requirements
- Requirements for controls of materials and manufacturing:
  - Fracture toughness requirements
  - Material and Post-Weld Heat Treatment requirements
  - Delta ferrite limitation requirements
  - Limitation or prohibition of unacceptable materials and/or composition of materials (low melting point metals, detrimental materials such as halides, etc.)
  - Welding qualifications and process requirements (ASME Section IX)
  - Cladding material specifications and processes restrictions (preheat, heat input)
- Examination and testing requirements for materials and manufacturing:
- Volumetric examination (UT) of base material and final as-clad material

- Surface examination (MT) of base material after quench and temper and also prior to cladding
- Surface examination (PT) of final cladding
- Hydrostatic testing

Through these requirements and in-service inspection activities, such aforementioned degradation mechanisms are properly managed or even precluded.

20F.3.4.1 Compatibility with Environment

The RCP will be designed to operate satisfactorily with the reactor coolant water chemistry guidelines provided by Electric Power Research Institute (Reference 20F.7) and the primary coolant chemistry specification as given in Reference 20F.3. As noted in Reference 20F.2, there is over two decades nuclear industry experience of pumps utilising similar design materials for the pump pressure boundary while operating in contact with borated water without experiencing problems.

20F.3.4.2 In-Service Inspection

The design of the RCP is such that access is provided in the installed condition for inspections as specified by Section XI of the ASME code. The AP1000 design philosophy includes a design for inspectability programme to ensure that the design has been optimised to minimise uninspectable regions, to reduce the occupational radiation exposure, reduce inspection times, to allow state of the art inspection systems to be used and to enhance flaw detection and characterisation reliability. Full details of the inspectability assessment of the RCP are not yet available.

Based on the review presented in the AP1000 ISI requirements (Reference 20F.11), the components requiring in-service examination include, at a minimum, the pump casing to cold leg welds, the pump casing, the flange surface and bolting, and the terminal assembly to the RCP shell. The following design features help minimise the number of regions that require ISI.

- The pump casing, heat barrier assembly, and motor casing assembly components are manufactured as single-piece forgings; no fabrication welding is included.
- The flywheel is designed for low stress to meet the requirements of US NRC Regulatory Guide 1.14.

The final ISI requirements will be specified by the relevant utility as part of the site specific justification.

20F.3.4.3 Vibrational and Loose Parts Monitoring

The RCP is equipped with a three-axis vibration monitoring system that continuously monitors pump structure vibrations. This provides early warning of factors which could lead to premature failure of the pumps rotating component or higher than anticipated vibrational loading which could lead to fatigue crack growth.

20F.4 Strength of the Safety Case

The RCP has been subject of an extensive design development process, starting in 2004/2005 and culminating with the Final Design Review in December 2010. The final design review information package is documented in Reference 20F.12. The design review package demonstrates the level of maturity of the design and the robustness of the development process. Based on the robust design process and supporting evidence strong arguments are presented, which justify the integrity of the RCP to a standard appropriate to a Standard Class 1 component.

The RCP Final R&D Report, Reference 20F.2 references a dossier of technical data and supporting analyses. In addition to this report, the Final Design Report (Reference 20F.12) summarises the supporting design process, including a series of dedicated design reviews on the flywheel and thermal barrier, hydraulic design, pressure boundary, motor, bearing material, high pressure cooler and rotor dynamics.

In addition to this design process, a ½-scale hydraulic test as well as a ½-scale model pump test was conducted to support the design process, confirm the appropriateness of the design solution, and to confirm the analytical methods used in the design development and substantiation, as well as to demonstrate the manufacturability of the design.

The analyses and testing summarised in References 20F.2 and 20F.12 and the safety arguments based around compliance with ASME Section III requirements in Section 20F.3 demonstrate how RCP integrity will be achieved based on extensive quality assurance measures in analysis, design, fabrication, manufacture, materials, testing and inspection. The development and subsequent application of a testing and inspection programme in accordance with specifications will provide evidence and assurances that the RCP will be tolerant to through-life degradation and that any defects will be detected in good time.

In combination these elements will provide a cogent argument to substantiate integrity commensurate with the classification of the RCP for the 60-year design life.

20F.5 Index of Technical Reports

A list of the technical references supporting the substantiation is included within Reference 20F.12 and its supporting references, especially Reference 20F.2. The technical index is also provided in Table 20F-5.

20F.6 Review of Open Issues

There are no open issues for the RCP that affect the basis of the safety case arguments. Further updates to the design analyses are planned as part of the design finalisation. These updates will be controlled under robust QA-controlled procedures and will not affect the basis of the safety case arguments made in this report.

20F.7 Conclusions

The RCP has been classified in accordance with the methodology described in Reference 20F.1 as a Standard Class 1 component. This is because a DEGB of the primary loop is within the design basis and can be protected by the AP1000 passive protection systems, further, a disruptive failure of the RCP pressure boundary would be contained within the SG compartment and hence would not lead to the loss of essential safety systems or the containment pressure boundary. A disruptive failure of the RCP leading to a coincident

disruptive failure of the SG pressure boundary is not considered credible. In view of this, the RCP has not been classified as HSS.

For a Standard Class 1 component, the main element of the safety case argument is firstly, that the RCP will be manufactured in accordance with the high standards of the ASME Code, as applicable. This includes appropriate controls on material properties, manufacturing processes, design, testing, inspection and installation, such that there is a high level of confidence in the quality of the component and that it will enter service free from significant manufacturing flaws that could affect the integrity of the component over its lifetime.

The second element of the safety case argument is that the RCP design considers all credible loads and load combinations and complies with the appropriate requirements of the applicable ASME Code. This includes consideration of dynamic effect, flywheel disintegration and rotor seizure. The analyses presented in Reference 20F.2 provide evidence to support this argument.

Thirdly, that measures to prevent, detect or forewarn of in-service degradation, such as the implementation of a suitable ISI regime and vibration monitoring are specified, which will mitigate against the mechanisms identified as threatening the integrity of the component through life. The arguments presented support the claim that the structural reliability of the RCP pressure boundary will be commensurate with its consequences of gross failure.

APPENDIX 20G
PASSIVE RESIDUAL HEAT REMOVAL HEAT EXCHANGER COMPONENT SAFETY REPORT

20G.1 Introduction

This is the component safety report (CSR) for the passive residual heat removal (PRHR) heat exchanger (HX) as introduced in Section 20.2.The safety arguments herein substantiate the structural integrity of the PRHR HX to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20G.6 that supports the design, manufacture, installation and operation of the PRHR HX.

20G.1.1 Scope

This report presents arguments to support the claim that the nuclear and radiological risks potentially arising from gross structural failure of the PRHR HX are tolerably low for the design lifetime of 60 years. Conventional hazards to personnel safety are outside the scope of this Appendix 20G.

20G.1.2 Objectives

This report supports the claim the AP1000 plant risk remains both tolerable and as low as reasonably practicable for the design lifetime. This claim is substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case; if these can be maintained, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the PRHR HX are identified in Section 20G.3.

20G.1.3 Interface with Other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data and analyses. These are listed in the Technical Index (Section 20G.6) along with the role of each document in supporting the safety case argument.

20G.2 PRHR HX Description

20G.2.1 Overview

The PRHR HX is a component of the passive core cooling system (PXS) and provides emergency core decay heat removal. The PRHR HX provides core residual heat removal during postulated design basis non-loss-of-coolant accident (non-LOCA) events.

20G.2.2 Description

The PRHR HX consists of inlet and outlet channel heads connected together by 689 vertically oriented, C-shaped, thermally treated Alloy 690 tubes. The tubes are assembled into a tube sheet supported by the wall of the in-containment refuelling water storage tank (IRWST) and are normally submerged below the IRWST water surface. The PRHR HX is AP1000

Equipment Class A and is designed to meet seismic Category I requirements. Figure 20G-1 shows a diagram of the component. The design life of the PRHR HX is 60 years.

The heat exchanger inlet piping connects to an inlet channel head located near the top of the IRWST. The inlet channel head and tube sheet are attached to the tank wall via a support shell. The heat exchanger is supported by a frame attached to the IRWST floor and ceiling. The extended flange is designed to accommodate thermal expansion. The heat exchanger outlet piping is connected to the outlet channel head, which is vertically below the inlet channel head, near the tank bottom. The outlet channel head has a similar structural configuration to the inlet channel head. Materials used in the manufacture of the PRHR HX subcomponents, as detailed in Reference 20G.2, are shown in Table 20G-1. Further details of the PRHR HX design can be found in the PRHR HX Design Specification (Reference 20G.2) and in the Interface Control Document (Reference 20G.8).

20G.2.3 PRHR HX Function

Operation of the PXS is initiated (valves opened) upon receipt of any of the following signals: low steam generator level narrow range with concurrent low startup feedwater flow to any steam generator, low steam generator level wide range, high hot leg temperature, and also core makeup tank or automatic depressurisation system (ADS) actuation. The PRHR actuation signal automatically opens the normally closed valves in the line from the PRHR HX to the steam generator cold leg plenum. Driven by natural circulation, the PRHR HX takes suction from one of the RCS hot legs and injects cooled reactor coolant into the steam generator cold leg plenum on the same loop. The PRHR HX can provide decay heat removal with or without the reactor coolant pumps running. The PRHR HX transfers heat from the reactor coolant system (RCS) to the water contained in the IRWST. The water in the IRWST provides a large heat sink that acts to delay direct steaming into the containment for several hours. For additional details concerning the PRHR HX operation please refer to Chapter 6 and section 9C.

PRHR HX flow inlet and outlet line temperatures are monitored by indicators and alarms. The operator has the capability to manually throttle the discharge valves to control flow through the PRHR HX during a controlled plant cooldown.

The basic functions of PRHR HX are:

1. The PRHR HX removes sufficient heat from the RCS to mitigate loss of main feedwater and/or main feedwater line break accident assuming natural circulation.

2. The PRHR HX is capable of automatically rejecting core decay heat from the RCS to the IRWST for an extended period of time assuming the steam generated in the IRWST is returned to the tank. After a period of approximately two hours, the IRWST water reaches the saturation point and the IRWST water steams to the containment atmosphere. There it condenses on the steel containment shell which is cooled by the passive containment cooling system and is collected by a gutter arrangement at several elevations of the containment vessel and drained back into the IRWST. This process maintains the PRHR HX heat sink.

3. The PRHR HX is capable of reaching safe shutdown conditions within 36 hours, and maintaining these conditions for greater than 14 hours following non-LOCA faults, with or without AC power or the RCPs. This is substantiated using realistic analysis; safe shutdown conditions represent cooling the RCS core average temperature to 215.6°C (420°F) (average of hot leg and cold leg temperatures). Using traditional conservative design basis analysis assumptions, the RCS conditions are brought to a safe and stable

state, below the ADS actuation criteria, and this condition is maintained for greater than 72 hours. This cooldown allows the RCS pressure to be reduced, which reduces the stress in the RCS and connecting pipes to low levels, greatly reducing the chance of a subsequent LOCA. Eventually, PRHR performance is degraded to a point where the RCS conditions would approach ADS actuation criteria, and the operators would transition to open loop cooling should power not be restored (See Appendix 9C). It is important to note that "safe shutdown mode" (Mode 4) only applies to normal operation and does not apply to the post fault condition of "safe shutdown" as discussed here and explained further in Appendix 9C.

Full details of the functional requirements are given in Reference 20G.3.

The plant is allowed to operate within specified limits of PRHR HX tube leakage. The AP1000 Technical Specifications allow for PRHR HX tube leakage of up to 1893 litres/day (500 US gallons/day). If the tube leakage exceeds this rate, the Technical Specifications require that the PRHR HX will be isolated and the plant shut down. A forced plant outage will occur in case of a significant leakage or a rupture of a PRHR HX tube. The design, maintenance, and inspection of the PRHR HX in accordance with ASME requirements make this a highly unlikely event during the 60-year life of the plant.

20G.2.4 PRHR HX Boundaries

The physical boundaries for safety case assessment of the PRHR HX are shown in Reference 20G.2 and identified below:

- All pressure containing materials up to, but excluding, the circumferential welds between the inlet and outlet nozzle safe ends and the attached field piping.
- Vent and drain nozzle terminal ends, excluding field pipe weld.
- Circumferential structural weld between mounting ring and the IRWST wall liner.
- Housing upper lateral support including attachment bolting to its interfacing building embedment plate, but excluding the building attachment plate.
- Housing lower support base plate including the anchor bolts to its interfacing building embedment plate, but excluding the embedment plate.
- Circumferential weld attaching the tube sheet forging to the extended flange.

20G.3 Safety Case Requirements

The main focus of this report is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate the classification of the PRHR HX as Standard Class 1, as outlined in Section 20G.3.2 of the report. To achieve this, the safety argument is presented as three key elements, as follows:

Claim 1: Quality of Build: High quality is achieved through good design and manufacture.

Objective: Provides evidence of good design and manufacture based on established design and manufacturing processes and use of proven materials. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with an objective of achieving quality of build

and the avoidance of defects (Section 20G.4.1).

Claim 2: **Good Design: Good design is achieved through compliance with the American Society of Mechanical Engineers (ASME).**

Objective: Incorporates the build experience as embodied in the design codes (Section 20G.4.2).

Claim 3: **Mitigation and Management of In-Service Degradation: Components are tolerant to through-life degradation over the design life of the plant**

Objective: Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval (Section 20G.4.3).

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure.

The three elements of the safety argument are provided in Section 20G.4 and the strength of the argument is discussed in Section 20G.5.

20G.3.1 Safety Functional Requirements

Chapter 20 identifies structural integrity safety design bases for AP1000 SSCs. These are requirements of plant systems, some duty, and some accident response, which must be maintained to provide assurance of plant nuclear and radiological safety. The Safety Functional Requirements (listed in Table 20-1) for the PRHR HX have been derived from the following performance and safety design basis criteria, which apply when normal heat removal paths are not available:

- During anticipated RCS heatup or makeup transients, the PRHR HX must automatically be actuated to cool the reactor coolant.

- During excessive cooldown events such as a steam line break or an inadvertent PRHR HX operation, the PRHR HX must not remove too much heat such that the core is damaged or cause the ADS to be actuated.

- During a non-LOCA event, the PRHR HX must be capable of cooling the core such that the plant will meet the safety analysis acceptance criteria of maintaining primary and secondary system pressures below 110% of their design values, ensuring that the minimum departure from nucleate boiling ratio remains above the applicable limit, and ensuring that pressuriser water volume is not relieved through the pressuriser safety valves.

Detailed discussion of the emergency core decay heat removal criteria for the PRHR HX is provided in Reference 20G.14. Based on these, the following Safety Function Requirements have been identified which reflect the overall role of the component in plant safety:

- **SFR 20.6.1** The PRHR HX is required to maintain the integrity of the primary coolant pressure boundary during standby, normal operation and under design basis faulted conditions for the design life of the plant.

- **SFR 20.6.2** The PRHR HX is required to remove core decay heat in accordance with the component performance requirements.

Postulated failure modes which result in a loss of these functional requirements lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20G.3.2.

20G.3.2 PRHR HX Structural Integrity Classification

For the United Kingdom (UK) AP1000 plant, a structural integrity classification methodology, described in Section 20.5, has been applied with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct (e.g., LOCA) and indirect (e.g., missiles and pipe whip, etc.) consequences of gross failure. The details of the classification for the PRHR HX classification are presented in Table 20-13 and in Reference 20G.1.

Evaluation of the consequences of failure of the PRHR HX concludes that the direct consequences of gross failure of the PRHR HX would be an isolable LOCA that could be protected by the passive protection systems without causing core damage. Although failure of the PRHR HX tube would lead to a LOCA and result in the loss of an important element of the passive protection system, plant performance analyses have shown that loss of the rupture of a PRHR HX tube does not lead to core damage. The analysis to support this is presented in Section 9.6.5.

Considering the indirect consequences, the risk of consequential damage due to a failure of the PRHR HX tubing is considered small primarily because the heat exchanger is located under several feet of water in the IRWST and its configuration is unlikely to lead to the generation of missiles that could challenge the integrity of essential systems or containment. The indirect consequences of gross failure of the inlet and outlet PRHR lines have been evaluated and it is considered that they would not lead to escalated consequences of failure. On this basis the PRHR HX has been categorised as a Standard Class 1 component. The safety case requirements for such components are as described in Section 20G.3.

20G.4 Safety Case Arguments

The PRHR HX has been classified as a Standard Class 1 component in accordance with the structural integrity classification methodology. The structural integrity claim is therefore based on arguments that substantiate the claims listed in Section 20G.3. Consistency with the appropriate ASME III Code Class provides the basic demonstration of fitness-for-purpose for the PRHR HX.

Compliance with ASME III rules for an ASME Safety Class 1 component provides the primary element in the safety case for the AP1000 PRHR HX.

20G.4.1 High Quality Is Achieved through Good Design and Manufacture

In order to demonstrate that high quality is achieved through good design and manufacture, evidence to support the following claims is provided:

- The fabrication specification (Reference 20G.4) complies with ASME Code requirements for Class 1 components, including ASME NQA-1 (Reference 20G.5) quality requirements.

- Supplementary requirements are specified to avoid defects and to ensure quality.

The reliability of the PRHR HX is dependent upon the design quality. The design intent is translated into a manufacturing route controlled by a Quality Assurance Programme that complies with rigorous design codes, including the ASME Boiler and Pressure Vessel Code (Code). Section 2.3 of the PRHR HX Design Specification (Reference 20G.2) provides a list of the industry codes, specifications, and standards applied to the component.

The justification of the quality of build of the PRHR HX and of materials includes:

- Special processes used for manufacturing and fabrication – The PRHR HX is classified as AP1000 Equipment Classification Class A. Design and fabrication of the PRHR HX is carried out in accordance with ASME Code, Section III, Class 1 requirements. Special procedures and supplemental fabrication requirements to avoid manufacturing defects through, for example weld procedures and heat treatment controls, are detailed in References 20G.2 and 20G.6.

- Material Specifications – The applicable PRHR HX materials specifications and testing requirements have been specified in accordance with the requirements of Section II of the ASME Code. Of specific note is the use of Alloy 690 seamless tubing and the special procedures in place to ensure it is not susceptible to environmentally assisted cracking (EAC) through tight compositional control and strict heat treatment procedures.

- Nondestructive Examination (NDE) – The NDE of the PRHR HX is conducted in accordance with ASME Code, Section III requirements using ultrasonic examination, penetrant examination, magnetic particle examination, surface examination and weld examination. Supplemental inspection requirements include but are not limited to those detailed in Reference 20G.6.

- Fracture Toughness – Assurance of adequate fracture toughness of ferritic materials in the PRHR HX (input and output nozzles, channel heads and tube sheets) (ASME Code, Section III, Class 1 component) is provided by compliance with the requirements for fracture toughness testing included in NB-2300 and Appendix G to Section III of the ASME Code. This is described in further detail in Section 20G.4.3.3 of this document.

Together these provide a keystone for a demonstration that the PRHR HX is well designed, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the component.

20G.4.2 Good Design Is Achieved through Compliance with ASME

In order to demonstrate that good design is achieved through compliance with ASME, evidence to substantiate the following argument is provided:

- The design has been analysed and has been shown to comply with the requirements of ASME Code, Section III for Class 1 components.

The AP1000 PRHR HX has been designed in accordance with the requirements of the ASME Boiler and Pressure Vessel Code Section III, Div 1 – 1998 Edition through 2000 Addenda. The assessment is reported in a suite of calculation notes, as listed in the Technical Index of this report. The ASME Code, Section III subsection applicable to each sub-component is summarised below.

- Channel Heads (Upper & Lower) – Subsection NB

- Tube sheets (Upper & Lower) – Subsection NB
- Tube Sheet to Support Plate Weld – Subsection NB
- Tube Bundle – Subsection NB
- Tube Supports – Subsection NF
- Support Frame Housing, Including Upper & Lower Supports – Subsection NF
- Extended Flange – Subsection NF
- Support Shell to IRWST Liner Seal Weld – Subsection NF
- Support Shell – Subsection NF
- Support Plate – Subsection NF
- Mounting Ring – Subsection NF
- Vent/Drain Nozzle (upper and lower) Flow Restrictor – Subsection NB
- Vent/Drain Nozzle Pipe – Subsection NC

The design transients relevant to the PRHR HX are detailed in detail in Reference 20G.7; and are enveloped by the RCS transients shown in Table 20-22. The load cases considered include normal, upset, emergency and faulted conditions.

The external loads on the PRHR HX are specified in the Interface Control Document (Reference 20G.8). This includes nozzle external loads and seismic loads. In addition to conventional seismic loading, a dynamic assessment has been performed to evaluate the response of the PRHR HX assembly to sloshing effects, as well as the hydrodynamic loads due to pressure waves generated by the activation of the spargers in the IRWST or a PRHR HX tube rupture. The PRHR HX is therefore designed against design basis internal and external hazards.

An ASME sizing assessment of the critical locations of the PRHR HX is undertaken to ensure the designed thicknesses meet the minimum thickness required by the ASME Code, considering required loadings. Adequate sectional thicknesses/areas are specified throughout the component (Reference 20G.11).

The thermal and structural analysis has been undertaken using established procedures to demonstrate that for the load cases analysed, the stresses and cumulative fatigue usage factors are satisfactory and meet the appropriate limits set forth in the ASME Code, Section III. Details of these calculations are presented in the references calculation notes as detailed in the technical index.

20G.4.3 Mitigation and Management of In-Service Degradation

In order to demonstrate that the design has taken account of in-service degradation mechanisms, evidence to substantiate the following argument is provided:

- A structured process has been applied to identify in-service degradation mechanisms.

- The design has been optimised to mitigate against the risk from in-service degradation mechanisms.

20G.4.3.1 Identification of Degradation Mechanisms

Reference 20G.9 provides a failure modes and effects analysis (FMEA) which was carried out in order to identify design characteristics, potential hardware failures, or human errors associated with the design and operation of the PRHR HX that could lead to a potentially hazardous condition such as a LOCA.

The FMEA resulted in the identification of potential hazards or operational problems. Potential through-life degradation mechanisms considered included the following:

- Primary water stress corrosion cracking (PWSCC)
- Corrosion
- Fatigue
- Brittle fracture
- Vibration
- Erosion
- Failure arising from manufacturing defects

The basis of the safety case argument is that mitigation against corrosion, fatigue, vibration, erosion and manufacturing defects is essentially provided by compliance with ASME design and fabrication rules together with the associated in-service inspection (ISI) requirements and the operating experience embodied within the code to mitigate against these degradation mechanisms. Vibration analysis showed wide margin to established criteria for fluid-elastic excitation, vortex shedding and turbulence during the relatively short actuation periods. Further discussion of the measures associated with the mitigation and management of PWSCC in nickel alloys and the avoidance of brittle fracture (nonductile failure) is provided below.

It was determined in the FMEA study (Reference 20G.9) that there is sufficient mitigation in place to offset the potential hazards identified within the report, where the majority of hazards are assumed to be of minimal likelihood and minimal severity.

20G.4.3.2 Mitigation and Management of PWSCC

The main component of the PRHR HX is the Alloy 690 seamless tubing. Reference 20G.10 defines the guidelines for the manufacture, examination, quality assurance, testing and shipment of nickel-chromium-iron Alloy 690 (Alloy Unified Numbering System (UNS) N06690) seamless tubing. Alloy 690 is produced in accordance with the requirements of Section III of the ASME Code for ASME Class 1 components and has proven resistance to PWSCC.

ASME compliance will be achieved as the material manufacture of the seamless tubing complies with the applicable requirements of ASME Code, Section III Division 1 Subsection NB-2000, ASME Code, Section II Part B SB-163, including Supplementary Requirement S2 for high yield strength.

Material testing, for example, Ultrasonic Testing and Eddy Current Testing of Alloy 690 tubing, will be performed in accordance with the requirements stated in Reference 20G.10 supplemented by ASME SE-213 and ASME SE-571 respectively.

20G.4.3.3 Avoidance of Non-Ductile Failure

The Generic Design Report (Reference 20G.11) presents the calculations performed to safeguard the PRHR HX from non-ductile failure during normal, upset and test conditions, as required by the ASME Code, Section III, subsection NB.

Calculated stress intensity factors (K_I) were compared with the allowable critical values (K_{IR}). The analysis is based on the general methodology set forth in Appendix G of the ASME Code and in WRC Bulletin No. 175 (Reference 20G.15). Safety coefficients have

been applied to calculated stress intensity factors K_I in accordance with Appendix G, Articles G-2215 and G-2400.

In accordance with Appendix G of the ASME Code, Section III, the postulated defects for vessel walls are sharp surface defects normal to the direction of maximum stress. The depth of such defects is assumed to be 1/4 the shell section thickness with a length of 1.5 times the section thickness.

Reference 20G.11 provides further detail of the significant results of the fracture toughness calculations. The critical areas were found to be at the shell discontinuities and at the heel of nozzles. These regions cannot satisfy code requirements if a 1/4 thickness defect is assumed. Therefore, flaw depths 1/10 of the shell thickness were postulated, this is permitted by ASME Code, Section III Appendix G-2120 where there is a basis for ensuring smaller postulated defects, such as in regions remote from welds. Based on this assumption, the Heat Exchanger meets the Appendix G requirements for normal, upset and test conditions.

20G.4.3.4 In-Service Inspection

ISI provides forewarning of potential failure and a means of monitoring degradation. ISI forms an important element of the safety case argument. ISI is carried out in accordance with Section XI of the ASME Code. References 20G.12 and 20G.13 provide details of the inspectability assessment and details of the examination requirements for the PRHR HX using different techniques. Consideration is also given to the inspection coverage, limitations and access conditions at each location. A summary of the ISI requirements is shown in Table 20G-3.

Written instructions concerning PRHR HX inspection, maintenance, installation, operation, assembly details and disassembly details will be provided following generic design assessment (GDA). From this information, inspection of the PRHR HX will be carried out in accordance with appropriate maintenance and inspection and testing schedules. This will include as part of the ISI inspection regime, examination of the PRHR HX tubing over the entire tube length (tube end to tube end). NDE personnel performing such examinations will be qualified in accordance with ASME Code, Section XI Appendix VIII.

Inspection and maintenance of the PRHR HX will be performed during refuelling in accordance with the inspection plan and the refuelling frequency.

Both tube sheets can be accessed from outside the IRWST through the manways for inspection and maintenance without draining the IRWST. The channel head is designed to accomplish complete draining of the channel head, including the manway penetrations.

20G.5 Strength of the Safety Case

The PRHR HX is classified as a Standard Class 1 component. The safety argument in Section 20G.4 demonstrates how PRHR HX structural integrity is established based on extensive quality assurance measures in design, manufacture, materials, testing and qualified inspection. The strength of the safety case is underpinned by evidence to show that the PRHR HX has been specified and deterministically justified in accordance with the ASME Boiler and Pressure Vessel Code for Class 1 components. Additional mitigation against the effects of through-life degradation is provided by careful material selection and in-service inspection. In combination these elements provide a cogent argument to substantiate reliability commensurate with the classification of the PRHR HX.

To substantiate this claim, this report provides a structured argument supported by suitable and sufficient evidence. To achieve this, three key elements namely Quality of Build, Good Design and mitigation and management of in-service degradation have shown how this will be achieved.

Quality of Build has been demonstrated by compliance with ASME Code, Section III. Applicable material specification control has been achieved in accordance with Section II of the ASME code. NDE in accordance with ASME Code, Section III with adequate fracture toughness demonstrated by compliance with ASME code specifications.

Good design has been demonstrated by providing evidence, via the Generic Design Report (Reference 20G.11), that stresses arising during normal, upset, emergency and faulted conditions are within allowable limits specified in the ASME Boiler and Pressure Vessel Code Section III, Div 1 – 1998 Edition through 2000 Addenda.

Mitigation and management of in-service degradation has been demonstrated by identifying degradation mechanisms and potential hazards that could lead to loss of integrity of the PRHR HX. ISI will also provide forewarning of degradation with inspection carried out at appropriate intervals.

20G.6 Index of Technical Reports

Table 20G-4 provides a list of technical references supporting the safety case and the function of each document within the safety case.

20G.7 Review of Open Issues

There are no open issues for the PRHR HX that affect the bases of the safety case arguments presented in support of GDA.

20G.8 Conclusions

This report presents arguments that support the claim that the structural reliability of the PRHR HX is commensurate with the consequences of gross failure. To evaluate this, the PRHR HX has been classified in accordance with the procedure for structural integrity classification specified in Reference 20G.1. Based on this, the component has been evaluated as a Standard Class 1 component.

The PRHR HX is designed in accordance with the high standards of the ASME Code as applicable to ASME Class 1 components. This includes tight controls on material properties, manufacturing processes, design, testing, inspection and installation such that there is a high level of confidence the PRHR HX will be constructed with high quality; and will enter service free from significant flaws that could affect the integrity of the component over its lifetime. Secondly, measures to prevent or forewarn of in-service degradation, such as the use of EAC-resistant materials and in-service inspection, are specified, which will mitigate against the identified mechanisms having the potential to threaten the integrity of the component through-life.

APPENDIX 20H
CORE MAKEUP TANK COMPONENT SAFETY REPORT

20H.1 Introduction

This is the component safety report (CSR) for the core makeup tank (CMT) as introduced in Section 20.2.The safety argument herein substantiates the structural integrity of the CMT to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20H.5 that supports the design, manufacture, installation, and operation of the CMT.

20H.1.1 Scope

This report presents arguments to support the claim that the nuclear and radiological risks potentially arising from gross structural failure of the CMT are tolerably low for the design lifetime objective of 60 years. Conventional hazards to personnel safety are outside the scope of this Appendix 20H.

20H.1.2 Objectives

The objective of this report is to establish that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. This claim is substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the CMT are identified in Section 20H.2.1.

20H.1.3 Interface with Other Safety Case Documents

This report provides a safety argument to support the nuclear safety case claims relevant to the CMT. The safety argument presented in this report is supported by a dossier of technical specifications and analyses. These are listed in the Technical Index (Section 20H.5) and each is specifically identified in the relevant section of the structured safety argument.

20H.1.4 Core Makeup Tank Description

20H.1.4.1 Overview

The CMTs (two), as shown in Figure 20H-1, are components of the passive core cooling system (PXS). They are located inside the containment above the direct vessel injection (DVI) line connections. The basic function of the CMT is to provide reactor coolant system (RCS) makeup and boration during events when the normal makeup system is unavailable or insufficient. Upon receipt of a safeguards actuation signal, valves open to provide makeup water to the RCS.

20H.1.4.2 Description

Details of the CMT design can be found in the CMT design specification (Reference 20H.2). The two CMTs are vertical cylindrical tanks with hemispherical upper and lower heads. They are located inside the containment (on the 102.3-m floor elevation) (i.e., 7'2" above grade) above the DVI line connections to the reactor vessel, which are at an elevation near the bottom of the hot leg (Figure 20H-2).

The CMT is made of carbon steel with stainless-steel clad on the internal surface with hemispherical upper and lower heads supported on columns. The tank has an inlet diffuser welded to the inside of the upper head in the centre. A manway is provided for access to the inside of the tank. There are eight level taps to insert level instrumentation. There are six thermowell penetrations, two level/sample taps, and one fill tap. In addition, three lifting lugs are welded to the upper head. The CMT is designed with a linear-type support having a flanged interface for bolting the CMT to the building structure. The CMT is designed in accordance with the requirements of American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (Code) Section III, Subsection NB (Reference 20H.3). The CMT supports are qualified to the criteria of subsection NF of the ASME Code. Inside the containment, the secondary shield wall serves as a barrier between the reactor coolant loops and the CMTs.

20H.1.4.2.1 Materials

Materials used in the manufacture of the CMT subcomponents are shown in Table 20H-1. The cylinder and heads are made of low-alloy carbon steel and are clad on the internal surfaces with stainless steel for corrosion resistance. The nominal cladding thickness will be 5.6 mm (0.22 inch). Machining of as-deposited cladding is not required if the surface finish is suitable for required nondestructive examination (NDE) inspections. All clad surfaces including nozzles and manway will be 100 percent ultrasonically inspected for both bond and defects by the straight beam method. Materials in contact with the reactor coolant fluid are fabricated with corrosion resistant materials or are cladded. The cladding and stainless steel is carried through the rest of the tank features which include a manway, various small nozzles (level indicators, thermowells, pressure taps, and sample taps), and larger inlet/outlet nozzles. The cobalt content of materials used in the construction of component surfaces which come into contact with the primary coolant, including screws, bolts, washers, weld cladding and locking cups, has been specified to be no greater than 0.05 percent weight, integrated average. The cobalt content of all other welding materials is excluded from this requirement.

20H.1.4.2.2 Design Temperature and Pressure

The structural design of the CMT is based on the maximum steady state internal design pressure and design temperature values of 17.13 MPa gauge (2485 psig) and 343°C (650°F), respectively. These values are to be used in conjunction with the appropriate values of external pressure and temperature defined in the Design Specification (Reference 20H.2).

During normal operation, the CMTs are completely full of borated water (with a boron concentration of about 3500 ppm). The temperature of the borated water in the CMTs is generally about the same as that of the containment at a nominal operating temperature of 10°C to 48.89°C (50° to 120°F), since the tanks are not insulated or heated. Normally, the CMT outlet is isolated from the RCS and the cold leg pressure balance line is open, which keeps the tank at a pressure generally equal to the RCS.

20H.1.4.2.3 Total Volume/Flowrate

The free internal volume for the CMT is approximately 70.792 m^3 (2500 ft^3).

The discharge line from each CMT contains a flow-tuning orifice that provides a mechanism for the field adjustment of the injection line resistance. The orifice is used to establish the required flow rates assumed in the CMT design. The CMTs provide injection for an extended time after CMT actuation. The duration of injection will be much longer when the CMTs operate in the water recirculation mode as compared to the steam condensation mode.

20H.1.4.2.4 Manway

The CMT has an access manway in the shell of the tank to permit access for inspection and maintenance. The manway cover bolting is designed to facilitate the use of remotely operated stud tensioning and de-tensioning devices. The manway cover assembly is provided with design features to facilitate installation and removal of the cover away from the manway.

20H.1.4.2.5 Nozzles

The mechanical characteristics of the CMT nozzles are shown in Table 20H-2. All nozzles terminate in stainless steel material for compatibility with the interfacing piping material. The stainless steel safe ends are of sufficient length to prevent damage to the transition weld on the nozzle during field welding. Nozzles are buttered prior to final post-weld heat treatment (PWHT). In this way, the heat affected zone (HAZ) of the nozzle receives a PWHT. After final PWHT, the stainless-steel ends are welded to the buttered vessel nozzles. By following this procedure, sensitisation of the stainless steel ends is prevented.

20H.1.4.2.6 Lifting Lugs

The lifting lugs are designed in accordance with the criteria specified in American National Standards Institute (ANSI) N14.6-1993 (Reference 20H.5).

20H.1.4.2.7 Chemistry

The reactor coolant inside the CMT is controlled in accordance with the Electric Power Research Institute pressurised water reactor primary water chemistry guidelines (Reference 20H.6) as discussed in Chapter 21. The CMT water may contain dissolved oxygen at a concentration equal to saturation at atmospheric pressure. Samples from the CMTs are taken periodically to check the boron concentration. Connections are provided for remotely adjusting (if required) the boron concentration in the CMT during normal plant operation. Makeup water for the CMT is provided by the chemical and volume control system.

20H.1.4.2.8 Pressurisation

Overpressure protection of the CMT and RCS is provided by the use of ASME Code, Section III, Class 1 pressure safety valves which are located in the RCS piping.

20H.1.5 Core Makeup Tank Function

The basic function of the CMT is to provide RCS makeup and boration during events when the normal makeup system is unavailable or insufficient. Full details of the functional requirements are given in the AP1000 Core Makeup Tank Functional Specification (Reference 20H.7). CMT level and inlet and outlet line temperatures are monitored by indicators and alarms. The operator can take action (as required) to meet the technical specification requirements for CMT operability.

Each CMT is connected to the RCS through an outlet line that has normally closed isolation valves. Upon receipt of a safeguards actuation signal, these valves open to align the CMT to the RCS. The outlet line from each CMT is connected to one of the two DVI lines, which provides an injection path for the water supplied by the CMT. When the cold legs are filled, the CMTs operate in a water-recirculation mode driven by the density difference between the hot inlet line and the cold CMT. This mode of operation provides RCS water makeup and effective boration appropriate for non-loss-of-coolant accident (LOCA) events.

When the cold legs are voided, the CMTs operate in a steam-displacement (or steam-compensated injection) mode driven by the density difference between the cold leg steam and the cold water in the CMT. This mode provides greater injection rates than the water recirculation mode, which is appropriate for LOCA events. The CMT flow is based on limiting CMT and RCS temperatures and pressures to ensure that the CMTs can provide injection for a minimum of approximately 20 minutes after CMT actuation and the initial steam condensation transient. For non-LOCA events, the duration of injection will be much longer. Each CMTs inlet has an inlet diffuser designed to reduce steam velocities into the cold CMT water, thereby minimising potential water hammer and reducing the amount of mixing that occurs during initial CMT operation.

20H.1.6 Core Makeup Tank Boundaries

The physical boundaries of the CMT are defined in Reference 20H.2, as summarised below.

The equipment boundary of ASME Code jurisdiction includes all components in Figure 20H-3 and Figure 20H-4.

Figure 20H-3 shows the ASME Code jurisdictional boundaries of CMT, which include all pressure retaining materials up to the circumferential welds between the piping and nozzle safe ends or nozzle and piping (nozzle to pipe weld is not in the CMT jurisdictional boundary). The manway cover (including bolts), tank supports, shear block and shear block weld are ASME Code qualified components. As depicted in Figure 20H-4, the anchor bolts and associated hardware, slide and embedment plates are not ASME components.

The CMT is supported by eight columns. Each column support will have an individual base plate at the bottom. This serves as an interface for attaching the CMT to the embedded plate on the building floor. Auxiliary pipe connections including the quantity and size for the nozzles are specified in Reference 20H.2.

20H.2 Safety Case Requirements

The main focus of this report is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate a structural reliability commensurate with the requirements of a Standard Class 1 component, as outlined in Section 20H.2.2 of this report. To achieve this, the safety argument is presented as three key elements, as follows:

Claim 1: **Quality of Build: High quality is achieved through good design and manufacture (Section 20H.3.1).**

Objective: Provides evidence of good design and manufacture based on established design and manufacturing processes and use of proven materials. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with the objective of achieving quality of build and the avoidance of defects.

Claim 2: **Good Design: Good design is achieved through compliance with ASME (Section 20H.3.2).**

Objective: Incorporates the build experience as embodied in the design codes.

Claim 3: **Mitigation and Management of In-Service Degradation: Components are tolerant to through-life degradation over the design life of the plant (Section 20H.3.3).**

Objective: Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval.

The three elements of the safety argument are provided in Section 20H.3 and the strength of the argument is discussed in Section 20H.4.

20H.2.1 Safety Functional Requirements

Chapter 20 identifies structural integrity safety design bases for the SSCs. These are requirements of plant systems, some duty and some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. Identification of the SFRs for the CMT follows from the performance and safety functional requirements outlined in Reference 20H.7, as follows:

The CMT is a large tank containing borated water (at RCS pressure) that drains into the RCS during certain plant transients and accidents. Based on this, the following SFRs have been identified that reflect the overall role of the component in plant safety:

- **SFR 20.7.1** The CMT pressure boundary must remain intact during standby, normal operation, and under design basis faulted conditions for the design life of the plant.

- **SFR 20.7.2** The CMT is required to store cold borated water under reactor coolant system pressure for high-pressure reactor coolant makeup in accordance with the component performance requirements.

- **SFR 20.7.3** The CMT is required to deliver borated water to the RCS in the event of a LOCA or non-LOCA when the normal makeup system is unavailable or insufficient.

Postulated failure modes that result in a loss of these functional requirements lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20H.2.2.

20H.2.2 Core Makeup Tank Structural Integrity Classification

For the United Kingdom (UK) AP1000 plant, the structural integrity classification methodology (Reference 20H.1), has been applied with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct consequences (e.g., LOCA) and indirect consequences (e.g., missiles/pipe whip etc) of gross failure. The detail of the classification for the CMTs is presented in Reference 20H.1.

This concluded that the direct consequences of gross failure of the CMT is bounded by the more limiting DVI line failure which is shown not to lead to core damage and is within the design basis analysis of Section 9.6.5. Considering the indirect failure consequences, due to the proximity of the CMTs to the containment vessel (CV) it is possible that damage to the containment could occur. An analysis of the effectiveness of the containment cooling with damaged containment has been undertaken and results show that the CV pressure is reduced to and maintained near atmospheric pressure. Also, CMT failure cannot impact the containment below elevation (102.1 m), thus the mass loss from the CV does not deplete the water inventory inside the containment quickly. In summary, damage to the containment would not prevent the passive protection system from cooling the core but the release rate would be increased. There is also potential for damage to Category 1 control and instrumentation cables but this would not prevent the redundant train of the affected safety system from operating properly. On this basis, the CMT has been categorised as a Standard Class 1 component.

20H.3 Safety Case Arguments

As discussed in Section 20H.2.2, the CMT has been classified as a Class 1 component in accordance with Reference 20H.1. The structural integrity claim is, therefore, based on arguments which substantiate the claims listed in Section 20H.2. Consistency with the appropriate ASME III Code class provides the basic demonstration of fitness-for-purpose for the CMT.

Compliance with ASME Code, Section III rules for a Class 1 component provides the primary element in the safety case for the AP1000 CMTs.

20H.3.1 High Quality is Achieved through Good Design and Manufacture

In order to demonstrate that high quality is achieved through good design and manufacture, evidence to support the following claims is provided:

- The fabrication specification complies with ASME Code requirements for Class 1 components.
- Supplementary requirements are specified to avoid defects and to ensure quality.

The reliability of the CMT depends upon the equipment design quality. The design intent is translated into a manufacturing route which is controlled by a Quality Assurance Programme which complies with rigorous design codes including the ASME Boiler and Vessel Pressure Code (Reference 20H.3). Section 2.3 of the CMT Design Specification (Reference 20H.2) provides a comprehensive list of the industry codes, specifications and standards applied to the component.

The justification of the quality of build of the CMT and materials includes:

- **Processes used for manufacturing and fabrication** – Design and fabrication of the CMT is carried out in accordance with ASME Code, Section III, Class 1 requirements as defined in the Design Specification (Reference 20H.2).
- **Material Specifications** – The CMT materials specifications and testing requirements have been specified in accordance with the requirements of Section II of the ASME Code. Material specifications also include relevant Westinghouse Standards, ANSI/ASME/ASTM standards, United States (US) Code of Federal Regulations and US Nuclear Regulatory Commission Regulatory Guides as defined in Reference 20H.2. The primary coolant boundary will be fabricated from ASME plate and/or forging material. Charpy V-notch tests and drop weight fracture toughness tests are required. Nozzles will terminate in stainless steel material for compatibility with the interfacing piping material. The stainless-steel safe ends will be of sufficient length to prevent damage to the transition weld on the nozzle during field welding. Nozzles will be buttered prior to final PWHT. In this way, the HAZ of the nozzle will be receiving a PWHT. After final PWHT, the stainless steel ends will be welded to the buttered vessel nozzles. By following this procedure sensitisation of the stainless-steel ends is prevented.
- **Material Test Reports** – Materials for parts within the jurisdiction of the ASME Code will have certified material test reports (CMTR) clearly presenting the results of all ASME Code required testing. All other materials will be certified as required by the applicable material specifications, but as a minimum by a certificate of compliance.

- **Mechanical Testing** – Hydrostatic tests will be carried out in accordance with the requirements of the ASME Code, Section III, using working fluids meeting the appropriate water chemistry specifications. The hydrostatic test will be performed at a test pressure of 1.25 times the design pressure and at a test temperature safe from brittle fracture. The minimum hydrostatic test temperature will be 33.3°C (60°F) above the reference temperature nil-ductility temperature (RT_{NDT}).

- **In-Manufacture NDE** – The NDE of the CMT is conducted in accordance with ASME Code, Section III requirements using ultrasonic examination, liquid penetrant examination, magnetic particle examination, surface examination and weld examination. These provide confidence that the required weld quality is achieved during manufacture. All clad surfaces, including nozzle and manway will be 100% ultrasonically inspected for both bond and defects by the straight beam method. Clad thickness will be measured in accordance with approved procedures. No seams will pass through or interfere with nozzles, and they are designed for 100 percent inspectability where required by the code. Only personnel qualified and certified in accordance with ASME Section III will perform Section III examinations.

- **Pre-Service and In-Service Examination Requirements** – The pre-service and in-service examination and acceptance criteria for of the CMT will comply with the 1998 Edition with Addenda up through and including 2000 of ASME Code, Section XI, Subsection IWB for pressure boundary welds and Subsection IWF for all other welds. Inspection personnel qualified and certified in accordance with the requirements of ASME Code, Section XI, IWA-2300 will perform the pre-service examination.

- **Weld Qualifications** – All pressure boundary welding procedures and welders qualifications will be in accordance with the ASME Code, Section III and Section IX. All non pressure boundary welding procedures and welders qualifications will be in accordance with the ASME Code, Section IX or equivalent approved standards.

Together these provide a keystone for a demonstration that the CMT will achieve a high quality, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the vessel.

20H.3.2 Good Design is Achieved through Compliance with ASME

In order to demonstrate that good design is achieved through compliance with ASME, evidence to substantiate the following argument is provided:

- The design has been analysed and has been shown to comply with the requirements of ASME Code, Section III for Class 1 components.

  The AP1000 CMT has been designed in accordance with the requirements of the ASME Code, Section III, Div 1 – 1998 Edition with Addenda up through and including 2000. The CMT has been assessed against the limits specified in Subsection NB and the tank supports are assessed against Subsection NF. The assessment is reported in a suite of calculation notes, as listed in the Technical Index of this report. The subsection applicable to each sub-component is summarised below.

  The design transients used in the analysis are shown in Reference 20H.9. The load cases considered include normal, upset, emergency, and faulted conditions. The external load combinations on the CMT are specified in the CMT Design Specification (Reference 20H.2);

these include nozzle external loads, seismic loads and all other loads and loading combinations. The design of the CMT has, therefore, been designed against all design basis internal and external hazards.

Reference 20H.9 summarises an ASME sizing assessment of the critical locations of the CMT showing the minimum required thickness/minimum required areas compared to the actual thickness/actual area. Adequate thickness and/or actual area are provided for all locations.

Reference 20H.9 provides the results of a thermal and structural analysis which has been undertaken using established procedures to demonstrate that for the load cases analysed all the stresses and cumulative fatigue usage factors are satisfactory and meet the appropriate limits set forth in the ASME Code, Section III. This evaluation includes:

- A basic sizing and justification of the main parts and components of the CMT.
- A dynamic seismic analysis by the response spectrum method.
- Evaluation of stresses from internal pressure, earthquake effects, dead weight and externally applied loads at significant locations of the vessel shell, manway and nozzles.

Based on the results of the assessments presented in Reference 20H.9, it can be shown the design of the CMT meets all the applicable requirements of ASME Code, Section III.

20H.3.3 Mitigation and Management of In-Service Degradation

To demonstrate that the design has taken account of in-service degradation mechanisms, evidence to substantiate the following argument is provided:

- A structured process has been applied to identify in-service degradation mechanisms.
- The design has been optimised to mitigate against the risk from in-service degradation mechanisms.

20H.3.3.1 Identification of Degradation Mechanisms

Reference 20H.10 provides a failure modes and effects analysis (FMEA), which was carried out to identify design characteristics, potential hardware failures, or human errors associated with the design and operation of the CMT that could lead to a potentially hazardous condition such as injury, fatality, or loss of equipment and product.

The FMEA resulted in the identification of potential hazards or operational problems. Potential through-life degradation mechanisms considered were:

- Thermal cycling
- Fatigue
- Brittle fracture
- Corrosion
- Failure arising from manufacturing defect

The basis of the safety case argument is mitigation against corrosion, fatigue and manufacturing defects is essentially provided by compliance with ASME material specification, design and fabrication rules. The associated in-service inspection (ISI)

requirements and the operating experience embodied within the Code mitigate against these degradation mechanisms.

20H.3.3.2 **Avoidance of Non-Ductile Failure**

Reference 20H.9 presents the calculations performed for the CMT vessel shell, CMT inlet and outlet nozzles, and manway to provide confidence that the CMT is safeguarded against non-ductile failure during normal, upset, and test conditions, as required by ASME Code.

The non-ductile failure evaluation of the CMT was performed in accordance with Appendix G of the ASME Code. The ANSYS finite element analysis code was used to obtain the temperature and stresses. The FRMECH programme, Reference 20H.12, was used to obtain the stress intensity factors. Methods of evaluating non-ductile behaviour are based on linear elastic fracture mechanics of thick sections.

The postulated flaw is assumed to be perpendicular to the direction of maximum stress. The postulated flaw for the vessel shell is typically in the hoop direction and for the CMT inlet nozzle to be perpendicular to the direction of maximum stress, which is typically the hoop direction. The regions of the manway which may be susceptible to a non-ductile failure are the centre of the manway cover, the inside surface of the manway knuckle, and the inside surface of the shell

Calculated stress intensity factors (K_I) were compared with the allowable critical values (K_{IR}). The analysis is based on the general methodology set forth in Appendix G of the ASME Code and in WRC Bulletin No. 175 (Reference 20H.11). Safety coefficients have been applied to calculated stress intensity factors K_I in accordance with Appendix G, Articles G – 2215 and G – 2400.

The analysis presented demonstrates that the AP1000 CMT satisfies the structural requirements of Section III of the ASME Code for all loading conditions specified in Reference 20H.2.

20H.3.3.3 **In-Service Inspection**

ISI provides forewarning of degradation mechanisms and this forms an important element of the safety case argument. ISI will be carried out in accordance with Section XI of the ASME Code. An inspectability assessment of the CMT has been carried out. This assessment (Reference 20H.13) provides evidence that the design of the CMT has been optimised to permit ISI, including consideration of the examination requirements for the CMT using different techniques, the inspection coverage, limitations and access conditions at each location. A summary of the ISI requirements is shown in Table 20H-4.

20H.4 Strength of the Safety Case

The CMT is classified as a Standard Class 1 component. The safety argument in Section 20H.3 demonstrates how CMT structural integrity is established based on extensive quality assurance measures in design, manufacture, materials, testing, and qualified inspection. The strength of the safety case is based on achievement of integrity and that the CMT has been deterministically justified in accordance with ASME Code, Section III. The arguments presented are considered to provide a cogent basis to substantiate reliability claims commensurate with the Standard Class 1 classification of the CMT.

To substantiate this assertion this report provides a structured argument supported by suitable and sufficient evidence to achieve this, three key elements namely; Quality of Build,

Good Design and mitigation and management of in-service degradation have shown how this will be achieved.

Quality of Build has been demonstrated by compliance with ASME Code, Section III. Material specification control has been achieved in accordance with Section II of ASME Code, NDE in accordance with ASME Code, Section III with adequate fracture toughness demonstrated by compliance with the ASME Code.

Good design has been demonstrated by providing evidence that design transients including normal, upset, emergency and faulted conditions have been analysed and loadings shown to be within the allowable limits of ASME Code, Section III, Div 1 – 1998 Edition with Addenda up through and including 2000.

The approach to mitigation and management of in-service degradation has been demonstrated by identifying all design characteristics, degradation mechanisms and potential hazards that could lead to injury, fatality or loss of operation of the CMT. ISI will also provide forewarning of degradation with inspection and maintenance carried out at appropriate intervals.

20H.5 Index of Technical Reports

Table 20H-5 provides a list of technical references supporting the safety case and the function of each document within the safety case.

20H.6 Review of Open Issues

There are no open issues for the CMT that affect the basis of the safety case arguments presented in support of generic design assessment (GDA).

20H.7 Conclusions

This report presents arguments that support the claim that the structural reliability of the CMT is commensurate with the consequences of gross failure. To evaluate this, the CMT has been classified in accordance with the procedure for structural integrity classification specified in Reference 20H.1.

The main element of the safety case argument is that the CMT has been designed in accordance with the high standards of the ASME Code as applicable to ASME Class 1 components. This includes tight controls on material properties, manufacturing processes, design, testing, inspection and installation such that there is a high level of confidence in the quality of the CMT and that it will enter service free from significant flaws that could affect the integrity of the CMT over its lifetime. Section 20H.5 of this report identifies the detailed specifications and analyses that provide the evidence to support this argument. In addition, an FMEA was performed to identify potential threats to the structural integrity of the CMT through its design life. Appropriate measures have been incorporated into the design and inspection requirements to mitigate against these threats.

Based on the arguments presented, together with the referenced supporting evidence, it is considered that the structural reliability of the CMT has been justified to a standard commensurate with the consequences of its gross failure.

APPENDIX 20I
ACCUMULATOR COMPONENT SAFETY REPORT

20I.1 Introduction

This is the component safety report (CSR) for the accumulator as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the accumulator to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20I.5 that supports the design, manufacture, installation, and operation of the accumulator.

20I.1.1 Scope

This CSR presents arguments to support the claim that the nuclear and radiological risks potentially arising from gross structural failure of the accumulator are tolerable for the design lifetime objective of 60 years. Conventional hazards to personnel safety are outside the scope of this Appendix 20I.

20I.1.2 Objectives

The safety claims made for the AP1000 plant design establish that AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime, and are substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the accumulator are identified in Section 20I.2.1.

The other objectives of this CSR are: i) to support the nuclear safety claims made for the AP1000 accumulator design and ii) to present arguments that support the claim that the structural reliability of the accumulator is commensurate with its consequences of failure. That is, where failure is intolerable, the probability of gross failure should be shown to be so low that such failure can be discounted, or where failure does not lead to intolerable offsite consequences, the target reliability is linked to the consequences in accordance with the methodology described in the AP1000 United Kingdom (UK) Structural Integrity Classification document (Reference 20I.1). This is discussed in Section 20I.2.2.

20I.1.3 Interface with Other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical specification and design analyses listed in the Technical Index (Section 20I.5). Each is specifically identified in the relevant section of the structured safety argument.

20I.1.4 Accumulator Description

20I.1.4.1 Overview

The accumulators (two), as shown in Figure 20I-1, are components of the passive core cooling system (PXS). They are located inside the containment on the floor just below the core make-up tanks. The basic function of the accumulator is to provide core cooling in the event of a large loss-of-coolant accident (LOCA) by delivering a high flow of borated water to the reactor vessel. The accumulator tanks are pressurised with nitrogen gas maintained at approximately 700 psig (4.826 MPa gauge). When the reactor coolant system (RCS) pressure falls below the accumulator pressure, check valves open and borated water is forced into the RCS by the gas pressure.

20I.1.4.2 Description

Details of the accumulator design can be found in the design specification (Reference 20I.2). The two accumulators are spherical tanks (approximately 4.9 m (16 ft) outside diameter) made of low alloy steel and clad on the internal surfaces with stainless steel. They are located inside the containment on the floor just below the core makeup tanks (CMTs). The accumulator is constructed from a top and bottom head welded to an intermediate shell section. The accumulator tank is designed with a skirt type support having a flanged interface for bolting the accumulator tank to the building structure. The accumulators are AP1000 Equipment Class C and are designed to meet seismic Category I requirements. Claims, arguments and evidence related to the designation of the accumulators as AP1000 plant Class C equipment are presented in Reference 20I.3. Therein, it is concluded that due to the similar construction requirements, the costs of volumetric inspection, and the fact that increased inspections would have no significant benefit on the reliability of the accumulator sub-system to function, it is ALARP to retain the accumulator AP1000 plant Class C classification as is because the cost on increasing the safety classification to AP1000 plant Class B is grossly disproportionate to the safety benefit.

The pressure retaining parts of the accumulator tank are qualified to American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code (Code), 1998 Edition with Addenda up through and including 2000, Section III for Class 3 components. The skirt support is qualified per the criteria of Subsection NF of the ASME code.

20I.1.4.2.1 Materials

Materials used in the manufacture of the accumulator pressure boundaries are shown in Table 20I-1. All surfaces that can become wetted during operation will be clad with stainless steel weld overlay. The nominal cladding thickness is 5.6 mm (0.22 in). The cobalt content of materials used in the construction of component surfaces which will be in contact with the primary coolant with the exception of the screws, bolts, washers, weld cladding and locking cups, are designed to be no greater than 0.05 weight percent, integrated average. The cobalt content of cladding materials are designed to be no greater than 0.05 weight percent. The cobalt content of all other welding materials is excluded from this requirement. The sulphur content of the base material and all welding materials are also controlled to prevent hot cracking.

20I.1.4.2.2 Design Temperature and Pressure

The structural design of the accumulator tank is based on the maximum steady state internal design pressure and design temperature values of 5.516 MPa gauge (800 psig) and 149°C (300°F), respectively. These values are used in conjunction with the appropriate values of

external pressure and temperature defined in Reference 20I.2. The temperature of the borated water in the accumulator is approximately equal to the containment temperature since the tanks are neither insulated nor heated. Over pressure protection is provided through an alarm and one safety relief valve. The relief valve is located outside of the accumulator tank jurisdictional boundary so that overpressure protection requirements are fully complied with and the safety relieving devices cannot be isolated from the accumulator tank during operation.

20I.1.4.2.3 Total Volume/Flowrate

The accumulators are designed to deliver a high flow of borated water to the reactor vessel in the event of a LOCA. This large flow rate is used to quickly establish core cooling following a large loss of reactor coolant system inventory.

Each accumulator tank has a minimum volume of approximately 56.6 m^3 (2,000 ft^3). The total wetted volume is approximately 48.1 m^3 (1,700 ft^3). The accumulator provides injection after the reactor coolant system pressure drops below the static accumulator pressure.

The injection line from each accumulator contains a flow-tuning orifice that provides a mechanism for the field adjustment of the injection line resistance. The orifice is used to establish the required flow rates assumed in the accumulator design.

20I.1.4.2.4 Manway

The accumulator tank has an access manway (457 mm (18 inch) nominal minimum diameter) in the shell of the tank to permit access for inspection and maintenance. The manway cover bolting is designed to facilitate the use of remotely operated stud tensioning and de-tensioning devices. The manway gasketed closure is leak tight without requirement for seal welding of the joint perimeter. The manway cover includes a lifting eye(s) to facilitate installation and removal.

20I.1.4.2.5 Nozzles

The mechanical characteristics of the accumulator tank nozzles are shown in Table 20I-2. All nozzles terminate in stainless steel material for compatibility with interfacing piping material. All nozzles are welded in accordance with Section III Subsection ND of the ASME Boiler and Pressure Vessel Code, of the 1998 Edition with Addenda up through and including 2000 and applicable Code Cases. The DN 25 (NPS 1) nozzles are welded to the weld build up on the cladding on the inside wall of the vessel.

20I.1.4.2.6 Lifting Lugs

The lifting lugs are designed in accordance with the criteria specified in ANSI N14.6-1993 (Reference 20I.4). The lifting lugs are capable of holding three times the weight of the accumulator tank including the shipping container without exceeding a combined tensile and shear stress equal to the yield strength of the lifting lug material, and will be designed to be capable of lifting five times that weight without exceeding the ultimate strength.

20I.1.4.2.7 Chemistry

The chemistry composition for the reactor coolant inside the RCS will be controlled in accordance with the well established Electric Power Research Institute guidelines for primary chemistry (Reference 20I.5) shown in Table 20A-3. The accumulator tank water may contain dissolved oxygen at a concentration equal to saturation at atmospheric pressure. Connections

are provided for remotely adjusting the level and boron concentration of the borated water in each accumulator during normal plant operation. Samples from the accumulator will be taken periodically to check the boron concentration.

20I.1.4.2.8 Pressurisation

Accumulator pressure is maintained by a supply of nitrogen gas that can be adjusted as required during normal plant operation. However, the accumulators are normally isolated from the nitrogen supply system. Gas relief valves on the accumulator protect them from over pressurisation. The accumulator can also be remotely vented if required. The liquid level and gas pressure are monitored by indicators and alarms. Accumulator water level may be adjusted either by draining or by pumping borated water from the chemical and volume control system to the accumulator. The operator can take action, as required, to meet the technical specification requirements for accumulator operability.

20I.1.5 Accumulator Function

The basic function of the accumulator is to provide safety injection to the RCS to ensure adequate core cooling during a LOCA. Full details of the functional requirements are given in the AP1000 Accumulator Functional Specification (Reference 20I.6).

The two accumulators contain borated water and a compressed nitrogen cover gas to provide rapid injection at a high flow rate in the event of a large LOCA. This high flow rate is used to quickly establish core cooling following a large LOCA. The accumulators discharge to their respective reactor vessel direct vessel injection (DVI) lines. A deflector in the reactor vessel downcomer annulus directs the flow downward to minimise core bypass flow.

During normal operation, the accumulator is isolated from the reactor coolant system by two check valves in series. When the reactor coolant system pressure falls below 700 psig, the check valves open and borated water is forced into the RCS by the gas pressure. Mechanical operation of the check valves is the only action required to open the injection path from the accumulators to the core.

The accumulator size, water volume, and nitrogen cover pressure are selected so that both of the accumulators are sufficient to recover the core cooling before significant clad melting or zirconium water reaction can occur following a large break LOCA. One accumulator is adequate during a small break LOCA where the entire contents of one accumulator can possibly be lost via the pipe break.

During large LOCAs or automatic depressurisation system operation, the accumulators rapidly inject a large volume of borated water into the reactor vessel through the same connections used by the CMT and the in-containment refuelling water storage tank injection. The accumulator injection rate is dependent on the RCS pressure transient. The accumulator injection provides for rapid re-flooding of the core during a large LOCA, which prevents excessive core fuel cladding temperatures.

The accumulators also help provide adequate core cooling during smaller LOCA events and automatic RCS depressurisation events. During small LOCAs as large as a DVI line break, the accumulators assist in keeping the core covered.

20I.1.6 Accumulator Boundaries

The physical boundaries for safety case assessment of the accumulator, are defined in Reference 20I.2, and identified below.

The equipment boundary of ASME Code jurisdiction includes all components in Figure 20I-2 and Figure 20I-3. The welds at the safe end/piping interface or the nozzle/piping interface are considered as part of the connecting piping systems. These figures show the end of the nozzle or safe end as the equipment boundary and the boundary for support.

The manway cover and attachment hardware and support skirt are included within the equipment boundary. The accumulator shell, upper and lower heads, nozzles, manway cover and bolting are designed to ASME Code, Section III, subsection ND. The accumulator vessel supports are designed to ASME Code, Section III, subsection NF.

The accumulator interfaces with other components through the following nozzles, openings, and supports:

- Flanged Support Skirt
- One (1) Outlet Nozzle
- One (1) Safety Relief Nozzle
- One (1) Nitrogen Inlet Connection
- Two (2) Pressure Taps
- One (1) PXS Test Header Connection
- One (1) Sample Tap
- Two (2) Level Measurement Nozzles

20I.2 Safety Case Requirements

The main focus of this CSR is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate the reliability of the accumulator, commensurate with the classification of the accumulator as Standard Class 1, as outlined in Section 20I.2.2 of the report. To achieve this, the safety argument is presented as three key elements, as follows:

Claim 1: Quality of Build: High quality is achieved through good design and manufacture.

Objective: Provides evidence of good design and manufacture based on established design and manufacturing processes and use of proven materials. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with an objective of achieving quality of build and the avoidance of defects. (Section 20I.3.1)

Claim 2: Good Design: Good design is achieved through compliance with ASME.

Objective: Incorporates the build experience as embodied in the design codes. (Section 20I.3.2)

Claim 3: Mitigation and Management of In-service Degradation: Components are tolerant to through-life degradation over the design life of the plant.

Objective: Provides an assessment of through-life degradation mechanisms and shows that such mechanisms will not threaten integrity over a specific interval. (Section 20I.3.3)

The three elements of the safety argument are provided in Section 20I.3 and the strength of the argument is discussed in Section 20I.4.

20I.2.1 Safety Functional Requirements (SFR)

The structural integrity safety design bases for AP1000 SSCs are requirements of plant systems, some duty, some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. Identification of the SFRs for the accumulator follow from the performance and safety design bases as follows:

- Deliver a large volume of borated water to the reactor vessel at a high flow rate in the event of the large LOCA.

- Provide adequate core cooling during smaller LOCA events and automatic RCS depressurisation events.

- During small LOCAs as large as a DVI LOCA, the accumulators assist in keeping the core covered with water.

Based on these, the following SFRs have been identified which reflect the overall role of the accumulator in plant safety:

- **SFR 20.8.1** The accumulator tanks pressure boundary must remain intact during standby, normal operation and under design basis faulted conditions for the design life of the plant.

- **SFR 20.8.2** The accumulator tanks are required to store borated water and a compressed nitrogen cover gas to provide rapid injection of borated makeup water to the RCS in the event of a large LOCA.

- **SFR 20.8.3** The accumulator tanks are required to deliver a large volume of borated water to the reactor vessel at a high flow rate in the event of a large LOCA in accordance with the component performance requirements.

Postulated failure modes which result in a loss of these functional requirements lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20I.2.2.

20I.2.2 Accumulator Structural Integrity Classification

For the UK AP1000 plant, the structural integrity classification methodology (Reference 20I.1), has been applied with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct consequences (e.g., LOCA) and indirect consequences (e.g., missiles/blast etc) of gross failure. The details of the classification for the accumulators are presented in Reference 20I.1.

The direct consequences of gross failure of the accumulator would not lead directly to unacceptable consequences. The normally closed check valves on the injection line would prevent a LOCA in the event the accumulator pressure boundary fails. If these valves did not remain shut, the resulting LOCA would be bounded by a single DVI line failure, which has been analysed within the design basis in section 9.6.5 and can be mitigated by a single accumulator. Assessment of the indirect consequences included consideration of the effects of missiles/jet/blast from disruptive failure of the accumulator tank shell. A review of the 3D model for the accumulator concludes that the risk of consequential damage is small as the accumulators are situated within protected compartments which would contain the energy arising from a disruptive failure of the shell and so is unlikely to lead to the generation of missiles that could challenge the integrity of essential systems or containment. This review considered the proximity of essential safety systems within line of sight of the accumulators. On this basis the accumulator has been categorised as a Standard Class 1 component.

20I.3 Safety Case Arguments

As discussed in Section 20I.2.2, the accumulator has been classified as a Class 1 component in accordance with Reference 20I.1. The structural integrity claim is therefore based on arguments which substantiate the claims listed in Section 20I.2. Consistency with the appropriate ASME III Code class provides the basic demonstration of fitness-for-purpose for the accumulator.

Compliance with ASME III rules for a UK Class 1 component provides the primary element in the safety case for the AP1000 accumulator tank.

20I.3.1 High Quality is Achieved through Good Design and Manufacture

In order to demonstrate that high quality is achieved through good design and manufacture, evidence to support the following claims is provided:

- The fabrication specification complies with AMSE Code requirements for Class 3 components.

- Supplementary requirements are specified to avoid defects and to ensure quality.

The reliability of the accumulator is dependent upon the achievement of good design and manufacture. The design intent is translated into a manufacturing route controlled by a Quality Assurance Programme that complies with rigorous design codes including the ASME Boiler and Vessel Pressure Code. Section 2.3 of the Accumulator Design Specification (Reference 20I.2) provides a list of the industry codes, specifications and standards applied to the component. Reference 20I.8 details supplemental fabrication and inspection requirements.

The justification of the quality of build of the accumulator and of materials is based on the following:

- **Processes Used for Manufacturing and Fabrication** – Design and fabrication of the accumulator is carried out in accordance with ASME Code, Section III, 1998 Edition with Addenda up through and including 2000 and applicable code cases as discussed in the Design Specification (Reference 20I.2).

- **Material Specifications** – The accumulator materials specifications and testing requirements have been specified in accordance with the requirements of Section II of the ASME Code as defined in the Design Specification (Reference 20I.2). Material specifications also include relevant Westinghouse Standards, ANSI/ASME/ASTM standards, US Code of Federal Regulations and US NRC Regulatory Guides as defined in Reference 20I.2. The primary coolant boundary will be fabricated from plate and/or forging material as allowed by ASME Code. Charpy V-Notch impact testing will be carried out as required by ASME Code. The stainless steel safe ends are sized to be of sufficient length to prevent damage to the transition weld during field welding. Nozzles will be buttered prior to final post weld heat treatment (PWHT). After final PWHT, the stainless steel safe end will be welded to the buttered outlet nozzle.

- **Material Test Reports** – Materials for parts within the jurisdiction of the ASME Code will have certified material test reports clearly presenting the results of all ASME Code required testing. All other materials will be designed to be certified as required by the applicable material specifications, but as a minimum by a certificate of compliance.

- **Mechanical Testing** – A hydrostatic test in accordance with ASME Code Section III Class 3 requirements will be carried out. This will be performed at a test pressure of approximately 6.9 MPa (1000 psi) and at a test temperature to be safe from brittle fracture.

- **In-Manufacture Nondestructive Examination (NDE)** – The NDE of the accumulator and its appurtenances is conducted in accordance with ASME Code, Section III (NC-2500 and NC-5000) requirements using ultrasonic examination, liquid penetrant examination, magnetic particle examination, surface examination and weld examination. These provide confidence that the required weld quality is achieved during manufacture. All clad surfaces, including nozzle and manway will be 100% ultrasonically inspected for both bond and defects by the straight beam method. Clad thickness will be measured in accordance with approved procedures. Only personnel qualified and certified in accordance with ASME Section III will perform Section III examinations.

- **Pre-Service and In-Service Examination Requirements** – The pre-service and in-service examination of the accumulator tank will comply with the ASME Code Section XI, Subsection IWD and IWF. The acceptance criteria are also per the ASME Code. Inspection personnel qualified and certified in accordance with the requirements of ASME Code, Section XI will perform the pre-service examination.

- **Weld Qualifications** – All pressure boundary welding procedures and welders' qualifications will be in accordance with the ASME Code, Section III and Section IX. All non-pressure boundary welding procedures and welders' qualifications will be in accordance with the ASME Code, Section IX or equivalent approved standards.

Together these provide a keystone for a demonstration that the accumulator will be of a high quality, that it will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the vessel.

20I.3.2 Good Design is Achieved through Compliance with ASME

In order to demonstrate that good design is achieved through compliance with ASME, the accumulator design has been analysed and shown to comply with the requirements of ASME

Code, Section III for Class 3 components. The assessment is reported in a suite of calculation notes, as summarised in the ASME generic design report (Reference 20I.9) for the accumulator. The design transients used in the analysis are shown in the design report. The load cases considered include normal, upset, emergency and faulted conditions.

The external loads on the accumulator are specified in the Design Specification document (Reference 20I.2); these include nozzle external loads, seismic loads, and all loads and loading combinations. In addition, Reference 20I.10 provides a dynamic assessment to evaluate the response of the accumulator assembly to sloshing effects. The accumulator has therefore been designed against all design basis internal and external hazards.

The pressure boundary components of the accumulator have been shown to comply with the minimum required thickness compared to minimum drawing thickness in Reference 20I.9 as required by the ASME Code. The thickness requirements for all boundary components are satisfied.

Reference 20I.10 provides a detailed stress evaluation of the accumulator including all loads and loading combinations specified in Reference 20I.2 in accordance with the ASME Code Section III Sections ND and NF. This evaluation includes:

- A basic sizing and justification of the main parts and components of the accumulator.
- A dynamic seismic analysis by the response spectrum method.
- Evaluation of stresses from internal pressure, earthquake effects, dead weight and externally applied loads at significant locations of the spherical wall and skirt.

The thermal and structural analysis has been undertaken using established procedures to demonstrate that for the load cases analysed all the stresses and cumulative fatigue usage factors are satisfactory and meet the appropriate limits set forth in the ASME Code. Details of these calculations are presented in the ASME Design Report (Reference 20I.9), with the referenced calculation notes as detailed in the technical index.

Based on the results of the assessments presented in References 20I.9 and 20I.10, it can be shown that the design of the accumulator meets all the requirements of ASME Boiler and Vessel Code Section III Sections ND and NF.

20I.3.3 Mitigation and Management of In-Service Degradation

In order to demonstrate that the design has taken account of in-service degradation mechanisms, evidence to substantiate the following argument is provided:

- A structured process has been applied to identify in-service degradation mechanisms.
- The design has been optimised to mitigate against the risk from in-service degradation mechanisms.

20I.3.3.1 Identification of Degradation Mechanisms

Reference 20I.11 provides a failure modes and effects analysis (FMEA) which was carried out in order to identify design characteristics, potential hardware failures or human errors associated with the design and operation of the accumulator that could lead to a potentially hazardous condition such as injury, fatality, or loss of equipment and product. Potential through-life degradation mechanisms considered in the FMEA include the following:

- Brittle Fracture
- Fatigue
- Corrosion
- Failure arising from manufacturing defect

The basis of the safety case argument is that mitigation against corrosion, fatigue and manufacturing defects is essentially provided by compliance with ASME material specification, design and fabrication rules. The associated in-service inspection (ISI) requirements for ASME Class 3 components and the operating experience embodied within the code to mitigate against these degradation mechanisms.

20I.3.3.2 In-Service Inspection (ISI)

The ISI provides forewarning of failure and a means of monitoring degradation and this forms an important element of the safety case argument. ISI of the accumulator tank will comply with the 1998 Edition with Addenda up through and including 2000 of the ASME Code, Section XI, Subsection IWD.

Written instructions concerning accumulator tank inspection, maintenance, installation, operation, assembly details and disassembly details will be provided following the generic design assessment (GDA). From this information inspection of the accumulator will be carried out in accordance with an inspection plan and Refuelling and Maintenance Outage Schedules.

20I.4 Strength of the Safety Case

The accumulator is classified as a Standard Class 1 component. The safety argument in Section 20I.3 demonstrates how accumulator structural integrity is established, based on extensive quality assurance measures in design, manufacture, materials, testing and qualified inspection. The strength of the safety case is based on achievement of integrity and that the accumulator has been deterministically justified in accordance with ASME Boiler and Pressure Vessel Code Section III. In combination these elements provide a cogent argument to substantiate reliability commensurate with the classification of the accumulator.

To substantiate this assertion this report provides a structured argument based on three key elements, namely Quality of Build, Good Design and mitigation and management of in-service degradation. Quality of build and good design is based on compliance with ASME Code Section III.

Quality of Build has been demonstrated by compliance with ASME Code Section III. Material specification control has been achieved in accordance with Section II of ASME code and NDE in accordance with ASME Code, Section III.

Good design has been demonstrated by providing evidence that design transients including normal, upset, emergency and faulted conditions are within ASME Code Section III, Div 1 – 1998 Edition with Addenda up through and including 2000 limits.

Mitigation and management of in-service degradation has been demonstrated by identifying all design characteristics, degradation mechanisms and potential hazards that could lead failure of the accumulator. The ISI will also provide forewarning of degradation with an inspection plan and Refuelling and Maintenance Outage Schedules.

20I.5 Index of Technical Reports

Table 20I-4 provides a list of all technical references supporting the safety case and the function of each document within the safety case.

20I.6 Review of Open Issues

There are no open issues for the accumulator that affect the basis of the safety case arguments presented in support of the GDA Step 4.

20I.7 Conclusions

This report presents arguments that support the claim that the structural reliability of the accumulator is commensurate with the consequences of failure. To evaluate this, the accumulator has been classified in accordance with the procedure for structural integrity classification specified in Reference 20I.1. Based on this the accumulator has been evaluated as a Class 1 component.

The accumulator has been designed in accordance with the high standards of the ASME Code as applicable to ASME Class 1 components. This includes tight controls on material properties, manufacturing processes, design, testing, inspection and installation such that there is a high level of confidence in the quality of the accumulator and that it will enter service free from significant flaws that could affect the integrity of the component over its lifetime. Secondly that an FMEA has been carried out to identify potential threats to integrity through life and appropriate measures have been incorporated into the design and inspection requirements to mitigate against these threats. Taken together with the referenced evidence, these claims and arguments support the structural reliability claim for the accumulator tanks.

APPENDIX 20J
REACTOR VESSEL INTERNALS COMPONENT SAFETY REPORT

20J.1 Introduction

This is the component safety report (CSR) for the reactor vessel internals (RVI) as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the RVI (including the reactor vessel flow skirt (RVFS)) to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20J.5 that supports the design, material selection, manufacture, installation, operation and in-service inspection (ISI) of the RVI and RVFS.

20J.1.1 Scope

This CSR supports the claim that the nuclear and radiological risks potentially arising from gross structural failure of the RVI and RVFS are tolerably low for the design lifetime objective of 60 years. Non-nuclear hazards to personnel safety are outside the scope of this Appendix 20J.

20J.1.2 Objectives

This CSR supports nuclear safety claims that the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. These claims are substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the RVI and RVFS are identified in Section 20J.2.

The approaches to achieving this objective are 1) to support the nuclear safety claims made for the AP1000 RVI and RVFS design and 2) to present arguments that support the claim that the structural reliability of the component is commensurate with its consequences of failure. That is, where failure is intolerable, the probability of gross failure should be shown to be so low that failure can be discounted, or where failure does not lead to intolerable consequences, the target reliability is linked to the consequences in accordance with the methodology detailed in Reference 20J.1. This is discussed in Section 20J.2.2 below.

20J.1.3 Interface with Other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data and analyses. These are listed in the Technical Index (Section 20J.5) and each is specifically identified in the relevant section of the structured safety argument.

20J.1.4 Reactor Vessel Internals and Flow Skirt Description

20J.1.4.1 Overview

The RVI and RVFS, contained entirely within the RV, as shown in Figure 20J-1, are part of the reactor system (RXS). The RVI are classified as either a core support structure (CSS) or an internal structure (IS). The CSS are components which provide direct support or restraint

to the core. The IS are all structures within the reactor pressure vessel other than the CSS, fuel, control assemblies, and instrumentation. The CSS and IS components are listed below.

Core Support Structure

- Upper support assembly (USA)
  - Upper support plate (USP)
  - Upper support flange and upper support skirt
  - Upper support columns (USCs)
  - Upper core plate (UCP) and clevis inserts
  - UCP fuel alignment pins
- Lower core support assembly (LCSA)
  - Core barrel (CB) cylinder
  - CB flange
  - CB outlet nozzles
  - Lower core support plate (LCSP)
  - LCSP fuel alignment pins
  - LCSP radial keys and clevis inserts
  - Alignment plates, bolts, and dowel pins
  - Threaded structural fasteners (TSFs) and pins that provide direct load-carrying capabilities of the CSS

Internal Structure

- Core shroud (CS) and top plate clevis inserts to the CS
- Instrumentation grid assembly (IGA)
- Direct vessel injection (DVI) flow deflector
- Secondary core support structure (SCSS)
- Vortex suppression plate (VSP)
- Irradiation specimen basket
- Neutron shield panels
- Head and vessel alignment pin (HVAP)
- Guide tube flange hold-down bolts
- Miscellaneous items, e.g., head-cooling nozzles, support column nozzles and guides, irradiation access plugs

- TSFs, locking caps, locking bars, pins, etc., that do not provide direct load-carrying capabilities of the CSS
- Internals hold-down spring
- Control rod guide tubes and support pins

In addition to supporting and restraining the core, the RVI provide for the controlled circulation of coolant through the core. Additional control over the coolant flow is achieved by the RVFS at the bottom of the RV, which, although not considered part of the RVI, is covered within this CSR.

20J.1.4.2 Description

The RVI, when assembled in the RV, provide the appropriate guidance, protection, alignment and support for the core and control rods to enable safe and reliable reactor operation. The lower and upper support assemblies are shown in Figure 20J-2 and Figure 20J-3, respectively. The internals are supported by the RV ledge and are restrained against upward movement by the vessel head. The lower end of the internals is restrained against rotational and/or lateral movement by four lower radial support keys that engage clevises attached to the RV.

The other key function of the internals is to control the passage of coolant through the core as well as providing a specified by-pass flow to other regions of the RVI and RV, such as the RV closure head (RVCH) plenum, outer CS and the control rod drive mechanism regions, in order to maintain the appropriate component operating conditions. The RVFS, which provides additional control over coolant flow in the lower RV plenum beneath the lower RVI, is an upright perforated circular cylinder, as detailed in Figure 20J-4. The RVFS is attached by full penetrating welds to eight support blocks on the RV shell.

The RVI and RVFS are both designed for a service life of 60 years.

Materials used in the manufacture of the RVI and RVFS sub components are given in Table 20J-1.

20J.1.5 Reactor Vessel Internals and Flow Skirt Function

20J.1.5.1 Upper Support Assembly

The USA (Figure 20J-3) provides the vertical restraint, lateral restraint, and lateral alignment to the top of the core through its main components: the USA, USCs, the UCP, and the interface with the RV. The assembly also supports the IS, such as the IGA, and supports the reactor control rod guide tubes. The USA, which is supported on its outer edge by the RVCH and the hold-down spring compression, transfers the loading of the upper support assembly to the RV. Keyways are located in the outer edges of the subassembly to align the USA to the RV and lower core support assembly during initial installation of these assemblies at the nuclear plant site and during subsequent refuelling operations. There are penetrations in the subassembly for the spray nozzles that allow limited flow into the RV upper head area. Flow holes are incorporated in the USP to allow for draining the upper head region during depressurisation accidents.

Upper Support Columns

The primary function of USC is to transfer vertical and lateral reaction loads to the USA. These columns are attached to the bottom side of the USA and form the plenum between the USA and the UCP. The USC also serve as guidance and support members for the in-core instrument thimble assemblies (IITAs).

Upper Core Plate

The UCP, which is attached to the bottom of the USC, forms the upper boundary of the core cavity. It transfers core loads to the upper support columns, and when in place within the RV, compresses the fuel assembly springs, creating the core preload. The plate is perforated to allow coolant flow while maintaining an acceptable velocity profile. It contains the upper fuel alignment pins that engage the top of the fuel assemblies. The upper-core periphery to lower core periphery alignment is provided through keyways in the outer edges of the UCP. The keyways contain customised inserts that provide the required alignment plate engagement gaps. In addition, this keyway and insert system limits any torsional rotation or translation of the UCP.

20J.1.5.2 Lower Core Support Assembly

The LCSA (Figure 20J-2) is the major core support assembly. The functions of this assembly are as follows:

- Support the core and the attached IS
- Transfer the loads from the bottom of the core, attached IS, and other design loadings to the RV
- Provide restraint and alignment of the core
- Provide directional and metered control of reactor coolant flow through the core
- Provide sufficient neutron shielding with the CSS and neutron panels for the RV

Each fuel assembly that forms the core is placed within the CS assembly and is rested on the LCSP. The LCSP contains the fuel alignment pins that locate the bottom of the fuel assembly nozzles. The LCSP has perforations to provide relatively equal flow to each assembly and to limit the flow jet velocity entering the fuel assemblies. The LCSA transmits the loading to the RV through the RV ledge and the lower radial supports, and potentially through the outlet nozzles. The LCSP has an access port that allows access to the lower radial supports with the lower RVI installed in the RV, enabling customisation of the lower radial support clevis inserts.

Rotational Support System

The rotational support system consists of keys that are attached to the rim of the LCSP. These keys engage clevis inserts that are bolted to the RV core support blocks. This system restricts the lower end of the CB from rotational and/or translational movement, and provides a load path for LCSP horizontal loadings, while allowing for radial and axial thermal displacements of the CB and LCSP.

Core Barrel Alignment Plate Assemblies

The CB alignment plates ensure alignment of the UCP and CS top support plate is maintained under lateral load conditions. There are four alignment plate assemblies attached to the CB at the same elevation as the UCP and the same angular orientation as the four inlet nozzles. The alignment plates are attached to the CB with dowel pins and hex cap screws. To assist in the radial positioning of the alignment plate relative to the CB, the alignment plate sits in a radial recess machined into the CB to match the radius of the outside surface of the alignment plate.

Core Barrel Outlet Nozzles

The CB outlet nozzles provide the passageway for the reactor coolant from the core to the RV outlet nozzle projection. The radial gap size between the CB outlet nozzles and RV outlet nozzles is controlled to restrict the amount of bypass flow.

20J.1.5.3 **Internal Structures**

Head and Vessel Alignment Pins

The head and vessel alignment pins attach to and extend above and below the flange of the LCSA. The portions of the pins extending below the flange engage pockets in the RV to provide alignment of the LCSA to the RV. The portions of the pins extending above the flange engage the upper support assembly and extend into pockets provided in the RVCH, thereby ensuring alignment of all the assemblies. Minimal clearance is maintained between the pins and the engagement pockets to ensure functional alignment and facilitate assembly.

Reactor Control Rod Guide Tubes

The reactor control rod guide tubes perform the following functions:

- Provide a straight, low-friction path for control rod insertion and withdrawal from the fuel assemblies in the core.
- Provide protection for withdrawn control rods from possible damage due to loads imposed by reactor coolant flow and/or other mechanical/vibratory loading.
- Provide storage for the control rod drive shafts during removal of the upper CSS from the vessel. The guide tubes also perform the function of removing all the uncoupled drive rods from the vessel, when the RVI are removed for refuelling.
- Allow coolant flow exiting the fuel assemblies to pass into the outlet plenum without causing significant loads on the control rods, or maldistributions in the core outlet flow pattern.
- Are removable for repair or replacement (if damaged) without affecting the upper support assembly.

Irradiation Specimen Baskets

The irradiation specimen baskets, which are attached to the outside of the CB, support and restrain the irradiation specimens. There are eight surveillance capsules, excluded from the RVI scope of supply, which will be field-installed. Capsule exposure lead factors relative to the RV are designed to the appropriate range for reactor operation. At specific intervals during the design life of the reactor, a specimen will be removed from the specimen basket and material samples will be tested to determine the current cumulative effects on the RV. The external geometry of the specimen baskets will minimise undesirable flow phenomena in the downcomer annulus, such as flow vortices and flow-induced vibration (FIV).

Secondary Core Support Structure

A SCSS is provided in the plenum area between the bottom of the CB subassembly and the bottom of the RV. (Note that this assembly is an internal structure even though the core support nomenclature is used.) The function of the secondary core support is to perform the following after a postulated failure and downward movement of the CB subassembly:

- Absorb a portion of the energy generated to limit the dynamic force imposed on the RV.
- Transmit the vertical load of the core to the RV.
- Limit the displacement to prevent withdrawal of the control rods from the core.
- Limit the displacement to prevent loss-of-alignment of the core with the UCP, so that the control rods can be inserted into the reactor.

Instrumentation Grid Assembly

The IGA is designed to prevent excessive vibration of the IITA, which contains the fixed in-core flux detectors and core-exit thermocouples. The IGA provides a path from the QuickLoc instrument nozzles through USCs and the USA to the top of the fuel assemblies. The pathway protects and guides the IITAs during initial installation, reactor operation, and withdrawal/insertion during outages.

Lower Plenum Vortex Suppression Plate

The lower plenum vortex suppression plate is positioned in the vessel lower plenum to suppress the formation of any unsteady flow vortices formed in the reactor coolant flow. The vortex suppression plate is supported by columns that are attached to bottom of the LCSP.

Internals Hold-Down Spring

The RVI hold-down spring is a circumferential spring located between the flanges of the upper and lower CSS flanges when they are assembled in the RV. This spring provides a preload to limit axial movement of the upper and lower core support assemblies during reactor operation. The preload of the hold-down spring is provided when the RVCH is properly secured by tensioning of RVCH studs.

Core Shroud

The CS assembly is located inside the CB and above the LCSP. This assembly forms the lateral periphery of the core and through the dimensional control of the cavity, i.e., the gap between the fuel assemblies and the CS, provides directional and controlled flow of the

reactor coolant through the core. The arrangement of the CS provides a transition from the cylinder-like CB to the fuel assemblies. The CS allows cooling water (i.e., bypass) to flow through the cavity between the CB and the CS lateral periphery panels while still providing sufficient material to perform the neutron reflection and radiation shielding functions.

Neutron Shielding

Neutron shielding is provided over the active core elevations on the outside of the CB by the neutron shield panels. This shielding is in the form of strategically located panels. The shielding protects the RV from detrimental radiation effects by limiting total exposure.

Direct Vessel Injection Deflector

The function of the DVI deflector is to prevent cold water from the DVI nozzle from impinging directly on the CB and to direct the water downward.

20J.1.5.4 Reactor Vessel Flow Skirt

The RVFS (Figure 20J-4) aides in the development and maintainability of an acceptable core inlet flow distribution, ensures the RV pressure drop limit is not exceeded and minimises the risk of developing undesirable flow phenomena (e.g., unstable flow vortices in the lower head) considering the full range of expected flow rates.

20J.1.6 Reactor Vessel Internals Boundaries

The physical boundaries for safety case assessment of the RVI and RVFS are shown in Reference 20J.2 and Reference 20J.3, and are identified below:

- The interfaces of the RVI with the RV occur at the internals support ledge, the outlet and DVI nozzle internal projections and the core support blocks for the internals radial support keys.

- The interface of the RVFS with the RV is at the RVFS attachment weld.

- The internals and fuel assembly have interfaces between the UCP and the fuel hold-down springs or core components and fuel alignment pins at the fuel assembly top nozzles and the LCSP at the fuel assemble bottom nozzles and fuel alignment pins at the fuel assembly bottom nozzles.

- The CSS-to-IS boundaries at:

  – USP at the intermediate flange of the lower guide tube flange and hold-down bolts
  – LCSP at the CS bottom plate
  – CB flange and upper support flange at the head and vessel alignment pins
  – CB flange and upper support flange at the RVI hold-down spring
  – CB flange at the upper head flow nozzles
  – LCSP at the secondary core support columns and fasteners
  – UCP at the guide tube support pins
  – IGA Guide studs to USP top surface
  – IGA at the top surface of the USP and inside diameter of the USCs
  – USC instrumentation adapter to USC base
  – CB cylinder at the DVI deflector
  – CB cylinder at the CS ring bands
  – CB alignment plates at the CS top plate

- CB cylinder at neutron shield panels
- CB cylinder at the irradiation specimen baskets
- USP female threads in the flange at Roto-Lock inserts male threads
- CB female threads in the flange at Roto-Lock inserts male threads

20J.2 Safety Case Requirements

The main focus of this CSR is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate the structural reliability of the RVI and RVFS commensurate with the structural integrity classification, as outlined in Section 20J.2.2. The RVI have been classified as Standard Class 1 according to the procedure adopted in Reference 20J.1. To substantiate this, the safety argument is presented as three key elements, as follows:

Claim 1: **Quality of Build: High quality is achieved through good design and manufacture.**

Objective: Provides evidence of good design and manufacture based on established design and manufacturing processes and use of proven materials. It provides a keystone for a demonstration of high reliability and embodies the code and plant operating experience with objective of achieving quality of build and the avoidance of defects (Section 20J.3.1).

Claim 2: **Good Design: Good design is achieved through compliance with American Society of Mechanical Engineers (ASME).**

Objective: Incorporates the build experience as embodied in the design codes (Section 20J.3.2).

Claim 3: **Mitigation and Management of In-service Degradation: Components are tolerant to through-life degradation over the design life of the plant.**

Objective: Provides an assessment of through-life degradation mechanisms and show that such mechanisms will not threaten integrity over a specific interval (Section 20J.3.3).

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure.

The three elements of the safety argument are provided in Section 20J.3 and the strength of the argument is discussed in Section 20J.4.

20J.2.1 Safety Functional Requirements

The safety design bases are requirements of plant systems, some duty and some accident response, which must be maintained at all times to provide assurance of plant nuclear and radiological safety. Identification of the SFRs for the RVI and RVFS follow from the performance and safety design bases allocated in Reference 20J.2 and 20J.3, as follows:

- Support, orient, and guide the core components, namely the fuel assemblies and control rod assemblies.
- Direct the main coolant flow to and from the fuel assemblies.

- Absorb control rod dynamic loads, fuel assembly loads, and other loads, and transmit these loads to the RV.
- Support IITA within the RV.
- Convey cooling water to the core for a postulated loss-of-coolant accident (LOCA).
- Provide protection for the RV against excessive irradiation exposure from the core.
- Inhibit undesirable flow phenomena (e.g., FIV, unstable flow vortices in the lower head and flow jetting into the core).
- Not permit the RV pressure drop limit to be exceeded.
- Position and support RV irradiation specimen baskets

Based on these, the following SFRs, identified in Table 20-1, reflect the overall role of the RVI and RVFS in plant safety:

- **SFR 20.10.1** The RVI are required to support, orient and guide the core components, namely the IITA, fuel assemblies and rod cluster control assemblies (RCCAs) during standby, normal operation and under design basis faulted conditions for the design life of the plant.
- **SFR 20.10.2** The RVI and RVFS are required to inhibit undesirable flow phenomena and to direct the main coolant flow to and from the fuel assemblies and convey cooling water to the core for a postulated LOCA. Furthermore, the RVI and RVFS are required to maintain the RV pressure drop within specified limits.
- **SFR 20.10.3** The RVI are required to absorb control rod dynamic loads, fuel assembly loads, and other loads, and transmit these loads to the RV.
- **SFR 20.10.4** The RVI are required to provide protection for the RV against excessive irradiation exposure from the core.
- **SFR 20.10.5** The RVI are required to position and support the RV irradiation specimen baskets.

Postulated failure modes which result in a loss of these functional requirements lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20J.2.2.

20J.2.2 Reactor Vessel Internals Structural Integrity Classification

The structural integrity classification methodology described in Section 20.5 and further in Reference 20J.1 has been applied with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct (e.g., reactivity insurgence or disruption of flow) and indirect (loose articles) consequences of gross failure. The details of the classification for the RVI classification are presented in Reference 20J.1.

This concludes that the direct consequences of gross failure of the upper RVI would be the potential for either disruption to internal flow leading to fuel damage or an inability to insert control rods. As the upper RVI are supported by an independent flange to the core barrel and have their supporting structure sandwiched between the (spring loaded) UCP and RVCH, there will be no significant displacement as a result of a failure of an USA circumferential weld. To similar effect, failure of a core barrel circumferential weld will only result in an allowable vertical displacement of the lower RVI and the core on account of the SCSS and radial clevis supports. Consequently, coolant flow and control rod insertion will be retained. Additionally, the safety evaluation described in Chapter 9 demonstrates that even with the highest worth control rod assembly stuck in the fully withdrawn position, the necessary shutdown margin (with combined use of chemical shimming) is maintained during long-term xenon decay and plant cooldown, thus accounting for any local failures of the RCCA guides. On this basis, the RVI have been categorised as Standard Class 1 components.

20J.3 Safety Case Arguments

The RVI have been classified as Standard Class 1 components in accordance with Reference 20J.1 as discussed in Section 20J.2.2. The structural integrity claim is therefore based on arguments which substantiate the classification in Section 20J.2.

Consistency with ASME Boiler & Pressure Vessel (ASME Code), Section III, Subsection NG provides the basic demonstration of fitness-for-purpose for the RVI. Based on this, a satisfactory structural reliability can be claimed on account of the quality requirements, material selection, manufacturing control, stress limits, and inspection requirements associated with compliance to ASME Code, Section III, Subsection NG, as well as accounting for known degradation mechanisms.

Compliance with ASME Code therefore provides the primary element in the safety case for the AP1000 RVI.

20J.3.1 High Quality Is Achieved through Good Design and Manufacture

In order to demonstrate that high quality is achieved through good design and manufacture, evidence to support the following claims is provided:

- The fabrication specification complies with ASME Code, Subsection NG, requirements.
- Supplementary requirements are specified to avoid defects and to ensure quality.

The reliability of the RVI is dependent upon the design quality. The design intent is translated into a manufacturing route which is controlled by a Quality Assurance Programme which complies with rigorous design codes including the ASME Code. The RVI Design Specification (Reference 20J.2) and the RVFS Design Specification (Reference 20J.3) provide lists of the industry codes, specification and standards applied to the components.

The justification of the quality of build of the RVI and of materials used includes:

- All materials comply with the applicable requirements of the design and construction codes and standards including requirements of ASME Code, 1998 Edition with Addenda up through and including 2000 Addenda. The materials used in the AP1000 will be selected from materials proven in-service in pressurised water reactors (PWRs). Proven materials are those with the same nominal composition and subsequent processing steps (e.g., heat treatment, fabrication, and installation) and same exposure conditions (e.g., stress levels, water chemistry environment, temperature, or radiation fluence) as those

used successfully in existing PWRs. Only if it can be demonstrated that they have been proven to be appropriate in similar components subject to equivalent operating environmental conditions and loadings will materials potentially susceptible to degradation mechanisms in PWR environments be permitted. Maximum limits are set on the cobalt level in RVI and waterside components to minimise plant radiation levels.

- A heat treatment, for dimensional stability or relaxation of residual stresses, will be applied to CSSs and IS that undergo bending, welding, or re-straightening. Stabilisation and residual stress heat treatment requirements are specified in Reference 20J.6 and will be noted on the design drawings, as applicable. Locking cups and caps are generally annealed after machining. The annealing process to be performed will be noted on the applicable design drawing.

- Welding procedure specifications for fabrication will comply with the requirements of Section IX, Welding and Brazing Qualifications, and Section III, of the ASME Code. Specific welding requirements include (References 20J.2 and 20J.7):

  – All welders, including tack welders, will be qualified and identified for each weld joint.

  – Welding of stainless steel materials will be in accordance with the United States Nuclear Regulatory Commission (NRC) Regulatory Guide 1.44, “Control of the Use of Sensitized Stainless Steel” (Reference 20J.14).

  – In addition to the delta ferrite requirements, the requirements of US NRC Regulatory Guide 1.31 (Reference 20J.15), will be applied. Ferrite content will be determined on undiluted weld deposits.

- Interpass temperatures will be limited to 350°F (176°C) on assemblies whose constituent parts are joined by welding and to 800°F (426°C) during hardsurfacing of stainless steel and nickel based alloys that contain carbon lower than 0.03 weight percent.

- In general, austenitic stainless steels will be limited to temperature below 800°F (427°C) during the fabrication process, except instantaneously and locally by welding and thermal cutting.

- Each pass will be cleaned by stainless steel wire brushing or other mechanical means. Stainless steel brushes must be new or previously used only on stainless or nickel-based materials.

- In cases of limited accessibility a performance qualification will include testing of the welder in accordance with US NRC Regulatory Guide 1.71, ‘Welder Qualification for Areas of Limited Accessibility’ (Reference 20J.16), the test will simulate the most restrictive production weld for access by a welder and requalification is required for production welds considered more restrictive.

- Fabricators are permitted two attempts at repairing a defect after final inspection. If the repair is not successful after the second attempt the fabricator is required to submit a non-conformance report.

- Tack welds that will be incorporated into the final weld will be deposited with a contour suitable for fusion with the root pass.

- Special welder qualification is required for locking bar welds and will include making several typical locking bar welds in the production position which will be evaluated by visual examination and macro-examination to show complete fusion and free of cracks.

- All fasteners internal to the RV will be designed such that the fastener is positively locked and the head, shank, and threaded portions will be captured should the fastener fail. Moreover, the use of high strength fasteners in the RVI susceptible to intergranular stress corrosion cracking (IGSCC) has been avoided and wherever possible joint crevices will be vented in order to minimise the potential of crevice corrosion effects.

- A special cleaning procedure, as detailed in Reference 20J.8, is required for the RVI due to the complex design of the completed assembly.

- Nondestructive examination (NDE) during manufacture, as a minimum, complies with the requirements of the ASME Code, Section III, Subsection NG.

- Pre-service inspection (PSI) of the RVI is in accordance with ASME Code, Section XI, using the visual inspection method VT-3.

- Qualification of personnel, procedures, and equipment will be in accordance with ASME Code, Section XI.

Together these provide a keystone for a demonstration that the internals are well designed, will enter service free from structurally significant defects and that the effects of through-life degradation on material properties will not have a deleterious effect on their structural reliability.

20J.3.2 **Good Design Is Achieved through Compliance with ASME**

In order to demonstrate that good design is achieved through compliance with ASME, evidence to substantiate the following argument is provided:

- The design has been analysed and has been shown to comply with the requirements of ASME Code, Section III for Class 1 components.

The RVI CSS (Reference 20J.2) and RVFS (Reference 20J.3) design specifications provide the basis for their construction to conform to the rules set forth in the ASME Code, Section III, Subsection NG, 1998 Edition with Addenda up through and including 2000 Addenda. The RVI IS will be constructed to the same requirements as the CSS. Moreover, the IS will be constructed such that they do not adversely affect the integrity of the CSS. Critical RVI design features have been identified and analysed or tested to demonstrate their conformance to code, or otherwise, requirements, including fatigue, are met. The results of these assessments are documented in the design reports for the RVI and RVFS, References 20J.17 and 20J.18, respectively.

The design transients used in the analyses are summarised in Table 20-22. The load cases considered include normal, upset, emergency and faulted conditions.

The various loadings to which the RVI and RVFS are subjected are presented in Reference 20J.2 and Reference 20J.3, respectively. The loads include any loads incurred during transportation, handling and installation, the deadweight, buoyant forces, differential pressure, hydraulic lift and drag forces, flow and reactor coolant pump (RCP) induced vibrations, spring forces, thermal loads (including those due to radiation (gamma) heating),

seismic and LOCA loads. Also, the RVI and RVFS will be capable of satisfying all functional requirements under normal, upset, emergency, faulted, and test operating conditions.

The gap criteria required to ensure the structural integrity and flow requirements (including bypass flow) of the RVI and RVFS are met are detailed in Reference 20J.2 and the functional deflection and displacement limits of the RVI are provided in Reference 20J.2. In addition, the guide tubes are designed beyond the requirements of the ASME Code in order to satisfy the Westinghouse specified control rod drop time. Retention of these dimensional limits is confirmed by analysis demonstrating compliance to ASME Code, Section III, Subsection NG.

The RVI SCSS mitigates the effect of the postulated core drop event. Analysis demonstrates that the SCSS satisfies the following requirements:

- The SCSS limits the load exerted on the RV during the postulated core drop event.
- The distortion of the lower internals is limited. This ensures the ability to insert the control rods and maintain the core in a configuration to be cooled.
- The design of the SCSS is such that, during the postulated core drop event, the contact area between SCSS and the RV precludes yielding of the RV cladding.
- With the exception of a postulated core drop event, the gap between the SCSS and RV is retained sufficient to preclude contact between them for all normal, upset, emergency, faulted, and test operating conditions.
- Fuel assemblies will not disengage the UCP fuel alignment pins during a postulated core drop event.
- The gap between the SCSS and the RV is retained sufficient to preclude contact between the bottom surface of the LCSP and RVFS for normal, upset, emergency, faulted, and test operating conditions, including a postulated core drop event.

The thermal and structural analysis has been undertaken using established procedures to demonstrate that for the load cases analysed all the stresses and cumulative fatigue usage factors are satisfactory and meet the appropriate limits set forth in the ASME Code, Section III, Subsection NG. Details of these calculations are presented in the calculation notes as detailed in the technical index (Section 20J.5).

Pre-operational tests at elevated pressure and temperature are referred to as hot functional tests. The hot functional tests (HFT) are part of a comprehensive reliability test of the RVI designed to meet the guidance of U.S. NRC Regulatory Guide 1.20 (Reference 20J.13) and are part of the pre-operational testing. Transient loadings and operating conditions for HFT and pre-operational testing are accounted for in the design transients identified in Table 20-22. The duration of the HFT is defined such that each critical component will have been subjected to at least 10^6 cycles of vibration prior to final inspection of the RVI. The steady-state portion of the HFT will be performed at the no-load temperature and at a flow rate maintained between the thermal design flow and maximum design flow rates. The core may not be present during HFT.

An internals vibration measurement programme is to be conducted during the HFT on the first AP1000 plant. During HFT, the AP1000 internals are subjected to operational system

flow conditions that are similar to those imposed on previous 3XL three-loop designs. Data are calculated over the ranges of HFT temperatures and during startup, shutdown, and steady-state operation of various combinations of RCPs. The duration of the hot functional flow testing will be the same as that for the previous design. Pre- and post-test inspections will be conducted to confirm that the AP1000 internals experience no excessive motion or wear. The test results will be evaluated in terms of comparison to existing plants of similar RVI design as well as to provide confirmation of the analytical models.

20J.3.3 Mitigation and Management of In-Service Degradation

In order to demonstrate that the design has taken account of in-service degradation mechanisms, evidence to substantiate the following arguments is provided:

- A structured process has been applied to identify in-service degradation mechanisms.
- The design has been optimised to mitigate against the risk from in-service degradation mechanisms.

20J.3.3.1 Identification of Degradation Mechanisms

References 20J.2, 20J.3, 20J.7, 20J.9, and 20J.11 identify design characteristics, potential hardware failures or human errors associated with the design and operation of the RVI and RVFS that could lead to a potentially hazardous condition such as inability to insert a control rod assembly or restricted flow of coolant to the core.

The following potential hazards or operational problems have been identified:

- IGSCC
- Primary water stress corrosion cracking (PWSCC)
- Irradiation-assisted stress corrosion cracking (IASCC)
- Irradiation swelling
- Stress Relaxation
- General corrosion
- Crevice corrosion
- Fatigue
- Brittle fracture
- Failure arising from manufacturing defect
- Galling
- Wear

The basis of the safety case argument is that mitigation against corrosion, fatigue, brittle fracture and manufacturing defects is essentially provided by compliance with ASME design and fabrication rules, the use of proven materials together with the associated ISI requirements and the operating experience embodied within the code as well as other plant experience to mitigate against these degradation mechanisms.

It was determined in the RVI and RVFS failure modes and effects analysis (FMEA) studies (References 20J.9 and 20J.10, respectively) that there is sufficient mitigation in place to offset the potential hazards identified within the report, where the majority of hazards are derived to have a minimal expectation of failure occurrence.

20J.3.3.2 **Avoidance of Primary Water Stress Corrosion Cracking**

Materials known to be susceptible to PWSCC are forbidden and Alloy 600 (Unified Numbering System (UNS) N06600) will not be used for wetted environments with sustained temperatures above 400°F (204.4°C).

20J.3.3.3 **Avoidance of Inter Granular Stress Corrosion Cracking**

In addition to the close control over the reducing coolant chemistry, the stainless steel structural and weld material chemistry and delta-ferrite number (FN) will be controlled to minimise sensitisation to prevent IGSCC. Material processing and RVI material sensitisation is minimised by high quality fabrication and will not adversely affect material IGSCC resistance. As a minimum, the guidance of Regulatory Guide 1.44 (Reference 20J.14) is followed. If, during the course of fabrication, stainless steel is inadvertently exposed to the sensitisation temperature range, the material will be tested according to a process specification, following the guidelines of American Society for Testing and Materials A262, to verify that it is not susceptible to intergranular attack. Testing is not required for the following:

- Weld metal with a ferrite content of 5 percent or more
- Material with a carbon content of 0.03 percent or less
- Material exposed to special processing, provided the processing is properly controlled to develop a uniform product and adequate documentation exists of service experience and/or test data to demonstrate that the processing will not result in increased susceptibility to intergranular attack.

Material not verified to be non-susceptible to intergranular attack will be subject to re-solution annealing and water-quenching or will be rejected.

20J.3.3.4 **Avoidance of Irradiation Induced Degradation**

The irradiation exposure and/or strain limits for the RVI, including fasteners, is demonstrated based on applicable data from operating nuclear plants and/or materials test reactors. The following approaches will be considered:

- All CSS have been evaluated for radiation swelling and IASCC based on the projected peak fluence at the end-of-life for the design basis of the plant (Reference 20J.11).
- Available data for radiation relaxation have been applied where they are significant; for example fasteners.
- Heating resulting from the absorption of gamma ray energy, i.e., gamma heating, is accounted for in the evaluation of RVI components.

20J.3.3.5 **Avoidance of Wear and Galling**

Anti-galling materials and chrome plating will be used where appropriate (i.e., potential wear locations). The core inlet flow distribution will be sufficiently uniform to limit the vibration-induced fuel rod wear. This is accomplished by the core design parameters and compliance with all applicable normal operation and transient events. The RVI hold-down spring maintains a sufficient compressive preload during Level A and Level B operations to minimise sliding, wear, and vibration under all normal operating conditions, but the average

bearing stress between the RV ledge/CB flange and RV head/upper support assembly flange during Level A conditions is limited in order to prevent galling which could result from radial differential expansion between the RV and RVI at these interfaces. The guide tubes, which can suffer wear degradation, will be replaceable and subject to an appropriate ISI schedule, to be determined.

20J.3.3.6 In-Service Inspection

ISI provides forewarning of failure and a means of monitoring degradation and this forms an important element of the safety case argument. ISI is carried out in accordance with Section XI of the ASME Code. The CSS requires visual examination (VT-3 – general mechanical and structural condition) of all accessible surfaces. The visual examinations must be performed at each inspection interval, typically defined as 10 years.

The only requirement to satisfy the above mentioned examination is that the core internals structures be removed from the RV. Current ASME Code requirements do not specify what particular features of the core support and internal structures need to be examined. However, future ASME Code requirements may be more specific and as such the RVI have been designed to accommodate such examinations wherever practical. Areas that may be specified in the future for inspection and their anticipated examination requirements are included in Table 20J-2.

Features that will increase examination reliability and facilitate the inspection process for the internals include properly conditioned welds and easy remote access to the examination surfaces. For ultrasonic testing (UT) of bolting, the bolts should provide sufficient surface area for such examinations. The use of external hex head bolts is a design configuration that has proven to be amenable for such examinations in current plant designs.

Written instructions concerning RVI inspection, maintenance, installation, operation, assembly details and disassembly details will be provided following the generic design assessment (GDA).

20J.4 Strength of the Safety Case

The RVI has been classified as a Standard Class 1 component according to Reference 20J.1. The safety argument in Section 20J.3 demonstrates how the internals structural integrity is established based on extensive quality assurance measures in design, manufacture, materials, testing and qualified inspection. The strength of the safety case is based on the assurance of integrity and that the RVI and RVFS have been deterministically justified in accordance with ASME Code, Subsection NG. Additional arguments provide evidence to demonstrate that the internals are tolerant to through life degradation and this conclusion will be supported by inspection. In combination these elements provide a cogent argument to substantiate reliability commensurate with the Class 1 classification of Reference 20J.1 for the RVI.

To substantiate this claim, this report provides a structured argument supported by suitable and sufficient evidence. To achieve this, three key elements, namely Quality of Build, Good Design, and Mitigation and Management of In-Service Degradation have shown how this will be achieved.

Quality of Build and material selection has been demonstrated by compliance with ASME Code Section III, Subsection NG.

Good design has been demonstrated by providing evidence, including a summary of the results from referenced calculation notes, that design transients including normal, upset,

emergency and faulted conditions are within allowable limits specified in the ASME Code Section III, Subsection NG.

Mitigation and management of in-service degradation has been demonstrated by identifying all design characteristics, degradation mechanisms and potential hazards that could lead to loss of integrity of the RVI. ISI will also provide forewarning of degradation with engineering maintenance and inspection schedules carried out at appropriate intervals.

20J.5 Index of Technical Reports

Table 20J-3 provides a list of the relevant technical references of the RVI and RVFS, supporting the safety case and the function of each document within the safety case.

20J.6 Review of Open Issues

The design of the reactor internals has been finalised and the ASME Design Report has been issued. There are no open issues for the RVI or RVFS that affect the basis of the safety case arguments presented in support of GDA Step 4.

20J.7 Conclusions

This CSR for the United Kingdom (UK) AP1000 plant RVI and RVFS presents the safety arguments to show how the SFRs are maintained for these components. This report presents arguments that support the claim that the structural reliability of the RVI is commensurate with the consequences of failure. To evaluate this, the RVI has been classified in accordance with the procedure for structural integrity classification specified in Reference 20J.1.

The main elements of the safety case argument are firstly that the component has been designed in accordance with the high standards of the ASME Code, Subsection NG. This includes tight controls on material properties, manufacturing processes, design, testing, inspection, and installation such that there is a high level of confidence in the quality of the component and that it will enter service free from significant flaws that could affect the integrity of the component over its lifetime. Secondly, that measures to prevent and forewarn of any potential in-service degradation, such as selection of proven materials and specialised fabrication procedures to avoid IGSCC and the application of ISI at appropriate time intervals, are specified that will mitigate against the mechanisms identified that could threaten the integrity of the component through-life.

Based on the arguments presented together with the referenced supporting evidence, it is considered that the structural reliability of the RVI and RVFS has been justified to a standard commensurate with its consequences of gross failure.

APPENDIX 20K
CONTAINMENT VESSEL COMPONENT SAFETY REPORT

20K.1 Introduction

This is the component safety report (CSR) for the containment vessel (CV) as introduced in Section 20.2. The safety argument herein substantiates the structural integrity of the CV to a degree of rigour commensurate with the consequences of gross structural failure. The safety argument is supported by a suite of documentation outlined in Section 20K.5 that supports the design, fabrication, construction, inspection, and operation of the CV.

20K.1.1 Scope

The CV acts as a secondary pressure containment boundary in the unlikely event of a demand caused by a breach of the primary or secondary system pressure boundary within containment, actuation of the automatic depressurisation system (ADS) valves, or long-term operation of the passive residual heat removal heat exchanger. This CSR presents arguments to support the claim that the nuclear and radiological risks potentially arising from structural failure of the CV for the entire design lifetime objective of 60 years are tolerably low. Conventional hazards to personnel safety are outside the scope of this Appendix 20K.

20K.1.2 Objectives

This CSR supports the claim the AP1000 plant risk remains both tolerable and as low as reasonably practicable (ALARP) for the design lifetime. These claims are substantiated by satisfying structural integrity safety design bases for all safety-significant AP1000 systems, structures, or components (SSCs). The safety design bases, applied across the operational, process and lifecycle scope of the safety case, embody the technical scope of the safety case: if these can be maintained at all times, the plant will be acceptably safe. Specific safety functional requirements (SFRs) for each particular component are developed from the structural integrity safety design bases, and correspond to the functions that need to be maintained to provide assurance of nuclear and radiological safety. The SFRs applicable to the CV are identified in Section 20K.2.

20K.1.3 Interface With Other Safety Case Documents

The safety argument presented in this report is supported by a dossier of technical data and analyses, which are listed in the Technical Index (Section 20K.5). Where applicable, the supporting documents are identified in the relevant section of the structured safety argument.

20K.1.4 Containment Vessel Description

20K.1.4.1 Functional Overview

The containment building is defined as the CV and the structures contained within the CV. The containment building is an integral part of the overall containment system with the functions of containing the release of airborne radioactivity following postulated design basis accidents (DBAs) and, along with the shield building, of providing shielding for the reactor core and the reactor coolant system (RCS) during normal operations. The CV is an integral element of the passive protection systems since it contains the coolant inventory within the containment thereby allowing passive recirculation of the cooling water during DBA.

The CV is also an integral part of the passive containment cooling system (PCS). The CV facilitates core residual heat removal during postulated loss-of-coolant accident (LOCA) or main steam line break (MSLB) accident events where steam generator (SG) heat removal is not available or is insufficient. The CV provides the heat transfer interface with the surrounding atmosphere, which acts as the heat sink. The rate of cooling can be increased by pouring water onto the outside of the CV steel shell during accident conditions as described herein. Cooling is required to remove sufficient energy to prevent the containment from exceeding its design pressure and temperature following postulated DBAs.

To provide these functions, the CV is designed to provide a leak tight barrier against the uncontrolled release of radioactivity to the environment, to ensure that the coolant inventory is maintained within the containment in the event of a LOCA, and to assure that the containment design conditions are not exceeded for as long as postulated accident conditions and their aftermath require.

The CV also acts as a support for the polar crane, which is supported by a girder that is welded around the circumference of the CV inner surface. Other less significant items are also attached to the inner surface. Justification for the polar crane and girder is covered in Chapter 17.

The CV is an AP1000 Class C (United Kingdom (UK) Safety Class 1) component and serves as the final barrier for preventing the release of radioactive material from the AP1000 plant. The CV must be able to withstand the effects of natural phenomena such as earthquakes, tornadoes and floods, as well as airplane crash, without loss of capability to perform its safety function. It is therefore also classified as seismic Category I. The structural integrity classification of the CV is discussed in Section 20K.2.2.

20K.1.4.2 Design Description

The CV is a cylindrical welded steel vessel with elliptical upper and lower heads. Figure 20K-1 shows the general outline and major dimensions of the CV structure including the locations of the major penetrations, the crane girder and the stiffeners.

The CV is supported by embedding the lower portion in concrete below the 100 m elevation on the outside and the 102.184 m (107.17 ft) elevation on the inside. The 100 m level is the nominal vertical datum for the UK design; this corresponds to the United States (US) nominal vertical datum of 100 feet, and is the ground level elevation.

The CV is an independent, free-standing structure above elevation 100 m. Vertical and lateral loads on the CV and internal structures are transferred to the basemat below the CV by shear studs, friction, and bearing. The shear studs are not required for design basis loads; they provide additional margin for earthquakes beyond the safe shutdown earthquake (SSE).

The containment, shield and auxiliary buildings are structurally integrated on a common basemat which is embedded below the finished plant grade level. The CV is surrounded by a seismic Category I shield building, which provides shielding for the CV and the radioactive systems and components located in the containment building and also provides protection from external hazards.

Seals are provided at the surface of the concrete inside and outside of the CV so that moisture is not trapped next to the steel just below the top of the concrete. The seals accommodate radial growth of the CV due to pressurisation and heatup.

A seismic Category I polar crane is provided within the CV and its bridge is sized for lifting the steam generator. The crane is supported on a stiffened ring girder, fabricated from steel plates, which is welded to the CV. Figure 20K-1 shows the elevation of the crane girder. Figure 20K-3 shows the girder's general arrangement and basic fabrication details.

A stainless steel downspout and gutter arrangement is attached to the inside of the CV to collect steam condensate inside containment during containment pressurisation events and return it to the in-containment refuelling water storage tank. The gutter loads on the CV shell are negligible.

The CV supports most of the containment air baffle, where panels are attached to the outside of the CV to direct air flow along the CV outside surface for passive containment cooling. The air baffle permits inspection of the exterior surface of the CV.

Materials used in the construction of the CV, as specified in Reference 20K.3, meet the requirements of the American Society of Mechanical Engineers (ASME) Section III, Article NE-2000 and the additional requirements summarised in Table 20K-1.

The thickness of the heads is approximately 41.3 mm (1.625 in). The heads are ellipsoidal with a major diameter of about 39.624 m (130 ft) and a height of about 11.468 m (37.6 ft), based on inside surface dimensions. The plate thickness for the head is constant, and is established by the stresses in the knuckle. As a result, the pressure stresses in the regions away from the knuckle are well below the allowable stress, providing margin in the unlikely event of corrosion in this region. The thickness of the lower head is the same as that of the upper head. There is no reduction in shell thickness even though essentially the entirety of the lower head is embedded in concrete.

The wall thickness in most of the cylinder is approximately 44.4 mm (1.75 inches). The wall thickness of the lowest course of the cylindrical shell is increased to approximately 47.6 mm (1.875 inches) to provide margin in the event of corrosion in the embedment transition region. For the current AP1000 under construction in China and the US, the axial welds in the thickened cylindrical first course are post-weld heat treated (PWHT), with all other seam welds being left in the as-welded condition in accordance with ASME for SA-738 for the CV wall thicknesses. ASME Code Case N-841 (Reference 20K.14) has been approved to extend the PWHT exemption from 44.4 mm (1.75 inches) to 60.3 mm (2.375 inches).

As discussed in Reference 20K.13, the following arguments are made regarding the merits of PWHT:

- Fracture analysis has demonstrated significant tolerance to fracture even when a generous allowance is made for the presence of weld residual stress.
- Flaw growth of any undetected flaws is considered to be negligible due to the mild service conditions of the CV.
- SA-738 Grade B has demonstrated excellent fracture toughness properties.
- PWHT is likely to increase the tolerable flaw size from 33% to 60% of the shell thickness.
- UT is expected to provide reliable detection of flaws 10% to 20% of the shell thickness.
- PWHT may reduce the physical strength and/or the fracture toughness of the CV material.
- There is a risk of producing reheat cracking associated with PWHT.

- Local PWHT presents a risk of introducing unquantified residual stress into the structure:
    - Prediction of these stresses is anticipated to be challenging.
    - Controlling local PWHT process on a large scale represents a significant challenge.
    - There is a risk of introducing local distortion that may reduce the buckling capacity of the CV shell.

Based on this discussion regarding the benefits and risks associated with local PWHT, and the margin demonstrated between the reliable detection of UT and the relatively large tolerable flaw size, even when considering a generous weld residual stress, Westinghouse considers the decision not to perform PWHT on the majority of the CV shell welds to be ALARP.

The containment atmosphere during normal operating conditions is maintained within prescribed pressure, temperature, and humidity limits by means of the containment recirculation cooling system (VCS), and the central chilled water system (VWS). The recirculation system cooling coils are provided with chilled water to provide sufficient temperature control. The containment air filtration system (VFS) supply and exhaust subsystem can be utilised to purge the containment air for pressure control. Periodic inspection and maintenance are performed to verify functional capability.

Certain design basis events and credible inadvertent systems actuation have the potential to result in ambient external pressure exceeding the internal CV pressure. For the design external pressure, a conservatively large magnitude of 1.2E-2 MPa (1.7 psi) differential pressure is used, which bounds the external pressure at which the vacuum relief system actuates to mitigate the external pressure. The vacuum relief subsystem is part of the VFS, which is described in section 6.9.1.2 and section 23.3. Evaluation of the design external pressure load is performed in accordance with ASME Code, Section III, Subsection NE.

Containment pressure is monitored by redundant Class 1E pressure transmitters, principally as an indication of increased leakage or a high energy line break. Similarly, the containment average temperature is monitored using temperature instrumentation at the inlet to the containment fan cooler as an indication of increased leakage or a high energy line break. The VFS provides intermittent venting of air into and out of the containment to maintain the containment temperature and pressure within their normal range during normal plant operation as described in Section 23.3.

20K.1.4.2.1 Penetrations

Two equipment hatches are provided. One is at the operating floor elevation (110.744 m, 135.25 ft) with an inside diameter of about 4.9 m (16 ft). The other is at floor elevation (102.184 m, 107.1 ft) to permit grade-level access into the containment, with an inside diameter of about 4.9 m (16 ft). The hatches consist of a cylindrical sleeve with a pressure seated dished head bolted on the inside of the CV (Figure 20K-5). The containment internal pressure acts on the convex face of the dished head and the head is in compression. The flanged joint has double gasketed compression seals with an annular space that may be pressurised for leak testing the seals. Each of the two equipment hatches is provided with an electrically powered hoist and with a set of hardware, tools, equipment and a self-contained power source for moving the hatch from its open position and moving it to its closed position.

Two personnel airlocks are provided, each located adjacent to each of the equipment hatches (Figure 20K-4). Each personnel airlock barrel has about a 3.0 m (9.8 ft) diameter and a door at each end. The airlocks are long enough to provide a specified clear distance unimpaired by the swing of the doors within the airlock. The airlocks extend radially outward from the CV through the shield building, and are supported entirely by the CV. The doors have double-gasketed, pressure-seated seals. The doors are mechanically interlocked to prevent simultaneous opening of both doors and to allow one door to be completely closed before the second door can be opened. The interlock can be bypassed by using special tools and procedures, as during outages.

The mechanical penetrations consist of the fuel transfer tube (FTT) penetration, main steam, main feedwater, startup feedwater, steam generator blowdown, and normal residual heat removal penetration and other mechanical penetrations. Design requirements for the mechanical penetrations are as follows:

- Design and construction of the process piping follow ASME Code, Section III, Subsection NC. Design and construction of the remaining portions follow ASME Code, Section III, Subsection NE. The boundary of jurisdiction is according to ASME Code, Section III, Subsection NE.

- Penetrations are designed to maintain containment integrity under design basis accident conditions, including pressure, temperature, and radiation.

- Guard pipes are designed for pipe rupture protection.

- Bellows are stainless steel or nickel alloy and are designed to accommodate displacements between the piping and the containment vessel. These displacements include thermal growth of the main steam and feedwater piping during plant operation, relative seismic movements, and containment accident and testing conditions. Cover plates are provided to protect the bellows from foreign objects during construction and operation. These cover plates are removable to permit in-service inspection.

Figure 20K-6, sheet 1 shows typical details for the main steam penetration. The main steam penetration includes bellows to minimize piping loads applied to the containment vessel and a guardpipe to protect the bellows and to prevent overpressurisation of the containment annulus in a postulated pipe rupture event. Similar details are used for the feedwater penetration. The bellows form a part of the containment pressure boundary for these penetrations. The main steam and feedwater penetrations are combined into a common 95 mm (3-3/4-inch)-thick insert plate. The main steam penetration has an inside sleeve diameter of approximately 1448 mm (57 inches). The feedwater penetration has an inside sleeve diameter of approximately 965 mm (38 inches). The insert plates for the main steam and feedwater penetrations are shown in Figure 20K-6, Sheet 7. The insert plate also includes the penetration for the DN 150 (NPS 6) startup feedwater pipe. The insert plate is designed in accordance with ASME Code, Section III, Subsection NE-3330.

Figure 20K-6, sheet 2 shows typical details for the startup feedwater penetration. The startup feedwater penetration includes a guardpipe to prevent overpressurisation of the containment annulus in a postulated pipe rupture event. Similar details are used for the steam generator blowdown penetration.

Figure 20K-6, sheet 3 shows typical details for the normal residual heat removal penetration. The normal residual heat removal penetration and other mechanical penetrations below elevation 102.184 m (107’-2”) (where there is concrete inside the containment vessel) have flued heads integral with the process piping and welded to the containment sleeve. The welds

are accessible for in-service inspection. The containment sleeve is separated from the concrete by compressible material.

Figure 20K-6, sheet 5 shows typical details for the FTT penetration. The FTT penetration is provided to transfer fuel between the containment and the fuel handling area of the auxiliary building. The FTT is welded to the penetration sleeve. The containment boundary is a double-gasketed blind flange at the refuelling canal end. The FTT is fitted with expansion bellows that are not a part of the containment boundary. Rather, they are water seals during refuelling operations and accommodate differential movement between the CV, containment internal structures, and the auxiliary building.

Figure 20K-6, sheet 4 shows representative details for the other mechanical penetrations. These consist of a sleeve welded to containment with flued head welded to the sleeve (detail A), a sleeve welded to containment with the process pipe welded directly to the sleeve and in direct contact with the process fluid (detail B), a sleeve welded to containment with process pipe passing through the sleeve (detail C), and a sleeve welded to a thicker insert plate welded to containment with sleeve welded to pipe and in contact with process fluid (detail D). Flued heads are used for stainless piping greater than DN 50 (NPS 2) and for piping with high operating temperatures. The type of weld connecting the sleeve to pipe may vary.

Figure 20K-6, Sheet 6 shows a typical DN 450 (NPS 18) diameter electrical penetration. The electrical penetration assemblies consist of conductor modules (or medium voltage cable modules in a similar penetration) passing through a bulkhead attached to the containment nozzle. Electrical design of these penetrations is described in section 18.6.5.

Electrical penetrations are designed to maintain containment integrity under DBA conditions, including pressure, temperature, humidity and radiation. Double barriers permit testing of each assembly to verify that containment integrity is maintained. Design and testing is according to IEEE Standard 317-83 and IEEE Standard 323-74.

20K.1.5 Containment Vessel Boundaries

The CV is essentially defined by its pressure boundary functions including the portion embedded in concrete. The design boundaries for the CV are in accordance with the boundaries of jurisdiction as listed in ASME Code, Section III. In addition, the following interface boundaries are defined to clearly establish locations where the containment is in contact with non-vessel structures:

- All pressure retaining materials up to, but excluding, the non-pressure-retaining attachments such as the air baffle supports. This includes the stiffening function of the polar crane ring girder and two other stiffening rings in the event of the external pressure exceeding that within the CV.

- Pressure retaining containment penetrations. Refer to Reference 20K.3 where each penetration's boundary limit is defined.

- The welds between the CV wall and the pipework and electrical penetrations. The pipework and penetration components including bellows and guard pipes are justified separately.

- The welds between the CV wall and the mechanical FTT penetration. The penetrations and hatches themselves are mechanical components and are justified in Chapter 17.

The CV is supported by the Nuclear Island concrete structures in which the bottom ellipsoidal head is embedded. Shear studs welded to the bottom head provide additional seismic margin against overturning and uplift of the containment internal structures and the CV. These shear studs are considered non-structural attachments as defined by ASME Section III, Subsection NE. Shear studs will not be attached to CV weld locations. The CV bottom head has been designed for the ultimate stud load. The containment internal structures are supported within the bottom ellipsoidal head and transmit loads through the CV bottom head into the Nuclear Island basemat.

20K.2 Safety Case Requirements

The CV will prevent leakage, under all conditions of specified design loading that may occur during its lifetime. Section 20K.3.2 summarises the specified design load combinations used to design the CV.

The main focus of this CSR is to provide a structured safety argument, supported by suitable and sufficient evidence, to substantiate the classification of the CV as a Standard Class 1 type component, as outlined in Section 20K.2.2. To achieve this, the safety argument is presented as three key elements, as follows:

Claim 1: **Quality of Build: High quality is achieved through good design and manufacture.**

Objective: Provides evidence of good design and manufacture based on established practices and track record. It provides a keystone for a demonstration of appropriate reliability and embodies the code and plant operating experience with the objective of achieving quality of build and the avoidance of defects (Section 20K.3.1).

Claim 2: **Good Design: Good design is achieved through compliance with ASME.**

Objective: Incorporates the build experience as embodied in the design codes (Section 20K.3.2).

Claim 3: **Mitigation and Management of In-service Degradation: Components are tolerant to through-life degradation over the design life of the plant.**

Objective: Provides an assessment of through-life degradation mechanisms and show that such mechanisms will not threaten integrity over a specific interval. It is also established that potential degradation mechanisms are understood and that the inspection and maintenance programme will detect degradation before it affects the performance requirements (Section 20K.3.3).

The safety argument is tailored according to the structural reliability claims derived from a process of component classification, with the purpose of demonstrating that component structural reliability is commensurate with the consequences of gross failure.

The three elements of the safety argument are provided in Section 20K.3 and the strength of the argument is discussed in Section 20K.4.

20K.2.1 Safety Functional Requirements

Safety design bases are identified for each of the AP1000 SSCs. These include duty functions and design basis accident response requirements of plant systems, which must be maintained at all times or upon demand as appropriate to provide assurance of plant nuclear and

radiological safety. Structural integrity safety functional requirements for the CV were identified from the performance and safety design bases, as follows:

- The CV is an integral part of the containment system, which forms a structure that encloses the nuclear power system or that may be connected to other containment items and which is designed to provide a pressure containing barrier for the primary purpose of containing, within leakage limits, or of channelling, for containment or for controlled disposal, radioactive or hazardous effluents released from the system.

- The CV is also part of the PCS whose function is to provide the safety grade ultimate heat sink for the removal of the reactor coolant system normal heat, core decay heat, and decay heat associated with accident sources.

- The CV supports the polar crane girder which in turn supports the polar crane. The CV also supports the majority of the containment air baffle on the exterior surface of the cylinder. The containment air baffle is a functional component of the PCS which promotes heat removal during postulated accidents.

Based on these, the following Safety Function Requirements have been identified which reflect the overall role of the component in plant safety:

- **20.9.1** **Standby function**:

  The CV is required to provide a leak tight barrier against the uncontrolled release of radioactivity to the environment under postulated accident conditions for the design life of the plant, to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require and to retain coolant inventory in the event of a LOCA.

- **20.9.2** **Duty function**:

  The CV is required, along with the shield building, to provide shielding for the reactor core and the reactor coolant system during normal operations.

- **20.9.3** **Standby function**:

  The CV is required to facilitate core residual heat removal during postulated LOCA or MSLB accident events where SG heat removal is not available or is insufficient.

- **20.9.4** **Duty (normal)/Standby (faulted)**:

  The CV is required to act as a support for the polar crane at all times, including normal and faulted conditions, including seismic events.

Postulated failure modes which result in a loss of these functional requirements lead to identification of structural reliability targets commensurate with the consequences of gross failure, as determined through the process of component classification as described in Section 20K.2.2 below.

20K.2.2 Containment Vessel Structural Integrity Classification

For the AP1000 plant, a structural integrity classification methodology, Reference 20K.1, has been applied to pressurised components with the aim of determining the required level of structural reliability for each of the major plant components based on an evaluation of the direct (e.g., LOCA) and indirect (e.g., missiles/pipe whip, etc.) consequences of gross failure. The CV is not specifically covered by the structural integrity classification methodology because it is not normally pressurised. The CV provides a pressure boundary function on demand in the event of a fault of another component. In accordance with the UK AP1000 classification of SSCs described in Section 5.2, the CV is a Class 1 component because the CV is the final barrier for maintaining nuclear safety upon demand. Failure of the CV has the potential for radioactivity release to the environment during post-accident conditions. Recognising the important role that the CV has in the performance of the AP1000 passive protection systems, it is necessary to provide assurance of adequate structural reliability commensurate with the frequency of demand. The structural integrity classification methodology is not specifically applicable to the CV. A review against the methodology determined the CV would not merit classification as a high integrity (HI) or highest safety significance (HSS) component. However, for the purpose of assuring adequate structural reliability, the structural integrity of the CV is evaluated as if it were a Standard Class 1 component.

20K.3 Safety Case Arguments

Consistent with other Class 1 components, the basis of the structural integrity claim is centred on arguments and evidence to substantiate the claims listed in Section 20K.2.

Claim 1: High quality is achieved through good design and manufacture (Section 20K.3.1).

Claim 2: Good design is achieved through compliance with the ASME Code (Section 20K.3.2).

Claim 3: Components are tolerant to through-life degradation over the design life of the plant (Section 20K.3.3).

Consistency with the ASME Code, Section III for Class MC (metal containment) components provides the basic demonstration of fitness-for-purpose for the CV and forms the primary element in the safety case for the AP1000 CV.

20K.3.1 High Quality Is Achieved through Good Design and Manufacture

The reliability of the CV is dependent upon the quality of the design and the fabrication. The design intent is translated into a manufacturing plan which is controlled by a Quality Assurance Programme compliant with rigorous design codes including the ASME Code. The CV Design Specification (Reference 20K.3) provides a list of the industry codes, specification and standards applied to the CV.

The argument to support the achievement of high quality is supported by the following supplemental arguments:

- **Design and Fabrication in Accordance with ASME Code, Section III**: The CV is classified as UK AP1000 Class 1. Design and fabrication of the CV is carried out in accordance with ASME Code, Section III requirements. Fabrication and installation of the CV including forming, welding qualification, and heat treatment will meet the

requirements of ASME Code, Section III Article NE-4000 and the additional requirements specified in the Design Specification (Reference 20K.3).

- **Material Specifications**: The CV materials and testing requirements have been specified in accordance with the requirements of NE-2000 of the ASME Code. The basic containment material is SA-738, Grade B, carbon steel plate. The material fracture toughness has been selected to satisfy the lowest service metal temperature requirement of -28°C (-18°F). This temperature is established by analysis for the portion of the CV exposed to the environment when the minimum ambient air temperature is -40°C (-40°F).

Carbon steel plate for the personnel airlock is to conform to SA-516 Grade 70. Carbon steel forgings are to conform to ASME SA-350, Grade LF2. Stainless steel forgings are to conform to ASME SA-182 Gr. F304L.

- **Supplemental Requirements**: The procurement specification for the SA-738, grade B, plate includes supplemental requirements S1, Vacuum Treatment and S20, Maximum Carbon Equivalent for Weldability (Reference 20K.4). Welding will be carried out in accordance with the ASME Code, Section III and Section IX for all safety class, seismic Category I components as described in Reference 20K.3. Thermal post weld heat treatment of welds for plates exceeding 44 mm (1.75") thickness is required in accordance with the ASME Code (see Table NE-4622.7(b)-1). Although ASME Code Case N-841 (Reference 20K.14) has been approved to extend the PWHT exemption from 44.4 mm (1.75 inches) to 60.3 mm (2.375 inches), PWHT will still be performed on plates in this thickness range, thus providing additional margin. Tolerances are as specified by the ASME Code, except that the difference between the maximum and minimum diameter at any cross-section will not exceed 0.5 percent of the nominal diameter of the CV. The diameter at any cross-section will not deviate more than 0.25 percent of the nominal diameter. Out of plumb will not exceed 0.25 percent, measured between tangent lines after making allowance for out of roundness as specified.

- **Avoidance of non-Ductile Failure**: As a minimum requirement, impact testing will be as specified in Section III of the ASME Code, Paragraph NE-2300 as applicable to demonstrate material ductility. Charpy V-notch specimens will be used for all impact testing. Weld test plates will be made and impact tested in accordance with Subsection NE of Section III of the ASME Code as described in Reference 20K.3.

- **Quality Control**: The quality control programme involving welding procedures, erection tolerances, and nondestructive examination (NDE) of shop and field-fabricated welds conforms to Subsections NE-4000 and NE-5000 of the ASME Code. In particular, NDE of shop and field-fabricated welds will conform to Subsection NE-5000 of the ASME Code using radiographic examination, ultrasonic examination, penetrant examination, magnetic particle examination, and surface examination as appropriate.

- Radiography, as required by the ASME Code, is capable of detecting and length sizing structurally significant planar and volumetric flaws. However this method does not provide a through-wall size for a planar flaw. UT would provide this additional dimension and could also serve to enhance the detectability of smaller and tilted/skewed planar flaws. Therefore this RT requirement will be augmented or replaced with UT. The design specification for the CV in the UK will require that UT be used in addition to or in-lieu of RT for plants constructed in the UK. Westinghouse will petition the ASME Boiler & Pressure Vessel Code to extend Code Case N-659-2 that allows UT in lieu of RT, to NE welds in metal containments. If UT is allowed in lieu of RT, a performance

demonstration would be required, as dictated by N-659-2. This performance demonstration needs to consider the specific fracture assessments to determine the flaw matrix for the qualification block(s).

The CV is designed to permit construction using large subassemblies, each of which will be subjected to NDE as will the final assembly welds. These subassemblies consist of the two heads and three or more ring sections. The intention is that these will be assembled in an area near the final installed location in the nuclear island, using plates fabricated in a shop facility.

Personnel performing NDE will be qualified and certified using a written practice prepared in accordance with ANSI/ASNT CP-189, Standard for Qualification and Certification of NDE Personnel (Reference 20K.9).

- **Testing and Examination**: Testing is in accordance with ASME NE-6000. Pre-service examination is in accordance with ASME Article IWE-2200. This is a 10% overpressure pneumatic test (Reference 20K.3).

Together, these arguments provide a basis for a demonstration that the CV will achieve a high quality of design and fabrication, will enter service free from significant structural defects and that the effects of through-life degradation on material properties will not have a deleterious effect on the structural reliability of the CV. The outcome of the materials testing including fracture toughness testing, NDE and CV pressure testing will provide supporting evidence on a case-by-case basis in due course.

20K.3.2 Good Design Is Achieved through Compliance with ASME

The CV is designed and constructed according to the 2001 Edition of the ASME Code, Section III, Subsection NE, Metal Containment, including the 2002 Addenda. Stability of the CV is evaluated using ASME Code, Case N-284-1, Metal Containment Shell Buckling Design Methods, Class MC, Section III, Division 1, as published in the 2001 Code Cases, 2001 Edition, July 1, 2001. Full ASME Code compliance has been demonstrated.

20K.3.2.1 Load and Load Combinations

The design and analysis procedures for the CV are according to the requirements of the ASME Code, Section III, Subsection NE. Loading conditions are derived from an assessment of applicable normal and abnormal operating conditions, as well as from those identified from the consideration of internal and external hazards, as discussed in Chapters 9, 11, and 12. These hazards are often conveniently classified as basic (dead load, live load), operational (pressure, temperature), natural (seismic, wind, tornado), and man-made (blast, impact, dropped load). Reference 20K.3 details the load combinations and which ASME Service Levels apply to the various loads and combinations. A summary of the load combinations analysed for qualification of the CV design to the ASME Code is provided in Table 20K-4.

The numerical analysis methods are summarised in Table 20K-3. The overall CV was modelled as an axisymmetric shell and analysed using the ANSYS computer programme (Reference 20K.8). Dynamic analyses of the axisymmetric model were performed to obtain frequencies and mode shapes. These were used to confirm the adequacy of the CV seismic stick model as input to the Nuclear Island model.

Stress analyses were performed for each of the following loads:

- Dead load
- Internal and external pressure
- Thermal
- Seismic
- Polar crane wheel loads
- Wind and tornado loads

DBAs produce the bounding containment internal pressures and temperatures and are discussed in section 20K.3.2.2.

The personnel airlocks and equipment hatches are modelled in ANSYS using in a 3-D shell finite element model of the containment to consider the effect of the penetrations and their quasi-static response due to a seismic event. Static analyses are performed using the finite element model for internal pressure, dead load (including the polar crane in the parked position), thermal loads and seismic loads. Stresses are evaluated against the stress intensity criteria of ASME Code, Section III, Subsection NE for the load combinations described in Table 20K-4.

20K.3.2.2 Design Basis Accident Conditions

The containment system is designed such that for all pipe break sizes, up to and including the double-ended severance of a reactor coolant pipe or secondary side pipe, the containment peak pressure and temperature remain below the design limits. Hence, Code compliance is assured in the worst operational accident case. As described in Section 9D, the containment analyses are performed taking into account single failures that maximise stresses on the CV. A summary of the results of the containment analysis is presented in Table 9D.1-1.

The results of the containment analysis indicate that the peak pressure and peak temperature are not coincident. However, the temperature refers to the containment atmosphere and lasts for a short duration such that the CV metal does not exceed its design limit. Also, the passive containment cooling system is cooling the CV metal during this event.

The peak stresses experienced by the CV during a DBA were quantified by using an ANSYS finite element model as shown in Figures 9 through 18 of Reference 20K.2. The peak stresses were found to be fairly localised near the hoop stiffeners and the knuckle region of the top head. Reference 20K.2 gives a more extensive description of the stress analyses.

The bottom head is fully embedded in the concrete base at elevation 100 m, the nominal vertical datum for the UK design. This results in the generation of localised stresses at this location under thermal and pressure loading associated with the DBA due to restrained radial movement. The CV design includes a Service Level A combination in which the CV above elevation 102.184 m (107.16 ft) is specified at the design temperature of 149°C (300°F) and the portion of the embedded CV (and concrete) below elevation 100 m (100 ft) is specified at a temperature of 21°C (70°F). The temperature profile for the CV is linear between these elevations. Containment shell buckling in this region is evaluated against the criteria of ASME Code Case N-284-1. Code Case N-284-1 is also used for the evaluation of the CV upper head and equipment hatches.

Conservative design basis static, dynamic and transient natural and man-made loads have been defined and appropriately combined for design and substantiation purposes. The conditions considered include normal, upset (accident), emergency and faulted conditions.

As discussed in section 20K.1.4.2.1, mechanical penetrations for the large-diameter high-energy main steam and feedwater piping include expansion bellows that are part of the containment boundary. The piping and flued head have large pressure capability. The response of expansion bellows to severe pressure and deformations is described in NUREG/CR-5561 (Reference 20K.5). The bellows can withstand large pressure loading but may tear once the containment vessel deflection becomes large, beyond design conditions. Testing reported in NUREG/CR-6154 (Reference 20K.10) has shown that the bellows remain leaktight even when subjected to large deflections sufficient to fully compress the bellows. Such large deflections of the containment vessel would not occur in response to design basis events. The containment penetration bellows are designed for a pressure of 0.60 MPa (87 psig) at design temperature within Service Level C limits, concurrent with the relative displacements imposed on the bellows when the containment vessel is pressurised to these magnitudes.

20K.3.2.3 Thermal Loads

Thermal stresses have been considered in the design and evaluation of the CV at Service Levels A, C and D both with and without design pressure for the temperature conditions specified in Table 20K-5.

The CV has been designed for the temperatures given in Table 20K-5. These are metal temperatures. The thermal gradient through the wall is negligible as the CV shell is relatively thin, any effects will be secondary and the margins to gross failure are generous. Two cases are specified: one corresponding to normal operation in extreme cold weather, which maximises the temperature differences at the crane girder, the insulated enclosure (upper equipment hatch and personnel airlock) and the external stiffener, and one corresponding to the DBA condition in hot weather which maximises the temperature difference at the embedment. A step change in temperature has been assumed for normal operation at elevation 109.677 m (131.75 ft) (except in the insulated enclosure region), at the interface between the crane girder and the shell, and the internal stiffener and the shell. Analyses close to the embedment for the DBA considered a temperature profile that decreases linearly between elevations 102.184 m (107.16 ft) and 100 m (100 ft). The temperature of the concrete structures is assumed to remain at 21°C (70°F).

20K.3.2.4 Seismic Loading

Safe shutdown following a SSE requires the use of safety significant systems to bring the site to a safe state without the need for operator action. A SSE is defined as the maximum potential vibratory ground acceleration for safe shutdown without loss of plant capability to perform safety functions and is taken as the design basis earthquake for the purpose of this assessment. The design intent is for the CV to remain elastic under postulated earthquake loading.

The CV is a seismic Category I structure. The overarching claim for seismic hazards is that there will be no loss of key safety functions in a credible seismic event. To support these claims, it is argued that a generic envelope for site seismology has been defined for the AP1000 design and that a SSE has been defined that generally bounds the UK design basis. Chapter 16 present a generic seismic justification for the AP1000 design.

The peak horizontal ground acceleration of the SSE has been established as 0.30g for the AP1000 design. The vertical peak ground acceleration is conservatively assumed to equal the horizontal value of 0.30g; UK practice is to scale the horizontal spectra by two thirds.

Both horizontal and vertical design response spectra are based on the US NRC Regulatory Guide 1.60 (Reference 20K.7) spectra augmented at the higher frequencies.

A fixed-base ANSYS interaction model for the nuclear island is described within Section 16.8. This has predicted the dominant modes and frequencies in three orthogonal directions; direction Z denotes the vertical direction. The results from the ANSYS shell model for the various load cases were factored and combined as shown in Table 4 of Reference 20K.15. The stress results from the design basis seismic load show an axial compression and a tangential shear at the base of the cylindrical portion of the CV, which were evaluated in accordance with ASME Code Case N-284-1, Revision 1 and shown to be compliant.

20K.3.2.5 Wind Loading

Chapter 4 details the wind and tornado derivation and loadings used in the AP1000 design. The portions of the CV which will be exposed above grade prior to the construction of the shield building were designed for the wind loads on the projected area of the circular shape in accordance with the American Society of Civil Engineers code: ASCE 7-98 (Reference 20K.6). A basic wind speed of 31.3 m/s was used to calculate the wind load during construction. This bounds any wind loading experienced once the shield building has been constructed.

The shield building is justified for the design basis wind and therefore protects the CV from the direct effects of wind loading including wind-borne missiles. Nevertheless, the CV has been evaluated and found to be acceptable for design wind and tornado, which induce a reduction in atmospheric pressure external to the CV and non-uniform pressures assumed to occur at the same time.

20K.3.2.6 Conservatism in Material Property Data

The CV is designed using SA-738, Grade B material, which has a stated specified minimum yield of 415 MPa (60 ksi) and an ultimate capacity 585 MPa (85 ksi). Test data for materials having similar chemical properties were reviewed by Westinghouse. In a sample of 122 tests for thicknesses equalling or exceeding 38.1 mm (1.5 in) and less than 44.4 mm (1.75 in), the actual yield had a mean value of 476 MPa (69 ksi), with a standard deviation of 23 MPa (3 ksi). This results in an actual yield about 15 percent higher than the minimum yield. This additional capacity has not been claimed in the design of the CV or in the internal pressure ultimate capacity analysis results presented in Table 20K-6. Membrane yield of the cylinder is predicted to occur at an internal pressure of 1.23 MPa (178 psi) gauge.

Ultimate capacity analyses were also performed that displayed a generous margin to gross yield and ductile behaviour beyond yield. A series of stress and buckling ultimate limit analyses that were carried out to determine the maximum internal pressure capacity at a fixed 38°C (100°F). The results are based on the minimum ASME–specified material properties and are presented in Table 20K-6. Reasonable margins beyond the design pressure of 0.407 MPa (59 psi) were predicted with no brittle failure modes. The pressure related to gross hoop yield of the cylindrical shell was a predicted ultimate internal pressure of 1.069 MPa (155 psi). A temperature compensation at 204°C (400°F) using the tables given for material properties in the ASME Code reduced the yield stress by 17% and the pressure capacity corresponding to shell gross yield reduced from 1.069 to 0.889 MPa (155 to 129 psi) gauge.

20K.3.2.7 Fracture Assessment Above and Beyond ASME

Fracture analysis of the CV above and beyond the requirements of ASME has been performed to demonstrate that it will provide an adequate barrier to large release in the event that it is called on to do so (Reference 20K.13). The analysis examines the flaw tolerance associated with PCS flow actuation following an initiating event in which containment has been pressurized. Conservative loadings and stresses are applied to reflect the worst case thermal shock event. The combined stress used envelopes all credible defect locations and orientations. The flaw location is chosen at the top of the containment vessel to maximise the temperature difference between the PCS flow and the containment metal. The orientation of the postulated flaw is assumed to be along the direction of the weld as the welding process is unlikely to produce transverse flaws. Flaws transverse to the weld are likely contained within the weld and thus will be small enough as to not challenge the structural integrity of the CV.

The flaw tolerance is determined by postulating a range of flaw sizes and determining the conditions where the applied stress intensity factor is equal to a fracture toughness that is conservatively assumed. The results of the analysis demonstrate that for a relatively long flaw, which has a length equal to ten times the depth, the criteria are met with a flaw depth that is 33% of the wall thickness. For an elongated flaw, with length equal to 1000 times the depth, a depth of 25% of the wall thickness is shown to be acceptable.

Ultrasonic inspection will be used to detect possible flaws in the CV as it has a higher reliability for detecting, characterizing and sizing planar defects with reliable detection rates for defects 10% - 20% of the weld thickness and is roughly equal to radiographic inspection for the detection of volumetric defects. UT inspection of 100% of the welds will be performed during manufacture.

Based on the above, there is confidence that the flaws which were determined to be tolerable are larger than those that can be detected with the chosen inspection technique such that the CV will enter service free from defects of structural significance.

20K.3.3 Mitigation and Management of In-Service Degradation

20K.3.3.1 Corrosion

Reasonable and appropriate steps as described below have been implemented in the design of the CV to minimise the level of surface corrosion which, in conjunction with the inspection regime summarised in section 20K.3.3.2, provides a robust justification for the 60 year design life.

There is no specific Code requirement for corrosion allowance. The wall thickness in most of the cylinder is 44.4 mm, which is a standard US off-the-shelf plate thickness (1.75 in).

The wall thickness of the lowest course of the cylindrical shell, which interfaces with the CV interior concrete, is approximately 47.6 mm (1.875 inches) to provide margin to compensate for corrosion in the concrete embedment transition region. The 44.4 mm (1.75 in) walls of the CV have a nominal additional allowance against the ASME overall sizing thickness which, although it has not been designed as a corrosion allowance, is available to offset minor corrosion. Note that the ASME sizing thickness is for the entirety of the CV shell. Locations of postulated localised degradation that result in shell thickness well below the sizing thickness are tolerable with respect to structural integrity and the functions of containing radioactivity and providing shielding.

The National Association of Corrosion Engineers (NACE) Corrosion Engineer's Reference Book (Reference 20K.11) provides a single face corrosion rate of 0.1-0.3 mm/year for carbon steel in a "quiet seawater" environment. At the higher corrosion rate of 0.3 mm/year it will take more than 12 years to erode through the sizing allowance in the thickened region for single face corrosion and more than 6 years for double face corrosion. At the same rate, it will take two years to erode the nominal sizing allowance elsewhere for single face corrosion. Owing to the differing internal and external environments above the concrete embedment, it is not reasonable to presume that corrosion will occur simultaneously on both faces in the same region. Note, however, that the margins to gross failure beyond the design basis are generous and that a ductile response is expected as described in section 20K.3.2.6.

The AP1000 CV is coated with an inorganic zinc coating to an elevation of at least 30.4 cm (12 in) below the top surface of the concrete inside and outside of the CV. Electrical and mechanical penetrations are generally coated with inorganic zinc coating. The outside of the CV shell is coated to a distance of 30.4 cm (12 in) beyond the penetration blockout in the concrete where applicable. This coating provides an effective barrier to both oxygen and water which reduces the rate of corrosion to negligible levels in the treated area. Outside of these coating requirements, surface treatment (other than cleaning or wetting) of the lower portions of the bottom head prior to concrete embedment is not required.

Loss of material due to corrosion in inaccessible areas is considered not to be significant because the following conditions will be satisfied:

- Concrete will meet the requirements of American Concrete Institute (ACI) 318-08 (Building Code Requirements for Structural Concrete and Commentary) or ACI 349-06 (Code Requirements for Nuclear Safety-Related Concrete Structures and Commentary) enhanced by the guidance of ACI 201.2R-01 (Guide to Durable Concrete) on durability for the containment concrete in contact with the embedded containment shell or liner.

- The concrete will be inspected and monitored to ensure that it is free of penetrating cracks that could provide a path for water seepage to the surface of the containment shell.

- The moisture barrier (concrete seal), at the junction where the shell becomes embedded, is subject to aging management activities in accordance with ASME Code, Section XI, Subsection IWE requirements. The concrete seals will be visually inspected periodically as required by the ASME Code and will be repaired if necessary. The corrosion allowance does not claim benefit from the seal between the CV wall and the concrete.

Borated water spills and water ponding on the containment concrete floor are uncommon and when detected will be cleaned up in a timely manner.

The air baffle promotes air flow over the external surface of the CV under all conditions. This is specifically designed to aid in the evaporation of any moisture. The CV internal atmosphere is humidity controlled.

Considering the steel embedded in the concrete, the design philosophy is that there will be no significant corrosion because there will be no oxygen present in the unlikely event that water is present, and there will be an alkaline environment that will impede corrosion.

The approach for localised corrosion is that if corrosion were to occur, localised thinning will not result in a structural or containment concern provided that there is sufficient material surrounding the localised thin area and there remains sufficient wall thickness at the thinned region to withstand the pressure and maintain containment.

The inside containment surface from approximately elevation 102.2 m (107 ft) to 110 m (33 ft) (i.e., approximately the operating deck level) is coated with an epoxy topcoat to facilitate cleaning of the coated CV.

20K.3.3.2 Testing and In-Service Inspection

The AP1000 has a 60-year design life. It must be demonstrated that the structural integrity of the CV is maintained throughout the design life such that the component continues to deliver it functions. Assurance in this respect is provided by minimising the degradation as discussed in section 20K.3.3.1 and by implementing a suitable in-service inspection and maintenance strategy.

The following design and in-service inspection aspects have been considered and incorporated to mitigate the effects of corrosion of the AP1000 CV:

- The concrete seals provided at the top surfaces of the concrete along the CV shell/concrete interface inside and outside containment will be visually inspected in accordance with ASME Code Section XI.

- In-service inspection (Visual Examination) of the exposed surfaces of the CV is required approximately every 40 months in accordance with ASME Code Section XI. Note that both the inside and outside steel surfaces are accessible for inspection. Any degradation will be detectable by evidence of bubbling, flaking or peeling of the inorganic zinc coating.

- The presence of the inorganic zinc coating reduces the corrosion rate to negligible levels; hence, the 40 month interval is considered reasonable. Also, as discussed in section 20K.3.2.6, the margins to gross failure are generous and a ductile response is expected.

- Containment leak testing is performed approximately every 40 months. Testing of the CV and the pipe assemblies forming the pressure boundary within the CV will be according to the provisions of NE-6000 and NC-6000, respectively. The expansion bellows have a test enclosure to allow leak testing the flexible bellows external to the containment atmosphere.

20K.4 Strength of the Safety Case

The CV is classified as an AP1000 Standard Class 1 component. As such, the strength of the safety case is based on the achievement and maintenance of integrity. The CV has been deterministically justified in accordance with the ASME Code for Class MC components. The safety argument in Section 20K.3 demonstrates how CV structural integrity is established based on extensive quality assurance measures in design, fabrication, manufacture, materials, testing and qualified inspection. Additional arguments show that the design of the CV considers all recognised loads and load combinations applicable to the UK and provide evidence to demonstrate that acceptable margins to failure (gross yield) have been achieved, and that ductile response beyond yield is expected. Further arguments provide evidence to demonstrate that the CV is sufficiently tolerant to credible through-life degradation; this conclusion is supported by start-of-life inspection of the whole assembly and regular through-life inspection of the region above the concrete embedment. In combination, these elements provide a cogent argument to substantiate integrity commensurate with the classification of the CV for the 60 year design life.

20K.5 Index of Technical Reports

Table 20K-7 provides a list of technical references supporting the safety arguments within this CSR.

20K.6 Review of Open Issues

The Technical Index for this CSR will be updated before generic design assessment (GDA) closeout to reflect a representative set of calculations supporting the claims in this report. There are no additional open issues for the CV that affect the GDA.

20K.7 Conclusions

The CV acts as a secondary pressure containment boundary on demand in the unlikely event of a breach of the primary or secondary system pressure boundary component within containment or actuation of the ADS valves. The CV is also an integral part of the AP1000 pressure protection systems. The CV is an integral part of the PCS, which, together with the passive core cooling system, provides heat removal during postulated accidents by containing, cooling and recirculating the coolant inventory. To provide these functions, the CV provides a leak tight barrier against the uncontrolled release of radioactivity to the environment and assures that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

The CV is classified in accordance with the UK AP1000 Classification of SSCs as a Class 1 component because the CV is the principal means for maintaining nuclear safety upon demand. Although it is not normally pressurised, a review against the methodology presented in Reference 20K.1 determined the CV should be evaluated as a Standard Class 1 component. For such components, the main elements of the safety case argument are:

- Firstly, that the component has been designed in accordance with the high standards of the ASME Code as applicable to Class MC structures. This includes appropriate controls on material properties, manufacturing processes, design, testing, inspection and installation such that there is a high level of confidence in the quality of the component and that it will enter service free from significant flaws that could affect the integrity of the component over its lifetime.

- Secondly, that the design considers all credible loads and load combinations and complies with the appropriate requirements of the applicable ASME Code. This has been demonstrably achieved for the AP1000 CV with sufficient margins to failure (gross yield) and ductile response beyond yield.

- Thirdly, that measures to prevent, detect or forewarn of in-service degradation, such as the application of the inorganic zinc coating and implementation of a suitable in-service inspection regime, are specified which will mitigate the mechanisms identified which could threaten the integrity of the component through life. Such measures have been identified for the CV.

Based on the arguments presented, together with the referenced supporting evidence, the structural reliability of the CV has been justified to a standard commensurate with the consequences of its gross failure.

Table 20K-2. General Design Characteristics (Reference 20K.3)

Condition	Parameter
General Design Characteristics	Nominal Inside Diameter: 39.624 metres (130 ft) Nominal Inside Height: 65.634 metres (215.33 ft) Design Code: ASME III, Division 1, Subsection NE Material: SA-738, Grade B; also conforming to the requirements of specification SA-1 and SA-20 Design Pressure (internal): 0.407 MPa (59 psi) (gauge) at the internal design temperature Design Temperature (internal): 149°C (300°F) Design External Pressure: 0.012 MPa (1.7 psi) design differential at 21°C (70°F) Long Term Accident Pressure: 0.16 MPa (23 psi) (gauge) Long Term Accident Temperature: 110°C (230°F)
Normal Operation	Internal temperature = 10°C to 49°C (50°F to 120°F) External temperature = -40°C to 46°C (-40°F to 115°F) Internal Pressure = -1.4 kPa to +6.9 kPa (-0.2 psig to 1 psig) Humidity = 0 to 100% Radiation[1] = 4.5×10^{-1} rad/hr Gamma Dose Rate 2.4×10^{5} rads-air 60 year Gamma Dose
Abnormal Operation (short term = 4 hrs.)	Internal Temperature = 10°C to 66°C (50°F to 150°F) Pressure = atmospheric Humidity = 100% Radiation[1] = 4.5×10^{-1} rad/hr Gamma Dose Rate 2.4×10^{5} rads-air 60 year Gamma Dose
Abnormal Operation (long term = 30 days)	Internal Temperature = 10°C to 121°C (50°F to 250°F) Pressure = 124 kPa (18 psig) Humidity = 100% Radiation[1] = 4.5×10^{-1} rad/hr Gamma Dose Rate 2.4×10^{5} rads-air 60 year Gamma Dose
Accident	Internal Peak Temperature = 216.7°C (422°F) Maximum vessel temperature = 149°C (300°F) Pressure = 407 kPa (59.0 psig) Humidity = 100% Radiation[1] = 1.2×10^{6} rads-air/hr Peak Gamma Dose Rate 6.7×10^{6} rads-air/hr Peak Beta Dose Rate

Note:

1. Location of radiation measurement is outside RCS loop compartment walls.

Table 20K-3. Summary of Containment Vessel Models and Analysis Methods

Model	Analysis Method	Program	Purpose
Axisymmetric shell	Modal analysis	ANSYS	To calculate frequencies and mode shapes for comparison against stick model
Lumped mass stick model	Modal analysis	ANSYS	To create equivalent stick model for use in nuclear island seismic analyses
Axisymmetric shell	Static analyses using Fourier harmonic loads	ANSYS	To calculate containment vessel shell stresses
Axisymmetric shell	Nonlinear bifurcation	BOSOR5	To calculate buckling capacity close to base under thermal loads To calculate pressure capacity of top head
Finite element shell	Linear bifurcation	ANSYS	To study local effect of large penetrations and embedment on buckling capacity for axial and external pressure loads
Finite element shell	Modal analysis	ANSYS	To calculate frequencies and mode shapes for local effects of equipment hatches and personnel airlocks
Finite element shell	Static analyses	ANSYS	To calculate local shell stress in vicinity of the equipment hatches and personnel airlocks

Table 20K-4. Load Combinations and Service Limits for Containment Vessel (Reference 20K.3)

Load Description	Service Limit Design Cases[1,2]										
	Const	**Test**	**Des1**	**Des2**	**A1**	**A2**	**A3**	**C1**	**C2**	**D1**	**D2**
Dead, D	X	X	X	X	X	X	X	X	X	X	X
Live, L	X	X	X	X	X	X	X	X	X	X	X
Wind[(5)], W	X						X				
SS earthquake, E_s								X		X	X
Tornado, W_t									X		
Test pressure, P_t		X									
Test temperature, T_t		X									
Operating pressure, P_o							X		X		
Design pressure, P_d			X			X		X			X
Design external pressure, P_e				X	X					X	
Normal reaction, R_o				X	X		X		X	X	
Normal thermal[(4)], T_o				X	X		(3)		(3)	X	
Accident thermal reactions, R_a			X			X		X			X
Accident thermal, T_a			X			X		X			X
Accident pipe reactions, Y_r											X
Jet impingement, Y_j											X
Pipe impact, Y_m											X

Notes:

1. Service limit levels are per ASME-NE.
2. Where any load reduces the effects of other loads, that load is to be taken as zero, unless it can be demonstrated that the load is always present or occurs simultaneously with the other loads.
3. Temperature of vessel is 21°C (70°F).
4. Temperature distribution for normal operation in cold weather.
5. Wind load for the construction load combination is based on a 31.29 m/s (70 mph) wind. Wind load for the Service Level A load combination is analysed as a reduction in external pressure.

Table 20K-5. Containment Vessel Metal Temperatures (Reference 20K.3)

Location	Case 1 Metal Temperatures °C (°F) Normal Operation in Cold Weather of -40°C (-40°F) Ambient.	Case 2 Metal Temperatures °C (°F) Design Basis Accident in Hot Weather of 46°C (115°F) Ambient.
Vessel shell above elevation 109.677 m (131 ft – 9 in)	-28[1] (-18.5)	149 (300)
Crane girder and inner stiffener[2]	21 (70)	149 (300)
Upper equipment hatch and upper personnel airlock insulated enclosure region.	See Figure 10 of Reference 20K.3.	149 (300)
Outer stiffener at elevation 109.677 m (131 ft – 9 in) [3]	-28 (-18.5)	149 (300)
Vessel shell at elevation 109.677 m (131 ft – 9 in) to 102.184 m (107 ft-2 in)[2]	21 (70)	149 (300)
Vessel shell from elevation 102.184 m (107 ft-2 in) to elevation 100 m (100 ft) (Linear Profile)	21 (70)	149 to 21 (300 to 70)
Vessel embedded below elevation 100 m (100 ft)	21 (70)	21 (70)

Notes:

1. For Case 1, -28°C (-18.5°F) is conservative and bounding.
2. These components are conservatively assumed to be at the CV inside air temperature. For the crane girder and inner stiffener, there is a step change at the CV shell to the CV shell temperature.
3. Outer stiffener is assumed to be at the CV shell temperature above the stiffener, except that all outer stiffener gussets inside or outside of the insulated enclosure are at 21°C (70°F).

Table 20K-6. Containment Vessel Pressure Capabilities

Containment Element		Pressure Capability (SI units)				
		Deterministic Severe Accident Capacity[1]			Maximum Pressure Capability[2]	
Temperature		37.78°C	148.89°C	204.44°C	37.78°C	204.44°C
Cylinder		0.931 MPa gauge	0.807 MPa gauge	0.772 MPa gauge	1.069 MPa gauge	0.889 MPa gauge
Ellipsoidal Head		0.717 MPa gauge	0.627 MPa gauge	0.600 MPa gauge	1.200 MPa gauge	0.993 MPa gauge
16-foot equipment hatch	F.S. = 1.67	0.869 MPa gauge	0.834 MPa gauge	0.814 MPa gauge	1.448 MPa gauge	1.365 MPa gauge
	F.S. = 2.50	0.579 MPa gauge	0.558 MPa gauge	0.545 MPa gauge		
Personnel airlocks[3]		>1.124 MP a gauge	>1.124 MPa gauge	>1.124 MPa gauge	>2.068 MPa gauge	>2.068 MPa gauge

Containment Element		Pressure Capability (US customary units)				
		Deterministic Severe Accident Capacity[1]			Maximum Pressure Capability[2]	
Temperature		100°F	300°F	400°F	100°F	400°F
Cylinder		135 psig	117 psig	112 psig	155 psig	129 psig
Ellipsoidal Head		104 psig	91 psig	87 psig	174 psig	144 psig
4.9 m equipment hatch	F.S. = 1.67	126 psig	121 psig	118 psig	210 psig	198 psig
	F.S. = 2.50	84 psig	81 psig	79 psig		
Personnel airlocks[3]		>163 psig	> 163 psig	>163 psig	>300 psig	>300 psig

Notes:

1. The buckling capacity for internal pressure of the ellipsoidal head is taken as 60 % of the critical buckling pressure calculated by nonlinear analyses; the buckling capacity at higher temperatures is calculated by reducing the capacity at 37.78°C (100°F) by the ratio of yield at 37.78°C (100°F) to yield at the higher temperature. Evaluations of the equipment hatch covers are shown both for ASME paragraph NE-3222 (F.S. = 2.50) and Code Case N-284-1 (F.S. = 1.67). Evaluations of the other elements are according to ASME Service Level C.
2. The estimated maximum pressure capability is based on minimum specified material properties.
3. The capacities of the personnel airlocks are estimated from test results.

21 REACTOR CHEMISTRY

21.1 Introduction

This chapter describes the application of chemical controls and treatments in the AP1000 plant design. It provides outline descriptions for a number of systems in the AP1000 design that contain fluids essential to their functions, including heat transfer and control of core reactivity. The quality of these fluids and their interactions with system components and materials can have a substantial impact on the reliable and safe operation of the individual systems. Chemical additives are employed to optimise the performance of the fluids and minimise potential negative effects such as corrosion of materials of construction. Chemical additives are also used to mitigate the impact of various accident and fault conditions.

The AP1000 plant is designed to operate safely within the Electric Power Research Institute (EPRI) chemistry guidelines (References 21.2, 21.3, and 21.4), AP1000 plant-specific chemistry operating specifications, and the AP1000 Chemistry Manual guidance (References 21.5 and 21.6) as discussed in the rest of this chapter. The EPRI guidelines are developed and continually updated from accumulated industry-wide research and pressurised water reactor (PWR) operating experience. As such, these guidelines provide an authoritative best-practice operations envelope for the AP1000 plant subject to the modifications necessary to address unique AP1000 design features. The effects of these unique AP1000 design features are addressed in the AP1000 Chemistry Manual and in Westinghouse supplement to the EPRI chemistry guidelines; however, the detailed operational chemistry control strategy will be the responsibility of the plant operator, who may choose to vary and optimise the operating parameters within the bounds of the plant- and site-specific operating safety case. Limits and conditions for chemistry are described in Section 5.6.

21.2 Objectives

The chemistry of important systems in the AP1000 plant is described in this chapter. This description includes chemistry control, its impact on reactor safety, and the factors influencing its specification.

21.3 Approach

The chemistry functions in the AP1000 plant are dealt with under three headings: primary system, secondary system, and auxiliary systems. The essential safety requirements of the chemistry in each system are identified. The various physical systems and their design basis functions are described briefly. The technical background to the main chemistry functions are discussed in each case to provide an understanding of the main issues involved. This approach also provides evidence to justify arguments that the safety functions of the chemistry have been met. Compliance with the chemistry safety requirements is demonstrated for each operational mode of the AP1000 plant. This includes a description of the chemistry strategy and the standards that are applied.

The chemical aspects of accident scenarios, the potential hazards and the hazard mitigation measures, are then discussed. Arguments are presented detailing how the chemistry strategy in such situations supports the overall safety claims of the plant.

21.4 Safety Requirements

The AP1000 design is much simpler than previous PWR designs and enhances safety by virtue of the reduced number of components and provides economic benefits through simplified construction and reduced operation costs. The design utilises passive safety systems that rely on simple natural processes. The safety of the design is based on adherence to a number of inviolate principles given in Chapter 1.

Adherence to these principles is achieved by defining what safety function is required during normal modes of operation and in response to design basis events. This chapter discusses the reactor chemistry and chemistry control systems that support these functions, for example, by aiding control of core reactivity; ensuring the integrity of the pressure boundary; and optimising the quantities, distribution, and containment of radioactive materials.

21.5 Primary Circuit

This section describes the systems used to maintain and monitor the chemical properties of primary reactor coolant. The interfacing systems whose performance depends on the maintenance of the chemical environment are described in Section 21.7.

The following systems are covered:

- Primary circuit
- Primary sampling system (PSS)
- Chemical and volume control system (CVS)

21.5.1 Description of the Primary Circuit

The primary circuit comprises the reactor core and coolant system, including the reactor pressure vessel (RPV), steam generators (SGs), pressuriser, cold and hot leg pipework, and reactor coolant pumps (RCPs). A description of the major components of the primary circuit is given in Sections 6.4 and 6.5.

The boundary of the system, for the purposes of assessing chemistry influences on containment of radioactive material, can be taken as the limits of the reactor coolant pressure boundary. This includes the vessels, piping, pumps, and valves that are part of the reactor coolant system (RCS); or that are connected to it up to and including the following:

- The outermost containment isolation valve in system piping that penetrates the containment. The second of two valves closed during normal operation in system piping that does not penetrate containment.

- The RCS overpressure protection valves. The RCS pressure boundary provides a barrier against the release of radioactivity generated within the reactor and is designed to provide a high degree of integrity throughout the operation of the plant.

The RCS is also served by a number of auxiliary systems, including the passive core cooling system (PXS), normal residual heat removal system (RNS), steam generator system (SGS), PSS, liquid radwaste system (WLS), and component cooling water system (CCS).

21.5.2 Functions of the Primary Circuit Related to Chemistry

The primary circuit design basis functions related to chemistry are as follows:

- The RCS provides the water used as the core neutron moderator and reflector conserving thermal neutrons and improving neutron economy. The RCS also provides the water used as a solvent for the neutron absorber used in chemical shim reactivity control (boric acid).
- The RCS maintains the homogeneity of the soluble neutron poison absorber concentration and the rate of change of the coolant temperature so that uncontrolled reactivity changes do not occur.
- The pressuriser maintains the system pressure during operation and limits pressure transients. During the reduction or increase of plant load, the pressuriser accommodates volume changes in the reactor coolant.
- The SGs provide steam of the required quality to the turbine. The tubes and tube sheet boundary prevent the transfer of radioactivity generated within the core to the secondary system.
- The RCS contains the coolant under operating temperature and pressure conditions and limits leakage (and activity release) to the containment atmosphere.
- The RCS contains a solution of boric acid, lithium hydroxide (LiOH), and zinc; and is dosed with dissolved hydrogen. This solution is circulated at a flow rate and temperature consistent with achieving the reactor core thermal and hydraulic performance.
- The RPV head is connected to the head vent system.
- The pressuriser surge line and each loop spray line connected with the RCS are instrumented with resistance temperature detectors (RTDs) attached to the pipe to detect thermal stratification.

21.5.3 Primary Circuit Chemistry Safety Requirements

The safety requirements of the primary circuit chemistry are as follows:

- The primary circuit chemistry aids the control of reactivity of the core to within operating limits.
- The primary circuit chemistry assists in maintaining the integrity of the primary circuit and the fuel cladding.
- The primary circuit chemistry aims to minimise the slow buildup of radioactivity outside the core region by minimising the transport of corrosion products.

To achieve these safety requirements, a coolant chemistry control strategy aimed at maintaining chemical conditions in the primary circuit within specified ranges is adopted. This involves the monitoring and control of a number of chemistry parameters. A summary of the control parameters is given in the following sections, together with specified ranges (included or referred) and a brief justification for the adopted control. Most of the information given relates to operation in mode 1 (power operation). Further details of chemistry control during other operating modes are given in Section 21.8. Further arguments and evidence are given in later sections. A description of the control and monitoring of chemistry parameters through use of the PSS and CVS is given in Sections 21.5.7 and 21.5.8.

The AP1000 plant reactor coolant water chemistry specification is given in the AP1000 Chemistry Manual (Reference 21.5, Chapter 4). This chapter of the AP1000 Chemistry Manual and its references provide guidance for reactor coolant power operation control and diagnostic parameters. For control parameters, EPRI provides specific guidance on action levels, which are summarised in the AP1000 Chemistry Manual. However, it is noted that operating plants normally operate with site-specific administrative limits well below the EPRI action level guidelines and Westinghouse expects each plant to create site-specific administrative guidelines as a basis for operation. Safety limits for each parameter defined by the designers are also included in Table 21-5 for the parameters identified and discussed below.

21.5.4 Reactivity Control and Fuel Performance

21.5.4.1 Use of Boron

Safety Requirements

Boron (in the form of boric acid) dissolved in primary coolant is varied to control reactivity changes due to fuel burnup. The dissolved boron can also compensate for xenon burnout reactivity changes and maintain the reactor in the cold shutdown condition. Dissolved boron is used to establish the required shutdown margin under normal and accident conditions where a cooldown to ambient temperature is required.

During power operation, the AP1000 plant controls normal fluctuations in reactivity by the use of grey rods and not by adjustments in boron concentration as is the case with conventional PWRs. If load following is practiced, this is also done using grey rods. Please see Chapter 22 for further details, along with the safety evaluation performed for the PSS where these AP1000 plant differences are discussed in the context of boron monitoring requirements (Reference 21.72). Refer to Table 21-5 for safety limits applicable to boron in the primary circuit.

Technical Basis

Boron dissolved in the primary water is used as a chemical reactivity shim to regulate fission through absorption of neutrons. ^{10}B is an absorber of thermal neutrons, with the added advantage that the product is a transitory high-energy form of ^{11}B, which rapidly decays into ^{7}Li, with the emission of an alpha particle. ^{7}Li is already present in the coolant as a normal additive.

The concentration of boron within the primary water is varied throughout the operating range by the use of the CVS to control reactivity changes that occur relatively slowly, including the effects of burnup; fission product poisoning, including xenon and samarium; burnable absorber (BA) depletion; and the cold-to-operating temperature moderator change.

Boron concentration in the coolant is adjusted to allow maintenance of the desired control rod position, i.e., above the control rod insertion limits, to maintain the shutdown margin (see Section 22.6.2.12 for further details). Boron concentration in the coolant is adjusted to allow maintenance of the desired control rod positions and/or to maintain the reactor coolant average temperature in the operating band. Control rods are inserted or withdrawn to control or, as appropriate, to induce, relatively rapid reactivity changes.

Method of Control

The boron is added and removed in the form of a solution of boric acid mixed with demineralised water to the required concentration. The programmed pressurised level is maintained by removing coolant through the CVS letdown line if required. A dedicated tank is provided for boric acid supply via the CVS. The boron concentration is varied throughout a fuel cycle to maintain control rod position. The concentration of boron is varied during normal operations only to control reactivity changes that occur relatively slowly,principally to accomodate the effects of fuel burnup. The boron storage and dosing system are described in Section 21.5.8.3.

Other sources of water input to the RCS are also borated to avoid inadvertent dilutions, which could constitute an increases in reactivity. This includes the core makeup tanks (CMTs), accumulators, and in-containment refuelling water storage tank (IRWST). These other sources of water input are described in Section 21.7.3.1 under the PXS.

Monitoring

The boron concentration is monitored in accordance with the AP1000 plant Technical Specification (Tech Spec) (Reference 21.74) by grab-sampling through the PSS. During periods when reactivity may be changing more rapidly, such as startup or shutdowns, boron analysis will be performed much more frequently to ensure that large mismatches in boron concentration do not occur between different locations within the primary circuit. A boron concentration monitoring system is also provided within the PSS for monitoring and trending purposes.

Faults

Clearly, too high a concentration of boric acid will result in loss of reactivity More significantly, too low a boron concentration will result in an increase in core reactivity and potential loss of control. A number of automatic and manual systems are in place to deal with boron dilution faults. Analyses of effects and consequences in the following situations are given: refuelling, cold shutdown, safe shutdown, hot standby, startup, and full power operation. The impact of loss of external power as a consequence of a turbine trip is also considered. The description of the plant response when the reactor is in automatic and manual rod control, is discussed in Section 9.4.6.

Inadvertent dilution during refuelling is prevented by administrative controls that lock specified valves in the CVS during refuelling operations. This isolates the RCS and prevents any nonborated water from entering the system. In other scenarios, the rate of dilution is low enough to allow time for detection and operator or automatic intervention. In most cases, the source range nuclear instrumentation detects the rise in neutron flux. The protection and safety monitoring system automatically initiates valve movements to terminate the dilution flow and sounds an alarm.

During startup, the reactor is in manual control and the operator withdraws the control rods and dilutes the reactor coolant with nonborated water at controlled rates until criticality is achieved. Excessive or continued dilution due to an unknown source would lead to a more rapid power escalation, which would be mitigated by an automatic reactor trip. In the event of such a trip, the demineralised water transfer and storage system (DWS) is automatically isolated and the CVS pumps are realigned to draw water from the boric acid storage tank (BAST). More information on dilution during refuelling and startup is provided in Section 9.4.6.

21.5.4.2 Crud-Induced Power Shift and Crud-Induced Localised Corrosion

Crud-induced power shift (CIPS) or axial offset anomaly (AOA) can be described as a condition in which the difference in the relative power produced in the upper and lower parts of the core deviates from predicted values by more than 3 percent (Figure 21-1). The axial offset (AO) should be close to zero early in the fuel cycle and stay close to zero for plant normal operations. In some cases, however, the AO has been found to be negative near midcycle. CIPS or AOA is more common in high-duty cores with significant subcooled nucleate boiling and has been attributed to the buildup of boron and lithium-boron compounds on fuel elements in the upper part of the core. Where such localised boiling occurs, dissolved species may precipitate as crud deposits. These deposits may contain boric acid and lithium salts.

Crud-induced localised corrosion (CILC) can result where local crud deposits thicken to the point that liquid coolant is prevented from reaching the cladding surface so that only a steam layer forms near the cladding surface. The reduced heat transfer through the steam leads to an increased surface temperature and consequently higher oxidation rates, which can result in cladding failures.

Corrosion product transport management can aid in the mitigation of CIPS and CILC. Measures taken include material choices, surface finish, and better chemistry control (e.g., pH programme selection, adherence to latest industry guidance). Also, shutdown and restart strategies that optimise corrosion product removal are managed within the constraints of the outage schedule requirements. Crud formation and deposition are discussed in Section 21.5.10 in addition to chemistry practices that aid in mitigation. Nickel-rich crud, which has been associated with the occurrence of CIPS, is more difficult to remove by the current outage chemistry practices. However, outage chemistry regime is not meant to decontaminate the primary system, as the main goal is to prepare the system for opening it to the atmosphere for refuelling.

The AP1000 plant incorporates systems designed to minimise the risk of CIPS and CILC. Zinc addition is employed to lower the system corrosion rate and consequently aids in the mitigation of CIPS and CILC, along with the other systems used for maintenance of primary circuit integrity described in Section 21.5.5. Section 22.7.3 describes the AP1000 plant

specific analyses and consideration that have been performed on the overall risk and minimisation of CIPS and CILC.

21.5.5 Maintenance of Primary Circuit Integrity (Chemistry Control)

The maintenance of primary circuit integrity is achieved by controlling primary coolant chemistry in all reactor operating modes to minimise the risk of corrosion of the primary circuit, the core materials, or the fuel cladding. In practice this involves the following:

- Providing a high-quality demineralised water supply free from contaminants for coolant makeup and cleanup via the demineralised water treatment system (DTS) and CVS, respectively
- Controlling the pH at temperature (pH_T) (coordinated with the boric acid concentration) to within target limits (refer to Section 21.5.5.2 below).
- Maintaining low potential in the makeup water by deoxygenation via the DWS
- Removing oxidising species by dosing with controlled amount of hydrogen sufficient to maintain a hydrogen residual and low electrochemical potential
- Dosing with zinc to lower oxidation rates and to minimise corrosion product buildup on fuel (resulting in lower risk for CIPS and CILC)

Chemistry control is achieved largely through the CVS, which controls the following:

- Chemical additions to the coolant
- Maintenance of the reactor coolant lithium and boron concentration through dilution, addition, or demineralisation
- Purification of the coolant

Monitoring is achieved by chemical analysis of grab samples from the PSS. Additionally, online measurements for oxygen and hydrogen can be taken. The hydrogen concentration range selected for the AP1000 plant is consistent with current operating experience. The major components of the primary circuit are described briefly in Section 21.5.1 and the design basis functions are given in Section 21.5.2. For more detail, see Chapter 6. The functions of the CVS, in terms of maintaining chemical composition and removing any impurities, are presented in Section 21.5.8. A detailed consideration of the corrosion issues, the relevant chemistry factors, and the technical background to justify the primary circuit chemistry specification is given in Section 21.5.9. Emerging corrosion issues are further discussed in Section 21.5.9.

21.5.5.1 Contaminants

Safety Requirements

A number of chemical species, such as chloride, sulphate, fluoride, and silica are known to have detrimental contributions to corrosion of primary circuit materials and therefore, over time, to threaten the integrity of the primary circuit and fuel cladding. Refer to Table 21-5 for safety limits applicable to contaminants in the primary circuit.

Technical Basis

Chloride and sulphate can initiate pitting or crevice corrosion of stainless steels and nickel alloys (Reference 21.8). Chloride can also cause stress corrosion cracking (SCC) of stainless steels in oxygenated conditions and sulphate can enhance the susceptibility of stainless steels and nickel alloys to SCC in deaerated conditions. Fluoride can have effects similar to chloride. Aluminium, calcium, and magnesium can form oxides and silicates in primary coolant. Zeolite minerals in particular could cause densification of crud deposits and increase the risk of CILC.

Method of Control

In practice, the chloride, fluoride, and sulphate concentrations are maintained as low as reasonably possible and maximum concentrations are given in the primary coolant specification. Boric acid and raw demineralised water are both sources of contaminants. The boric acid used for chemical shim is specified as 99.9-percent purity with low levels of specified impurities (Reference 21.5). The maximum chloride, fluoride, and sulphate concentrations are specified for the BAST and primary makeup water (per the Westinghouse supplemental guidelines) (Reference 21.6).

The AP1000 plant design does not use Boraflex racking material (identified as a silica source) or recycle boric acid, therefore, silica levels are expected to be low. The primary coolant specification limits calcium, aluminium, and magnesium concentrations to low levels and silica to 1 ppm in accordance with the Westinghouse supplemental guidelines. The Westinghouse supplemental guidelines for the AP1000 plant (Reference 21.6) also limit aluminium, calcium, and magnesium to low concentrations in primary makeup water (20, 5, and 5 ppb, respectively). Since elevated silica and hardness elements in boric acid storage tank can result from impurities in makeup water and boric acid additions, limits are also placed on these species in the BAST. Silica limits for the BAST are set at [ ] ppb (Reference 21.6).

Control of contaminant species in the primary coolant is achieved by the use of high-purity makeup water from the DWS and continual cleanup of the coolant by the CVS demineralisers and filters.

Monitoring

Contaminant concentrations in the primary coolant are monitored by analysis of grab samples taken via the PSS. Chapter 4 of Reference 21.5 describes the guidance and requirements for the frequency of contaminant analysis.

Faults

Deviations above the specified limits will increase the risk of SCC and will lead to higher general corrosion rates in the long term; however, these processes are relatively slow so that a small excursion for a short period is unlikely to have any serious effect. In addition, owing to the relatively slow turnover of primary coolant, contaminated makeup water will take some time to significantly alter the composition of primary coolant; therefore, grab sampling of primary coolant is sufficient to allow adequate monitoring.

21.5.5.2 pH Control with Lithium Hydroxide

Safety Requirements

The primary coolant pH_T strongly influences the corrosion processes that affect the primary circuit and fuel cladding integrity. pH_T also significantly impacts crud production and mobilisation around the primary circuit. Alkaline conditions (high pH) minimise the general corrosion rates of primary circuit materials and lead to a lower primary circuit crud inventory, therefore reducing the risk of CIPS and CILC. Additionally, the formation of tritium is minimised through the use of ^{7}Li and the overall amount of Li minimises the amount of fuel clad degradation. Refer to Table 21-5 for safety limits applicable to pH control in the primary circuit.

Technical Basis

EPRI guidelines discuss possible pH control strategies and the Westinghouse supplemental guidelines for the AP1000 plant (Reference 21.6) specify a pH_T (the pH at operating temperature) range of [ ] during power operation. This range is supported by plant experience of crud production (Reference 21.2) and by laboratory corrosion testing. Section 21.5.9 gives further details of environmental effects on corrosion rates and Section 21.5.10 discusses crud production. The actual pH_T control adopted in the plant is the responsibility of individual operators and will be optimised within this range. Expected pH levels and associated lithium concentrations for different types of pH control programs are provided in Section 4.3.6 of Reference 21.5.

Method of Control

Lithium (in the form of LiOH) is added as the pH control agent. This is coordinated with boric acid concentration to achieve the desired pH_T. The concentrations of lithium and boron are determined by analysis of grab samples of the primary coolant. Tests using cladding material have indicated that high concentrations of lithium can lead to excessive corrosion of fuel cladding. In view of this concern, the primary coolant lithium concentration is limited to a maximum of [ ], in accordance with the fuel vendor (Westinghouse) warranty and recommendations (Reference 21.6), with a safety limit of [ ] (refer to Table 21-5). More recent work has suggested that the lithium concentrations required to significantly affect oxidation of the cladding material are much higher than those expected under normal power operation, in the presence of boric acid (21.2). As increased crud formation due to operating at lower pH is likely to have a significant effect on cladding life, options for operating at higher lithium concentrations are being investigated.

LiOH enriched to 99.9 percent in the ^{7}Li isotope is used. This particular isotope is specified because ^{6}Li will form tritium under neutron irradiation and there is a requirement to avoid the elevated primary circuit radioactivity that tritium imparts. ^{7}Li is much less likely to form tritium in these conditions.

Limiting the lithium concentration will result in an initial phase at the start of the fuel cycle where pH_T may be at the lower end of the operating band. As the boron concentration is decreased throughout the fuel cycle, to compensate for fuel burnup, the pH_T may increase to the maximum of the range. After this point, LiOH concentration will be coordinated with that of boric acid to maintain the target pH_T, reducing steadily until the end of the fuel cycle. Figure 21-2 illustrates an example of pH control profile. Boron-induced offset anomaly model calculations for the AP1000 design predict that primary coolant pH_T will not drop below [ ] during a fuel cycle (Reference 21.77).

Control of lithium in the primary coolant is achieved through the use of the CVS makeup pumps with the chemical addition tank for addition, and through the intermittent use of the cation demineraliser and letdown in the CVS for removal.

Monitoring

Grab samples will be taken from the hot leg and pressuriser liquid space, along with the downstream CVS demineralisers sample location to enable monitoring of boron and lithium concentrations and calculation of the pH_T. Deviations from the target pH_T are likely to be gradual and small, and the impacts of small changes from the target pH_T on corrosion and crud production are relatively slow, so that regular monitoring is adequate for timely adjustment. EPRI guidelines recommend a specified routine for sampling of boron, lithium, and pH_T during power operation (Reference 21.2). Changes to pH_T are achieved by dosing makeup water with additional LiOH or removing lithium in the CVS. Strategies for managing pH_T in conjunction with periodic boron reductions are discussed in the 'Technical Basis' and 'Control' sections above.

Faults

Operating outside the recommended pH_T range increases the risk of corrosion damage to the primary circuit and fuel and leads to greater oxidation of primary circuit materials and a consequent increase in primary circuit activity. Primary coolant dilution, similar to that described for boron, can affect the coolant pH_T. In such cases, the changes in reactivity would trigger alarms as for boron dilution. Errors in chemical analysis and dosing or inadvertent lithium removal could result in unintended pH_T changes. In these cases, pH_T calculations based on normal sampling would detect the changes in adequate time to avoid any significant impact. Control of pH_T during shutdown and startup is more important to avoid the possibility of crud bursts. This is discussed in Section 21.8.

21.5.5.3 Removal of Oxidising Species by Dosing with Controlled Levels of Hydrogen

Safety Requirements

Even low concentrations of oxygen have a strong impact on electrochemical potential, which has a significant effect on the susceptibility of primary circuit materials to SCC. Oxygen also affects the oxidation rate of primary plant materials (see Section 21.5.9.2), and therefore leads to increased crud in the primary circuit. A further effect of increased oxygen is increased oxidation rate of fuel cladding.

During operations typical sources of oxygen in the coolant are from radiolysis in the core, and from any oxygen in the makeup source from the boric acid storage tank. Control of oxygen concentration in the reactor coolant system is provided by injecting hydrogen from the CVS.

Refer to Table 21-5 for safety limits applicable to oxidising species and hydrogen control in the primary circuit.

Technical Basis

If the hydrogen concentrations were to become too low, there would be a rise in the electrochemical potential and a consequent increase in general corrosion rates. This in turn would lead to an increase in primary circuit crud levels. In addition, the increased electrochemical potential would increase the probability of SCC of stainless steels.

Hydrogen influences the susceptibility of nickel alloys to primary water stress corrosion cracking (PWSCC). The optimum hydrogen concentration is still the subject of research. Alloy 690 and its weld materials (Alloys 52 and 152) are highly resistant to PWSCC and no cases have been reported in the field. Laboratory testing of Alloy 600 has demonstrated an effect of hydrogen on SCC crack growth rates (CGRs), which indicates a maximum CGR at a hydrogen concentration equivalent to a potential close to the Ni/NiO transition. In addition, work with Alloy 600 has suggested a minimum crack initiation rate in primary circuit conditions with a hydrogen concentration of 30 cc (standard temperature and pressure (STP))/kg H_2O [1]. This has led to the following two proposed alternative strategies for hydrogen control in PWR primary water:

- Adoption of a very low hydrogen concentration (around 5 cc/kg H_2O)
- A very high hydrogen concentration

Both these strategies are aimed at avoiding the hydrogen concentration for peak CGRs. Whilst the majority of reported lab data relate to Alloy 600, it should be noted that this material is not used for pressure boundary components in contact with primary coolant in the AP1000 design (Chapter 20). Instead, the AP1000 design uses only Alloy 690. No PWSCC initiation data are available for Alloy 690 under normal conditions and data relating CGRs to hydrogen concentration are so far inconclusive. Therefore, the AP1000 design specifies a hydrogen concentration range of 25 to 50 cc/kg H_2O as operational limits, with the safety limits provided in Table 21-5. This is a prudent choice given the lack of a firm consensus regarding the effect of alternative hydrogen concentrations on the PWSCC performance of Alloy 690 and current operating experience.

Method of Control

In view of the deleterious effects of high oxygen levels, the concentrations in the primary coolant are maintained at very low levels during power operation, and target maximum levels to be achieved at certain stages of startup are specified. In addition, makeup water is limited to a maximum oxygen concentration of 100 ppb (Reference 21.6).

It should be appreciated that oxygen (and other oxidising species) are generated by the radiolytic degradation of water in the core during power operation. Hydrogen is, therefore, added to the primary coolant to ensure the removal of oxidising water degradation products and the maintenance of a low electrochemical potential. Hydrogen is injected into the primary coolant via the CVS. This hydrogen addition controls general oxidation of circuit materials and fuel cladding, and also suppresses PWSCC of primary circuit materials. The maximum oxygen concentration in primary coolant during power operation with hydrogen dosing is specified as 5 ppb.

Hydrogen gas is provided to the hydrogen injection package, located in the turbine hall, by a regulated supply from high-pressure storage bottles within the plant gas system (PGS) which are located outside in the plant yard. The hydrogen injection system consists primarily of piping, valves, and instrumentation. There are two parallel flow paths: one for continuous addition of hydrogen during power operation, and one for batch additions of hydrogen during startup and restart when it is desirable to change the hydrogen concentration in the coolant quickly. Each line has a control valve and flow transmitter to provide operators with system parameters and control capabilities.

1. An abbreviated version of this unit, cc/kg H_2O, will be used in the rest of the chapter.

The hydrogen injection point is downstream of the CVS regenerative heat exchanger shell side outlet line. Any undissolved hydrogen enters the RCS on the suction side of reactor coolant pumps 1A and 1B, which provide the adequate source of mixing aside from the mixing that occurs from the hydrogen injection package to the RCS.

The criteria the hydrogen injection system is designed for includes:

- Maximum Allowable Injection – the maximum rate at which hydrogen can be added and still absorb into the coolant shall be significantly larger than the required injection rate for all operating modes.
- Startup – bringing the concentration up from [ ] cc (STP)/kg of H_2O/kg in 8 hours and then from [ ]cc (STP)/kg of H_2O /kg within 24 hours of reaching criticality.
- Normal Power Operation – maintaining a concentration of [ ] cc (STP)/kg of H_2O
- Transients – maintaining a concentration of [ ] cc (STP)/kg of H_2O as water is added/removed from the RCS.

These design criteria for the hydrogen injection system are demonstrated and substantiated within Reference 21.73.

Additional measures to maintain low potentials (and low oxygen levels) are employed during startup. The procedures invoked include the following:

- Dosing with hydrazine (a powerful reducing agent)

- On first fill, evacuating the air-filled circuit prior to adding water (vacuum filling) to prevent oxygen in trapped air from dissolving in the water

Monitoring

Dissolved hydrogen concentration is monitored by grab sampling at least three times daily during power operation in order to adequately monitor hydrogen injection. More frequent sampling may be necessary during operations that may significantly impact hydrogen concentration (e.g., during plant transients or exchanges of coolant during boration or dilution) or periods of hydrogen instability (Reference 21.6).

Additionally, the primary sampling system (PSS) contains hydrogen and oxygen on-line monitors within the grab sample panel to continuously monitor trends of hydrogen and oxygen in the coolant.

The appropriateness of these means of monitoring is justified in Reference 21.72.

Faults

The injection of hydrogen into the primary coolant means that equipment failures lead to an immediate change in dosing rate. Considering a control band of [ ] cc/kg, the regular analysis of the primary coolant proposed by Westinghouse supplemental guidelines (three times daily) (Reference 21.6) ensures that changes will be detected before they are significant.

Considerations for faults that lead to unintended concentration changes within the reactor coolant system are discussed and substantiated within Reference 21.73.

21.5.5.4 Zinc

Safety Requirements

Zinc (in the form of zinc acetate) is to be added to the primary circuit to control crud production and primary circuit activity. Zinc helps to stabilise oxides on primary circuit materials and decreases the degree of deposition of ^{58}Co in the corrosion film. These two effects lead to a lower crud inventory in the primary circuit, resulting in improved fuel performance and lower circuit radioactivity.

The justification for the incorporation of zinc addition into the AP1000 plant design is based on laboratory studies and operating experience, particularly at plants which have injected zinc from the beginning of plant life or immediately following SG replacement. The addition of zinc minimises the risk of PWSCC in susceptible materials, and reduces ongoing corrosion in the primary circuit. Lower corrosion release, in turn, reduces the risk of CIPS/CILC, and also minimises plant dose rates. Hence, zinc injection in the AP1000 plant follows the as low as reasonably practicable (ALARP) principle.

It is noted that the elevated levels of zinc within the primary circuit may cause zinc oxide or zinc silicate to deposit within crud on the core and increase fuel cladding corrosion due to the solubility limit of zinc. Thus, the concentration of zinc is controlled to maintain the benefits of the dose reduction from zinc, while limiting the potential for fuel cladding corrosion.

Refer to Table 21-5 for safety limits applicable to zinc control in the primary circuit.

Technical Basis

The current target concentration for zinc in AP1000 plants during power operation is [ ] ppb with an operating band of ± [ ] ppb around the target (Reference 21.6). The target zinc concentration chosen will decrease ongoing corrosion rates for RCS materials and lower the corrosion products released to the coolant, resulting in a reduction in fuel crud deposits. The recommended target concentration also remains well below the solubility limit for zinc, providing operating margin for any unexpected increases in zinc concentration. Similar target concentrations in operating plants have been successful in reducing plant dose rates and mitigating PWSCC in susceptible materials as described in Reference 21.2. The target zinc concentration is appropriate for high boiling duty plants based on current operating experience.

Zinc acetate is available as either natural or depleted zinc. “Natural” zinc acetate has the natural mix of zinc isotopes that contains 48.6 percent ^{64}Zn, which can be activated in the neutron flux to generate ^{65}Zn (1.1-MeV gamma emitter with a 243.8-day half-life). “Depleted” zinc acetate typically contains less than 1 percent ^{64}Zn and its use would therefore result in comparatively lower plant dose rates than the application of natural zinc. For this reason, most, if not all, plants worldwide currently use depleted zinc. Although either may be used, it is recommended that depleted zinc be used in the AP1000 plants to maintain dose rates ALARP (Reference 21.5).

Method of Addition

Zinc acetate solution is injected into the RCS (via the CVS) from the zinc injection package addition tank via a positive displacement pump located in the turbine building. Injection of zinc acetate solution is continuous at a low flow rate. Grab samples are taken for zinc analysis periodically during power operation. This is sufficient to allow timely adjustment to maintain the zinc concentration within the target limits given the slow dosing rate. The dosing system can be calibrated during hot functional testing (HFT) when there is no risk to the fuel.

Monitoring and Faults

One caution associated with adding zinc to a PWR is the possibility of zinc oxide or zinc silicate depositing within the crud on the core if the boiling concentration process within the crud were to cause the zinc concentration to exceed the solubility limit. Such deposition could decrease heat transfer through porous crud, potentially increasing fuel cladding corrosion. Maintaining the zinc concentration within the targeted limits eliminates this concern for the AP1000 plant. Zinc addition rates will be calibrated during HFT when there is no fuel present, and regular monitoring of addition rates and coolant concentrations will be used during power operation to maintain a steady-state target concentration. Note also that short-term transients above the targeted value are not expected to be detrimental to the fuel (refer to Reference 21.6 for additional information), and zinc injection will be secured as needed to allow for cleanup in the case of an inadvertent overfeed.

21.5.5.5 Conductivity

Safety Requirements

Conductivity measurements give a rapid, although nonspecific, indication of changes in primary coolant chemistry and are therefore an important monitoring tool.

Refer to Table 21-5 for safety limits applicable to conductivity in the primary circuit.

Technical Basis

The conductivity of the coolant depends on all of the ionic chemical species present and is therefore a nonspecific measurement that varies throughout the fuel cycle. The relatively large concentration of boric acid and LiOH will account for most of the conductivity because the other ionic species (primarily zinc and impurities) will be present in orders of magnitude less concentration.

Monitoring

Conductivity is monitored (typically as a diagnostic parameter) to provide rapid indication of problems or ingress of species that could only be specifically analysed by more time-consuming methods, and to assess for consistency with boron and lithium measurements.

21.5.6 Design for the Minimisation of Buildup of Primary Circuit Radioactivity

Primary circuit activity is largely due to activated crud that has deposited throughout the primary circuit. The AP1000 plant design is optimised to reduce crud production ALARP while also maintaining primary circuit integrity and reactivity control. Refer to Reference 21.80 for additional details.

The crud control function is achieved by chemical monitoring and regulation via the CVS and PSS. While further details of the operational and shutdown chemistry control are described in Section 21.5.10.3, the control of crud transport is achieved by the following:

- Minimising the concentration of oxidising species
- Deaerating makeup water via the catalytic oxidation reduction system (CORS)
- Hydrogen addition via the CVS
- Maintaining pH_T within the range [ ]
- Controlling chemical conditions during shutdown and startup to avoid crud bursts and maximise removal of species which are subject to radiological activation.
- Adding zinc to the coolant to promote the formation of passive oxides and decrease the content of radionuclides in the crud, both during normal operation and as a part of HFT during commissioning
- Appropriate material selection for systems, equipment, and components to minimize corrosion and degradation, preventing additional corrosion product formation

21.5.6.1 Construction and Commissioning

A number of measures have been adopted during the construction and commissioning of the AP1000 plant to minimise the production of crud and hence circuit activity. These measures include specification of low-cobalt primary circuit construction materials, surface finishes to reduce corrosion, HFT with zinc, and cleaning procedures. Additional details are given in Section 21.10.

Primary circuit materials are specified and selected to minimise primary circuit activity. Low cobalt levels are specified for all materials in contact with primary coolant as far as practicable. Exceptions to this are some valve seats and components in the control rod drive mechanism (CRDM), RCPs, and reactor vessel internals (RVI), which are specified as a high-cobalt alloy, Stellite™, for its wear resistance. Steps are being taken to identify and qualify a low-cobalt alternative but the current choice is considered to be consistent with ALARP goals as alternatives wear faster and generate more crud.

21.5.6.2 Suspended Solids

Safety Requirements

Primary circuit activity outside of the core is largely due to mobilised deposits and corrosion products. Monitoring suspended particulate or colloidal material in the primary coolant gives information regarding the degree of solid transport around the circuit.

Refer to Table 21-5 for safety limits applicable to suspended solids in the primary circuit.

Technical Basis

Filtration of coolant in the CVS helps to control the level of suspended material. The levels of suspended solids in the primary coolant are, therefore, typically very low; however, monitoring is recommended under EPRI and Westinghouse supplemental guidelines to detect problems that lead to crud movement around the circuit. Too high a level of suspended material could lead to problems due to deposition on the fuel, possibly leading to CIPS/CILC and increased primary circuit activity.

Control

A diagnostic limit of [ ] ppb of suspended solids is specified in the Westinghouse supplemental guidelines (Reference 21.6), and grab sampling is carried out on a regular basis to allow identification of trends.

21.5.6.3 Other Radionuclides

Safety Requirements and Technical Basis

Safety limits on the RCS and secondary side specific activities are specified in the plant technical specifications for consistency with the plant's offsite dose analyses in the event of postulated fault conditions.

Refer to Reference 21.74 for details on these limits.

Monitoring and Control

The recommended types of monitoring in the primary circuit and secondary coolant (principally measurement for dose-equivalent iodine) are described in Section 12 of Reference 21.5.

21.5.7 Primary Sampling System

The PSS is a manually operated system, including two liquid sample lines; one containment atmosphere sample line; and one containment return line penetrating the containment, which is accessed through one of the three ovation stations. The PSS allows access for obtaining representative samples of fluids from the RCS and various primary auxiliary system process sources for analysis. This sampling process is performed during HFT, startup, shutdown, and power plant operations. It provides information to operators, enabling timely actions to maintain the chemical conditions needed to meet the primary coolant chemistry safety requirements.

The PSS performs the following functions:

- Provides a central location to collect both liquid and gaseous samples in normal operation mode
- Provides for local grab samples during normal operation mode
- Provides samples of the RCS, containment sump, and containment atmosphere for analysis during post-accident and accident recovery phases

The PSS provides the means to sample the primary system under various system conditions for analysis. Local sample points (not within the scope of the PSS) are provided at various process points of the auxiliary systems for taking samples for analysis. All PSS samples are

collected at the grab sampling unit and provides capability to collect samples in the radiochemistry laboratory.

During normal operation, the PSS provides a central location outside of containment to obtain representative samples of fluids in the RCS, auxiliary primary systems process streams, and the containment atmosphere for analysis.

The results of the sample analyses are used to perform the following functions:

- Monitor core reactivity
- Monitor fuel rod integrity
- Evaluate ion exchanger (demineraliser) and filter performance
- Specify chemical additions to the various systems
- Maintain acceptable hydrogen levels in the RCS
- Detect radioactive material leakage

During the post-accident and accident recovery phases the PSS provides the capability to sample from the RCS hot legs, the WLS containment sump, and the containment atmosphere. The collection of these samples allows for the analysis of reactor coolant for boron, containment atmosphere for hydrogen and fission products, and containment sump water for pH.

More information on the PSS is provided within Section 6.4.4. Further details of the overall system design and sampling procedures are given in the system specification document (SSD) for the PSS (Reference 21.13).

The PSS consists of two separate portions: liquid sampling and gas sampling. These are detailed separately below.

21.5.7.1 Liquid Sampling

For liquid sampling, the PSS provides a sample header that has two dedicated sample header lines for use of RCS based samples and a separate sample line that is dedicate for only the use of the PXS samples.

The PSS sample lines utilises proper piping and tubing to promote the integrity of connections to high-energy systems. Additionally, 10 mm DN (3/8-inch NPD) orifices are fitted in the sample lines originating directly from the RCS pressure boundary to limit reactor coolant loss to less than CVS makeup capacity (Section 6.4.2).

A delay coil of tubing is installed inside containment to provide at least 60 seconds of transit time for the sampling fluid to exit the containment from the RCS hot leg. The 60-second delay is provided for N-16 decay in order to lower radioactivity levels and potential personnel exposure from the sample fluid prior to exiting containment.

The grab sample panel used for collecting samples utilises proper valve orientation and design to promote quick sample collection with minimum radiation exposure. Prior to the collection of liquid samples, the lines are first purged with source liquid to ensure that representative samples are obtained. Sample representativeness is also further ensured through the segregation of the RCS based samples and the PXS samples within the sample header. The purging and excess sample flow is sent to the WLS Effluent Holdup Tanks (EHTs) for waste processing. The sampling lines are fitted with radiological and temperature-

monitoring equipment such that in the event of an excessive temperature or radiation level, the proper outside containment isolation valve is closed and an alarm informs the operator. The continuous sample line also provides for the capability to obtain corrosion product sampling using capillary lines to a filter for laboratory analysis.

21.5.7.2 Gas Sampling

The PSS collects gaseous samples from the containment atmosphere. This is achieved using an ejector as the motive force for sample collection.

Gaseous sampling is conducted in the sample room in the auxiliary building. Like the liquid sampling system, gas sampling can also be manually operated with extension stems on the valves. Unlike the liquid sampling capabilities, only grab samples are collected for the gas sampling. The lines are purged prior to sample collection to provide representative samples. The purged gas returns to containment. The sampling line is fitted with radiological-monitoring equipment such that in the event of an excessive radiation level, the outside containment isolation valve is closed and an alarm informs the operator of this event.

Containment atmosphere samples can be used as a backup to the containment hydrogen control system (VLS) hydrogen analysers. Reactor coolant pressure boundary (RCPB) leakage is detected with the containment atmosphere radiation monitoring skid, which continuously monitors for airborne noble gases and ^{18}F particulates.

21.5.7.3 Post-Accident Sampling Capabilities

Post-accident sampling sources and measurement procedures that may be performed with the PSS are listed in Reference 21.13, Table 2-1.

The PSS in post-accident conditions is used for sampling the conditions in containment; the PSS has the capability to obtain liquid reactor water samples for boron analysis post-accident and for reactor coolant for boron, containment atmosphere for hydrogen and fission products, and the containment sump water for pH. The primary means for sampling of the containment atmosphere for hydrogen analysis is performed by the hydrogen analysers of the VLS and is not part of the PSS post-accident sampling capabilities. Containment atmosphere samples for radionuclide analysis, however, can be obtained following an accident using the PSS. Samples collected during post-accident conditions will be returned to the containment rather than the WLS, which is the location for sample volume during normal liquid sampling operations.

Refer to Reference 21.72 for justification for the appropriateness of the post-accident sampling capabilities of the AP1000 plant PSS.

21.5.8 Chemical and Volume Control System

The CVS consists of regenerative and letdown heat exchangers (HXs), demineralisers and filters, makeup pumps, and tanks; and associated valves, piping, and instrumentation. It provides performs chemistry control during normal operations and defence in depth support to the safety requirements of the primary coolant chemistry by providing the means to control the coolant composition in terms of boron concentration for reactivity control, pH, dissolved hydrogen concentration for oxygen control, zinc dosing, and removal of contaminant species.

In addition to the chemistry control functions the CVS performs the following safety functions:

- Containment isolation
- Preservation of the reactor coolant pressure boundary
- Reactor coolant system inventory control and makeup
- Borated makeup to auxiliary equipment
- Pressuriser auxiliary spray
- Reactor coolant system degassing prior to shutdown

More discussion on the CVS and the evidence for the system capability to support the safety functions described above is discussed within Section 6.4.2. Demonstration of the adequacy of the CVS to perform its normal operation and defence in depth functions and incorporate relevant good practice has been provided (refer to Reference 21.78).

The ability for the CVS to provide chemistry control for the reactor coolant is described within the rest of this section.

21.5.8.1 Chemical and Radioactivity Control through Purification

The CVS removes radioactive corrosion products, ionic fission products, ionic impurities, and fission gases from the RCS to maintain low RCS activity levels. The CVS purification capability considers occupational radiation exposure (ORE) to support ALARP goals.

The CVS is designed to maintain the RCS activity level at less than the Tech Spec limit (Reference 21.74) for normal operations with design basis fuel defects. The purification rate is based on minimising occupational radiation exposure and providing access to the RCS equipment. Justification for the capability of the current mixed bed demineralizer sizing and flow capacity to support this function was provided in Reference 21.78.

The normal CVS purification loop is inside the containment and operates at RCS pressure, utilising the developed head of the RCPs as the motive force for the purification flow. During power operations, fluid is continuously circulated through the CVS from the discharge of one of the RCPs. The flow then passes through the regenerative HX where it is cooled by the returning CVS flow, and is further cooled by component cooling water in the letdown HX. This two-stage cooling achieves a final temperature that is compatible with the demineraliser resins, which would be degraded if exposed to excessive temperatures. The purification fluid flows through a mixed bed demineraliser, and optionally through a cation bed demineraliser, before finally flowing through a filter designed to trap resin fines emanating from the demineraliser. The flow from the filter returns to the suction side of an RCP after being reheated in the regenerative HX.

The mixed bed demineralisers are provided in the purification loop to remove ionic corrosion products, ionic impurities, and certain ionic fission products; they also remove zinc. In addition, the demineralisers act as filters. One mixed bed is normally in service, with a second demineraliser acting as a backup in case the bed in service should become exhausted during operation. Each demineraliser and filter is sized to provide a minimum of one fuel cycle of service without change out.

The mixed bed demineraliser in service can be supplemented by intermittent use of the cation bed demineraliser. The cation bed demineraliser is used during power operation for removal of excess lithium, both for pH control and for removal of lithium generated from neutron activation of boron. The cation bed can also provide additional purification in the event of fuel defects.

During plant shutdowns when the RCPs are stopped, the RNS provides the motive force for the CVS purification. Purification flow from the RNS HX is routed directly through the normal CVS purification loop. Boron changes and dissolved gas control are still possible by operating the CVS in a semiclosed loop arrangement.

21.5.8.2 Chemical Shim and Chemical Control

The CVS provides the means to vary the boron concentration in the RCS. The system also controls the RCS chemistry for the purpose of limiting corrosion and enhancing core heat transfer, as discussed further in the ensuing subsections.

Small reactivity changes (due to load following, for example) are achieved via control rod movements. This avoids frequent boron concentration changes, as used in current operating PWRs, and the consequent production of additional liquid waste through repeated dilution and boration.

The concentration of boron in the RCS is adjusted with the aim of achieving the desired control rod position with core depletion. The CVS has the capacity to accommodate a cold shutdown followed by a return to power at the end of core life and also (as an independent case) to borate the plant to cold shutdown immediately following return to power from refuelling.

Boric acid is made up in batches by dissolving solid boric acid (as a crystalline solid) in demineralised water at elevated temperature in the boric acid batching tank to a final concentration of 2.5 wt% boric acid (equivalent to approximately 4375 ppm boron).

Changes in RCS boron levels are controlled by a main control room (MCR) operator by interfacing with the reactor makeup control system (RMCS). In normal operation, the RMCS allows the operator to add makeup while maintaining the coolant boric acid concentration. Boration is achieved by aligning the suction side of the makeup pumps to the BAST via a three-way valve. When dilution of the dissolved boron levels is desired, the three-way valve is operated to align the pumps with the demineralised water supply. Towards the end of fuel life, the boron concentration in the primary coolant is low and precise dilution by this process becomes increasingly difficult. In this case the operators may optionally use flow through the standby mixed bed demineraliser to deborate the coolant. The second demineraliser will not be borated as it is reserved for end of cycle boration.

21.5.8.3 pH Control

Lithium is used to control the pH_T of the RCS. The required concentration of lithium is varied with boric acid concentration to achieve target pH_T, according to the pH_T control strategy adopted for the plant and within the lithium concentration limit. The concentration of the ^6Li isotope is minimised to limit the formation of tritium, which contributes to primary circuit radioactivity. The concentration of ^6Li is controlled by the isotopic specification for a high percent of ^7LiOH as discussed in Section 21.5.5.2.

21.5.8.4 Oxygen Control

The CVS maintains the proper conditions in the RCS to minimise corrosion of the fuel cladding and primary surfaces. During plant heatup, hydrazine is added to the reactor coolant (including the pressuriser) to scavenge dissolved oxygen. As discussed in Section 21.5.9.3, hydrogen is dissolved in the reactor coolant to minimise the levels of dissolved oxygen. The CVS is capable of maintaining the concentration of dissolved hydrogen in the RCS at a

minimum of 25 cc/kg H_2O hydrogen required during power operation, assuming anticipated operating losses. Hydrogen makeup is supplied to the RCS by CVS piping and is described in more detail within Reference 21.14 and Reference 21.73.

During plant startup from cold shutdown, the CVS introduces hydrazine into the RCS via the chemical addition tank. The solution is used only for oxygen control at low RCS temperatures during startup from cold shutdown conditions. At other times during plant operation, hydrogen is used for oxygen control.

21.5.9 Maintenance of Primary Circuit Integrity (Materials)

A second major function of primary circuit chemistry is controlling the corrosion of materials exposed to the primary coolant, including structural components and fuel cladding. This section describes the principal materials used in the primary circuit, the potential mechanisms of corrosion, the influence of primary coolant chemistry parameters, and chemistry control strategies employed to minimise corrosion.

21.5.9.1 Materials

The AP1000 plant, like all PWRs, operates at temperatures that can accelerate corrosion of materials; therefore, materials with proven ability to operate in these conditions have been selected. A brief summary is provided of these materials, their applications, and material fabrication techniques that could potentially alter a material's corrosion resistance.

Primary System Materials of Construction

The RPV is constructed from low-alloy steel (LAS). It is clad on its internal (wetted) face with austenitic stainless steel for corrosion resistance. Vessel head penetrations, including CRDM housings and vent pipes, are constructed from Alloy 690. All primary circuit components in contact with the primary coolant are constructed from, or clad with, austenitic stainless steels (with some exceptions where justified). SG tubes and passive residual heat removal (PRHR) HX tubes are manufactured using thermally treated (TT) Alloy 690 (Alloy 690TT). RCP piping and the surge line are made from austenitic stainless steels. Valve components are made from austenitic stainless steels but valve seals and stems may be constructed from Alloy 718, Type 630, or Type 316 steel. Based upon lessons learned from the previous generation of nuclear power plants, Alloy 600 is not used in the AP1000 plant primary circuit except in small quantities in the RCPs, and is not used for pressure boundary components in contact with primary coolant. Details of primary circuit materials are given in Chapter 20.

The major core support materials for the reactor internals are Type 304, 304L, 304LN, or 304H stainless steels. For threaded structural fasteners, the material used is strain-hardened Type 316 stainless steel, and for the clevis insert-to-vessel bolts, either Alloy 718 or Alloy 750. The remaining internal parts not fabricated from Type 304, 304L, 304LN, or 304H stainless steels typically include wear surfaces such as hard facings on the radial keys, clevis inserts, alignment pins (Stellite-6 or low-cobalt hard faces), dowel pins (Type 316), hold-down springs (Type 403 stainless steel (modified) or 415), clevis inserts (Alloy 690), and irradiation specimen springs (Alloy 750). Instrument guide assembly materials that are not Type 304, 304L, 304LN, or 304H stainless steel are the guide bushings and guide stud tip (UNS S21800) and the instrument guide tube spring (Alloy 718). The use of cast austenitic stainless steel (CASS) is minimised in the AP1000 reactor internals. If used, CASS will be limited in both carbon (low carbon grade: L grade) and ferrite content and will be evaluated in terms of thermal aging effects.

Moreover, compatible weld materials are used throughout, including Alloys 52, 52M, and 152 for Alloy 690. For austenitic stainless steels, the weld materials are Types 308, 308L, 309, 309L, 316, and 316L.

In addition, susceptibility to irradiation-assisted SCC or void swelling in reactor internals identified in the current PWR fleet are being addressed in reactor internals Material Reliability Programmes (MRPs). The selection of materials for the AP1000 plant reactor internals considers information developed by these programmes. Decidedly, Ni-Cr-Fe Alloy 600 is not used in the AP1000 plant reactor internals.

Fuel Cladding and Fuel Assemblies

Fuel cladding and fuel assembly intermediate support grids are made from zirconium alloy (ZIRLO™). ZIRLO, an advanced zirconium-based alloy used in the AP1000 plant, has equal or better corrosion resistance than Zircaloy-4 (Reference 21.15). Controls on fuel fabrication specify maximum moisture levels to preclude clad hydriding. In addition, the top, bottom, and protective grids of the fuel assemblies are made of nickel-chromium-iron (Ni-Cr-Fe) alloy (Alloy 718). Control and grey rod cladding are made from cold-worked Type 304L stainless steel.

Sensitisation and Cold Working

Sensitisation and cold working can change a material's resistance to different corrosion mechanisms. The approach used in developing the AP1000 plant to minimise the impact of sensitised or cold-worked materials is described below.

Sensitisation may occur when stainless steel is subjected to certain combinations of temperature and exposure time that precipitate chromium carbides at the grain boundaries, resulting in a chromium-depleted layer adjacent to the grains that provides a path of lower corrosion resistance along the grain boundaries. Therefore, sensitised stainless steel is more susceptible to intergranular stress corrosion cracking (IGSCC). Also, the chemistry of the reactor coolant is controlled to prevent the intrusion of aggressive species; testing has shown that, even with sensitised materials, IGSCC of stainless steel should not occur in the reducing- and low-chloride conditions of PWR primary coolant (Section 21.5.9.2). Nevertheless, sensitisation is avoided to further minimise the risk. Low carbon grades are applied wherever possible in the AP1000 plant. The AP1000 plant uses austenitic stainless steels in the solution-annealed and water-quenched condition to avoid introducing sensitised material. An example of using materials that avoid the potential for sensitisation is the single-piece forging technology implemented for the "hot leg with side nozzles" (and cold legs), which eliminated welds and in-service inspections.

In addition, welding processes are controlled to prevent sensitisation, and any other processes that may result in sensitisation during manufacture are avoided. Testing is carried out on any stainless-steel components where sensitisation through processing is suspected, and any sensitised material is heat-treated or rejected. Materials having a carbon content greater than 0.03 wt% receive a suitable intergranular corrosion test (practice E American Society for Testing and Materials (ASTM) A262-70 (Chapter 20). This confirms that the welding procedures used for the manufacture of components in the primary pressure boundary and the reactor internals do not result in the sensitisation of heat-affected zones (HAZs). The delta ferrite content of weld materials is specified as 5 to 16 FN for Mo-containing material, and 5 to 20 FN for other materials. Weld procedures are controlled to avoid hot cracking in stainless-steel welds.

The use of cold-worked stainless steels is restricted to small components such as pins, fasteners, and cladding of control and grey rods; and is avoided in pressure boundary components by selecting raw materials and controlling manufacturing processes to avoid or minimise residual cold work and the resultant elevated yield stresses that may predispose the material to SCC. Solution heat-treated materials are normally used and reheating in the range of 426.7 to 815.6°C (800° to 1500°F) is avoided. Pressure boundary parts and components made of stainless steel do not have specified minimum yield strength greater than 620.53 MPa (90 ksi).

21.5.9.2 Degradation Mechanisms

Oxidation

General corrosion (oxidation) of primary circuit materials can occur in high temperature (HT) aqueous environments and at a uniform rate over the entire surface area of a material. The rate of general corrosion depends on a number of factors, including material, metallurgical condition and history, surface finish, temperature, pH, oxygen concentration, electrochemical potential, and the concentration of aggressive species such as chloride and sulphate. Thus, Westinghouse has chosen materials such as Alloy 690 and ZIRLO with proven performance in PWR chemistry environments.

The primary system materials of construction that come into contact with reactor coolant include Alloy 690 and austenitic stainless steels. Alloy 690 has been selected, in part, due to its low general oxidation rate in PWR primary coolant conditions as compared with previous-generation high-nickel alloys, such as Alloy 600. The SG tubing is made of Alloy 690, which is the largest application of this material in the AP1000 plant. In addition, the AP1000 pressure vessel steel is clad with austenitic stainless steel on its inner (wetted) face to provide a corrosion-resistant barrier. This is more effective than an unclad vessel since stainless steels form a relatively protective surface oxide in HT water. Also, RCS pressure boundary materials, as noted in Section 21.5.9.1, are made of materials that have demonstrated resistance to oxidation in AP1000 plant primary water chemistry.

In addition to Alloy 690 and stainless steels, zirconium alloys are used in the primary system as cladding for the fuel. Oxidation of zirconium alloys can depend on the alloy microstructure and distribution of minor alloying elements. Fuel cladding oxidation rates are related to the temperature of the metal-oxide interface. When a surface oxide layer accumulates on the zirconium alloy surface, it imposes an additional barrier to the conduction of heat through the clad (i.e., it has a partially insulating effect). As a result, a thickening surface oxide results in a steadily increasing interface temperature and an accelerating corrosion rate at the interface so that the corrosion rate increases throughout the fuel life. An additional exacerbating effect is the deposition of corrosion products (crud) from other parts of the primary circuit. This takes the form of nickel ferrites, nickel oxide, and nickel metal. A further concern is that hydrogen produced by the corrosion reaction can penetrate the zirconium alloy and cause embrittlement of the material.

ZIRLO is used as the fuel cladding material in the AP1000 plant. ZIRLO has been developed by Westinghouse to replace the formerly used Zircaloy-4 alloy. While ZIRLO has been demonstrated to have mechanical properties comparable with Zircaloy-4 (Reference 21.15), both operational experience in the North Anna PWR and trials in the BR-3 test reactor have demonstrated that the levels of oxidation are considerably lower for ZIRLO as compared with Zircaloy-4 (Reference 21.15).

The lower oxidation of ZIRLO mitigates the potential of excessive thinning of the clad wall or exceeding the thermal limits of the ZIRLO cladding. Furthermore, results have indicated that ZIRLO and Zircaloy-4 have comparable hydrogen pickup at an equivalent level of oxidation; therefore, the potential for hydrogen inventory impairing the mechanical performance of the cladding will be mitigated by the lower levels of oxidation for ZIRLO.

During transitions between normal operation and shutdown conditions, the AP1000 plant water chemistry is controlled to ensure that proper redox conditions of the reactor coolant are maintained. For full-power operations, the reactor water is maintained at alkaline-reducing conditions. During shutdown, the reactor water chemistry transitions from alkaline-reducing to acid-reducing and then to acid-oxidising chemistry conditions. During startup, the reactor water chemistry is returned to acid-reducing and then to alkaline-reducing to resume full-power operation. This general control strategy has a proven history in the industry and improves plant performance and reliability by reducing the formation of particulate corrosion products from general corrosion of austenitic stainless steels and Alloy 690. The AP1000 plant has included this proven chemistry strategy to obtain the same plant performance and reliability. Additional details on overall chemistry operations are provided in Section 21.8.

The EPRI guidelines (Reference 21.2), which generally provide input to the primary water chemistry control programme for the AP1000 plant (Reference 21.5), also consider the chemistry to control the oxidation of zirconium alloys, including ZIRLO. First, a maximum lithium concentration (as determined by the fuel vendor) is imposed by the EPRI guidelines for input to Reference 21.5; additional information on lithium limits is provided in Section 21.5.9.3. These guidelines impose and ensure a reducing chemistry around the primary circuit that facilitates the effective performance of ZIRLO in terms of levels of oxidation and associated hydrogen pickup.

Pitting and Crevice Corrosion

Pitting and crevice corrosion are a common, localised corrosion mechanism of stainless steels that rely on a thin protective oxide layer for their corrosion resistance. Disruption of this layer by aggressive chemical species such as chloride ions, leads to local activation and self-propagating local attack, which can result in pitting or crevice corrosion. The attack is initiated in solutions containing contaminant species such as chloride and sulphate in oxidising conditions. At ambient temperatures, relatively high concentrations of these species (>100 ppm) are required for pitting or crevice corrosion to occur. Attack occurs more readily at higher temperatures with low pH conditions at low electrochemical potential (ECP) than in PWR primary coolant. To mitigate pitting and crevice corrosion of stainless steels, the AP1000 plant chemistry is controlled to much lower impurity levels and at an alkaline pH during full-power operation, compared to that required during shutdown.

Stress Corrosion Cracking

SCC is a notable form of localised corrosion and can lead to premature failure of engineered components, often leading to leaks. A variety of factors are involved, but SCC only occurs given certain combinations of material, stress, and chemical environment. PWR materials of construction, such as Alloy 600, have previously experienced SCC. Therefore, the potential for SCC to occur has been extensively studied in stainless steels and nickel alloys in a variety of environments, including light water reactor (LWR) primary coolants (Reference 21.17). In addition, SCC in zirconium alloys has also been studied in LWR primary coolants. The selection of AP1000 plant primary system materials, such as Alloy 690, stainless steels, and

zirconium alloys, as well as the development of AP1000 plant primary water chemistry requirements have applied this operating experience and testing results.

The AP1000 plant primary coolant chemistry specification is designed to minimise the risk of SCC of primary circuit materials by controlling levels of contaminants, oxygen, hydrogen, $pH_{T,}$ and electrochemical potential in accordance with the recommendations of the EPRI guidelines (Reference 21.2). During full-power operations, the chemistry of the primary coolant is maintained at alkaline-reducing conditions with a low levels of impurities, particularly fluoride, chloride, and sulphate, to mitigate the occurrence of SCC. Combined with the selection of resistant materials and correct manufacturing processes, this design implements a mitigation strategy based on the best industry-wide understanding of PWSCC. A brief discussion follows on the impact of metallurgical properties, interaction with the chemical environment, fabrication methods, and design. Further details of PWSCC mitigation measures involving materials and construction methods are given in Section 21.10.

Alloy 690

The AP1000 plant has benefited from the study of SCC in Alloy 600 and the subsequent development of Alloy 690, which is more resistant to SCC than Alloy 600. Analysis of data from a range of laboratory test programmes on SCC of cold-worked Alloy 600 exposed to simulated PWR primary coolant indicated that the dominant factors were more frequently material and stress rather than chemistry effects (Reference 21.18). Laboratory CGR testing has demonstrated that SCC also occurs in cold-worked Alloy 690 materials; however, most Alloy 690 materials appear to be highly resistant (Reference 21.17), and CGRs are substantially lower than the most susceptible heats of Alloy 600. SCC of Alloy 690 has been observed on cold-worked material when stressed in susceptible orientations, including TT heats. It should be emphasised that all the information to date on PWSCC of thick-walled Alloy 690 relates only to laboratory tests for crack growth in heavily and unidirectionally cold-worked material. The mechanism by which this sometimes induces susceptibility is the subject of both research and speculation but is presently unclear. The Alloy 690 weld metals (Alloys 152 and 52) are also being studied but are currently thought to be highly resistant to the effect of simulated primary water (or other HT water and steam environments) on crack growth, even from pre-existing defects. Finally, no evidence has yet been obtained of crack initiation occurring through PWSCC in Alloys 690, 152, and 52, either in laboratory testing or in nearly 20 years of operation in the field under primary water conditions; therefore, Alloy 690 has been chosen for the AP1000 plant.

Austenitic Stainless Steels

Austenitic stainless steel, another material of construction in the AP1000 plant primary circuit, has been previously linked to SCC in other PWR primary circuits. The industry then studied SCC in stainless steels and determined a number of factors, including material manufacturing methods and environmental conditions that influence SCC. For example, cold work has also been shown to increase the susceptibility of stainless steels to SCC. Also, particular forms of SCC in austenitic stainless steels have been associated with specific environmental conditions. Environmental conditions for SCC have been defined in a number of studies (Reference 21.19), and electrochemical potential, pH, and impurities (chloride and sulphate, notably), are all known to influence susceptibility to SCC.

The combined effect of environmental conditions (oxygen and chloride concentration) on the susceptibility of stainless steels to SCC in various metallurgical conditions has been examined and is shown in Figure 21-3. In deoxygenated HT good-quality PWR primary

water at low potential, IGSCC of nonsensitised stainless steels is not generally thought to occur. Transgranular SCC (TGSCC) of solution-annealed stainless steel is most common in the presence of chloride, although some degree of oxygenation is required.

Also, many cases of SCC of stainless steels in operating plants have been attributed to the development of local aggressive conditions. Occluded regions of the plant where exchange with the bulk primary coolant is low can retain oxygen or contaminants such as chloride following startup. This leads to an HT environment that is not representative of the majority of the primary circuit: it is mainly within such local environments that SCC occurs.

In recent years, increasing attention has been directed to the possible SCC susceptibility of cold-worked stainless steels under normal chemistry conditions in the primary circuit. In a 2007 EPRI presentation (Reference 21.20), around 140 events of stainless steel field cracking were described in a variety of PWR components. Of these, about 15 percent were ascribed to the effects of cold work (leading to hardness > 300 HV) during exposure to flowing primary water without contaminants (Figure 21-4). None of these were associated with thermal sensitisation, although the observed SCC was predominantly intergranular.

In addition to environmental interactions, cold-worked areas of nonsensitised austenitic stainless-steel components (e.g., pressuriser heater sleeves) in French PWRs have experienced a limited of number of cases of IGSCC, and widespread research into this topic is ongoing in France (References 21.20, 21.21, and 21.22). In general, the material condition and the loading parameters have been found to control cracking susceptibility, with the exact primary water chemistry, at most, a secondary factor (Reference 21.23). A higher propensity to cracking was noted, however, in an unusually high pH environment representing the conditions that might arise following actual leakage through a pressuriser heater sleeve.

Thus, for stainless steels, IGSCC in the AP1000 plant is mitigated by the use of low-carbon materials and control of welding procedures (see Section 21.5.9.1) to eliminate the risk of sensitisation. Maintaining low oxygen and halogen concentrations effectively mitigates IGSCC in sensitised stainless steels and this, combined with control of manufacturing procedures to minimise cold work, also helps to minimise the risk of TGSCC.

Fuel Cladding

With respect to fuel and clad chemical interaction, it is postulated that the fission product iodine is the corrosive agent for SCC. Out-of-pile tests have shown that in the presence of high clad tensile stresses, large concentrations of iodine can chemically attack the ZIRLO tubing and may lead to eventual clad cracking by pellet-clad interaction (PCI) SCC. Extensive post-irradiation examination has produced no evidence that this mechanism has been operative in Westinghouse commercial PWR fuel. A Westinghouse model (see Section 22.4) has been developed to evaluate the risk of PCI and has been applied to ZIRLO clad fuel for the AP1000 plant. The model is based on data from the Westinghouse performance and analysis design (PAD) model (Reference 21.16) and power ramp test results using ZIRLO rodlets irradiated in Vandellos II and Belleville reactors. The model predicts a comfortable margin for PCI at the end of a fuel cycle.

AP1000 Design Features

In addition to chemistry control and material selection, improved design concepts in the AP1000 plant have reduced the susceptibility of components to SCC. A number of cases of SCC related to canopy seal welds have been reported. The CRDM lower canopy seal weld is eliminated in the AP1000 plant, and there are no spare penetrations with threaded and canopy seal-welded head adapter plugs and capped latch housing joints. A single-piece forging is used for the "hot leg with side nozzles" (and for the cold legs) to eliminate welds and in-service inspections. Also, the AP1000 plant reactor vessel head uses cold leg cooling to reduce the temperature of the head. The lower temperature of the materials in the head in turn reduces the susceptibility of SCC in the reactor vessel head.

Another design feature of the AP1000 plant that mitigates SCC is the addition of zinc acetate to the primary coolant. Laboratory data and plant operating experience related to Alloy 600 PWSCC mitigation with zinc are well documented (Reference 21.37). Benefits have been demonstrated even in plants with low zinc concentrations (e.g., 5 ppb). Although there has been no evidence of cracking of Alloy 690TT in operating PWRs to date, zinc injection is still expected to be beneficial in reducing the susceptibility of AP1000 plant materials to SCC.

Corrosion of Low-Alloy Steels due to Primary Coolant Leakage

A particular concern in PWRs arises from the leakage of borated primary coolant from joints such as gasketed flanges and its impingement on carbon and LAS components (e.g., flange studs). Solid boric acid at room temperature and dilute, deaerated boric acid solutions regardless of temperature have little effect on carbon steels and LASs; but as the boric acid concentrates, corrosion rates of up to about 1 mm per year (1 mm/a) may be reached. Aerated solutions can be much more aggressive, with the attack increasing with acid concentration. Note that as hot coolant escapes to the environment, its boric acid content (which may be nominally 2000 ppm or more as elemental boron) concentrates by evaporation. At temperatures near 100°C (212°F), which are attained by surfaces impacted by coolant flashing to steam, corrosion rates can reach approximately 250 mm/a (Reference 21.24).

In some situations, flow effects can exacerbate the attack: e.g., they are implicated in the corrosion of PWR pressure-vessel steel by borated coolant leaking through cracked penetrations in the RPV head (Reference 21.25). At the Davis Besse PWR in 2002, such corrosion had threatened the integrity of the vessel. The sequence of events that can lead to cavity formation next to a nozzle was postulated to consist of three phases: initially, slow seepage of coolant into the external annulus (crevice) in the head would be accompanied by low corrosion rates; next, when the crevice had opened enough and the crack had lengthened to give substantial leak rates, an evaporating coolant jet would accelerate the attack through flow effects; finally, leakage into a cavity would create a turbulent evaporating pool, extending the attack sideways.

An extensive testing programme sponsored by EPRI is investigating the phases of boric acid attack at Davis Besse and its implications for possible leakage at either top or bottom RPV heads in other PWRs. The second phase, which experienced substantial flow effects, was simulated with laboratory experiments in which a flashing jet of borated coolant was directed onto a heated sample of pressure-vessel steel and the damage assessed in terms of system parameters, notably, coolant chemistry and flow rate (Reference 21.26). Volumetric (or massive) metal loss was correlated with volumetric coolant flow and seemed to behave differently from metal penetration, which was correlated with jet velocity.

The miniature scallops in the damage craters that formed around (but some distance away from) the points of jet impact provided indications of flow-assisted corrosion (FAC). Metal loss rates attained about 3 cc/a at a flow rate of 200 mL/min with a boric acid concentration equivalent to 1500 ppm (B) and $pH_{300°C}$ of 6.9 adjusted with lithium; the rate depended on the volumetric flow in the jet raised to the power 0.84. Under the same chemistry conditions, the penetration rate reached 200 mm/a at a jet velocity of 140 m/s and the two were correlated via the velocity raised to the power 4.3. It was notable that neither $pH_{300°C}$ nor the boron concentration was the controlling chemistry parameter; rather, it was the ratio of (B)/(Li) (Figure 21-6).

Leakage at RPV head penetrations is not expected for the AP1000 plant, owing to better materials and improved design, so the above mentioned chemistry effects are unlikely to play any direct role with regard to ensuring component structural integrity. They illustrate, however, the complexity of assessing the aggressiveness of concentrated primary coolant toward carbon and LASs if it were to escape from the circuit.

21.5.9.3 Environmental Factors Influencing Degradation

It is necessary to consider several parameters of the solution chemistry to assess whether environmentally assisted cracking or other corrosion mechanisms are likely to occur. These parameters include the following:

- pH
- Electrochemical potential
- Contaminant species, such as chlorides, fluorides, and sulphates
- Dissolved hydrogen
- Boron
- Lithium
- Zinc
- Temperature

Some of these parameters, such as contaminants, are controlled to ALARP. Other chemicals, such as dissolved hydrogen, boron, lithium, and zinc are added to the coolant to control the environmental conditions that influence corrosion. The pH and electrochemical potential are directly influenced by the control of these chemical parameters. Also, system temperature, which is largely independent of the above variables, impacts corrosion rates but is determined by plant operations. The impact of each of these parameters on corrosion is discussed below.

Effect of pH

In general terms, an alkaline pH environment promotes passivation and low general corrosion rates as well as reduced incidence of localised corrosion in a variety of steels and nickel alloys in aqueous environments. In PWRs, the target pH_T control is generally achieved by coordinating the concentration of lithium with the required boron concentration for reactivity control and within the constraints of the maximum acceptable lithium concentration.

Westinghouse guidelines recommend operating to an elevated pH_T to control the development of CIPS and CILC, within a maximum lithium concentration of [ ] ppm (Reference 21.6). The upper limit of the lithium concentration is determined based on the corrosion resistance of ZIRLO. pH_T has a strong effect on crud deposition on fuel, which subsequently affects fuel cladding corrosion.

Crud buildup on fuel cladding is greater at lower pH_T but higher cladding corrosion rates can occur at higher pH where subcooled boiling occurs. The Westinghouse supplement (Reference 21.6) suggests a pH at temperature (core average temperature, pH_T) of greater than [ ] to limit corrosion and crud buildup. More recently, target pH_T values of up to 7.4 have been adopted. Corrosion rates for both stainless steels and nickel alloys are known to decrease as the pH_T is raised from [ ] (Reference 21.29). This reduces crud release rates and there has been an increasing trend of operating PWR plants at elevated pH_T, up to pH_T [ ] (Reference 21.6).

In addition to general corrosion rates, pH also affects SCC. In austenitic stainless steels, alkaline pH also lowers the incidence of SCC initiation (Reference 21.27). Figure 21-7 shows the results of susceptibility tests on sensitised Type 304 stainless steel at constant load in aerated sodium sulphate solutions at 300°C (572°F). The minimum electrochemical potential for SCC susceptibility was similar over the $pH_{300°C}$ range 2 to 5.6. SCC was also noted at higher pH although the mechanism was different (Reference 21.19). Constant extension rate tests (CERTs) of sensitised Type 304 stainless-steel samples in solutions using a variety of pH buffers (which have the effect of limiting the variation of pH) indicated that crack initiation was suppressed at a pH of greater than 7 (Reference 21.28). This work was conducted at low temperature, but the effect could be assumed to apply under PWR conditions; although as the pH neutral point changes with temperature, the broad pH effects may be the same. A study of CGRs using sensitised Type 304 in oxygenated NaOH solutions at pH 5.6 to 10 (Reference 21.27) found a tenfold reduction in CGR at pH 9 (Figure 21-8). A further study concluded that pH_T over the range of 5.7 to 7.8 had no significant effect on CGRs of Alloy 600, Inconel™ X-750, or cold-worked Type 304 stainless steel tested under PWR conditions (Reference 21.2). Additional details on SCC are provided in Section 21.5.9.2.

Therefore, the AP1000 plant water chemistry maintains an alkaline pH_T of [ ] during operation (Reference 21.6). The alkaline pH_T reduces the amount of general corrosion that occurs and mitigates the probability of SCC occurring. Additional details on PWR pH control strategies are available in EPRI PWR Primary Water Chemistry Guidelines (Reference 21.2).

Electrochemical Potential

The ECP has been shown in laboratory studies to strongly influence the susceptibility of stainless steels to SCC. If the ECP is reduced below a critical value, IGSCC does not occur; however, the value of the critical potential is influenced by material and environmental factors, including sensitisation, temperature, and concentrations of contaminant species such as chloride or sulphate ions. The threshold potential for TGSCC of solution-annealed stainless steels in deaerated solutions is more positive than that for IGSCC of sensitised material. That is, for plants such as PWRs that normally operate at low ECP, slow rises in the ECP due to fault conditions could induce IGSCC degradation before TGSCC degradation.

It has been shown that there is equivalence between oxygen content in HT water and applied ECP in deaerated water in slow strain rate tensile (SSRT) tests. Low concentrations of oxygen have a great influence on ECP because of the change in cathodic reaction from water reduction to oxygen reduction. The presence of small amounts of oxygen in water can significantly increase general and localised corrosion rates (Figure 21-7). SCC susceptibility of stainless steels and nickel alloys increases rapidly with increasing oxygen concentration, especially in the presence of contaminants such as chloride and sulphate.

Increased general corrosion can lead to higher crud levels and circuit activity. Hydrogen added to the primary coolant reduces the ECP, removes oxygen generated in the core, and eliminates oxygen introduced via makeup water.

Contaminant Species

A number of chemical species are known to influence corrosion of primary circuit materials. Fluoride, chloride, and sulphate are directly associated with the degradation of primary circuit materials and have been designated as control parameters, which require corrective actions if control limits are exceeded. Aluminium, calcium, magnesium, and silica are not directly associated with degradation of primary circuit materials and are designated as diagnostic parameters. The AP1000 plant controls the impact of these contaminant species by limiting their concentration in the primary circuit through the application of the AP1000 Chemistry Manual, EPRI Guidelines, and the Westinghouse supplemental guidelines (References 21.5, 21.2, and 21.6); however, a brief introduction on the basis for control is provided.

Fluoride, chloride, and sulphate have a demonstrated direct impact on the degradation of primary circuit materials. Chloride can induce SCC of stainless steels in oxygenated conditions and can enhance localised corrosion at higher concentrations. Sulphate can also accelerate localised corrosion and is known to influence initiation of SCC under deoxygenated conditions. SCC of Alloy 600 at two plants was attributed to the presence of reduced sulphur species; IGA of sensitised Alloy 600 was related to ingress of large amounts of ion exchange resin, which gave rise to high sulphate concentrations (greater than 20 ppm). The effect of fluoride is less well understood but is known to influence SCC of Alloy 600 and the corrosion of zirconium. The work of Whyte and Picone (Reference 21.33), however, indicated that sensitised stainless steels were susceptible to fluoride-induced SCC but only at concentrations of at least 10 ppm. No SCC was found where boric acid was present in the test environment. Therefore, the concentrations of chloride, sulphate, and fluoride anions in the AP1000 plant primary coolant are controlled to levels that have proven material performance in the field (References 21.2 and 21.6).

Aluminium, calcium, and magnesium can form oxides and silicates in the primary coolant. As the solubilities of these salts have a negative temperature coefficient (i.e., solubility decreases as the temperature is increased), it is expected that they could deposit on fuel cladding and possibly lead to enhanced corrosion. Zeolite minerals in particular could cause densification of crud deposits.

In many current operating PWRs, silica is present in the spent fuel pool (SFP) water in relatively high concentrations because of the use of Boraflex in the fuel racks and can enter the primary coolant during refuelling operations or from recycled boric acid. Silica solubility is relatively high in primary coolant conditions and deposits are unlikely. It is possible, however, that high concentrations of silica will precipitate low concentrations of zeolites with aluminium, calcium, or magnesium. Thermodynamic calculations suggest that calcium and magnesium borates will precipitate preferentially over silicates except when boric acid concentrations are low at the end of cycle, so that is unlikely to present a real problem. In practice, aluminium, magnesium, and calcium are controlled at low levels, and plants operating with high silica levels (greater than 1 ppm) have reported no problems. Crud deposit analyses have revealed silicon contents of 2 to 5 percent but low levels of zeolite-forming elements. EPRI guidelines (Reference 21.2) recommend minimising silica ingress and maintaining a control level related to aluminium, magnesium, and calcium concentrations. Westinghouse supplemental guidelines (Reference 21.6) specify limits for these contaminants. The AP1000 design does not use Boraflex fuel racking or boron

recycling, so silica contamination of the primary coolant is expected to be below the 1-ppm limit.

Dissolved Hydrogen

Hydrogen is added to the primary circuit in the AP1000 plant as well as other PWRs to maintain reducing conditions (low ECP). The low potential reduces oxidation rates and reduces the incidence of SCC of stainless steels and nickel alloys. Specifically, dissolved hydrogen reacts with any dissolved oxygen to form water, as shown below.

$$2H_2 + O_2 \leftrightarrow 2H_2O$$

To ensure that the low potential is maintained, the hydrogen concentration is maintained from 25 to 50 cc/kg H_2O to ensure that any oxygen that might be introduced into the primary circuit reacts with hydrogen to form water. Also, the hydrogen residual ensures that the radiolytic decomposition of water does not favour the production of oxygen. While benefit is achieved by adding hydrogen to maintain reducing conditions in the primary circuit to reduce both general oxidation and localised corrosion in the AP1000 primary circuit, the potential impact of hydrogen on primary circuit materials of construction is discussed briefly.

While Alloy 600 has ostensibly been replaced by Alloy 690 in the AP1000 plant, previous experimental work on Alloy 600 is provided to allow for comparison with Alloy 690. Experimental work suggested that higher hydrogen concentrations increased the susceptibility of mill-annealed (MA) Alloy 600 to SCC in HT water; however, CGR tests on Alloy 600 specimens, in which the hydrogen fugacity was changed in steps from 20 through 40 to 80 cc/kg H_2O (Reference 21.30), showed a slight reduction in CGR at higher hydrogen concentrations. Tests on Alloy 182 weld material indicated a clear reduction in CGR at higher hydrogen levels.

Studies of PWSCC carried out at General Electric-Global Research Center (GE-GRC) as part of the EPRI MRP investigated CGRs of Alloy 600 and 182/82 weld metals under good-quality PWR coolant conditions. A peak rate was identified at ECPs equivalent to the Ni/NiO transition potential, which is close to the H_2/H_2O transition potential. In practice, the corrosion potential in deaerated water is controlled by the hydrogen activity, which can be used to drive the potential either above or below the Ni/NiO potential. Operating at hydrogen activities away from the Ni/NiO boundary will minimise CGRs. In theory, the CGR, relative to the peak rate at the Ni/NiO potential, could be reduced by a factor of as much as 16 for Alloy 82/182 weld materials, and up to a factor of three for Alloy 600.

This tendency for a hydrogen content at which SCC CGRs peak is seen across a range of temperatures. The hydrogen activity giving a potential corresponding to the Ni/NiO boundary increases with temperature: about 4.2 cc/kg H_2O at 290°C, 10.4 cc/kg H_2O at 325°C (554°F), and 15.3 cc/kg H_2O at 340°C (644°F). The current operating regime for PWRs (EPRI) targets H_2 at 35 cc/kg H_2O and a range of 25 to 50 cc/kg H_2O. This regime of PWR dissolved hydrogen concentration is above the concentration at which peak SCC CGRs are observed. To give an equivalent CGR, on the low hydrogen side of the peak, to that expected at 35 cc/kg H_2O, would require 7.7 cc/kg H_2O at 343°C (649°F), decreasing with temperature to 0.5 cc/kg H_2O at 290°C (554°F).

This pattern of hydrogen effect appears to be independent of temperature, stress intensity, boron or lithium concentration, or heat of alloy. If very low hydrogen levels were to be used, there would be concerns that radiolytically produced oxygen could locally raise the ECP due

to lack of hydrogen in the water. That, in turn, would raise concerns of increased general corrosion and SCC. The chosen hydrogen content has therefore been specified to avoid localised regions of high potential and to avoid peak susceptibility to SCC.

Also, PWSCC initiation studies of Alloy 600 have shown a minimum initiation rate at a hydrogen concentration of 30 cc/kg H_2O (Reference 21.32). Data from Bettis (Reference 21.17) demonstrated a loss of the mitigation effect of low hydrogen at high stress intensity values, but this was reversed at low stress intensity values.

In comparison, recent CGR tests performed on Alloy 690 materials showed a higher CGR at 50 cc/kg H_2O hydrogen concentration compared with tests at 23 cc/kg H_2O. Also, this work used cold-worked materials previously shown to be highly susceptible (Reference 21.31). Since 1989, when Alloy 690 tubing was used in the first PWR SG, there has not been any reported impact of hydrogen concentration on SCC of Alloy 690. Thus, the amount of cold-working in PWR components has not been significant enough to produce SCC in the field. Since no clear evidence of SCC initiation in Alloy 690 under PWR conditions has been produced, the influence of hydrogen on initiation, if any, is unknown, and work is continuing to determine the mechanism of possible SCC of Alloy 690. Thus both laboratory data and operational experience to date have not shown any apparent impact on SCC of Alloy 690 from dissolved hydrogen in primary circuit environments.

However, there is currently much debate regarding the optimum hydrogen concentrations in PWR primary coolant, mostly centred on the susceptibility of nickel alloys to SCC. Most of the existing data have been generated using Alloy 600, and the CGR data support a rise in hydrogen concentration. There is an argument for extrapolating this finding to other nickel alloys, such as Alloy 690. Some Alloy 690 test data appear to contradict the trend for Alloy 600 but work is still ongoing. Also, EPRI is considering increasing the existing range for hydrogen concentration specified in the existing guidelines (Reference 21.2). The specification of hydrogen concentration in the AP1000 plant (Reference 21.5) agrees with the current EPRI guidelines. Given the impact of hydrogen on Alloy 600 and the laboratory and operational experience of hydrogen concentration on Alloy 690, the current guidelines' value is a reasonable position that ensures that reducing conditions are maintained to minimise general corrosion and localised corrosion mechanisms, such as SCC and pitting, and also minimises any other potential detrimental impacts from hydrogen (Reference 21.2).

SCC performance of Alloy 690 and its weld materials is discussed in more detail in Section 21.5.9.2.

Boron

Andresen studied the effect of boron on CGRs of Alloy 600 in PWR water and found no effect (Reference 21.30). An EPRI-sponsored study of the effects of various chemistry parameters on CGRs of Alloy 600 nickel alloy concluded that boric acid at concentrations from 60 to 3200 ppm had no significant effect on CGRs (Reference 21.34). This is expected to hold true for the Alloy 690 used in the AP1000 plant as well.

Also, boric acid could potentially attack the RPV mild steel where primary coolant leaks onto the outer surface of the vessel and evaporates. Boric acid attack of mild steel surfaces is not expected in the AP1000 plant and is discussed in detail in Section 21.5.9.2.

Lithium

Lithium is added to the primary circuit to increase the pH_T and establish alkaline conditions, which reduces the rate of general corrosion and localised corrosion mechanisms, such as SCC; it is discussed in Section 21.5.9.2. While the concentration of lithium must be balanced with the boric acid concentration required for reactivity control, lithium addition for the AP1000 plant is limited to a maximum concentration of [ ] ppm. However, lithium concentration itself may impact primary circuit materials and is controlled within the AP1000 plant to minimise any potential unfavourable impacts.

A number of studies (Reference 21.36) have looked at the effect of lithium concentration on the initiation rate of PWSCC in Alloy 600. Tests of reversed u-bend samples of MA and TT Alloy 600 in primary coolant containing from 2 to 6.5 ppm lithium suggested a minimum propensity for PWSCC at 3.5 ppm lithium. The pH_T varied, however, with lithium concentration from 6.9 to 7.4 and the minimum initiation rate corresponded to a pH of 7.1. Statistical analysis of other data has indicated a tendency for increased initiation rate with increasing lithium concentration but the effect is considered to be small. Also, Andresen studied the effect of lithium on CGRs of Alloy 600 in simulated PWR primary coolant and found nothing significant (Reference 21.34).Early studies of the effect of lithium on CGRs of Alloy 600 specimens, monitored by direct current potential difference (DCPD), showed some increase in SCC propagation rates with increased lithium concentration. A further study showed an inconsistent relationship between CGRs and lithium. Recent DCPD testing of an Alloy 600 fracture mechanics specimen, in which the lithium concentration was reduced in a single step from 4.3 to 2.2 ppm and with the CGR continually monitored during the period, showed no effect on CGR, although pH_T and conductivity changed (Reference 21.30).

Moreover, plant experience up to 2003, during which lithium concentrations were increased from 2.2 to 3.5 ppm, showed no detectable increase in PWSCC occurrence in either Alloy 600 or 690 SG tubes. Similarly, no effect on PWSCC of Alloy 690 is expected. Therefore, based on both experimental and operational experience of both Alloys 600 and 690, the application of lithium in the design of the AP1000 plant is within industry experience and has been demonstrated to have a small, acceptable effect on the SCC of Alloys 600 and 690.

Zirconium alloys used for fuel cladding have also been evaluated. Experimental work has shown that elevated lithium concentrations can lead to higher corrosion rates on zirconium alloys. Tests indicated a two- to six fold increase at 70 ppm lithium and a smaller but measurable effect at 7 ppm. Local subcooled boiling in crevices could produce high local concentrations of LiOH, giving high corrosion rates. Analysis of cladding oxide thicknesses from plants employing coordinated chemistry (2.2 ppm lithium) with others using enhanced lithium chemistry (up to 3.5 ppm) suggest that the oxide thickness is increased in the latter case by 10 to 15 percent. Loop tests using electrically heated rods showed little effect of 10 ppm lithium on Zircaloy with a thin oxide but enhancement of up to two times at very high oxide void fractions; however, the effect has been shown to be reduced in the presence of high concentrations of boric acid. As the lithium concentration in PWRs is related to that of boric acid, the practical influence of lithium on cladding corrosion may be small and only significant where a large degree of subcooled boiling or boiling within pores occurs. The AP1000 design is aimed at avoiding departure from nucleate boiling and minimising crud production, which will mitigate this possibility.

Zinc

Zinc can be incorporated into primary circuit oxides on stainless steels and nickel alloys. Oxides of these materials grown in the presence of zinc in the primary coolant grow more slowly and tend to be thinner than they would be in the absence of zinc dosing and have been associated with reduced rates of corrosion in austenitic stainless steels and in Alloy 600. Zinc has also been shown to reduce the risk of initiation of SCC in Alloy 600 (Reference 21.37). Additional details on zinc addition are available in Sections 21.5.5.4 and 21.5.9.2.

Temperature

Temperature affects both general oxidation and susceptibility to the probability of SCC occurring. Increasing temperature has been shown to increase SCC CGRs of cold-worked Alloys 600 and 690 but the temperature dependence appears to be stronger in the former case.

Figure 21-9 shows the relationship among SCC of stainless steels, potential, and temperature (Reference 21.35).

21.5.10 Chemistry Controls for the Minimisation of Primary Circuit Activity

21.5.10.1 Safety Requirements

Deposition of activated material on out-of-core surfaces leads to increasing circuit radioactivity and consequently higher dose rates for operators. Primary coolant chemistry is controlled to minimise the production, mobilisation, and deposition of activated material and thus minimise primary circuit activity. While details of the various chemistry parameters controlled on the primary side are provided in Section 21.5.5, the chemistry controls for the minimisation of primary circuit activity are discussed in the following subsections. See Section 21.5.6 for information on AP1000 plant design features that aid in controlling the buildup of primary circuit activity.

21.5.10.2 Technical Basis

Primary circuit radioactivity is produced from a combination of fission products leaking from fuel, tramp uranium impurities on the cladding, activated coolant additives (boron and lithium), activated impurities (e.g., nitrogen), and structural materials that have become activated. Materials exposed to core radiation fields become activated over time and form a number of radionuclides. Much of this material will be generated and remain on the reactor core. Corrosion processes generate species that can be transported in the primary coolant. Where these are generated within the core, they will include radionuclides that can then be transported to and deposit on other parts of the primary circuit. In addition, material generated out of core can be deposited in the core, become activated, and then be transferred to other parts of the circuit. Over time, an inventory of deposited active material crud builds up in the primary circuit and increases radioactivity throughout the system, contributing to operator dose during maintenance and refuelling activities. In addition, local crud deposits on the fuel may increase the cladding corrosion (CILC), potentially resulting in fuel rod failure. Excessive crud deposition on the fuel may also increase the risk for CIPS (see Section 21.5.4.2).

In primary coolant, nickel alloys and stainless steels oxidise at a low rate. The nickel alloys form a surface layer comprising a nickel/iron/chromium spinel. Stainless steels form a protective chromium-rich oxide. An outer crud layer, largely consisting of nickel ferrite, is formed from material crystallising from solution and the base material. Analysis of SG tubing primary-side oxide has revealed that the crud layer consists mostly of nickel ferrite ($NiFe_2O_4$) and nickel metal crud deposits on fuel have been analysed as non-stoichiometric nickel ferrites ($Ni_xFe_{3-x}O_4$), nickel oxide, and nickel metal. A small amount of cobalt is also present. In cores experiencing significant boiling, the nickel content of the crud can be elevated and is believed to represent large amounts of nickel oxide. The nickel can be activated in the core to ^{58}Co, which contributes a large part of primary circuit activity. Other radionuclides can be incorporated into the crud by substitution into the crystal lattice, including ^{60}Co from activated ^{59}Co.

The production of fuel crud is a function of the release of precursor species by primary circuit material oxidation. This is balanced by removal of these species through deposition in other parts of the circuit and by the purification system in the CVS. Alloy 690 has exhibited a lower oxidation rate than Alloy 600 in tests and this is expected to mitigate crud production in the AP1000 plant primary circuit. The deposited layer on Alloy 600 has been observed to be much thinner than the one on stainless steels; the one on Alloy 690 is less again. Zinc dosing is known to stabilise oxides on primary circuit materials to reduce overall crud production. In addition, zinc will block the deposition of circulating radio cobalt, allowing removal by the CVS and thus reducing the rate of increase in the radionuclide inventory. Zinc treatment is particularly effective if applied in the initial stages of oxide development. Zinc treatment will be applied during HFT of the AP1000 reactor to develop a stable zinc-doped oxide film, and during normal operation.

Operating chemistry, and particularly the environmental changes occurring during startup and shutdown, strongly influences corrosion product transport and inventory as well as activity distribution around the primary circuit. A number of factors, including temperature, oxygen concentration, and pH, can influence crud production through effects on oxidation of primary circuit materials and deposition and dissolution processes. In practical terms, the control of pH has been shown to be particularly important to overall crud production.

21.5.10.3 Method of Control

Oxygen

The production, dissolution, and deposition of crud are sensitive to the oxygen concentration and redox potential. The redox potential is controlled during operation by the hydrogen content of the coolant, and changes in hydrogen content or in-leakage of oxygen can alter crud production and distribution. A number of incidents have been recorded in which oxygen ingress resulted in increased crud deposits and reactor problems. In the AP1000 plant, the demineralised water system supplies the primary makeup water that is deoxygenated to ≤100 ppb so that oxygen ingress through makeup source is minimised. Maintaining a relatively low concentration of hydrogen (1 to 5 cc/kg H_2O) is sufficient to suppress radiolytically produced oxidising species from the core and the AP1000 plant chemistry specification calls for hydrogen concentration to be in the range of 25 to 50 cc/kg H_2O at power.

pH

Operating pH_T can significantly influence primary circuit crud production. Oxidation of primary circuit materials is pH-sensitive with lower corrosion rates in more alkaline conditions. Consistent with EPRI recommendations, Westinghouse requirements call for a pH_T of at least [ ] during operation at power (References 21.5 and 21.6). The AP1000 plant is designed to be operated to EPRI guidelines within a maximum lithium concentration of [ ] ppm required by Westinghouse as the fuel vendor (Reference 21.6).

Zinc

Addition of zinc to the primary coolant reduces oxidation rates of primary circuit materials, which reduces overall crud production and therefore the source term for activation of corrosion products. In addition, the incorporation of zinc in the oxide film inhibits the deposition of activated corrosion products on RCS surfaces, hence reducing radioactivity. Zinc addition is being increasingly used in PWRs throughout the world to mitigate buildup of active crud in reactors and radiation exposure to operators. Zinc will be added (as zinc acetate) to the primary coolant of the AP1000 plant at a target concentration of [ ] ppb, during power operation. The use of depleted zinc is recommended to maintain dose rates ALARP. Treatment with zinc from initial exposure to coolant at elevated temperatures, in this case during HFT, results in relatively thin oxide layers and gives the greatest benefit in terms of overall reduction of crud. While some mature plants have experienced elevated levels of radio cobalt in the coolant upon initiation of zinc injection due to the presence of oxide radio cobalt, this situation does not apply to the AP1000 plant since zinc addition will be initiated from the very beginning of the plant life.

Shutdown Operations

Chemistry control during shutdown is particularly important for reducing overall primary circuit activity and radiation exposure during an outage, and avoiding problems such as crud bursts. Westinghouse recommends the adoption of an appropriate strategy during shutdown in accordance with EPRI guidelines (Reference 21.2) and Westinghouse supplemental guidelines (Reference 21.6). Based on operating experience in cases where early reduction of pH_T prior to an outage resulted in high crud levels, EPRI recommends that a minimum coolant pH_T be maintained while at operating temperature. Although EPRI permits reduction to below this minimum pH during the 24 hours before shutdown, Westinghouse does not endorse or recommend this practice.

Shutdown chemistry is controlled to minimise radiation fields during the outage so far as is reasonably practicable (SFAIRP) by preventing particulate release and optimising corrosion product removal and cleanup. This is achieved by maintaining reducing conditions as the plant cools down and the coolant becomes more acidic. Oxidising conditions are then created in a controlled manner by introducing hydrogen peroxide, which dissolves nickel and cobalt, allowing for their effective removal by CVS purification. See Section 21.8.5 for additional recommendations on shutdown chemistry control.

21.5.11 Primary Chemistry As Low As Reasonably Practicable Goals

The design of the AP1000 plant has been optimised to ensure the safety of the primary circuit. Primary chemistry is controlled to control the reactivity of the core, ensure the integrity of primary fuel cladding and primary circuit materials, and minimise the radioactivity around the primary circuit. This is consistent with the safety claims made for the primary circuit chemistry as a whole, given in Section 21.5. The specific chemistry controls that ensure that the safety risk for the primary circuit is ALARP are summarised below:

- The injection of zinc from the beginning of plant life will result in corrosion films on primary circuit materials that are more protective, lowering corrosion rates and minimising the risk for PWSCC. This in turn will minimise the deposition of corrosion products on the fuel, resulting in lower risk for CIPS and CILC and significantly reducing primary circuit radioactivity.

- The boron concentration in the primary coolant is maintained according to the reactivity control requirements of the core as appropriate in all operational modes.

- The concentrations of contaminant species are maintained below specified levels that have been shown to minimise the risk of SCC of primary circuit materials and fuel cladding.

- The concentration of hydrogen is designed to achieve good oxygen control and thus low ECP in the primary circuit, while minimising the risk of SCC of structural materials.

- The pH_T is expected to be controlled within EPRI guidelines during power operation to minimise general corrosion and corrosion product deposition on the fuel (Reference 21.2). Within this pH range, the maximum lithium concentration is [ ] ppm to minimise the risk of unacceptable fuel cladding corrosion (Reference 21.6). While pH_T does influence the risk of corrosion failure through its effect on SCC, the impact is small within PWR power operation ranges.

Note also that in many cases, measures directed toward achieving one ALARP goal also serve to minimise the risk in another area. For example, minimising the risk for SCC avoids the need for component repairs that would result in additional worker exposure to radiation fields. Similarly, controls that ensure fuel integrity and minimise crud deposition on the fuel directly affect the radiation sources associated with fission products and corrosion products, thus minimising worker dose. Therefore, the overall strategy above is considered to reduce the risks to fuel and primary circuit integrity and primary circuit radioactivity to levels that are ALARP.

21.6 Secondary Circuit

This section describes the systems used to maintain and monitor the chemical properties of the secondary circuit, as well as the expected operational controls on chemistry parameters and design safety limits.

The following systems are covered:

- Secondary circuit
- Secondary sampling system (SSS)

- Steam generator blowdown system (BDS)

21.6.1 Description of the Secondary Circuit

The secondary circuit removes heat from the primary coolant in the SGs and converts it to electrical power in the turbine generators. The steam generated in the two SGs is supplied to the high pressure (HP) turbine by the main steam system (MSS). After expansion through the HP turbine, the steam passes through the two moisture separator reheaters (MSRs) and is then admitted to the three low-pressure turbines. A portion of the steam is extracted from the HP and low-pressure turbines for seven stages of feedwater heating. Further details of the system are given in Chapter 6 and in the AP1000 Chemistry Manual (Reference 21.5, Chapter 5).

Exhaust steam from the low-pressure turbines is condensed and is partially deaerated in the main condenser. The heat rejected in the main condenser is removed by the circulating water system (CWS). The condensate pumps take suction from the condenser hot well and deliver the condensate through four stages of low-pressure closed feedwater heaters to the fifth stage, open deaerating heater. Condensate then flows to the suction of each feedwater booster pump and is discharged to the suction of each main feedwater pump. The feedwater booster pumps are horizontal, centrifugal pumps located upstream of the main feedwater pumps. Each feedwater booster pump takes suction from the deaerator storage tank and pumps forward to its associated main feedwater pump. An electric motor drives both the booster pump and the main feedwater pump. The booster pump is driven by one end of the motor shaft and the main pump is driven by the other end through a mechanical speed increaser. The booster pump, operating at a lower speed than the main feedwater pump, boosts the pressure of feedwater from the deaerator to meet the net positive suction head requirements of the main feedwater pump. The feedwater pumps discharge the feedwater through two stages of HP feedwater heating to the two SGs.

21.6.2 Functions of the Secondary Circuit

The functions of the secondary circuit are as follows:

- Transfer of heat from the primary circuit
- Production of steam for the turbines
- Disposition of any radioactive material that enters from the primary circuit because of leaks

21.6.3 Secondary Circuit Chemistry Safety Requirements

The safety requirement of secondary circuit chemistry is to control corrosion of secondary circuit materials, control oxygen and contaminant levels in the secondary circuit, and thus maintain the integrity of the secondary circuit and the primary and secondary interface at the SG tubes and support heat removal functionality of the SGs.

The secondary circuit chemistry regime and administrative limits are specified by the plant operator. Westinghouse endorses the adoption of EPRI guidelines and the AP1000 plant is designed to operate safely within them. The AP1000 Chemistry Manual (Reference 21.5, Chapter 5) provides secondary chemistry guidance to operators based on EPRI guidelines (Reference 21.4) and appropriate safety limits for operation of the secondary circuit plant.

These safety limits are summarized in Table 21-6. Any description of secondary chemistry operating parameters or strategies given herein is based on current options discussed in Reference 21.5, Chapter 5.

The secondary chemistry achieves its safety objectives by maintaining an environment compatible with circuit materials, i.e., all-volatile treatment (AVT) alkalinity and low ECP conditions, while minimising the concentrations of contaminant species. This especially relates to halides, sulphate, and low melting-point metals. An AVT chemistry is adopted to minimise the risk of sludge accumulation and hence localised corrosion of SGs and to enhance chemical control in the condenser.

21.6.4 Corrosion Control

Another major function of secondary circuit chemistry is controlling the corrosion of materials exposed to the secondary coolant, including structural components. This section describes the potential mechanisms of corrosion, the principal materials used in the secondary circuit, and the influence of secondary coolant chemistry.

21.6.4.1 Deterioration Mechanisms

Relevant deterioration mechanisms are briefly described in this section together with some simplified statements of the mitigation measures used in the AP1000 plant in each case. Corrosion control is achieved largely through a combination of SG design, materials selection, and chemistry control. Further details of chemical and materials mitigation measures are discussed in Sections 21.6.4.2 and 21.6.4.3.

Many of the material degradation issues of concern in the primary circuit, including SCC, also apply to the secondary side. However, the environment of the secondary circuit operates at lower temperature and much lower pressure than the primary circuit and comprises a two-phase system. Therefore, the secondary circuit is subject to several additional corrosion mechanisms relative to the primary system. Localised boiling flux in flow occluded regions (e.g., crevices) within the SG may concentrate dissolved impurities, resulting in sufficiently high impurity concentration and regions of elevated superheat that result in localised corrosion. In addition, various materials of construction are encountered so that SCC, general corrosion, and FAC are all potential corrosion mechanisms in the secondary circuit. Other deterioration mechanisms such as pitting and wear of SG tubes have been observed in the operating plants.

Oxidation

General corrosion (oxidation) of the pipework, low-alloy components in SGs, and turbine materials does occur because of the higher ECP in the secondary circuit and the presence of considerable amounts of low-alloy and carbon steels. Control of general corrosion is achieved by employing an AVT treatment for chemistry control in the secondary circuit and control of dissolved oxygen.

The AP1000 plant uses AVT chemistry control to create alkaline conditions in combination with a reduced oxygen environment to minimise ECP and thus mitigate the impact of general corrosion. In addition, the conditions established by AVT chemistry control promote the formation of a stable oxide layer on the steel surface, a key factor in minimising the general oxidation of ferrous materials and subsequent deposition of corrosion products on SG surfaces.

Both pH control additives and oxygen scavengers (e.g., hydrazine) are considered a part of AVT chemistry and are added to control the chemistry of both the liquid and two-phase regions of the secondary circuit. The volatility of these feedwater additives allows for simultaneous control in both liquid and two-phase regions from the same additives. For pH control, volatile additives, such as ammonia, amines, or a combination thereof, have been adopted to establish an alkaline environment to reduce the amount of general corrosion without contributing to the impurity concentration in crevices. For oxygen control, the AP1000 design specifies the addition of hydrazine, a volatile oxygen scavenger used as part of the overall AVT chemistry control strategy.

Pitting

Pitting is a form of localised corrosion characterised by the appearance of a cavity in the material and has been observed in the secondary side of operating PWR SGs. An active pit can quickly result in localised through-wall corrosion or provide an initiation site for SCC. Pitting observed on turbine blades and discs has generally been attributed to defects in the materials. Pitting on the SGs is seen on stainless steels exposed to acidic oxidising conditions, particularly in the presence of copper, chlorides, and to a lesser extent, fluorides. Alloy 600MA tubes have also been reported to show evidence of pitting, especially in acid-oxidising conditions in the presence of copper, chloride, or sulphate (Reference 21.4).

Along with the use of advanced alloys, the AP1000 plant mitigates pitting through strict control of chemistry including compliance with EPRI guidance. AVT chemistry is used to maintain alkaline conditions and control of oxygen concentration within the secondary circuit. Also, since chloride and sulphates have been associated with pitting in some PWR applications, vigilance in the control of contaminant levels is required. However, it should be noted that plants with observed pitting on SG tubing correlated with introductions of brackish water or seawater from the cooling system or from copper from the balance of plant components. The AP1000 design has greatly reduced the known culprits of pitting by using titanium condenser tubing, which is has demonstrated less susceptibility to corrosion; and eliminating copper or copper alloy components within the secondary circuit. The AP1000 design along with AVT chemistry coupled with rigorous operational impurity and maintenance foreign material exclusion control of the secondary systems reduces the likelihood of pitting corrosion.

Stress Corrosion Cracking

Many cases of field-related SCC on the secondary side of A600MA SG tubes have been reported and the causes have been extensively investigated. Varieties of environments leading to aggressive SCC degradation of SG tubes have been identified in the laboratory, and testing programmes have been refined to evaluate material performance in both isothermal and heat transfer environments, such as model boiler testing. Identification of aggressive corrosive conditions has facilitated laboratory testing, resulting in qualification of advanced materials for SG tubing.

As repair methodologies progressed beyond tube plugging to include sleeving of degraded SG tubing, advanced materials were used as the sleeve tubing of choice; these were sometimes further tailored to provide resistance to the field-observed SG specific corrosion environment. The most common materials for the >100,000 sleeves installed worldwide were either A600TT or A690TT. A clad tubing material with A625 on the outside diameter (OD) and A690TT on the inside diameter (ID) was also installed into field service (Reference 21.40). The clad tubing was chosen to give pitting resistance on the OD and PWSCC resistance on the ID. Field NDE of the sleeve materials showed good corrosion resistance in general and provided additional service experience for these materials.

The observation of caustic related SCC and intergranular attack (IGA) in the 1980s (Reference 21.41) spurred laboratory development work on SG tubing materials and a very extensive database was developed by Westinghouse and other research and development efforts worldwide. Many extremes of environments involving testing parameters of solution chemistry, deposit chemistry, temperature, stress level, material type and condition, heat transfer, flow conditions, crevice design, and so forth were evaluated. The database grew to such an extensive size and varied quality of information that citing of individual experiments could not be considered representative of the available data.

A reasonable attempt to interpret this large laboratory-based data set involved the creation of improvement factors that allowed the performance of one material tested in an environment to be compared to the result for a different material or material condition tested in the same or a similar environment (Reference 21.42). A600MA became the reference material as the base for comparisons. The overall comparative results for the performance of A690TT versus A600MA overwhelmingly favours A690TT for outside diameter stress corrosion cracking (ODSCC) as well as PWSCC. As an example, caustic environment improvement factors for A690TT compared with A600MA generally range from 2 to >200 based on material considerations alone (Reference 21.43).

Although the laboratory-generated materials improvement factors show benefit, the requirement of producing useful laboratory data in a relatively short exposure time results in laboratory conditions that are generally very aggressive and may be accelerated by using increased temperature, very high stress levels, and/or unusually aggressive chemical environments. These conditions are not likely to be experienced for sustained periods of time in actual operational experience and result in improvement factors that are overly conservative. Therefore, the better measure of field performance is field performance itself and A690TT SG tubing material, which in 2011 has been in commercial SG service for more than two decades, is presently generating an exceptional record.

An extensive evaluation of United States' experience with A690TT SG tubes in commercial PWRs has been compiled and published as a Nuclear Regulatory Commission technical report designation (NUREG) document (Reference 21.44). At the time of data compilation at the end of 2004, A690TT had been in service in replacement SGs since 1989.

The NUREG reports that of the 577,070 A690TT tubes placed in service, no corrosion failures had occurred and only 0.06 percent of the tubes had been removed from service for all other reasons including mechanical wear and pre-service plugging.

A more recent report (Reference 21.45) updates this continuing service exposure, confirming that as of October 2010, service-induced corrosion degradation has not been observed in A690TT SG tubing.

The performance record generated by the operation of A690TT SG tubing continues even under some corrosion-promoting conditions where the SG tubes are being subjected to non-design configurations as a result of denting occurring at the tube sheet region. In a recent SG operating experience summary, it was reported that top of tube sheet (TTS) denting at Almaraz 1 and 2 and at ASCO 1 and 2 had resulted in circumferential cracking of the Incoloy 800 SG tubing. Similarly the Belleville 2 A600TT tubing was degraded with circumferential cracking at the TTS as a result of denting. The Ginna instance of TTS denting has not resulted in cracking of the A690TT SG tubing material as of the last (2008) inspection (Reference 21.46).

It should be noted that the physical deformation caused by denting of SG tubing, which occurs under operational conditions, represents a highly unusual condition that has not been extensively tested with A690TT.

As result of the inherent A690TT material performance, coupled with secondary-side design and manufacturing and operations advances, such as redesigned support structures with corrosion-resistant materials, full-depth hydraulic expansion in the tube sheet crevices, and improved chemistry operations, continuing corrosion-free performance is expected to lead to higher improvement factor values as operational experience accumulates (Reference 21.45). These results support the appropriateness of the current AP1000 plant design recommendations for secondary circuit chemistry.

Crevice Corrosion and Denting

Particular features of secondary-side SG environments are the accumulation of sludge on the tube sheet, deposit buildup on the tubes, and corrosion in crevices formed between the tubes and tube sheet or tube support plate. In-situ formation of iron oxide within these crevices adjacent to tubing can result in denting. The localised stress gradient induced by the denting can lead to SCC of the tube. Such instances of SCC attributed to denting have been observed in operating plants. Denting occurs when elemental iron is oxidised in a geometrically restricted region (deep crevice or shallow crevice beneath a sludge pile), and the oxide formed from the corroded iron occupies more volume (Pilling-Bedworth Ratio), resulting in a localised force exerted on the tubing. In addition, the geometrically restricted region can produce crevices where local boiling leads to concentration of solutes and the formation of local shifts in pH. Contaminants, such as chloride, can become concentrated in crevices and form localised acidic or alkaline conditions. The original problem was mitigated in earlier plants by changing chemistry environments in the areas of concentration, boric acid soaks, and boric acid addition to neutralise the concentrated solutions.

Several features in the AP1000 plant SG minimise crevice areas and the deposition of contaminants from the secondary-side flow. The AP1000 SGs have stainless-steel tube support plate material for improved corrosion resistance and broached trefoil hole design with the flow area adjacent to the tube to reduce the risk of deposition. Also, the potential crevice between the tube-to-tube-sheet interface has been removed by full-depth hydraulic expansion. The length of the expansion is carefully controlled to minimise the occurrence of an overexpanded condition above the tube sheet and to minimise the extent of unexpanded tube at the top of the tube sheet. Thus, the AP1000 design has included design elements that provide improved ability to avoid or minimise the potential for crevice corrosion and denting. Chapter 15 of the AP1000 Chemistry Manual provides further guidance to identify and mitigate excessive sludge accumulation on the TTS.

Flow-Assisted Corrosion

FAC is an extension of a general corrosion process. FAC occurs through disruption of the normally protective oxide layer on the material surface under flow, leading to localised thinning of the oxide and subsequent increased corrosion rates. Under sufficient reducing conditions, the magnetite oxide layer at the oxide-water interface is dissolved. The material corrodes as it tries to re-establish the oxide under flow. FAC has been observed in all PWR secondary circuits to varying extents, and the AP1000 plant has used both design and operational recommendations to reduce the areas susceptible to FAC.

FAC has a parabolic relationship with temperature. FAC rates are typically highest at temperatures between 120 and 205°C (248°F and 478.4°F) because of the increased solubility of $Fe(OH)_2$ in that temperature range and are therefore a concern for the regions of the secondary circuit that operate in this range. Carbon steels and LASs are particularly susceptible, as are any materials that form a protective iron oxide (magnetite) layer. In addition, design and operational factors, such as piping geometry, materials of construction, stream velocity, and steam quality, also strongly influence FAC rates and material susceptibility. For example, moisture content in steam lines is minimised in the AP1000 plant through the use of condensate drains, chevrons, and reheat; the pipe system is designed to minimise abrupt changes in flow. Also, metal loss rates are strongly influenced by a number of chemistry factors, including pH control dissolved oxygen concentration and lack of copper alloys in the BOP. For chemistry control in particular, oxygen content and pH are controlled to reduce the risk of FAC on susceptible materials.

Material loss decreases with increasing pH of at least up to 10 (measured at 25°C (77°F). Studies have shown that FAC rates decrease by a factor of 25 if the pH_T increases from 6.7 to 7.1 (Reference 21.47). The pH in PWR secondary circuits is controlled by dosing with a pH control chemical, such as ammonia or an amine.

Oxygen has also been shown to have an effect on rates of metal loss due to FAC at operating temperatures. Very low concentrations of oxygen (<2 ppb, depending on temperature and flow conditions) result in increased rates of metal loss (Reference 21.48). At Seabrook, it was found that reducing the condensate dissolved oxygen concentration to 0.7 ppb increased the iron concentration to above 25 ppb; however, increasing the oxygen concentration to 2 to 3 ppb decreased the iron content to 5 to 6 ppb (Reference 21.49). This effect of increased oxygen content is interpreted as being due to the consequent upward shift in ECP providing a more stable passive oxide layer. Typically, plants aim to control condensate-dissolved oxygen to more than 2 but less than 10 ppb. In addition, materials for the AP1000 plant secondary circuit have been selected to minimise FAC and subsequent corrosion transport to the SG. In particular, copper alloys, which require low pH control regimes that are more susceptible to FAC, are prohibited for components that are in contact with feedwater, steam, or condensate. Material selection for MSRs, condenser tubes, and feedwater heaters is consistent with the recommendations given in EPRI NP-2294 (Reference 21.50). FAC-resistant materials employed include chromium alloy (ASTM A335 Grade P-11 or equivalent) and austenitic stainless steels. Where carbon steel is used, an additional thinning allowance of 2 mm is applied.

Chemical control measures (Section 21.6.4.3 below), material selection (Section 21.6.4.2 below), and design features have been employed in the AP1000 plant to reduce the material loss as a result of FAC. In addition, lower FAC reduces the quantity of corrosion products transported throughout the secondary circuit, which in turn reduces SG sludge accumulation. Excess SG sludge accumulation has been associated with increased potential for SG tubing degradation and reduced SG thermal and hydraulic performance.

Turbine Corrosion

Turbine blades and discs can suffer from pitting, corrosion fatigue, and SCC. The incidence appears to be related to oxygen ingress and condenser leaks. While the chemical environment could impact corrosion, the cause of turbine blade and disc corrosion has been attributed to defects in the materials and not chemistry. Current EPRI guidance, which is endorsed for the secondary system of the AP1000 plant and an ALARP approach to secondary chemistry, has demonstrated success in reducing or eliminating instances of turbine blade corrosion.

21.6.4.2 Materials

Secondary circuit materials are selected to be resistant to the various corrosion mechanisms that they are likely to encounter. EPRI NP-2294, the EPRI SG handbook, and the URD document (References 21.41, 21.50, and 21.51) provide material recommendations to overcome the various corrosion problems. AP1000 plant secondary-side material selections comply with these recommendations. The safety limits selected in Table 21-6 are principally related to the material selection process (refer to Reference 21.76). The following is a brief discussion on the materials used throughout the AP1000 plant secondary circuit.

The MSR tubes are made from a ferritic stainless steel. The chevrons are composed of stainless steel and the shell is constructed from carbon steel with chrome steel or stainless-steel overlays and impingement plates. The condenser shell is made from carbon steel with impingement plates to protect against erosion. The condenser tube sheet is made from titanium-cladded carbon steel and the tubes are titanium grade 2. Feedwater heater tubes are manufactured from a ferritic stainless steel and the feedwater heater shells are made from carbon steel with stainless-steel overlays and impingement plates; the tube sheets are carbon steel, clad with stainless steel in the HP heaters. Piping is made from carbon steel, chromium-molybdenum alloy steel or stainless steel.

Wall thinning from erosion-corrosion effects does not occur in the auxiliary stainless-steel piping and tubing because Series 300 austenitic stainless materials are highly resistant to these effects. There is no record of erosion-corrosion-induced wall thinning in the stainless-steel piping of operating plants.

The SGs use Ni-Cr-Fe alloys in contact with fluids wherever erosion-corrosion or FAC could be a problem, including the nozzles on the feedwater ring and startup feedwater sparger. The tubes are made from TT Alloy 690, which has a high resistance to general corrosion and SCC. The channel head divider plate is also Alloy 690. The interior surfaces of the reactor coolant channel head, nozzles, and manways are clad with austenitic stainless steel. The primary side of the tube sheet is weld-clad with Ni-Cr-Fe alloy. The tube support plates are made of corrosion-resistant Type 405 stainless-steel alloy. Further details are given in Table 20C-2.

The main condenser is a three-shell, single-pass, multi-pressure (or single pressure if the plant uses seawater as cooling water source), spring-supported unit. Each shell is located beneath its respective low-pressure turbine. The condenser is equipped with titanium tubes. The titanium material provides good corrosion- and erosion-resistant properties. Continuous online instrumentation is utilised to detect condenser leaks by monitoring for cooling water ingress at each condenser hot well segment. Depending on the cooling water chemistry and leak rate, analysis of hot well samples often can be used to locate the particular condenser tube bundle containing the tube leak. Once the affected tube bundle has been identified, reactor power must be reduced to a level that can be supported by the unaffected cooling water train. The cooling water supply to the leaking condenser tube bundle should then be isolated and the tube side of the condenser drained for repair.

Copper and copper alloys are not used for any components in contact with secondary circuit feedwater, steam, or condensate to avoid corrosion problems. The only exceptions are the HP turbine casing and HP turbine stop and control valve bodies, which are a cast 0.5 copper-nickel-chromium steel. This material is the standard design of the turbine supplier and has been used in other operating PWRs. The addition of a very small amount of copper provides better erosion resistance for the wet steam conditions in the HP turbine. The copper is bound and is not residual surface copper.

21.6.4.3 Chemistry

The secondary circuit chemistry is integral to the successful management of circuit materials. Much effort is put into optimising the chemistry to minimise corrosion risks discussed in Section 21.6.4.1 and to maximise the system performance. The secondary water chemistry is the responsibility of plant operators. As described within Reference 21.5, Westinghouse mandates strict adherence to EPRI guidelines. Each plant is required to develop and maintain a secondary-side strategic water chemistry plan that considers plant-specific design, operating parameters, operating history, component warranty requirements, and utility-specific goals.

The secondary circuit chemistry uses AVT to control the pH and dissolved oxygen concentration and an ALARP approach for impurity concentrations maintained within EPRI guidance. The selection of pH control additive(s) with the appropriate relative volatilities ensures adequate chemistry protection in both the liquid and steam phases in the secondary circuit. To preserve the integrity of the secondary circuit and comply with EPRI guidelines, an ALARP approach to impurity control is prudent. To maintain impurities at ALARP levels, ingress of ionic impurities, such as sodium, fluoride, chloride, and sulphate, is controlled through a combination of makeup water quality and removal of secondary ionic impurities through the BDS EDI unit and the CPS. Metal impurities, such as copper and lead, are controlled through specifications applied to AP1000 plant materials of construction. These specifications have eliminated materials such as copper-alloy tubing in the main condenser in favour of titanium tubing. For both dissolved and particulate impurities, control limits have been placed on the secondary circuit to minimise the impact on the corrosion of SG and secondary-side materials. Further control of FAC and ODSCC of SG tubing is achieved through pH and oxygen control in the secondary feedwater.

The secondary-side water chemistry pH is maintained in a basic regime to minimise the amount of corrosion product transport that occurs by lowering the solubility of ferrous metal corrosion products in solution. In addition to pH control, an optimum oxidation reduction potential (ORP) is maintained through dissolved oxygen control. The combination of alkaline pH and optimised ORP in secondary feedwater provides a thermodynamic region of protective oxide stability to reduce FAC in ferrous piping while still maintaining an environment against SG tubing that provides optimum protection against ODSCC. To maintain a stable passive oxide layer, proper control of pH and ORP is crucial. The passive oxide layer in secondary piping is a thin, tightly adherent oxide layer that forms on the metal surfaces and provides an increased resistance to FAC. The AP1000 plant uses AVT pH control additives, such as ammonia, amines, or a combination thereof to control pH in both the liquid and two-phase regions of the secondary circuit. Thus, an alkaline pH can be maintained in both the liquid and two-phase regions to reduce the rate of FAC of secondary circuit materials.

Also, the amount of dissolved oxygen is directly related to the control of electrochemical corrosion potential within the SG. Elevation of dissolved oxygen concentrations in the bulk fluid increases the following:

- General corrosion rates of carbon steels
- Pitting, IGA, and ODSCC susceptibility of nickel-based and austenitic alloys
- Formation of oxidising species such as hematite or cuprite

By controlling dissolved oxygen in the SG, the formation of magnetite against the tubing surfaces is promoted, and the formation of hematite is prevented. The oxygen concentration within in the secondary circuit is controlled by a catalytic oxygen recombining system and the addition of hydrazine to scavenge and react with any dissolved oxygen. However, as noted in Section 21.6.4.2, too low of a dissolved oxygen concentration may lead to FAC. Therefore, the concentration of oxygen in the secondary circuit must be balanced to control the ECP within the SG and FAC in the rest of the secondary circuit. Additional details on oxygen control are available in the AP1000 Chemistry Manual (Reference 21.5).

Impurity ions, such as sodium, fluoride, chloride, and sulphate, are measured in most nuclear power plants because of their role in promoting several different kinds of submodes of localised corrosion within the SG and FAC in the steam drum and steam flow path. In particular, SCC and pitting are two types of corrosion that have occurred in nuclear power plants and are associated with elevated levels of particular ionic impurities. While materials now used to construct SGs, such as Alloy 690TT, are much more resistant to SCC than the original mill-annealed or Alloy 600TT, laboratory testing has demonstrated their susceptibility to SCC and pitting in sufficiently off-normal chemistry conditions (e.g., caustic solutions with high concentrations of lead).

In addition, elevated ionic impurities in the presences of excess sludge piles or crevices have demonstrated the formation of environments conducive to denting, resulting in a localised stress condition against the tubing. Hence, controlling the concentration of dissolved impurities is still prudent for adequate protection of the SG and steam flow path materials. In addition, dissolved impurities concentrate in crevices, thereby producing localised regions of elevated concentrations and superheat leading to environments conducive to localised corrosion. In the AP1000 plant, the concentration of ionic impurities is minimised by compliance with EPRI guidelines and using ALARP methods. Also, conductivity, which is an overall measure of the concentration of dissolved solids, is continuously measured in the EDI stack inlet line and in the process outlet line as a means of detecting condenser leakage into

the secondary system. Two redundant trains of two series (roughing and fine) filters are located directly upstream of the EDI nozzles in order to prevent particulate from entering the EDI modules.

For the AP1000 plant, condensate polishers can be used to purify feedwater if a condenser leak rate is sufficient to approach or exceed the administrative action levels of a plants secondary chemistry. The condensate polishers require a reduction to 30% main steam rate to provide 'full flow' polishing capability (30% power allows full flow through the condensate polishers.

Further information on secondary circuit chemistry is given in the AP1000 Chemistry Manual (Reference 21.5, Chapter 5); including a detailed description of the condensate polishing system and the capabilities provided to support secondary chemistry control (Reference 21.5, Section 5.2.1). Additional discussion of secondary circuit chemistry recommendations during shutdown and startup are provided in Section 5.5 of Reference 21.5.

21.6.5 Secondary Circuit Sampling System

The AP1000 plant SSS delivers representative samples of fluids from secondary systems to sample analyser packages. Continuous or semi-continuous online secondary chemistry monitoring detects impurity ingress and provides early diagnosis of system chemistry excursions in the plant. Secondary sampling monitors send control signals to the turbine island chemical feed system (CFS) that automatically injects chemicals into the condensate and feedwater systems to control pH and dissolved oxygen concentration. PCSR Section 6.5.16 and Reference 21.38 contains further discussion of the SSS.

Within the secondary sampling system, some sample points are continuously or semi-continuously monitored. Other sample points are selectively monitored (where a single analyser package can be used to selectively monitor multiple sample points). A complete list of sampling points is given in Table 21-3 and Table 21-4.

After being analysed, noncontaminated samples are returned to the condensate system (CDS). Sample lines containing reagents and those from sink drains are collected in the waste water system (WWS) and processed for disposal.

The SSS monitors water samples from the CDS, feedwater system, MSS, BDS, auxiliary steam supply system (ASS), condensate polishing system (CPS), and heater drains. Water quality analyses are performed on these samples to determine the necessary parameters for controlling the water chemistry.

21.6.6 Steam Generator Blowdown System

The BDS assists in maintaining acceptable secondary coolant water chemistry during normal operation and during anticipated operational occurrences of main condenser inward leakage or primary-to-secondary SG tube leakage. It does this by removing a small fraction of the bulk fluid from the SG in which the impurities have become concentrated. The BDS accepts water from each SG and processes it as described below.

The blowdown from each SG is cooled by a regenerative HX, and the pressure is reduced by blowdown flow control valves. To recover the blowdown fluid, each blowdown train has an electrodeionisation (EDI) unit that removes impurities from the blowdown flow. The blowdown fluid is processed through the EDI units and [ ] percent of the flow is discharged to the CDS (condenser hot well) for reuse. The remaining [ ] percent is

discharged to waste. If radioactivity due to SG tube leakage is detected in the blowdown flow, BDS flow is automatically diverted to the WLS for processing and disposal.

Further details about the BDS are given in the AP1000 Chemistry Manual (Reference 21.5, Chapter 5), and Section 6.5.11.

21.6.7 Condensate Polishing System

The CPS is a secondary cycle condensate cleanup system consisting of deep bed ion exchange vessels aligned to remove corrosion products, dissolved solids, suspended solids, and other impurities from the condensate system. The CPS is used principally during startup to reduce the time necessary to achieve proper secondary circuit chemistry and can be used during power operation to maintain proper secondary circuit chemistry following impurity ingresses during abnormal event(s) such as a condenser tube leak.

Selection of a system type and mode of operation is site specific depending on the CWS water quality design basis. As a result, condensate polishing systems have been installed in various configurations. For plants using fresh or brackish water as the cooling medium in the CWS, a one-third condensate flow CPS may be used such that 100% of the condensate may be processed during plant operations in Modes 2, 3, 4 and 5 (startup, hot standby, safe shutdown and cold shutdown, respectively). A full condensate flow CPS may be specified for an AP1000 plant that uses seawater as the CWS cooling medium.

Refer to Section 6.5.15 of this report for additional details on the CPS.

21.7 Auxiliary Water Systems

Like the primary and secondary circuit material selection and chemical regimes, the auxiliary systems have been designed (chemically and materially) to reduce the risk of fault conditions occurring. The fault conditions for these systems from a chemical perspective are the corrosion effects (which can result in leaks) or fouling of the pipes, which could reduce flow rates and impact the effectiveness of the system. The chemical regimes selected for these are chosen to mitigate the risk of these events occurring.

21.7.1 Component Cooling Water System

21.7.1.1 Description of the Component Cooling Water System

Section 6.11.1.1 of this report provides a detailed description of the CCS design and configuration, including its safety functions and defence in depth functions.

21.7.1.2 Component Cooling Water System Chemistry

The safety requirement of the CCS chemistry is to minimise the risk of loss of integrity of the CCS through corrosion or a loss of function through fouling.

The CCS is chemically treated for the purpose of minimising corrosion of system materials and prolonging equipment life. Component cooling water essentially consists of demineralised water, to which one or more corrosion inhibitors and pH control agents are added to protect the materials of construction in contact with the fluid. Additional chemicals may be dosed to prevent biological growths or fouling (Reference 21.5).

Westinghouse does not dictate specific chemical regimes for the CCS, but directs the utilities operating the plant to follow the EPRI guidelines (Reference 21.3), as they apply to the chemical treatment options found suitable for use in the AP1000 plant. Westinghouse has performed calculations to support the design of the CCS within the limits of the EPRI guidelines to demonstrate that materials selected operate sufficiently within the proposed chemical regime. (Reference 21.81)

The operating ranges are suggested by EPRI for water chemistry. The AP1000 proposed chemical regime is presented in the AP1000 Chemistry Manual (Reference 21.5, Chapter 6), with safety limits for the chemistry provided in the summary report of AP1000 plant chemistry characterizations (Reference 21.76, Table 5-4).

In the event of deviation from proper chemistry in the CCS coolant, appropriate chemicals are added via the chemical addition tank and mixing is achieved through a recirculation line from the pump discharge header through the operating surge tank to the pump suction line.

Corrosion Inhibitors

The EPRI guidelines for closed-loop cooling water systems recommends various chemical treatment programmes to minimise the corrosion of the CCS materials. Specific corrosion inhibitors are dependent on utility preferences. The example inhibitors suggested by the guidelines are listed in the EPRI guidelines (Reference 21.3). pH control chemicals are also added to maintain the pH in a range where corrosion is minimised and treatment chemicals are most effective. In addition, Westinghouse has stated that the AP1000 plant design should not use chromates or silicates, which are suggested as coolant treatments in the EPRI guidelines (Reference 21.3).

Faults

Operation of the CCS outside of the proposed chemistry regime will result in increased risk of fouling and corrosion rates. The long-term consequence of an increased corrosion rate in the CCS is an increased risk of leaks in the system, either between the RCS and CCS, or out of the CCS to other CCS users or the environment.

The monitoring of the flow rate, temperatures, and pressure of the CCS can be used to indicate fouling or leaks.

Leaks

In the event of a leak from the CCS, the level in the surge tank will drop as the coolant drains from the system. The surge tank will then be supplied automatically with water from the DWS.

If there is a large leak, the level will drop further, actuating a second alarm that prompts the operator to investigate the leaks visually or through investigation of flow rates across components. If the components cannot be isolated or the leak sealed, then the level will drop further, initiating a third alarm that will shut off the pumps.

A leak from the CCS into the RCS is only possible during shutdown when the RCS is depressurised. Detection would be as above and any contamination of the RCS would be detected by normal sampling prior to startup and then rectified.

Leaks of the Reactor Coolant System in the Component Cooling Water System

In the event that a significant amount of primary coolant is lost (therefore a significant transfer of active inventory), the valves on the CCS within the containment isolation section will close to prevent radiation exposure out of containment.

21.7.2 Normal Residual Heat Removal System

21.7.2.1 Description of the Normal Residual Heat Removal System

The RNS consists of two trains, each with one RNS pump, one RNS HX, and interconnecting piping and valves configured to allow redundancy of any one component or pipe section. All components in the RNS circuit are designed and built to withstand full reactor temperature and pressure. Each RNS train discharges to a separate direct vessel injection (DVI) line, which is part of the PXS (discussed in Section 21.7.3) connected directly to the RPV.

See Section 6.4.3 for a full description of the RNS circuit.

21.7.2.2 Normal Residual Heat Removal System Chemistry

The RNS chemistry serves to minimise corrosion of RNS materials to maintain the structural integrity of the system.

During operation of the RNS in cooldown mode, primary coolant will be flowing through the RNS with nominal primary coolant chemistry. Sampling may be performed using the normal residual heat removal HXs channel head drain connections. Sampling of the RCS using these connections is available at shutdown.

The RNS is constructed of the same materials as the primary circuit and will operate with primary coolant chemistry but at a lower temperature and pressure (less than 177°C (350°F) and 3.10 MPa gauge (450 psia)); it is designed to maintain the coolant temperature at approximately 52°C (125°F). Given that the coolant chemistry has been designed to operate with the RCS and RNS materials at a higher temperature (therefore at an increased corrosion rate), the RNS should be sufficiently corrosion-resistant to cope with the flow of RCS coolant. For safety limits for the RNS chemistry, refer to the safety limits provided for the primary circuit in Section 21.5.

In the event of out-of-chemistry conditions, the RNS will react in a fashion similar to the RCS, but given the lower operating temperature and short duration of operation of the RNS, the effects would be greatly reduced.

21.7.3 Passive Core Cooling System

21.7.3.1 Description of the Passive Core Cooling System

The PXS is a Class 1 system consisting of two CMTs, two accumulators, the IRWST, the PRHR HX, depressurisation spargers, and pH adjustment baskets; and associated piping, valves, instrumentation, and other related equipment.

In addition to heat removal, the PXS is used to supply coolant to the core. This is provided by the CMTs. The CMTs provide RCS makeup and boration during events not involving loss of coolant when the normal makeup system is unavailable or insufficient.

Along with the CMTs, the AP1000 design utilises two accumulators containing borated water with a compressed nitrogen cover. The accumulators can deliver a very high flow of coolant into the RCS for a short duration. They are used in conjunction with the CMTs during loss-of-coolant accident (LOCA) events to maintain sufficient cover of the fuel to provide heat extraction. Please see Section 6.6.1 for a detailed description of the PXS.

The primary function of the PXS during a safe shutdown using only Class 1 equipment is to provide a means for boration, injection, and core cooling. The PXS is capable of maintaining the desired post-accident pH conditions in the recirculation water after containment flood up. Please see Chapter 22 for details related to pH control during post-accident conditions.

Refuelling

The IRWST is sized to facilitate the flooding of the refuelling cavity with borated water for normal refuelling and the post-LOCA flooding of the containment for RCS long-term cooling mode; to support the PRHR HX operation; and to supply borated water to the SFS (Reference 21.6). Flow out of the IRWST during the injection mode includes conservative allowances for spill flow during a DVI line break. The tank is lined with stainless steel and is provided with a vented cover to avoid the ingress of debris. The boron concentration can be adjusted by the CVS and is specified between 2600 and 2900 ppm boron.

21.7.3.2 Functions of the Passive Core Cooling System

The PXS has three functions: first, to provide a decay heat removal system through the PRHR HX for use after transients that prevent normal heat removal via the SGs; second, to provide emergency core cooling following postulated events; and third, to provide borated water to the refuelling cavity from the IRWST. To accomplish this, the PXS is designed to perform the following functions:

- Emergency core decay heat removal
- RCS emergency makeup and boration
- Safety injection
- System depressurisation
- Containment pH control
- Provide a source of borated water for flooding the refuelling cavity during refuelling

21.7.3.3 Passive Core Cooling System Chemistry Safety Requirements

The PXS chemistry has the following four safety functions:

- Boration of the core in accident scenarios where loss of primary coolant occurs
- Boration of refuelling cavity water
- Maintenance of system integrity by minimising the risk of corrosion damage
- Control of fission products in containment in the event of a leak by maintaining alkaline conditions in leaked coolant

21.7.3.4 Chemistry and Materials

Those portions of the PXS in contact with reactor coolant are fabricated from or cladded with corrosion-resistant material. Sulphur, lead, copper, mercury, aluminium, antimony, arsenic, and other low melting-point elements and their alloys and compounds are restricted in their use in the construction (both as construction materials and as substances that come into contact with the construction materials) of the PRHR HX that are in contact with RCS fluid or the IRWST. Contamination of stainless steel and Ni-Cr-Fe alloys by copper, low-melting-temperature alloys, mercury, and lead is prohibited. For these portions of the PXS, refer to the general primary circuit description of safety limits provided in Section 21.5.

The PRHR HX, accumulators, and CMTs are constructed from materials specified to minimise corrosion and erosion and to provide compatibility with the operating environment, including the expected radiation level. These include austenitic stainless steels of grades derived from American Iron and Steel Institute (AISI) Type 304 for the plates and forgings of the PRHR HX, and ASTM Ni-Cr-Fe alloy N06690 for the PRHR tubing. Chapter 20 details the fabrication, installation, and manufacturing processes and procedures to minimise the sensitisation of components and corrosion of the stainless steel, along with instruction on material selection, maintenance water chemistry within the specification, and minimising residual stress in the piping, all of which can have an impact on the potential for SCC.

The CMTs are filled with cold water borated to 3500 ppm (nominal) boron as boric acid to provide the required shutdown margin in the event of a loss of coolant. The accumulators are filled with cold water borated to 2700 ppm (nominal) boron as boric acid for use in the event of a loss of coolant. The IRWST is filled with cold water borated to 2700 ppm (nominal) boron as boric acid for use in refueling and in the event of a loss of coolant. For these portions of the PXS, refer to summary report of AP1000 plant chemistry characterizations (Reference 21.76, Table 5.2) for the chemistry safety limits.

The water in all major PXS components is borated. As the temperature in the system is relatively low, it is expected that the corrosion-resistant stainless steels and nickel alloys of the system will not be at risk from corrosion.

During any event involving leakage of primary coolant into containment, the leaked coolant floods baskets of trisodium phosphate (TSP), which dissolves in the water to maintain pH within the alkaline range to stabilise water-soluble iodine species and minimise the loss of iodine to the containment atmosphere (see Section 21.9.1).

21.7.4 Passive Containment Cooling System

21.7.4.1 Description of the Passive Containment Cooling System

The passive containment cooling system (PCS) is designed to remove heat from the containment vessel and transfer it to the environment to ensure that the containment vessel does not exceed the operating temperature for the vessel in the event of a major leak in the RCS circuit and PXS becoming operational.

The PCS cools the containment vessel in two ways: directing air flow between the steel containment vessel and concrete building and passing cooling water (from the passive containment cooling water storage tank (PCCWST) at the top on the reactor building) over the external skin of the steel containment vessel. The contents of the PCS tanks are recirculated to maintain acceptable chemistry and temperature conditions. See Section 6.6.2 for a detailed description of the PCS.

21.7.4.2 Functions of the Passive Containment Cooling System

The PCS performs the following functions directly related to the fluid in the PCCWST and the PCCAWST:

- Supports containment of fission product releases by transferring heat from the containment atmosphere to the environment. The removal of containment heat maintains containment pressure within design limits, thus supporting containment integrity
- Provides a makeup source and flow path to the SFP. In the event that SFP cooling is lost; under certain circumstances (see Chapter 9) the PCCWST and the PCCAWST provide the necessary makeup to the SFP to ensure that the spent fuel is not uncovered
- Provides a seismically qualified source of fire protection water
- Recirculates the contents of the PCCWST and the PCCAWST to monitor and maintain acceptable chemistry and temperature conditions within these tanks

21.7.4.3 Passive Containment Cooling System Chemistry Safety Requirements

The only safety requirement of the PCS water chemistry is to support the maintenance of the system integrity. The PCS is filled from the DWS. The PCCWST is dosed with 50 ppm of hydrogen peroxide to control biological growth in the tank. The concentration of hydrogen peroxide is analysed weekly and the concentration of impurities (chloride, sulphate, fluoride) is checked quarterly (Reference 21.5, Chapter 9). The stainless-steel lining of the PCCWST will provide sufficient corrosion resistance at ambient temperatures given the specified water quality. Hydrogen peroxide dosing is not expected to induce a significant corrosion risk provided that the levels of impurities in the water are kept low, as specified. For the PCS, refer to summary report of AP1000 plant chemistry characterizations (Reference 21.76, Table 5.12) for the chemistry safety limits.

21.7.5 Demineralised Water Treatment System

21.7.5.1 Description of the Demineralised Water Treatment System

The DTS is responsible for providing demineralised water for use as makeup to primary, secondary, and other systems. The DTS removes impurities from the raw water system (RWS) feedwater, utilizing three main unit operations: cartridge filtration (CF), reverse osmosis (RO) and EDI to remove impurities. See Section 6.11.1.5 and the AP1000 Chemistry Manual, Chapter 3 (Reference 21.5) for further details of the DTS.

21.7.5.2 Functions of the Demineralised Water Treatment System

The DTS is required to provide water of sufficient quality and quantity to meet the needs for makeup of the primary, secondary, and other plant systems. For the AP1000 standard plant, the DTS is designed to produce a maximum treated water flow rate of 68.1 m^3/hr (360 gpm).

Chapter 3 of the AP1000 Chemistry Manual (Reference 21.5) provides details regarding the functional requirements of the DTS, as well as a listing of recommended limits for key parameters of interest that are considered action levels to take immediate corrective actions should any of the concentration levels listed be exceeded. Continuously, the actual DTS effluent operating band for the parameters listed in Chapter 3 of the AP1000 Chemistry

Manual (Reference 21.5) must be kept below the values listed to ensure consistent production of high purity water.

21.7.5.3 Operation of the Demineralised Water Treatment System

The DTS supplies demineralised water of suitable quality to the DWS for further treatment to then supply the makeup to the primary and secondary circuits. Therefore, it supports the achievement of the operating safe chemistry standards in these systems.

Two parallel treatment trains consisting of CF, RO, ultraviolet germicidal irradiation (UV), EDI, and non-regenerable mixed bed exchanger (MB) units provide flexibility for system operation under various plant conditions, and allow for the cleaning and maintenance of a single train while the other train remains available for service. Chemicals to prolong, stabilize, and optimize the performance of the DTS are added via the CFS.

The CF units act as protective devices to prevent particulate matter from entering the RO units in the case where small particulates may be present in the pretreated RWS, and also from larger particulates that may carry over from any transient upsets. The RO units reject dissolved solids (salts), small amounts of nonbiodegradable organics, and colloids through the membrane diffusion process. The product water from the RO units is then pumped through UV treatment units. The UV light breaks apart and reduces the total organic carbon molecules within the flow stream. The water then flows to the EDI unit for secondary demineralization.

EDI is a membrane process that removes ions from the RO permeate water to produce high purity water. The water passes through the EDI stacks with alternating cation and anion permeable membranes and electrode plates across which a dc voltage attracts ions. The water in the EDI is split into brine (concentrate) and dilute (permeate) flows. The brine and permeate flows are directed by spacers between the membranes. The dilute flowpath contains high-grade ion exchange resin that acts as a conduit to quickly transfer ion contaminants to the respective paired anode or cathode membrane. After treatment, the EDI product water is sent to the MB. The MB is the final treatment process prior to prior to distribution to the DWS, and removes trace ionized impurities from the EDI effluent water.

The DTS effluent is fed to the DWS for further processing, storage, and transfer to subsequent downstream plant uses. If at any point the output of the DTS is outside the operating band setpoints, a three-way motorised valve is used to direct the flow to the inlet of the CFs for reprocessing through the RO and EDI units.

The quality of the DTS effluent is monitored by online analytical instruments and analysis of grab samples to ensure that the system is functioning properly.

21.7.6 Demineralised Water Transfer and Storage System

21.7.6.1 Description of the Demineralised Water Transfer and Storage System

The design of the DWS is described in detail in Section 6.11.1.4.

The DWS receives water from the DTS and provides a reservoir of demineralised water to supply the condensate storage tank (CST) and for distribution throughout the plant.

21.7.6.2 Functions of the Demineralised Water Transfer and Storage System

Demineralised water is processed in the DWS to remove dissolved oxygen. In addition to supplying water for makeup of systems that require pure water, the demineralised water is used to sluice spent radioactive resins from the ion exchange vessels in the CVS, the SFS (described in Section 6.12.4), and the WLS (described in Section 6.12.8) to the WSS.

21.7.6.3 Demineralised Water Transfer and Storage System Chemistry Safety Requirements

The DWS water is used for makeup of primary and secondary circuits and as feed to other systems, including the SFS and CCS. The quality of the water is important in achieving the chemistry functions of these systems, therefore the DWS acts to support the functioning of other systems. The chemistry requirement of the DWS is the provision of water deoxygenated to the level required for system makeup.

21.7.6.4 Demineralised Water Transfer and Storage System Operation

The water supplied by the DTS enters the DWS and is initially stored in the demineralised water storage tank (DWST), which has a capacity of 378.5 m^3 (99,989 US gal). The tank is equipped with a level control that controls the DWS to maintain the operational level. The temperature instrumentation controls an electrical heater used to heat the water to prevent it from freezing. The DTS final mixed bed units feature ion exchange resin traps to prevent resin fines from entering the DWST and CORS units.

The DWS is also responsible for deoxygenation of the demineralised water. This is performed by using CORSs. A CORS deoxygenates the water by adding hydrogen gas from the PGS and then passing the water, rich in dissolved hydrogen, through a catalytic chamber resin bed with a catalyst that combines dissolved hydrogen and dissolved oxygen to form water. The water entering the deoxygenation process is pumped from the DWST by the demineralised water transfer pumps. The water leaving the CORS unit is either recirculated through it for further oxygen reduction via the DWST or flows onto the demineralised water distribution header.

The water in the DWS is used to supply the CST and other plant systems.

Condensate Storage Tank

The CST has a capacity of 1835.9 m^3 (485,000 US gal) and is a vertical cylindrical tank constructed of stainless steel. Level and temperature instrumentation are provided with the tank level controlled by the makeup valve. Freeze protection is supplied by immersion-type electric heaters.

The CST has a CORS unit identical to the one used on the output of the demineralised water transfer pump to maintain the condensate water oxygen level within specifications. An oxygen analyser in the CST controls the catalytic oxygen reduction unit pump.

The CST provides a sufficient supply of water to the startup feedwater system to permit 8 hours of hot standby operation, followed by an orderly plant cooldown from normal operating temperature to conditions that permit operation of the RNS over a period of approximately 6 hours. The capacity of the CST is sufficient to maintain SG cooling for at least 24 hours following the loss of normal alternating current (ac) power.

The CST is also required to supply the ASS as needed to support the auxiliary boiler. Makeup water is supplied to heating, ventilation, and air conditioning (HVAC) humidifiers, storage tanks, and to other equipment for flushing, washing, and cooling operations as required to support plant operation.

Chemical and Volume Control System

The DWS is responsible for supplying water to the CVS used for reactor makeup water and for boron dilution evolutions. The water is also necessary for sluicing the resin beds in not only the CVS but also the CPS, SFS, WLS, and WSS.

21.7.7 Service Water System

21.7.7.1 Description of the Service Water System

The service water system (SWS) is responsible for the supply of cooling water to the two HXs in the CCS, located in the turbine building. See Section 6.11.1.1 for a detailed description of the CCS. The AP1000 standard design incorporates a recirculated fresh water SWS using cooling towers as discussed herein. As an option, the SWS can be configured using seawater in a once-through system.

The SWS is split into two mechanical trains, each consisting of the following:

- Service water pump
- Cooling tower
- Strainer

The piping leading to and from the HXs is interconnected to allow cooling water from either train to flow through either or both of the CCS HXs, and to then return to either cooling tower.

21.7.7.2 Functions of the Service Water System

The SWS provides cooling to two HXs in the CCS and maintains the CCS coolant within its operating temperature range.

21.7.7.3 Service Water System Chemistry Safety Requirements

The SWS provides heat removal from the CCS, which in turn cools a number of systems, including the RCPs and SFP, supporting their operation.

The function of the SWS chemistry is to minimise the risk of loss of integrity of the SWS through corrosion or a loss of function through fouling.

21.7.7.4 Service Water System Operation

The SWS coolant water is drawn from the cooling water basin by the SWS pump, and passes through the strainer before entering the CCS HX to remove heat from the CCS coolant. The heated SWS water returns to the cooling tower for cooling before entering the cooling tower basin for recirculation around the SWS.

During normal operation, the CCS operates only one HX with the SWS supplying the operating HX with service water at a temperature below 34.17°C (94°F). In transient

conditions, the CCS uses both HXs and the SWS supplies service water to both HXs to support the CCS cooling requirements. Cooling both HXs requires that both SWS cooling trains (pump, tower, and strainers) be brought into service.

Temperatures in the system are moderate and the pressure of the SWS fluid is kept above saturation at all locations. This, along with other design features of the system arrangement and control of valves, minimises the potential for thermodynamic or transient water hammer.

SWS materials are compatible with the cooling water chemistry and chemicals are used for the control of long-term corrosion and organic fouling. Water chemistry is controlled by the turbine island CFS.

The two cooling towers are identical with a storage basin beneath. The basin stores enough water to run the cooling of a single CCS HX for 72 hours with no refilling.

21.7.7.5 Materials

Diverse materials are used in the AP1000 plant SWS. Materials of construction may include the following:

- Piping consisting mainly of carbon steel with high-density polyethylene (HDPE) in the blowdown piping.
- Pumps manufactured of carbon steel, cast steel, and stainless steel; and with bearing material selection based on supplier experience.
- Strainers with carbon steel or stainless-steel bodies and stainless-steel screens.
- Cooling towers composed of a fibreglass composite material with polyvinyl chloride or polypropylene fill.
- Fan blades of moulded fibre-reinforced polyester/fibreglass composite with a cast-iron speed reducer.
- Concrete cooling tower basins.

21.7.7.6 Service Water System Water Chemistry

Chemical treatment is used to protect the SWS against corrosion of the materials and fouling through a variety of mechanisms, including chemical and biological processes. The precise treatment regime is defined by the operator within the guidance given in the AP1000 Chemistry Manual (Reference 21.5, Chapter 7), with safety limits provided in summary report of AP1000 plant chemistry characterizations (Reference 21.76, Table 5.19).

The chemicals can be divided into six categories based upon function: biocide, algaecide, pH adjustor, corrosion inhibitor, scale inhibitor, and silt dispersant. Specific chemicals used within the system, other than the biocide, are determined by the site water conditions. The pH adjustor, corrosion inhibitor, scale inhibitor, and dispersant are metered into the system continuously or as required to maintain proper concentrations. A sodium hypochlorite treatment system is provided for use as the biocide and controls microorganisms that cause fouling. The biocide application frequency may vary with seasons. Algaecide is applied, as necessary, to control algae formation on the cooling towers.

Chemical concentrations are measured through analysis of grab samples. As example, when adding sodium hypochlorite as a biocide, the chlorine residual is measured to ensure excess chlorine is maintained in the stream to prevent microbial growth. Addition of water treatment chemicals is performed by CFS injection metering pumps and is adjusted as required.

Chemical injections are interlocked with each service water pump to prevent injection into a train when the associated service water pump is not running.

21.7.7.7 Fault Conditions

Radiation in the Service Water System

The radiation in the SWS is detected via a monitor placed in the SWS blowdown line, and provision is in place for radiological analysis of grab samples. The valves in the blowdown line should be closed by the operator to prevent release and strainer back flush should be disabled.

The presence of radioactive species in the SWS requires a double leak from the RCS into the CCS and then a second leak into the SWS from the CCS. If a high-radiation alarm in the SWS is initiated, the first step is to check the activity in the CCS. It is then necessary to determine the leak source. A sample can be taken from valves near the HXs and it is possible to isolate and switch to a standby HX.

Failure of Service Water System

In the event that the SWS completely fails, i.e., no cooling water is supplied to the CCS HXs, within minutes the CCS will overheat and enter alarm/shutdown. The shutdown of the CCS will result in the shutdown of the RCPs and consequently the reactor.

The interconnecting pipework and the interchangeability of redundant components (through the interconnecting pipes and valves) reduces the likelihood of such an event resulting from a failure of a single active component, since the SWS operates with only one processing train under normal operation.

21.7.8 Spent Fuel Pool

21.7.8.1 Description of the Spent Fuel Pool

The SFP provides storage space for spent fuel. The SFS is designed to remove decay heat generated by stored fuel assemblies from the water in the SFP. A secondary function of the SFS is clarification and purification of the water in the SFP, transfer canal, and refuelling water. See Section 6.12.4 for a detailed description of the SFP; SFP faults are discussed in Chapter 9.

21.7.8.2 Spent Fuel Pool Chemistry Requirements

The SFP and SFS chemistry safety requirements are controlling reactivity by immersion in a solution of boric acid, and maintaining integrity of the SFP, SFS, and fuel cladding by minimising corrosion. These risks of corrosion and radioactivity are described in more detail within Section 21.5. The SFP is borated to a nominal concentration of 2700 ppm of boron, which controls reactivity.

The neutron-absorbing material used in the spent fuel racks is Metamic™, which is a metal composite of Type 6061 aluminium alloy matrix with boron carbide (B_4C) reinforcement. The minimum boron carbide concentration required by the design specification of the SPF to maintain a subcritical activity level is 30.5 wt%. The specified minimum boron carbide concentration equates to a minimum ^{10}B density of 0.0304 g/cm^3.

The Metamic alloy shows sufficient dimensional and ^{10}B areal density stability under irradiation testing. This testing has been used to show that the Metamic absorber sections of the rack will not be detrimentally affected by the radiation from the spent fuel cells even for the 60-year plant life (Reference 21.70).

The aqueous environment of the pool with a nominal dissolved Boron concentration of 2,700 ppm will be slightly acidic. Elevation temperature (93°C [200°F]) corrosion rate testing of 32 wt% B_4C Metamic (Reference 21.71) for 90 days indicated that "no corrosion was observed" and there was "no significant change in ^{10}B areal density." The complete lack of any chemical changes in the tests, combined with the knowledge of the effects of temperature and pH on corrosion rate, is sufficient to show that the aqueous spent fuel pool environment, even for 60 years, will not detrimentally affect the condition of the Metamic panels. Safety limits for the chemistry in the spent fuel pool are provided in the AP1000 plant Chemistry Manual (Reference 21.5, Sections 4.3.5) and the summary report of AP1000 plant chemistry characterizations (Reference 21.76, Table 5.2). For additional information on spent fuel pool chemistry, refer also to Reference 21.82.

The function of cooling and shielding the fuel in the SFP is performed by the water in the pool.

21.7.8.3 Spent Fuel Pool Cooling

The SFS is designed to maintain the cooling water temperature below 48.89°C (120°F) with a maximum fuel cell load plus either partial or full core loads (full core 120 hours after shutdown).

SFP boiling in the event of a loss of SFP cooling is discussed in Section 9.11.

21.7.8.4 Cooling Water Purification

The SFS is designed to remove contaminants from the cooling water in the SFP, refuelling cavity, and water in the IRWST. The SFS removes radioactive corrosion products, fission ions, ionic impurities, and particulates to do the following: maintain coolant activity levels in accordance with SFP ALARP goals, to limit corrosion, and maintain cooling water clarity.

The SFP is initially filled for use with water having a nominal boron concentration of 2700 ppm. Demineralised water can be added for makeup purposes, including replacement of evaporative losses, from the DWS. Boron may be added to the SFP from the CVS. The purity of the DWS is discussed in Reference 21.5, Chapter 3; the purity of the boron is discussed in Reference 21.5, Chapter 10.

The two SFS demineralisers are of mixed bed type. The demineralisers are initially charged with a cation resin in the hydrogen form and anion resin in the hydroxide form to remove fission and corrosion products. The demineralisers will be borated during initial operation with boric acid. Each demineraliser is sized to accept the maximum purification flow from its respective cooling train. The vessels are constructed of austenitic stainless steel.

The SFS filters are situated downstream from the demineralisers and are sized to collect small particles and resin fines escaping from the demineraliser resin beds. The filter assemblies are constructed of austenitic stainless steels (all piping in the SFS is austenitic stainless steel) with replaceable filter cartridges (PCSR Section 17.9.1).

21.7.8.5 Water Transfer

The SFS is also responsible for transferring the water from the IRWST to the refuelling cavity. The water level in the refuelling cavity, fuel transfer canal, and SFP must be sufficient to allow the extraction of fuel cells from the core with at least the minimum depth of the fuel rod submerged in cooling water. The SFS is also responsible for the return of the water in the refueling cavity to the IRWST.

In some current operating PWRs, the transfer of the water from the refuelling water storage tank to the refuelling cavity is traditionally through the residual heat removal system. This flow path is a concern because the refuelling water is directed into the cold leg and through the reactor, which can mobilise loose crud from fuel surfaces and increase turbidity. Since the AP1000 design uses the SFS to transfer refuelling water, this improves the clarity of water entering the refuelling cavity. The capability to transfer water through the RNS is available in the AP1000 design.

21.8 Operational Strategies in the AP1000 Design

This section provides a summary of the operational strategies for the primary circuit, which is described in detail within Section 4.4.4 of Reference 21.5. For secondary chemistry operational strategies, please see Section 5.5 of Reference 21.5.

21.8.1 Operational Modes

The operating modes of the RCS are as follows:

- Power operation
- Startup
- Hot standby
- Safe shutdown
- Cold shutdown
- Refuelling

Each mode corresponds to any one inclusive combination of core reactivity condition, power level, average reactor coolant temperature, and RPV head closure bolt tensioning with fuel in the RPV (see Table 21-6).

21.8.2 Power Operation (Mode 1)

During operation at power, the reactor primary coolant is a solution of boric acid, maintained at a concentration appropriate to the reactivity of the core. The boric acid concentration is gradually adjusted during a fuel cycle to compensate for fuel burnup and the buildup of xenon. The pH_T is maintained in alkaline conditions by the addition of LiOH. Target pH_T varies according to the chemistry regime adopted but Westinghouse requires that pH_T be kept above [ ] to minimise general corrosion and SCC risks to fuel cladding and primary circuit materials (References 21.5 and 21.6).

The pH_T requirements also reduce crud deposition on the fuel. In addition, the lithium concentration is limited to [ ] ppm in view of concerns regarding its effects on fuel cladding corrosion. The operating chemistry parameters are defined by Westinghouse endorsement of the EPRI guidelines (Reference 21.2) as well as the supplemental chemistry guidelines (Reference 21.6). The pH_T strategy is decided by individual plants within the constraints of the EPRI guidelines and with a maximum lithium concentration of [ ] ppm (Reference 21.6). Lithium concentration is controlled by adding LiOH via the chemical addition tank and by dilution or processing the primary coolant through the cation bed in the CVS purification loop. During this time, it is expected that the sampling frequency will increase to ensure proper concentrations of lithium are provided per Reference 21.2.

Hydrogen is dissolved in the primary coolant in the concentration range of 25 to 50 cc/kg H_2O to maintain a low ECP for the control of SCC and corrosion. The hydrogen residual will also scavenge oxygen generated by radiolysis within the core. Undesirable contaminants, including chloride, sulphate, fluoride, calcium, magnesium, and aluminium, are removed by the CVS to below the target levels given in the EPRI and Westinghouse Supplemental Guidelines (References 21.2 and 21.6). In addition, silica is monitored in the reactor coolant to minimise the risk of silicate deposition on the fuel. The purification flow is provided by the RCP head and does not require operation of the CVS makeup pumps. Thus, purification is continuous during power operation.

Control of the adopted chemistry regime is achieved by analysing grab samples of the primary coolant for boron, dissolved hydrogen, lithium, zinc, and radioactivity; which is followed by the subsequent chemistry adjustments via the CVS.

Load following power variations are achieved by movement of control rods and grey rods. In the primary circuit, adjustment of dissolved boron is used to compensate for fuel burnup only and adjustments are made to keep the rod control groups within their allowable insertion limits. The boric acid blending valve can be adjusted to achieve the desired makeup concentration. Boron dilution is carried out as needed by CVS makeup with demineralised water and the excess volume is discharged to the WLS via CVS letdown.

21.8.3 Startup Chemistry Operations (Mode 5 through to Mode 1)

During startup following a normal refuelling outage, the reactor needs to be filled with coolant and brought to operating conditions in a manner that protects the core and primary circuit materials from corrosion. It is also necessary to minimise crud redistribution to avoid increases in circuit radioactivity or risks of CIPS and CILC. Strategies have been devised to achieve these aims and Westinghouse will continue to work with utilities to develop them further. The AP1000 plant will be operated to EPRI guidelines (Reference 21.2), which discuss options for chemistry control during PWR reactor startup. This section will outline the startup chemistry strategies and their impact on the safety functions of the AP1000 plant primary circuit.

Refill water quality is checked prior to filling to ensure that contaminants are within specification. The AP1000 plant specification calls for halogen concentrations to be maintained within specification regardless of system temperature. The makeup pumps are used to fill the reactor with water from the demineralised water supply and the BAST to achieve the correct starting boron concentration.

The RCS is vented via the RPV head and pressuriser. The pressuriser may be filled via the auxiliary spray line. Alternatively, the RCS can be vacuum-filled as this reduces the

RCS oxygen concentration and supports heatup. Vacuum filling will be routinely adopted in the AP1000 plant.

Hydrazine is added to the pressuriser and the bulk reactor coolant to scavenge oxygen. The reaction between oxygen and hydrazine is slow and is favoured at alkaline pH and higher temperatures. Initially, during heatup, the pH will be acidic due to the high boron concentration in the coolant but is later increased by lithium dosing according to the plant chemistry strategy. The AP1000 Chemistry Manual (Reference 21.5) calls for oxygen to be controlled during power operation and prior to operation at temperatures above 121°C (250°F) in both the RCS and the pressuriser, which is within the EPRI guidelines target.

Good operational practice suggests that hydrazine is dosed after analysis of the residual oxygen in the coolant to allow the addition of only sufficient hydrazine to scavenge the remaining oxygen. Excess hydrazine can produce ammonia, which can impact the CVS resin beds, possibly leading to a release of chloride from them (Reference 21.2).

As the solubility of nickel, cobalt, and iron is reduced as the temperature of the primary coolant increases, there is a risk of deposition of dissolved metals on the primary circuit and particularly in the core. Nickel deposition is a concern because of the eventual impact on ^{58}Co inventory and, in high-duty cores, the increased risk of CIPS. To manage this, the CVS purification flow with ion exchange demineralisation can be employed during the startup operations.

Consistent with the EPRI guidelines (Reference 21.2), the Westinghouse Supplemental Guidelines (Reference 21.6) stipulate that hydrogen should be above 15 cc/kg H_2O when the reactor is critical and between 25 and 50 cc/kg H_2O within 24 hours of the reactor reaching critical. The AP1000 reactor will be operated to EPRI guidelines.

LiOH is added to increase the pH to the alkaline range to minimise corrosion of primary circuit materials and especially to reduce the risk of SCC. Lithium addition can be delayed to extend the time in acid-reducing conditions if it is necessary to remove nickel. The RNS needs to be isolated prior to addition of lithium to prevent addition of lithium to the reactor coolant during later uses of the RNS. Lithium dosing will be coordinated to achieve a target pH_T of at least [ ] at reactor criticality. LiOH is added via the chemical mixing tank to the suction manifold of the makeup pumps. The demineralised water supply is deoxygenated to an oxygen content of less than 100 ppb but the boric acid storage tank is normally open to the atmosphere so that the filling water is not fully deoxygenated. Hydrogen injection is started and the coolant hydrogen concentration is raised to the target level.

Once the reactor is critical, the primary coolant silica concentration has been confirmed to be less than or equal to 1000 ppb and zinc injection may be initiated (Reference 21.6).

The pressuriser heaters are operated to heat the water in the pressuriser and create a steam bubble. As the bubble grows, volume is maintained and pressure controlled by diverting the coolant through letdown to the WLS. With the shutdown control rod banks withdrawn, makeup is drawn from the demineralised water supply to reduce the boric acid concentration to that required for power operation. The hydrogen and boron concentrations and water quality are confirmed by chemical analyses and then the control banks are withdrawn to raise power and control neutron flux.

21.8.4 Hot Standby (Mode 3)

Spurious reactor trips or maintenance operations can result in the reactor being held at a subcritical condition but with the ability to return to power in the time taken to withdraw the control rods. The average temperature is maintained by dumping steam to the condenser or, at a later stage, by operating the RCPs. Xenon builds up during the shutdown and increases the criticality margin. If a rapid return to power is needed, the reactor coolant may be diluted by adding demineralised water to counteract this.

21.8.5 Safe/Cold Shutdown (Mode 4 to Mode 5)

Safe/cold shutdown involves moving the plant from normal operating temperature to cold conditions in preparation for refuelling or maintenance. Safe shutdown is defined as Mode 4 operation, i.e., where the reactivity is less than 0.99 but the temperature is above 93.3°C (225.5°F). Cold shutdown, or Mode 5, is the same but the average reactor coolant temperature is less than 93.3°C (225.5°F).

A major consideration during shutdown is the effect of environmental changes on crud mobility and the removal of activity from the primary circuit. Consistent with EPRI guidelines (Reference 21.2), Westinghouse makes a number of recommendations regarding shutdown chemistry practices aimed at minimising primary circuit activity buildup (References 21.5 and 21.6). These recommendations are summarised as follows:

- Control of reactor coolant pH during shutdown. This is defined as a plant-specific control and the EPRI guidelines do not define a precise pH band; however, plant experience suggests maintaining pH_T above [ ] while at power to avoid particulate transport (Reference 21.2). It is also important to avoid increasing the alkalinity of the coolant by adding LiOH. Lithium removal via the CVS cation demineraliser will most likely begin prior to shutdown.

- Acid-reducing conditions should be established during cooldown, before the temperature falls below 200°C (417.6°F), to enable decomposition of nickel ferrites, which form a major component of crud and contain cobalt. This allows removal of nickel and radio-cobalt from the circuit. Hydrogen needs to be maintained at 15 cc/kg H_2O or better.

- Monitor coolant chemistry and maintain adequate cleanup capability. This includes assessing the resin bed capacity.

- Maximise purification flow to optimise cleanup.

- Ensure that the RNS does not adversely impact RCS chemistry when it is brought into service. Procedures prevent inadvertent addition of lithium to the RNS, however, transient oxygen, or corrosion products may be present.

- Prior to chemical degassing operations, the reactor coolant drain tank (RCDT) hydrogen content shall be reduced to ≤4 percent volume hydrogen to prevent the risk of explosive gas mixtures. A stoichiometric amount of hydrogen peroxide is added to the RCS and pressuriser to react with the residual hydrogen in the RCS. Once the RCS hydrogen concentration has been reduced to less than 5 cc/kg H_2O, the chemical degassing operations have been completed.

- Create acid-oxidising conditions by adding hydrogen peroxide to solubilise nickel and radio cobalt.

- Prior to opening the RCS, the hydrogen concentration shall be confirmed to be less than 5 cc/kg H_2O to prevent the risk from an explosive mixture.

The exact chemistry practice is determined by the plant operator and the EPRI guidelines (Reference 21.2), which state that best practice may differ from plant to plant. An assessment needs to be made in each case and reviewed to optimise shutdown chemistry.

Some aspects of RCS shutdown chemistry are not well understood and relevant aspects of crud composition and chemistry are still being studied. It is likely, therefore, that shutdown chemistry practices will be modified in the future, so it is appropriate that responsibility for applying best practice lies with the operator.

The expected shutdown sequence for the AP1000 plant is as follows:

- The WLS and gaseous radwaste system (WGS) are prepared to accept waste generated from degassing operations, required letdown, or boration.

- The purification flow is routed to the WLS via CVS letdown where the coolant is stripped of gases and returned to the makeup system. This is carried out prior to shutdown to reduce fission gas inventory to support shutdown operations for personnel access. Active hydrogen injection will be continued through shutdown and boration to ensure an adequate residual of hydrogen is maintained in the RCS.

- Lithium removal is started 24 hours prior to shutdown by placing the CVS cation demineraliser in service. The pH_T is monitored and maintained at or above [ ] while at power.

- The BAST and IRWST are sampled and analysed for quality prior to shutdown.

- Boration is carried out by adding a measured volume of boric acid solution via the makeup system and verified by chemical analysis of reactor coolant. The reactor makeup control is set to the boron concentration required for shutdown, and the makeup during depressurisation and cooldown is automatic. This produces acid-reducing conditions to aid in the solubilisation of corrosion products. Lithium removal is completed following plant shutdown.

- The pressuriser is vented to reduce the gaseous hydrogen inventory, fission gases, and noncondensable gases. RCS-dissolved hydrogen degassing can then be completed by using the degasifier in the WLS and/or chemical degassing by the addition of hydrogen peroxide.

- Hydrogen peroxide is added to produce acid-oxidising conditions, which aids solubilisation of corrosion products (particularly nickel-metal) and activated corrosion products (notably ^{58}Co).

- The RCS dissolved oxygen and hydrogen peroxide concentrations shall be maintained at greater than 2 ppm to ensure that an oxidising chemistry environment is maintained.

- Cleanup of the primary coolant continues using the CVS demineralisers to minimise refuelling cavity dose rates and support clarity of cavity water.

21.8.6 Refuelling (Mode 6)

During refuelling operations, the clarity of the refuelling cavity water can degrade because of the formation of a ferrous iron colloid that, after partial oxidation, can produce a green colouration to the cavity water. This can be sufficiently dense to impede refuelling operations. Treatment of this problem is usually oxidation with hydrogen peroxide, including monitoring RNS peroxide levels before it is put into service and treatment if necessary. The peroxide converts the ferrous iron to a ferric form, which forms a gel that settles or can easily be removed by filtration.

Fission product removal can be an issue for refuelling outages. Gaseous and volatile fission products must be reduced to low levels prior to lifting the reactor head. Hard gamma emitters will be less than 0.05 μCi/cc (total of ^{58}Co, ^{60}Co, ^{54}Mn) prior to lifting the reactor head. Reference 21.5, Chapter 4 provides more information. Iodine can exist in a number of oxidation states and the coolant chemistry may be adjusted to favour iodide and maximise demineraliser removal. Iodine concentrations in the primary coolant should be monitored prior to shutdown to enable an iodine cleanup to be carried out as part of the shutdown procedure if needed.

21.9 Accident Chemistry

A list of possible fault and accident scenarios are discussed in detail in Chapters 8 to 12. In a number of these scenarios, including LOCAs, SG tube rupture (SGTR), reactor coolant leakage, and CVS faults, chemical means are used to mitigate the impact in the event that systems, structures, and components fail to prevent fault progression to a large release to containment and to the environment. Several important chemistry control features are discussed below.

21.9.1 Control of Fission Products in Containment

Airborne particulate material and aerosols released following a severe accident are removed from the containment atmosphere by a number of passive processes, including; diffusiophoresis, thermophoresis, and sedimentation. The AP1000 design includes a manual containment spray system but this is not credited in the analysis and is designed to be used only following severe accidents should high doses be observed outside containment. A study of the relative benefits of a spray system and a number of options for providing a recirculating spray system concluded that it had no real benefits in terms of offsite dose and entailed additional risks.

Release of molecular iodine from the water within the containment is minimised by dissolving TSP in the coolant to establish and maintain an alkaline pH that stabilises iodine in solution as iodide or iodate ions. The TSP is contained in baskets inside containment that are exposed to the containment floodup water. Sufficient TSP is placed in containment to neutralise acids from all possible sources, including nitric acid formed from dissolved nitrogen in the coolant and hydrochloric acid formed from breakdown of electric cable insulation (Reference 21.62).

To conservatively estimate the TSP required, the amount of boric acid was maximised by including the maximum amounts of boric acid contained in both accumulators, both CMTs, and the IRWST. In addition, the reactor coolant is assumed to be at its maximum boric acid

concentration and the maximum concentration from the CVS BAST and SFS cask loading pit (CLP) are considered in determining the required amount of TSP. Reference 21.62 also includes the following significant conservatisms in the calculation of the dissolution time:

- Only the front surface of the basket is exposed to the water.
- The TSP granules have agglomerated into a solid block so that the surface area is simply the basket width times the height of the TSP inside.
- The dissolution rate is based on a temperature of 71.1°C (160°F) with no agitation. It was calculated that the maximum dissolution time is 2.27 hours and determined that 12,000 kg (13.2 ton) of TSP is required to obtain a pH of 7 in the containment sump water (Reference 21.62).

21.9.2 Containment Atmosphere Hydrogen Control

In accident scenarios, release of hydrogen into the containment building could occur from oxidation of fuel cladding and containment materials, with the potential for the formation of a combustible mixture of hydrogen and air. The AP1000 design incorporates two systems in containment for removing atmospheric hydrogen: passive autocatalytic recombiners (PARs) and igniters. A description of the hydrogen control system is given in Section 6.7.3.

The containment is designed to allow natural convective flow and mixing of containment air and to avoid dead spaces where hydrogen-rich pockets could develop. Containment atmospheric hydrogen concentration is monitored continually.

The PARs are designed to prevent the buildup of hydrogen during a LOCA. Two PARs are located in containment to prevent the hydrogen concentration from reaching the flammability limit of 4-percent volume. The PARs are effective in a range of hydrogen and oxygen concentrations, under wet or steaming conditions, and at room or elevated temperatures.

In the case of a severe accident, it is assumed that 100 percent of the fuel cladding reacts with water and produces a rapid rise of hydrogen in the containment. The hydrogen igniters initiate a controlled burn of hydrogen at a concentration between the lower flammability limit and 10 percent by volume to prevent the occurrence of hydrogen detonation.

A total of 66 igniters are strategically located throughout the containment. The locations are based on the evaluation of hydrogen generation sites, flow around containment, hydrogen burn physics, and potential accumulation points. The igniters are located to avoid acceleration of the flame front during the burning. The igniters are divided into two power groups with 33 igniters in each group. Power is provided to each group normally by offsite power, however, should offsite power not be available, the igniters are powered by onsite Class 2 standby diesel generators and, should they fail, by the Class 2 standby electrical supply system (EDS). The igniters are located such that one power train of igniters provides sufficient coverage to control the concentration of hydrogen throughout the containment. Please see Chapter 10 for further details.

21.9.3 Steam Generator Tube Rupture

The complete severance of a SG tube is considered unlikely given the high resistance of the Alloy 690 tube material to corrosion and SCC under both primary and secondary conditions. It is more feasible that small leaks will occur, usually as a result of fretting wear, which will

be detected as changes in radioactivity in the secondary circuit. The sequence of events for a severance SGTR with automatic and operator-initiated actions is discussed in Chapter 9.

The radiological consequences of an SGTR have been analysed and the assessment assumes that all of the noble gases and volatile iodine carried with primary fluid into the secondary circuit are immediately released to the environment. The nonvolatile iodine and alkali metal activity in the primary coolant is also available for release, in proportion to the steam release from the ruptured SG.

The resulting offsite and onsite radiological doses for the limiting case analysed are within the Target 4 basic safety level (BSL) for frequent faults of 20 mSv onsite and 1 mSv offsite.

The major chemistry impact on this event is the availability of iodine in the source term. The alkaline-reducing conditions in primary and secondary coolant will mitigate molecular iodine release by favouring the ionic form in solution. The analysis assumes the maximum concentration of iodine in solution is equivalent to an iodine spiking event.

21.9.4 Loss-of-Coolant Accidents

A LOCA has been assessed for a range of pipe breaks within containment. The assessment is described in Chapter 9. Two types of LOCA are defined: a large-break LOCA involving a rupture with a total cross-sectional area of more than 0.09 m^2 (1 ft^2), and a small-break LOCA, which is anything smaller than this (an analysis of LOCA event is in Chapter 10t and also considers a medium-break LOCA). In all cases, borated water is injected into the primary circuit from a variety of sources, including the CMT, accumulators, and IRWST (when the pressure difference between the IRWST and RCS is less than 0.9 bar (13 psig)). The automatic depressurisation system (ADS) depressurises the primary circuit in stages. The insertion of the control rods (in the case of a small-break LOCA) or the injection of borated water and void formation (in the case of a large-break LOCA) are sufficient to bring the reactor to safe shutdown. The required technical specifications for the boron concentrations defined within Reference 21.74 is provided below:

Technical Specification	Surveillance Requirement	Limit	Applicable Modes
3.5.1	SR 3.5.1.4	Verify the boron concentration in each accumulator is ≥ 2600 ppm and ≤ 2900 ppm.	1, 2, 3, 4
3.5.2	SR 3.5.2.5	Verify the boron concentration in each CMT is ≥ 3400 ppm, and ≤ 3700 ppm.	1, 2, 3, 4
3.5.6	SR 3.5.6.4	Verify the IRWST boron concentration is ≥ 2600 ppm and ≤ 2900 ppm.	1, 2, 3, 4
3.5.8	SR 3.5.8.3	Verify the IRWST and refueling cavity boron concentration is ≥ 2600 ppm and ≤ 2900 ppm.	6

A small line break scenario is also considered for lines outside containment. This is possible only in the RCS sample line and the discharge line from the CVS to the WLS, when in use. In the former case, operator detection is immediate because of loss of sample flow and triggering of the air and area radiation detectors. In the latter case, the flow is limited and the iodine activity is reduced by the demineralisers. Even with conservative assumptions, i.e., a fuel defect level of 0.25 percent, maximum-permitted iodine, and an iodine spike at the time of the leak, the dose at the exclusion zone boundary is less than 0.021 Sv.

LOCA events within containment release the radioactive material carried in the coolant into the containment. For modelling and assessment purposes, the reactor coolant is assumed to have activity levels consistent with operation at the Tech Spec limits of 1.04E+07 Bq/g (280 μCi/gm) dose equivalent ^{133}Xe and 3.7E+04 Bq/g (1.0 μCi/gm) dose equivalent ^{131}I (Reference 21.74).

As the reactor coolant enters the containment, the noble gases and half of the iodine activity are assumed to be released into the containment atmosphere. In addition, nuclides from the fuel are assumed to be released into the coolant. Initially, three groups are considered: noble gases, iodine, and alkali metals (caesium and rubidium). After in-vessel core melt, tellurium, noble metals, cerium, and lanthanum group elements, barium and strontium are included.

The iodine form is consistent with the NUREG-1465 model (Reference 21.64). The model shows the iodine to be predominantly in the form of nonvolatile caesium iodide with a small fraction existing as elemental iodine. Additionally, the model assumes that a portion of the elemental iodine reacts with organic materials in the containment to form organic iodine compounds. The resulting iodine species split is as follows:

- Particulate 0.95
- Elemental 0.0485
- Organic 0.0015

Alkaline conditions favour the formation of soluble iodide ions, and elemental iodine is only stable in acidic and oxidising conditions. The PXS provides sufficient TSP to the post-LOCA cooling solution to adjust the solution pH to 7.0 (25°C (77°F)) within an acceptable period following a LOCA; see Section 6.6.1.2.3. The TSP is contained in baskets and dissolves in released coolant in containment to neutralise leaked coolant.

The AP1000 plant does not include Class 1 active systems for the removal of activity from the containment atmosphere. The containment atmosphere is depleted of elemental iodine and particulates as a result of natural processes within the containment. A limited containment spray system is provided in the design for severe accidents but is not credited in the analysis.

Elemental iodine is removed by deposition onto surfaces. Particulates are removed by sedimentation, diffusiophoresis (deposition driven by steam condensation), and thermophoresis (deposition driven by heat transfer). No removal of organic iodine is assumed.

Offsite dose calculations are based on the release of activity by way of the containment purge line prior to its isolation near the beginning of the accident and the release of activity resulting from containment leakage. A maximum design basis leak rate is used in the calculations for the first 24 hours and half that rate thereafter.

The exclusion area boundary dose, calculated for the worst 2-hour period following an incident and the low population area dose and calculated for the 30 days following an incident, are shown to be less than 0.25 Sv.

A further consequence of a LOCA is the potential for damage to structural materials through exposure to the post-LOCA aqueous environment in the containment. The majority of the reactor materials wetted following a LOCA will be low-alloy or stainless steels. The neutral or mildly alkaline environment will minimise the corrosion rates of LASs and reduce the risk of SCC of stainless steels.

A study performed by Westinghouse looked at the SCC behaviour of Type 304 and 316 stainless steels in aerated water with and without boric acid and with various concentrations of chloride or fluoride. Tests were conducted at peak temperatures up to 143°C (289.4°F). Low levels of chloride, produced cracking in acidic conditions but no cracking was found in alkaline solutions with up to 1000 ppm of chloride in either annealed or sensitised stainless steels. Moderate concentrations (100 ppm) of fluoride produced SCC in stainless steels but not in borated conditions (Reference 21.62).

21.9.5 Spent Fuel Pool Faults

The chemistry of the SFP coolant is to be monitored manually every 7 days to ensure that the boron concentration in the coolant is sufficient to maintain a subcritical level. The design specification states that the minimum boron concentration in the SFP coolant is 2300 ppm. This level is maintained as a defence in depth measure as subcriticality in the SFR (Spent Fuel Racks) is passively maintained through geometry. Spent fuel pool faults are discussed in Chapter 9.

21.9.6 Severe Accident Chemistry

Severe accident chemistry is discussed in Section 10.12. Additional information on the chemistry within the containment during severe accidents with an intact containment is also discussed within Reference 21.75.

21.10 Construction and Commissioning

A number of material factors are introduced or influenced by manufacturing and construction processes or during testing and commissioning activities can influence the performance of the material in terms of its corrosion resistance. The principal factors involved are discussed below.

Metallurgical Condition

Sensitisation of stainless steels is avoided by controlling manufacturing and the use of heat treatments where necessary (Chapter 20). Cold-working of stainless steels used in pressure boundary applications is controlled by limiting the hardness of material used and adopting appropriate procedures, e.g., the solution-annealed pressuriser surge line material is formed by hot-bending followed by a resolution-annealing heat treatment.

Surface cold work is avoided during manufacture by procedures, e.g., surface grinding of pressure boundary materials is followed by graded polishing to remove the cold-worked layer (Chapter 20).

A tailored metallurgical heat treatment has been adopted for Alloy 690 components in the AP1000 plant. This treatment refines the grain size, effectively decreasing the oxide layer formed and thus increasing the SCC resistance. This structured manufacturing process route produces a microstructure with closely spaced carbide precipitates on all of the grain boundaries with a very low-density intragranular carbide precipitation. In addition, detrimental materials are controlled and surfaces are cleaned to qualifying cleaning procedures to eliminate surface contaminants.

Surface Condition

Surface finish can alter susceptibility to SCC and oxidation rates as well as affecting deposition of material from coolant. Electropolishing is to be applied to SG channel heads to minimise crud deposition during operation. Electropolishing has been shown to reduce the activity of the channel head by approximately 40 to 80 percent on test pieces in core under nominal primary water conditions (Reference 21.67), resulting in an approximately 80-percent reduction in corrosion and metal release for flat plate sections and an approximately 50-percent reduction on tubular components.

Virgin metal surfaces exposed to primary coolant will oxidise relatively rapidly at first, with the rate decreasing as the surface oxide layer develops. During the early stages of oxide development, considerable amounts of material are released into the coolant and transported through the core. An important part of the AP1000 plant commissioning process prior to fuelling is HFT, during which primary circuit materials will be exposed to normal operating conditions to develop a passive oxide layer under nonactive conditions. This preconditioning is expected to considerably reduce crud production during operation. In addition, zinc dosing will be applied during this phase at high levels to promote the formation of a zinc-enriched oxide, which provides greater stability and limits incorporation of active species, thus reducing primary circuit activity. The secondary system will also undergo a, HFT process that will mimic the conditions from modes 5 to 2. HFT also provides an opportunity to test the PSS and SSS. The AP1000 Chemistry Manual contains details about HFT procedures (Reference 21.5, Chapter 9).

Contamination

The chemical environment in the primary, secondary, and various other systems needs to be controlled to ensure that the risk of corrosion-related failure is minimised. In particular, contaminant species, notably chloride, fluoride, sulphate, and a number of metals such as lead, cadmium, and copper are eliminated as far as possible. Procedures are applied during construction and commissioning to control contamination and to clean up surfaces before operation (Reference 21. 5, Chapter 13; and Reference 21.76).

Information on preoperational testing is in the AP1000 Chemistry Manual (Reference 21.5, Chapter 8).

21.11 Conclusions

For the AP1000 standard plant design, the development of the chemistry guidance and related material selections are based upon proven industry practices to ensure that the pressure boundary is maintained, reactivity is controlled, and radioactivity is minimised with the intent of achieving ALARP.

Through system design, material selection, and appropriate strategic water chemistry programs, degradation of systems and components can be minimized. To achieve the goal of maintaining plant integrity and personnel safety, the best chemistry strategy for the AP1000 plant is prevention, control, and mitigation, thereby resulting in a safe design, which incorporates:

- Proven system designs based upon industry standards and best practices.
- Material selections based on lessons learned, customer inputs, and best practices.

- Prevention of impurity ingress.
- Timely mitigation of contaminants using improved mechanical designs and shared industry knowledge.
- Real-time chemistry monitoring and control equipment and in-line instrumentation; as well as programs, guidelines, and procedures based upon industry guidelines.
- Westinghouse's in-house research and expertise and lessons learned during service to the existing fleet of operating PWRs.

Table 21-5 Primary Circuit Water Chemistry Safety Limits

Conductivity	0.1 to 70 μS/cm at 25°C.
Solution pH	4.0 to 10.5
Oxygen (1)	No explicit safety limit assumed beyond the expected action level of shutdown within 24 hours if oxygen is >100 ppb at temperatures >121°C.
Chloride (2)	0.1 ppm, maximum
Fluoride (2)	0.15 ppm, maximum
Hydrogen (3)	0-80 cc H_2 (STP) / kg H_2O
Suspended Solids (4)	2 ppm, maximum
Lithium (5)	[ ] ppm (typically limited to [ ] ppm in the fuels contract [[ ] ppm at hot zero power], material selection considered [ ] ppm to account for potential future increases in the operating limits)
Boric Acid	0 to 4000 ppm boron
Silica	1.0 ppm, maximum
Aluminum	0.05 ppm, maximum
Aluminum + Calcium + Magnesium	1000 ppb, maximum (combined)
Magnesium	0.025 ppm, maximum
Zinc (6)	0.04 ppm

Notes

1. Oxygen concentration must be controlled to less than 0.1 ppm in the reactor coolant through scavenging with hydrazine prior to plant operation above 93°C. During power operation with the specified hydrogen concentration maintained in the coolant, the residual oxygen concentration shall not exceed 0.005 ppm.
2. Halogen concentrations must be maintained below the specified values regardless of system temperature.
3. Hydrogen must be maintained in the reactor coolant for plant operations with nuclear power above 1 MW. The normal operating range should be 25-50 cm^3 (STP) H_2/kg H_2O.
4. Solids concentrations expected to be determined through filter having 0.45 μm pore size.
5. The specified lithium concentrations must be established for startup testing prior to heatup beyond 66°C. During cold hydrostatic testing and hot functional testing (in the absence of boric acid), the reactor coolant limits for lithium hydroxide must be maintained to inhibit halogen stress corrosion cracking.
6. Specification is applicable during power operation when zinc is being injected. The zinc concentration is maintained at the lower of 0.04 ppm or that specified in the cycle-specific reload safety analyses.

Notes	

1. During the first 48-72 hours during shutdown, hideout return occurs which causes elevated impurity levels in the bulk solution. Hideout return occurs when concentrated impurities in sludge diffuse back into the bulk solution upon a loss of the boiling flux that causes the impurities to concentrate. Concentration may exceed impurity transient values for a short duration.

22 FUEL SYSTEM, NUCLEAR AND THERMAL HYDRAULIC DESIGN

22.1 INTRODUCTION

Fuel element behaviour is of primary importance to the safety of a nuclear plant as the fuel contains the major part of the radioactive products in the plant. The fuel element performance as a heat source is crucial to safety because the release of its fission products is the likely consequence of some failure to transfer its heat to the coolant. In addition, there is a significant influence on the core reactivity and therefore upon the heat generation rate because of the feedback effect of the fuel reactivity coefficients.

The adequacy of the fuel element design and safety case is assessed in relation to relevant international standards (Reference 22.1) and best industry practice. For normal operation, this means that all reasonable steps should be taken to minimise the failure of the fuel rod cladding and thus minimise the release of radioactive fission products into the coolant. For fault conditions, the definition of satisfactory performance depends on the frequency with which the fault is expected to occur.

The limits within which the fuel can operate safely during both normal and fault conditions need to be defined and justified to demonstrate safe operation of the fuel. To achieve this, safety design bases are defined; considering the possible failure mechanisms of the materials and structures of the fuel assemblies and related components leads to the establishment of mechanical, nuclear, and thermal hydraulic design bases inherent in the safety design approach. It is also necessary to demonstrate that none of the design bases or limiting criteria are exceeded when the fuel is subjected to the full range of operational and fault conditions.

This chapter presents the safety case for the standard fuel element design in the AP1000 pressurised water reactor (PWR). This design provides very much flexibility in reload design.

First, the reactor core components are briefly described as an aid to understanding the following sections on the safety design basis (DB), safety design approach, and fuel system design. The design bases, functional requirements, and safety performance and justification for the nuclear and thermal and hydraulic design are then described.

This chapter refers extensively to Chapters 8 and 9 of this Pre-Construction Safety Report (PCSR); they define the conditions for frequent and infrequent faults both within the reactor and external to the reactor system. The results of the fault studies assessments are presented in Chapter 14. Chapter 21 is also particularly relevant as it describes the chemical controls and treatments applied in the AP1000 reactor to mitigate the impact of fuel failure in accident and fault conditions. This chapter also cross-references other relevant Westinghouse design documentation for additional details.

22.1.1 Fuel Assembly Description

The standard fuel assembly design for the AP1000 reactor is based on the Westinghouse 17x17 robust fuel assembly (RFA) design. Both the XL RFA fuel assembly and the standard AP1000 fuel assembly designs have the same active fuel length of 4.27 m. A difference between the two designs is that the AP1000 fuel assembly has been designed to interface with upper-mounted in-core instrumentation, versus bottom-mounted for the XL design.

Each standard fuel assembly consists of 264 fuel rods, 24 guide thimbles, and one instrumentation tube in a 17x17 array arranged within a supporting structure. The instrumentation thimble is located in the centre position and provides a channel for insertion of an in-core neutron detector if the fuel assembly is located in an instrumented core position. The guide thimbles provide channels for insertion of a rod cluster control assembly (RCCA), a gray rod cluster assembly (GRCA), a neutron source assembly, a burnable absorber (BA) assembly, or a thimble plug, depending on the position of the particular fuel assembly in the core. If control rods, source assemblies, and discrete BA assemblies are not required, thimble plugs are inserted to limit the fuel bypass flow. The guide thimbles are joined to the top and bottom nozzles of the fuel assembly and provide the supporting structure for the fuel grids. Figure 22-1 shows a cross-section of the fuel assembly array; Figure 22-2 shows a full-length view of the fuel assembly.

The fuel rods are loaded into the fuel assembly structure so that there is clearance between the fuel rod ends and the top and bottom nozzles. The fuel rods are supported within the fuel assembly structure by 10 structural grids (top grid (one), bottom grid (one), intermediate grids (eight)) and four non-structural grids (intermediate flow mixer (IFM) grids, plus one protective grid). Top, bottom, and intermediate grids provide axial and lateral support to the fuel rods. In addition, the four IFM grids located near the centre of the fuel assembly and between the intermediate grids provide additional coolant mixing. Debris failure mitigation is provided by a combination of the protective grid with the debris filter bottom nozzle (DFBN); the fuel cladding with oxide coating near the bottom; and the long, solid fuel rod bottom end plug.

Fuel assemblies are installed vertically in the reactor vessel and stand upright on the lower core plate, which is fitted with alignment pins to locate and orient each assembly. After the fuel assemblies are set in place, the upper support structure is installed. Alignment pins, built into the upper core plate, engage and locate the upper ends of the fuel assemblies. The upper core plate then bears down against the hold-down springs on the top nozzle of each fuel assembly to hold the fuel assemblies in place.

Improper orientation of fuel assemblies within the core is prevented by the use of an indexing hole in one corner of the top nozzle top plate. The assembly is oriented with respect to the handling tool and the core by means of a pin inserted into this indexing hole. Visual confirmation of proper orientation is also provided by an engraved identification number on the opposite corner of the top plate.

22.1.1.1 Fuel Rods

The fuel rods consist of uranium dioxide ceramic pellets contained in cold-worked and stress-relieved tubing constructed from a zirconium alloy (**ZIRLO**® High Performance Fuel Cladding Material), which is plugged and seal-welded at the ends to encapsulate the fuel. **ZIRLO** is selected for its mechanical properties and low neutron absorption cross-section (Reference 22.3). Figure 22-3 shows a schematic of the fuel rod.

The fuel pellets are right circular cylinders consisting of slightly enriched uranium dioxide powder that has been compacted by cold pressing and then sintered to the required density. The ends of each pellet are dished slightly to allow greater axial expansion at the pellet centreline and to increase the void volume for fission gas release. The ends of each pellet also have a small chamfer at the outer cylindrical surface, which improves manufacturability and mitigates potential pellet damage due to fuel rod handling.

Void volume and clearances are provided within the rods to accommodate fission gases released from the fuel, differential thermal expansion between the clad and the fuel, and fuel density changes during irradiation. To facilitate the extended burnup capability necessitated by longer operating cycles, the fuel rod is designed with two plenums (upper and lower) to accommodate the additional fission gas release. The upper plenum volume is maintained by a fuel pellet hold-down spring. The lower plenum volume is maintained by a standoff assembly.

Shifting of the fuel within the clad during handling or shipping prior to core loading is prevented by a stainless-steel helical spring that bears on top of the fuel pellet stack. The spring also prevents gaps from opening as pellets densify, and provides support to the cladding due to creepdown during steady-state operation. Assembly consists of plugging and welding the bottom of the cladding; installing the bottom plenum spacer assembly, fuel pellets, and top plenum spring; and then plugging and welding the top of the rod.

The solid bottom end plug has an internal grip feature and tapered end to facilitate fuel rod loading during fuel assembly fabrication and reconstitution. Additionally, the bottom end plug is designed to be sufficiently long to extend through the protective grid. The bottom section of the fuel rod has a protective zirconium-oxide-coated surface feature. Use of the protective grid with a longer end plug and the DFBN, in addition to the coated cladding surface, constitutes a three-level debris protection package, which enhances the fuel reliability performance against trapped debris. This precludes any breach in the fuel rod pressure boundary due to clad fretting wear induced by debris trapped at the bottom section of the fuel assembly.

The fuel rods are internally pressurised with helium during the welding process to minimise compressive clad stresses and prevent clad flattening under reactor coolant operating pressures. The fuel rods are pre-pressurised and designed so that:

- The internal gas pressure design limit referred to in Section 22.5.1 is not exceeded.
- The cladding stress-strain limits (Section 22.5.1) are not exceeded.
- Clad flattening will not occur during the fuel core life.

The AP1000 reactor fuel rod design may also include axial blankets. The axial blankets consist of fuel pellets of a reduced enrichment at each end of the fuel rod pellet stack. Axial blankets reduce neutron leakage axially and improve fuel utilization. The axial blankets use chamfered pellets that are longer than the enriched pellets to help prevent accidental mixing during manufacturing.

Furthermore, axial blankets do not significantly impact the source range detector response, since the reduction in power from the axial blanket is limited to the top and bottom 20.32 cm (8 inches) of the core, while the source range detectors are centred typically about 106.68 cm (42 inches) from the bottom of the core. Reference 22.98 shows that the axial weighting or importance of the neutron flux from the end 20.32 cm (8 inches) regions of the core to the source range detector response is relatively low compared to the centre region of the core. In addition, the neutron flux at the ends of the core is relatively low compared to the more important centre region. Therefore, the reduction in power at the ends of the core due to the introduction of axial blankets will not significantly impact the source range detector response. Additionally, the locations of the axial blankets are evident in Figure 22-20 which shows an example of a first cycle fuel rod design.

The AP1000 reactor fuel rods include integral fuel BAs (IFBAs). The IFBAs consist of zirconium diboride (ZrB_2) -coated fuel pellets, which are identical to the enriched uranium dioxide pellets except for the addition of a thin boride coating on the pellet cylindrical surface. Coated pellets occupy the central portion of the fuel column. The number and pattern of integral fuel BA rods within an assembly may vary depending on specific application (Reference 22.3).

[

]

22.1.1.2 Fuel Assembly Structure

As shown in Figure 22-2, the fuel assembly structure consists of a bottom nozzle, top nozzle, fuel rods, guide thimbles, and grids.

Bottom Nozzle

The bottom nozzle serves as the bottom structural element of the fuel assembly and directs the coolant flow distribution to the assembly. The nozzle is fabricated from Type 304 and Grade CF-3 stainless steel and consists of a perforated plate and casting that incorporates a skirt and four angle legs with bearing pads, as illustrated in Figure 22-2. The legs and skirt form a plenum to direct the inlet coolant flow to the fuel assembly. The perforated plate also prevents accidental downward ejection of the fuel rods from the fuel assembly. The bottom nozzle is fastened to the fuel assembly guide thimbles by locked thimble screws, which penetrate through the nozzle and engage with a threaded plug in each guide thimble. The flow hole pattern, together with top nozzle ligaments, limits the fuel rod movement within the cavity between the two nozzles.

Coolant flows from the plenum in the bottom nozzle upward through the penetrations in the plate to the channels between the fuel rods. The penetrations in the plate are positioned between the rows of the fuel rods.

In addition to serving as the bottom structural element of the fuel assembly, the bottom nozzle also functions as a debris filter. The bottom nozzle perforated plate contains a multiplicity of flow holes sized to minimise passage of detrimental debris particles into the active fuel region of the core while maintaining sufficient hydraulic and structural margins. Furthermore, the skirt provides improved bottom nozzle structural stability and increased design margins to reduce damage from abnormal handling.

Axial loads (from top nozzle hold-down springs) imposed on the fuel assembly and the weight of the fuel assembly are transmitted through the bottom nozzle to the lower core plate. Indexing and positioning of the fuel assembly is controlled by alignment holes in two diagonally opposite bearing pads that mate with locating pins in the lower core plate. Lateral loads on the fuel assembly are transmitted to the lower core plate through the locating pins.

The bottom nozzle also has a reconstitution design feature that facilitates easy removal of the nozzle from the fuel assembly. This design incorporates a thimble screw with a circular locking cup located around the screw head. The locking cup is crimped into a local spherical radius relief on the bottom nozzle. To remove the bottom nozzle, a counter clockwise torque is applied to the thimble screw until the locking cup (detents) is relaxed and the thimble screw is removed. This reconstitutable design permits remote unlocking, removal, and relocking of the thimble screws, as the same or a new bottom nozzle is reattached to the fuel assembly.

Top Nozzle

The reconstitutable top nozzle functions as the upper structural component of the fuel assembly and, in addition, provides a partial protective housing for the RCCA, discrete BA, or other core components. The top nozzle assembly includes four sets of hold-down springs, which are secured to the top nozzle top plate (Figure 22-4). The springs are made of Alloy 718. The other top nozzle components are made of Type 304L and Grade CF-3 stainless steel.

The adapter plate contains various-shaped holes to permit the flow of coolant upward through the top nozzle. Round holes are provided in the adapter plate to accept (guide thimble) inserts that are mechanically locked to the adapter plate using a lock tube. The unique design of the insert joint and lock tube are the key design features of the reconstitutable top nozzle.

The ligaments in the adapter plate cover the top of the fuel rods, precluding any upward ejection of the fuel rods from the fuel assembly. The enclosure is a box-like structure that establishes the distance between the adapter plate and the top plate. The top plate has a large square hole in the centre to permit access for the RCCA, BA assembly, or other components. Hold-down springs are mounted on the top plate and are retained by retaining pins located at diagonally opposite corners of the top plate.

The top plate also contains integral pads located on the two remaining top nozzle corners. The pads include alignment holes which, when fully engaged with the reactor internals upper core plate guide pins, provide proper alignment to the fuel assembly, reactor internals, and RCCA.

To remove the top nozzle assembly, a tool is first inserted through a lock tube and expanded radially to engage the bottom edge of the tube (Figure 22-5). An axial force is then exerted on the tool, which overrides local lock tube deformations and withdraws the lock tubes from the inserts. After the lock tubes have been removed, the nozzle assembly is removed by raising it off the upper slotted ends of the nozzle inserts, which deflect inwardly under the axial lift load.

With the top nozzle assembly removed, direct access is provided for fuel rod examination or replacement. Reconstitution is completed by the remounting of the nozzle assembly and the insertion of lock tubes. (Reference 22.16)

Unlike previous designs with bottom-mounted in-core instrumentation, the AP1000 design has upper-mounted instrumentation. As such, the top nozzle contains an instrumentation hole.

Guide Thimbles and Instrument Tube

The guide thimbles are structural members that provide channels for the neutron absorber rods, BA rods, neutron source rods, or other assemblies. Each guide thimble is fabricated from Zircaloy-4 or **ZIRLO** with constant outer and inner diameter over the entire length. Separate dashpot tubes, made from Zircaloy-4 or **ZIRLO** tubing, are inserted into the bottom portion of the guide thimble tubes. The larger tube diameter at the top section provides a relatively large annular area necessary to permit rapid control rod insertion during a reactor trip, as well as to accommodate the flow of coolant during normal operation. Holes provided on the guide thimble above the dashpot reduce the rod drop time and also provide sufficient cooling to the RCCAs and GRCAs when they are inserted into the core without unduly reducing the flow past the fuel rods.

The lower portion of the guide thimble with the dashpot tube results in a dashpot action near the end of the control rod travel during normal trip operation. The dashpot is closed at the bottom by means of an end plug, which is provided with a small flow port to avoid fluid stagnation in the dashpot volume during normal operation.

To accommodate the top nozzle reconstitutable feature, the top of the guide thimble is fastened to a tubular sleeve, or insert, by a three tier expansion bulge joint. An expansion tool is inserted inside the nozzle insert and guide thimble to the proper elevation. The four lobes on the expansion tool force the guide thimble and insert outward locally to a predetermined diameter, therefore joining the two components.

Upon installation of the top nozzle assembly, the bulge near the top of the nozzle insert is captured in a corresponding groove in the thimble hole of the top nozzle adapter plate. The mechanical connection between the nozzle insert-guide thimble and top nozzle is made by insertion of a lock tube into the insert (Figure 22-5). The design of the top grid sleeve-guide thimble and top nozzle insert-guide thimble bulge joint connections have been mechanically tested and found to meet applicable design criteria.

The fuel rod support grids, with the exception noted for the Alloy-718 protective grid, are secured to the guide thimbles using a similar bulge joint connection to create an integral structure. Attachment of the intermediate mixing vane and IFM grids to the guide thimbles is performed using the fastening technique depicted in Figure 22-6 and Figure 22-7.

The intermediate mixing vane and IFM grids employ a single-tier bulge connection between the grid sleeve and guide thimble as compared with the two-tier bulge connection used for the

top grid. The design of the single-tier bulge joint connection has also been mechanically tested and meets the design requirements.

The Alloy-718 bottom grid is secured to the guide thimble assembly by a double-tier bulge connection between the grid sleeve and guide thimble. The design of the double-tier bulge joint connection has also been mechanically tested and meets the design requirements.

The lower end of the guide thimble is fitted with a welded end plug. The Alloy-718 protective grid is secured to the guide thimble assembly by Alloy-718 spacers that are spot-welded to the grid. The spacer is captured between the guide thimble end plug and the bottom nozzle by means of a (thimble) locking screw (Figure 22-8).

The described methods of grid fastening are standard and have been used successfully since the introduction of guide thimbles in 1969.

The central instrumentation tube in each fuel assembly is constrained by seating in counterbores located in both top and bottom nozzles. The instrumentation tube has a constant diameter and provides an unrestricted passageway for the in-core neutron detector which enters the fuel assembly from the top nozzle. Furthermore, the instrumentation tube is secured to the top, bottom, IFM, and mid-grids with bulge joint connections similar to those previously discussed for securing the grids to the guide thimbles.

Grid Assemblies

The fuel rods are supported at intervals along their lengths by grid assemblies that maintain the lateral spacing between the rods throughout the design life of the assembly (Figure 22-2). Each fuel rod is given support at six contact points within each structural grid by the combination of support dimples and springs. The grid assembly consists of individual slotted straps assembled and interlocked into an egg-crate-type arrangement with the straps permanently joined at their points of intersection. The straps may contain springs, support dimples, and mixing vanes; or any such combination.

Two types of structural grid assemblies are used on the fuel assembly of the AP1000 design. One type, with mixing vanes projecting from the edges of the straps into the coolant stream, is used in the high-heat flux region of the fuel assemblies to promote mixing of the coolant. The other type, located at the top and bottom of the assembly, does not contain mixing vanes on the internal straps. The outside straps on the grids contain mixing vanes that, in addition to their mixing function, aid in guiding the grids and fuel assemblies past projecting surfaces during handling or loading and unloading of the core.

Because of its corrosion resistance and high-strength properties, the bottom grid material chosen for the fuel assembly design is Alloy-718. The top grid is fabricated from Alloy-718. The magnitude of the grid restraining force on the fuel rod is set high enough to minimise possible fretting without overstressing the cladding at the points of contact between the grids and fuel rods. The grid assemblies are designed to allow axial thermal expansion of the fuel rods without imposing restraint sufficient to develop buckling or distortion of the fuel rods.

The eight intermediate (mixing vane) or structural grids on the fuel assembly are made of **ZIRLO**. This material was selected to take advantage of its inherent low neutron capture cross-section. **ZIRLO**, like other zirconium alloys used in the nuclear industry, contains a high percentage of zirconium and therefore inherits the low capture cross section for thermal neutrons from zirconium. The percent of other elements [ ] in the zirconium alloy are limited to the content necessary for good mechanical properties and corrosion resistance.

The **ZIRLO** grids have thicker straps and incorporate the same grid cell support configuration as the Alloy-718 grid. The **ZIRLO** interlocking strap joints and grid/sleeve joints are fabricated by laser welding, whereas the Alloy-718 grid joints (except the protective grid) are brazed. The interlocking strap joints for the protective grid are also fabricated by laser welding.

The mixing vanes incorporated in the intermediate grids induce additional flow mixing among the various flow channels in a fuel assembly as well as between adjacent fuel assemblies. This additional flow mixing enhances thermal performance.

The IFM grids are located at selected spans between the mixing vane structural grids and incorporate a similar mixing vane array (Figure 22-2). Their prime function is mid-span flow mixing in the hotter fuel assembly spans. Each intermediate flow mixer grid cell contains four dimples that are designed to prevent mid-span channel closure in the spans containing intermediate flow mixers and fuel rod contact with the mixing vanes. This simplified cell arrangement allows short grid cells so that the intermediate flow mixer grid can accomplish its flow mixing objective with minimal pressure drop.

The IFM grids, like the mixing vane grids, are fabricated from **ZIRLO**. The IFM grids are manufactured using the same basic techniques as the structural grid assemblies and are joined to the guide thimbles and instrumentation tube via sleeves welded at the bottom of appropriate grid cells.

Grid impact testing has been performed on the **ZIRLO** structural grids and the IFM grids. The purpose of the testing was to determine the dynamic buckling, or crush strength of the grids. The grid impact testing was performed at an elevated temperature of 316°C (600°F). This temperature is a conservative value representing the core average temperature at the midgrid locations.

The IFM grids are not intended to be structural members but they do share the loads of the structural grids during faulted loading and, as such, contribute to enhance the load-carrying capability of the fuel assembly.

The dynamic crush strength of the structural grids and IFM grids envelop the calculated grid impact loading during combined seismic and pipe rupture events. A coolable geometry is therefore provided at the IFM grid elevations, as well as at the structural grid elevations.

An additional assessment was carried out to assess the structural and IFM grid response to the depressurisation of the primary circuit due to a double-ended guillotine (DEG) break of the RCS cold leg. This assessment, documented in Reference 22.97, concluded that [

] does not challenge coolable geometry of the core.

]

22.1.1.3 In-Core Control Components

Reactivity control is provided by neutron-absorbing rods, gray rods, BA rods, and a soluble chemical neutron absorber (boric acid). The boric acid concentration is varied to control long-term reactivity changes such as:

- Fuel depletion and fission product buildup
- Cold to hot, zero power reactivity changes
- Reactivity change produced by intermediate-term fission products such as xenon and samarium
- Burnable absorber depletion

The chemical and volume control system, which is used to adjust the level of boron in the coolant, is discussed in Section 6.1.

The rod cluster control assemblies provide reactivity control for:

- Shutdown
- Reactivity changes due to coolant temperature changes in the power range
- Reactivity changes associated with the power coefficient of reactivity
- Reactivity changes due to void formation

A negative power coefficient is maintained at hot, full-power conditions throughout the entire cycle to reduce possible deleterious effects caused by a positive coefficient during pipe rupture or loss-of-flow accidents. Since soluble boron alone is insufficient to provide a negative moderator coefficient, burnable absorber assemblies are also used. Use of burnable absorber assemblies during reloads is discussed in subsection 22.6.1.2.

The most effective reactivity control components are the RCCAs and the corresponding drive rod assemblies, which, along with the GRCAs, are the only kinetic parts in the reactor. Figure 22-9 identifies the RCCAs and drive rod assembly in addition to the arrangement of these components in the reactor relative to the interfacing fuel assembly, guide thimbles, and control rod drive mechanism (CRDM). The arrangement for the GRCAs is the same.

The guidance system for the RCCA is provided by the guide tubes (Figure 22-9). The guide tubes provide two regimes of guidance: first, in the lower section, a continuous guidance system provides support immediately above the core, which protects the rod against excessive deformation and wear caused by hydraulic loading; second, the region above the continuous section provides support and guidance at uniformly spaced intervals.

The envelope of support is determined by the pattern of the control rod cluster (Figure 22-10). The guide tubes provide alignment and support of the control rods, spider body, and drive rod while maintaining trip times at or below required limits.

Each reactivity control component is described in detail below. The neutron source assemblies provide a means of monitoring the core during periods of low neutron activity.

Rod Cluster Control Assemblies

The rod cluster control assemblies are divided into two categories: control and shutdown. The control groups compensate for reactivity changes due to variations in operating conditions of the reactor, that is, power and temperature variations. Two nuclear design criteria have been employed for selection of the control group. First, the total reactivity worth must be adequate to meet the nuclear requirements of the reactor. Second, in view of the fact that these rods may be partially inserted at power operation, the total power peaking factor should be low enough to confirm that the power capability is met. The control and shutdown groups provide adequate shutdown margin.

An RCCA comprises 24 individual neutron absorber rods fastened at the top end to a common spider assembly (Figure 22-10). The absorber material used in the control rods is silver-indium-cadmium alloy, which is essentially "black" to thermal neutrons and has sufficient additional resonance absorption to significantly increase worth. The absorber material is in the form of solid bars sealed in cold-worked stainless-steel tubes (Figure 22-11). Sufficient diametral and end clearance is provided to accommodate relative thermal expansions. The control rods have bottom plugs with bullet-like tips to reduce the hydraulic drag during reactor trip and to guide smoothly into the dashpot section of the fuel assembly guide thimbles. The material used in the absorber rod end plugs is Type 308 or 308L stainless steel. The design stresses used for the these materials are the same as those defined by the American Society of Mechanical Engineers (ASME) for Type 304 or 304L stainless steel which have essentially the same strength properties as Type 308 and 308L stainless steel, respectively.

The spider assembly is in the form of a central hub with radial vanes containing cylindrical fingers from which the absorber rods are suspended. Internal groove-like profiles to facilitate handling tool and drive rod assembly connection are machined into the upper end of the hub. Coil springs inside the spider body absorb the impact energy at the end of a trip insertion. The radial vanes may either be joined to the hub by welding and brazing, and the fingers are joined to the vanes by brazing, or the vanes and fingers may be integral with the spider body. A bolt that holds the springs and retainer is threaded into the hub within the skirt and welded to prevent loosening while in service. The components of the spider assembly are made from Types 304, 304L, and/or CF-3 (casting equivalent of 304L) stainless steel except for the retainer, which is of Type 630 material, and the springs, which are Alloy-718.

The absorber rods are fastened securely to the spider. The rods are first threaded into the spider fingers and then secured with a locking device. The end plug below the pin position is designed with a reduced section to permit flexing of the rods to correct for small operating or assembly misalignments.

The overall length of the RCCA is such that, when the assembly is withdrawn through its full travel, the tips of the absorber rods remain engaged in the fuel assembly guide thimbles so that alignment between rods and thimbles is always maintained. Since the rods are long and slender, they are relatively free to conform to any misalignments with the guide thimble. Any such misalignments are small and the RCCA rods remain positioned within the core so that flow-induced wear on the RCCA absorber rods as they sit at the top of the guide thimbles is evenly spread and within acceptable limits.

Gray Rod Cluster Assemblies

The purpose of GRCAs is to provide reactivity control capability during operation. GRCAs contain a smaller quantity of neutron absorber relative to RCCAs, and the 16 GRCAs in the AP1000 reactor are grouped into four banks with low reactivity worth. The GRCAs are used

in load follow manoeuvring and base load operation to control core temperature and power; they provide a mechanical shim capability that replaces the need for small changes in the concentration of soluble boron, that is, chemical shim, normally used for this purpose.

The mechanical design of the GRCAs plus the CRDM and the interface with the fuel assemblies and guide thimbles are identical to the RCCAs except that the 24 GRCA rodlets are fabricated of a tungsten absorber (of a reduced diameter as compared with the RCCA absorber) double encapsulated in an Alloy-718 sleeve and stainless-steel clad (Figure 22-12). The combination of the reduced diameter tungsten absorber and Alloy-718 sleeve provide the following benefits:

- [
  ]
- [
- [
  ]

Tungsten does not exhibit decreased absorber worth as a result of irradiation which provides [ ]. In addition tungsten does not introduce any detriments when compared to the silver-indium-cadmium alloy material and therefore it is deemed to be the best choice for the GRCA rodlets. Reference 22.36 provides further detail on the benefits and design of the tungsten absorber material utilised in the GRCA rodlets.

Burnable Absorber Assembly

The reactor core is cooled and moderated by light water under pressure. Soluble boron in the moderator/coolant serves as a neutron absorber. The concentration of boron is varied to control reactivity changes that occur relatively slowly, including the effects of fuel burnup. BA rods are also employed to limit the amount of soluble boron required and thereby maintain the desired negative reactivity coefficients.

Each BA assembly consists of discrete BA rods attached to a hold-down assembly (Figure 22-13). When needed for nuclear considerations, BA rods are inserted into selected thimbles within fuel assemblies.

Wet annular BAs (WABAs) consist of pellets of alumina-boron carbide material contained within zirconium alloy tubes. These tubes, which form the outer clad for the BA rod, are plugged, pressurised with helium, and seal-welded at each end to encapsulate the stack of absorber material. The absorber stack length is positioned axially within the BA rod by the use of a bottom-end spacer as necessary (Figure 22-13).

The BA rods in each fuel assembly are grouped and attached together at the top end of the rods to a hold-down assembly by a flat, perforated retaining plate, which fits within the fuel assembly top nozzle and rests on the adapter plate.

The retaining plate and the BA rods are held down and restrained against vertical motion through a spring pack attached to the plate and compressed by the upper core plate when the reactor upper internals assembly is lowered into the reactor. With this arrangement, the BA rods cannot be ejected from the core by flow forces. Each rod is attached to the baseplate by a nut that is crimped into place.

Neutron Source Assemblies

The purpose of a neutron source assembly is to provide a base neutron level to give confidence that the detectors are operational and responding to core multiplication neutrons. For the first core, a neutron source is placed in the reactor to provide a positive neutron count of at least two counts per second on the source range detectors attributable to core neutrons. The detectors, called source range detectors, are used primarily during subcritical modes of core operation.

The source assembly also permits detection of changes in the core multiplication factor during core loading, refuelling, and approach to criticality. This can be done since the multiplication factor is related to an inverse function of the detector count rate. Changes in the multiplication factor can be detected during addition of fuel assemblies while loading the core, changes in control rod positions, and changes in boron concentration.

Both primary and secondary neutron source rods are used. The primary source rod, containing a radioactive material, spontaneously emits neutrons during initial core loading, reactor startup, and initial operation of the first core. After the primary source rod decays beyond the desired neutron flux level, neutrons are then supplied by the secondary source rod. The secondary source rod contains a stable material, which is activated during reactor operation. The activation results in the subsequent release of neutrons.

Four source assemblies are typically installed in initial load of the reactor core: two primary source assemblies (Figure 22-14) and two secondary source assemblies (Figure 22-15). Each primary source assembly contains one primary source rod and a number of BA rods. Each secondary source assembly contains a symmetrical grouping of secondary source rodlets.

Neutron source assemblies are employed at opposite sides of the core. The source assemblies are inserted into the guide thimbles in fuel assemblies at selected locations. The source assemblies contain a hold-down assembly identical to that of the BA assembly (Figure 22-14 and Figure 22-15).

The primary and secondary source rods both use the same cladding material as the absorber rods. The secondary source rods contain antimony-beryllium pellets stacked to a height of approximately 2.23 m (88 inches). The primary source rods contain capsules of californium (plutonium-beryllium possible alternate) source material and alumina spacers to position the source material within the cladding. The rods in each assembly are fastened at the top end to a hold-down assembly.

The other structural members, except for the springs, are constructed of Type 304, 304L, and 308L stainless steel. The springs exposed to the reactor coolant are Alloy-718.

22.2 FAULT STUDY LIMITS

An overview of the safety case methodology is given in Figure 8-1 in Chapter 8. The approach to identifying faults for the AP1000 reactor is described in Chapter 8. A complete list of faults investigated for the fuel system design is provided in Appendix 8A. The plant characteristics and initial conditions assumed in the accident analyses for the fuel system design are shown in Chapter 9 (Tables 9.0-5 and 9.0-7). The results of the accident analyses for each fault investigated for the fuel system design, together with design-limiting values for safety-relevant parameters, are given in the appropriate sections of Chapter 9. The fundamental acceptance criteria for each fault are identified in Chapter 9, Table 9.0-3.

22.3 SAFETY DESIGN APPROACH

The safety design bases of Section 22.2 have led to the identification of a considerable number of design bases for the fuel rods, fuel assemblies, and in-core components; and for the nuclear and thermal hydraulic design of the reactor core. The design bases and acceptance limits used by Westinghouse are described in the Westinghouse Fuel Criteria Evaluation Process and its addendums (Reference 22.4), and the AP1000 Fuel Development Design Closeout Package (Reference 22.5). The fuel rods are designed to operate safely up to the design discharge burnup using the extended burnup design methods described in the Extended Burn-Up Evaluation report (References 22.6, and 22.29).

The fuel rod design for the AP1000 plant considers effects such as fuel density changes, fission gas release, clad creep, and other physical properties which vary with burnup. The integrity of the fuel rods is provided by designing to prevent excessive fuel temperatures; excessive internal rod gas pressures due to fission gas releases; and excessive cladding stresses, strains, and strain fatigue, as discussed in Section 22.5. The fuel rods are designed so that the conservative design bases of the following events envelop the lifetime operating conditions of the fuel. For each DB, the performance of the limiting fuel rod, with appropriate consideration for uncertainties, does not exceed the limits it has specified. The detailed fuel rod design also establishes such parameters as pellet size and density, clad and pellet diametral gap, gas plenum size, and helium pre-pressurisation level.

The design bases for the in-core control components are described in Section 22.5.1.3.

Compliance with the safety design bases described in Section 22.2 is demonstrated for all internally initiated faults within the reactor in the appropriate sections of Chapter 9, where an assessment of the numbers of fuel failures is made under various fault conditions. The mechanisms causing fuel failure are identified and discussed in Section 22.5.

Nonreactor faults, such as fuel failure as a result of a dropped load during refuelling and spent fuel storage, and faults arising from internal hazards also have an important impact on fuel safety. The safe operation of the fuel for nonreactor faults is demonstrated in Sections 9.11 and 9.14, and the impact on fuel safety due to internal hazards, including dropped and load mishandling, is discussed in Section 11.8.

In carrying out the transient calculations described in Chapter 9, bounding limits are defined for all safety-related parameters. These bounding limits represent a conservative assessment of the operating conditions before the fault, the inherent nuclear characteristics of the core during the ensuing transient, and the characteristics of the fuel and noncore systems for nonreactor faults and faults arising from internal hazards. As many of the safety-related parameters assume their extreme values during the first cycle, the design assessment concentrates on operation with the initial fuel loading. Where subsequent operation is expected to produce a more extreme value for any safety-related parameter, the design assessment is based on a representative equilibrium core condition.

Subsequently, each new core configuration after a refuelling operation is analysed before startup, making use of the known core state at the time. It is sufficient to establish that the safety-related parameters are still within the bounding limits and hence the fault analysis is valid.

The application of conservative bounding limits to all safety-related parameters in the assessment of the safety case gives confidence that the limiting values will never be approached during the operational lifetime of the plant. This confidence is augmented by the following:

- The use of validated codes and data to predict the reactor operating conditions
- The use of design and operational limits that are more restrictive than the bounding limits
- Administrative checks to confirm that the predicted values of the safety-related parameters are within the bounding limits
- Tests following refuelling shutdowns and during operation to validate the predicted values of the safety-related parameters
- The specification of operating procedures designed to ensure that the reactor is within operational or safe shutdown limits
- Alarm signals to indicate to the operator that a monitored safety-related parameter is approaching its operational limits
- Automatic reactor trips at settings designed to ensure that monitored safety-related parameters do not exceed their bounding limits

22.4 FUEL FAILURE CRITERIA AND SECONDARY LIMITS

In order to provide confidence that the cladding will not fail, limits are defined for the key parameters which govern clad stresses, fuel melt and other cladding failure modes. These limits are used in the safety analysis to ensure that cladding failure will not occur during frequent or infrequent faults. The parameters are listed below along with their respective limits.

The conditions at which fuel failure is assumed to occur are as follows:

- Departure from nucleate boiling ratio (DNBR) is less than or equal to the 95/95 limit.
- The volume averaged effective stress is equal to or greater than the yield stress.
- Local rod power is equal to or greater than 73.82 kW/m (22.5 kW/ft).
- Local clad stress is equal to or greater than the threshold stress due to pellet-clad interaction (PCI) during power ramps.
- Radial averaged peak fuel enthalpy rise in fast transients is greater than the limits discussed in Section 22.4.5. (Note that the at-power reactivity increase accident (RIA) failure criterion is based on DNBR; if DNB occurs the cladding is assumed to have failed.)

If any of the above criteria are exceeded for any fuel rod, then that rod is assumed to have failed. This is a conservative approach since there is only a small probability of failure at each of these conditions.

The individual criteria are discussed in more detail below.

22.4.1 Departure from Nucleate Boiling Ratio Less than or Equal to 95/95 Limit

The DNBR is the ratio of the heat flux necessary to cause departure from nucleate boiling (DNB) to the heat flux predicted to exist in the fuel rod under consideration. An empirical

DNB correlation, the WRB-2M correlation, has been developed by Westinghouse from a wide range of rod bundle test data. The correlation is used to predict the heat flux required to give DNB as a function of local fluid conditions. The WRB-2M correlation is supplemented with other DNB correlations (e.g. W-3) for conditions (e.g., low pressure) outside the WRB-2M-applicable range in safety analysis. The predicted DNBR is checked with the design limit DNBR value that accounts for uncertainties in the DNB correlation and design parameters. Above the design limit DNBR, there is at least a 95 percent probability at a 95 percent confidence level (95/95) that the limiting fuel rod in the reactor core will not experience DNB.

Additional DNBR margin is maintained when the safety analyses are performed to DNBR limits higher than the 95/95 design limit DNBR values. The difference between the design limit DNBRs and the safety analysis limit DNBRs is the DNBR margin conservatively maintained in the analysis. A portion of this margin is used to offset the rod bow DNBR penalty.

22.4.2 Clad Effective Tensile Stress Equal to or Greater than the Yield Stress

This criterion is used for normal operation and frequent faults in the fuel rod design to ensure that the cladding does not fail under high tensile stresses. It does not preclude some rod failures during normal operation and frequent faults due to minor manufacturing defects.

The possible local and average increases in rod power due to the transient are modelled in the Westinghouse fuel design code (PAD 4.0) (Reference 22.7) and bound all frequent faults. The stress calculation is conservatively made, taking into account the effects of manufacturing tolerances and local stress concentrations.

22.4.3 Local Rod Power Equal to or Greater than 73.82 kW/m

This limit assumes that uranium dioxide fuel melting will occur at above 73.82 kW/m (22.5 kW/ft) and that this will lead to fuel clad failure. Both assumptions are conservative. At a given linear heat rate, fuel temperatures are highest early in life when fuel densification is complete and clad creepdown is negligible. The calculations of fuel temperature in the Westinghouse design code contain sufficient conservatisms to be sure that, even then, fuel melting will not occur at 73.82 kW/m (22.5 kW/ft). Loading pattern variations could place fuel in higher power locations later in life, which could lead to higher actual operating fuel temperatures after the point when fuel densification is complete. However, the fuel temperatures associated with accident scenarios that could lead to reaching the linear hear rate limit of 73.82 kW/m (22.5 kW/ft) will always be lower than the fuel melt temperature.

The current limit of 73.82 kW/m (22.5 kW/ft) is consistent with current operating and fuel manufacturing practices and is consistent with the fuel centreline temperature DB (Ref. 22.74).

22.4.4 Local Clad Stress Equal to or Greater than the Threshold Stress for Pellet-Clad Interaction Failure

PCI is a potential failure mechanism for nuclear fuel. The failure occurs during power increases where the thermal expansion of the fuel pellet is greater than that of the surrounding fuel cladding. This causes stress on the cladding and is impacted further by fission products that can assist in stress corrosion cracking (SCC) of the zirconium cladding. With SCC, the clad may crack at stresses under the yield stress. A failure threshold for PCI is typically defined based on power ramp tests.

A set of methodologies exist for the evaluation of PCI fuel protection during frequent fault scenarios (Reference 22.9). These methodologies will be used to ensure that PCI limits are met during the reload fuel design process and will establish part of the basis for the overpower protection trip setpoints. Based on the evaluations and calculations performed using the Westinghouse PCI model, PCI limits will be maintained without unduly restricting normal plant operation.

22.4.5 Radial Average Peak Fuel Enthalpy in Fast Transients

This criterion covers pellet-cladding mechanical interaction (PCMI) failure of fuel clad in transients where the energy is deposited in times that are short compared with the thermal time constant of the fuel. The PCI criterion in Section 22.4.4 cannot be applied in such transients since it is only valid for times that are long compared with the time constant of the fuel. Thus, the radial average peak fuel enthalpy rise criterion is applicable for transients lasting less than 1 second, such as an RCCA ejection accident.

For transients of the same order as the time constant of the fuel, the radial average peak fuel enthalpy rise criterion is used along with DNB to ensure that conservatism is retained. In these transients, heat loss from the fuel in determining the enthalpy is taken into account. DNB is also conservative for a failure threshold since the clad ballooning that takes place under DNB may not result in failure because of the short duration of the event.

An acceptance criterion has been proposed for the peak fuel enthalpy rise, which is a function of fuel cladding corrosion in terms of the cladding oxide-to-wall-thickness ratio (Reference 22.10). The proposed interim limit is 628 J/g (150 cal/g) from 0 to 4 percent oxide thickness, reducing linearly to 314 J/g (75 cal/g) from 4 to 8 percent oxide thickness, and further reducing linearly to 251 J/g (60 cal/g) from 8 to 20 percent oxide thickness. [

] Any fuel calculated to exceed the interim limit during a simulation of the RIA is assumed to fail due to PCMI.

The limit on peak fuel enthalpy rise has been assessed for AP1000 using a bounding multidimensional rod ejection analysis (Reference 22.10). It has been confirmed that the percentage of fuel that will fail due to PCMI or other causes during the rod ejection event will not exceed the limit for fuel failure assumed in the offsite dose analysis. The bounding multidimensional rod ejection analysis was performed assuming multiple fuel loading patterns, which were developed to intentionally yield high ejected rod worths and peaking factors in high burnup fuel. The analysis includes significant conservatisms to account for potential future changes, and specific values may change in the future as the interim limits are finalised and inevitable enhancements to fuel assembly design and core analysis methodologies occur.

Application of the above criteria defined in Section 22.4 conservatively determines how many fuel rods will fail in a given accident. If the limits are not transgressed, the fuel is not damaged such that its performance in a subsequent accident is impaired. For example, if a fuel rod approaches the DNBR limit but the DNBR remains above the limit, it is not damaged such that it becomes more vulnerable to DNB or any other failure mechanism in later faults.

The one conceivable mechanism in which fuel behaviour in a fault might be influenced by a prior transient in which the failure limits were not transgressed is for the transient to give minor PCI damage without clad failure. This might take the form of partially penetrating cracks or local wall thinning.

As to the first possibility, SCC propagation is very sensitive to the stress in the clad so that a small reduction in stress, below the level at which complete penetration occurs, is sufficient to prevent any crack propagation. The stress threshold for PCI failure defined above is sufficiently conservative to be sure that there will be no appreciable crack propagation below the threshold and hence no effect in subsequent transients.

As to the second possibility, it is believed that local wall thinning (i.e., wall thinning in clad over radial fuel cracks) can accumulate during power cycling to eventually give rise to fuel clad failure. There is no evidence of local wall thinning in PWR clad and calculations indicate that many thousands of severe power cycles are required to produce clad failure in this way, since the local wall thinning at each power increase is extremely small. It is therefore concluded that fault transients that are below the failure limits will have no significant effect on subsequent fault behaviour.

In addition, there are a number of secondary limits for fuel rod failure, which are specified in Table 22-1 together with statements as to the fuel degradation mechanisms avoided by not transgressing the limits. The limits differ between the types of fault because of differences in the fuel environments arising in the faults in terms of the variation and duration of pressures and temperatures occurring during the transients.

The loss-of-coolant accident (LOCA) secondary limits have been derived from the available experimental evidence. The secondary limit for RIA, for example the rod ejection fault, is also justified by the experimental evidence. The limit is in terms of a maximum allowable peak fuel enthalpy rise and peak clad temperature during the fault.

The last category of faults for which a secondary limit has been derived is power cooling mismatch (PCM) faults. A PCM fault occurs when a change in coolant flow rate, pressure, or local rod power produces increasing clad temperatures due to the DNB. The degradation limit given in Table 22-1 is derived from the available experimental data and is imposed to limit the degree to which the clad becomes embrittled.

A limited range of postulated large-break LOCAs can give rise to temperature transients in which the fuel rod cladding may be calculated to reside for many tens of seconds at its most ductile condition. For such events, with the reactor depressurised, the internal gas pressure of the fuel causes the cladding to expand or balloon and possibly rupture. This behaviour, which is termed clad ballooning, leads to a reduction in the size of the coolant passages around those rods so affected. If several adjacent rods were to balloon in a similar manner, the ability to cool that region of the fuel could be brought into question. It is a requirement of the safety case to show that even in the unlikely event of such an accident, the fuel assemblies remain coolable during and after the event.

22.5 FUEL SYSTEM DESIGN

This section has two main sections: 22.5.1 (Design Bases), which details the design criteria of the fuel assembly and fuel rod, and 22.5.2 (Design Evaluation), which shows that the fuel assembly and fuel rod designs do not violate the design criteria.

The fuel rod design bases only apply to the fuel rods during normal operation and frequent faults. The number of fuel rod failures expected as a result of an infrequent fault is given in the appropriate sections of Chapter 9 or supporting topical reports. The fuel assembly design criteria also cover structural integrity under infrequent faults.

The design bases given in this section have been established to meet the safety design bases given in Section 22.2.

22.5.1 Design Bases

The fuel rods are designed for a maximum fuel rod average burnup of 62,000 megawatt days per metric ton of uranium (MWD/MTU) (References 22.6, and 22.29). Note that this is an extension of the original licensed limit of 60,000 MWD/MTU (Reference 22.4).

Integrity of the fuel assembly structure is provided by setting limits on stresses and deformations due to various loads and by preventing the assembly structure from interfering with the functioning of other components. The following three types of loads are considered:

- Nonoperational loads, such as those due to shipping and handling
- Normal and abnormal loads, which are defined for normal operation and frequent faults
- Abnormal loads, which are defined for infrequent faults

The design bases for the in-core control components are described in Section 22.5.1.3.

Fuel performance analyses are performed using the PAD code, as described in Section 22.5.2.

22.5.1.1 Fuel Assembly

As discussed above, the structural integrity of the fuel assemblies is provided by setting design limits on stresses and deformations due to various nonoperational, operational, and accident loads. These limits are applied to the design and evaluation of the fuel assembly components, including top and bottom nozzles, grids, guide thimbles, and thimble joints. The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5.

A summary of the individual criteria and design bases for evaluating the structural integrity are discussed below.

a) Nonoperational

The nonoperational load is a loading of 4G axial (longitudinal) and 6G lateral (transverse) with dimensional stability.

b) Normal Operation and Frequent Faults

For the normal operation condition and frequent faults the fuel assembly component structural design criteria are established for the two primary material categories, austenitic steels and zirconium alloys (including **ZIRLO**). The stress categories and strength theory developed by ASME are used as a general guide. The maximum shear theory (Tresca criterion) for combined stresses is used to determine the stress intensities for the austenitic steel components. The stress intensity is defined as the largest numerical difference between the various principal stresses in a 3-D field. The design stress intensity value, S_m, for austenitic steels and zirconium alloys is given by the lowest of the following:

- One-third of the specified minimum tensile strength or two-thirds of the specified minimum yield strength at room temperature.

- One-third of the tensile strength or 90 percent of the yield strength at temperature but not to exceed two-thirds of the specified minimum yield strength at room temperature.

The stress limits for the austenitic steel components are given below where S_m represents the design stress intensity:

- General primary membrane stress intensity – 1.0 S_m
- Local primary membrane stress intensity – 1.5 S_m
- Primary membrane plus bending stress intensity – 1.5 S_m
- Local primary plus secondary stress intensity – 3.0 S_m

The zirconium alloy structural components, which consist of guide thimbles and fuel tubes, are in turn subdivided into two categories because of material difference and functional requirements. The maximum shear theory is used to evaluate the guide thimble design. For conservative purposes, the zirconium alloy unirradiated properties are used to define the stress limits.

c) Infrequent Accidents and Limiting Faults

Typical worst-case abnormal loads during infrequent faults are represented by seismic and pipe rupture loadings. The design criteria for this category of loadings are as follows:

- Deflections or excessive deformation of components cannot interfere with the ability to insert the control rods or emergency cooling of the fuel rods.

- The fuel assembly structural components stresses under faulted conditions are evaluated primarily using the methods developed by ASME. Since the current analytical methods use linear elastic analysis, the allowable stresses are defined as the smaller value of 2.4 S_m or 0.7S_u (where S_u represents the material ultimate strength) for primary membrane and 3.6 S_m or 1.05S_u for primary membrane plus primary bending. For the austenitic steel fuel assembly components, the stress intensity is defined in accordance with the rules described in the previous section for normal operating conditions. For the zirconium alloy components, the stress intensity limits are set at two-thirds of the material yield strength (S_y) at reactor operating temperature, resulting in the zirconium alloy stress limits being the smaller value of 1.6 S_y or 0.70 material ultimate strength ($S_{u)}$ for primary membrane and 2.4 S_y or 1.05 S_u for primary membrane plus bending. For conservative purposes, the zirconium alloy unirradiated properties are used to define the stress limits.

The design bases for the principal fuel assembly components—top nozzle, bottom nozzle, and grids—are discussed in detail below.

Top Nozzle

The top nozzle assembly design for the AP1000 reactor fuel is a one-piece Westinghouse integral nozzle (WIN) with the removal top nozzle (RTN) type (split insert with lock tube) of joint connection for attachment to the skeleton assembly. The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5.

A summary of the individual criteria and design bases for the top nozzle are discussed below.

a) Requirement for Normal Operation and Frequent Fault Loads

Loadings on the top nozzle that are expected during the life of the fuel assembly shall not result in permanent deformations, loss of structural integrity, or excessive wear of mating components. These loads shall not result in any effects that prevent the continued use of

the fuel assembly for its full design life. The stress intensity for the worst combination of normal operation and frequent fault loads shall not exceed the stress intensity limits determined by the methods used in the mechanical design.

This criterion ensures that the top nozzle does not inelastically deform.

b) Requirement for Infrequent Fault Loads

Loadings on the top nozzle under accidents and other unanticipated events shall not result in deformation that would prevent effective emergency cooling of the fuel or that would prevent safe reactor shutdown. In particular, full insertion of the RCCA shall not be prevented. The stress intensity for the worst combination of infrequent fault loads shall not exceed the stress intensity limits. These limits permit some local yielding of the structure but prevent any major deformation.

c) Requirement for Shipping and Handling Loads

Loadings on the top nozzle during shipping and handling shall not result in permanent deformation, loss of structural integrity, or any other damage that would prevent the top nozzle from meeting all functional requirements for its design life. For a static force equivalent to 4G acting axially or 6G laterally, the stress intensity shall not exceed the limits for frequent fault loadings as determined by the methods used in the mechanical design.

The loadings of 4G axially and 6G laterally are based on fuel shipping and handling experience and have proven to be conservative (Reference 22.11). The stress limits and deformation limits ensure that no significant permanent deformations will result from shipping and handling; the top nozzle will not be damaged and will meet design drawing requirements.

d) Requirement for Cyclic Loads

Cyclic loadings on the top nozzle that are expected during the life of the fuel assembly shall not result in fatigue failure of the top nozzle. The cumulative usage factor shall be less than 1.0 for 1000 cycles of combined maximum range frequent fault loads and 1000 cycles of maximum shipping and handling loads. Normal operation and frequent fault loads are the combined effect of an RCCA scram and hold-down spring force. The maximum shipping and handling loads are calculated by the methods used in the mechanical design. The design fatigue curves for the materials involved are obtained at the maximum operating temperature.

The use of 1000 cycles is based on past practice and has been proven by experience to result in a satisfactory design. The 1000 cycles for design substantially exceeds the actual number of cycles.

e) Requirement for Materials

The materials used in the top nozzle shall provide satisfactory strength and other mechanical properties, corrosion resistance, dimensional stability, and fabrication characteristics for the range of environmental conditions that the top nozzle will experience in service. This includes consideration of temperature, coolant chemistry, fluency, and fabrication processes.

f) Requirement for Coolant Flow

The top nozzle shall maintain adequate distribution of reactor coolant flow from the exit of the flow channels between the fuel rods. It shall accomplish this without an unacceptable pressure loss and it shall ensure that adequate flow is maintained with the unanticipated condition where the upper ends of the fuel rods are in contact with the bottom of the top nozzle because of fuel rod displacement or growth. The uniformity of the flow leaving the coolant channels between the fuel rods and the total pressure loss shall be within the appropriate design allowances for the particular core design.

g) Requirement for Spring Containment

In the event of a single failure of a hold-down spring leaf or a spring fastener, the design of the top nozzle and spring pack shall be such that interference with the motion of core components, especially an RCCA, is unlikely. The top nozzle shall prevent rotation of a broken spring leaf such that it interferes with the movement of a core component, especially an RCCA. The top nozzle shall include design features that maintain all components of the hold-down spring pack in a captured state in the event of breakage of a single spring leaf or spring fastener.

This criterion ensures that control of fuel assembly reactivity, especially rapid RCCA insertion, is not prevented by interference with any component of the hold-down spring pack system such as might occur in the event of a fastener failing. This criterion also ensures that a broken spring leaf does not become a loose part in the core and damage other core or reactor coolant system (RCS) components or obstruct reactor coolant flow to the core. It also provides assurance that core components can be installed and removed without difficulty.

Bottom Nozzle

The DFBN in the AP1000 plant is a slight variation on the current Westinghouse DFBN, which was designed with 4G shipping and handling loads being limiting. The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5.

A summary of the individual criteria and design bases for the bottom nozzle are discussed below.

a) Requirements for Normal Operation and Frequent Fault Loads

The loads on the bottom nozzle that are expected during the life of the fuel assembly shall not result in permanent deformations. These loads shall not result in any effects that prevent continued use of the fuel assembly for its design life. The stress intensity value for the worst combination of normal operation and frequent fault loads shall not exceed the limits below:

- General primary membrane stress intensity – 1.0 S_m
- Local primary membrane stress intensity – 1.5 S_m
- Primary membrane plus bending stress intensity – 1.5 S_m
- Local primary plus secondary stress intensity – 3.0 S_m

This criterion ensures that the fuel assembly bottom nozzle does not deform and that dimensional stability is maintained.

b) Requirements for Infrequent Fault Loads

Loadings on the bottom nozzle under accidents and other unanticipated events shall not result in deformations of the components that would prevent emergency cooling of the fuel or safe reactor shutdown. The stress intensity for the worst combination of infrequent fault loads shall not exceed the limits below.

- Primary membrane stress intensity – 2.4 S_m or 0.70S_u
- Primary membrane plus bending stress intensity – 3.6 S_m or 1.05S_u

These limits permit some local yielding of the structure but prevent any major deformation.

c) Requirements for Shipping and Handling Loads

Loadings expected during shipping and handling shall not result in deformation of or damage to the bottom nozzle that would prevent it from meeting all operating requirements for its design life. For a static force equivalent to 4G acting axially and 6G acting laterally, the stress intensity shall not exceed the limits for normal operation and frequent faults.

In lieu of meeting the stress intensity limits, the permanent deformation for a static load of 4G may be determined by testing. For that testing, the permanent deformation shall not exceed 0.05 mm on top plate flatness and dimensional stability must be shown for interface considerations.

The loading of 4G is based on experience with fuel shipping and handling and has proved to be conservative. The use of stress intensity limits for normal operation and frequent fault loads will ensure that deformations are very small. The deflection limits have been proven by experience and testing to have no effect on the functions of the bottom nozzle.

d) Requirement for Cyclic Loads

Cyclic loadings on the bottom nozzle that are expected during the life of the fuel assembly shall not result in fatigue failure of the bottom nozzle. The cumulative usage factor shall be less than 1.0 for 1000 cycles of combined maximum range normal operation and frequent fault loads and 1000 cycles of maximum shipping and handling loads. Normal operation and frequent fault loads are the combined effect of an RCCA scram, hold-down spring force, and fuel assembly weight.

The use of 1000 cycles is based on past practice and has been proven by experience to result in a satisfactory design. The 1000 cycles for design substantially exceeds the actual number of cycles.

e) Requirements for Materials

The materials used in the bottom nozzle shall provide satisfactory strength and other mechanical properties, corrosion resistance, dimensional stability, and fabrication characteristics for the range of environmental conditions that the bottom nozzle will experience in service. This includes consideration of the temperature, coolant chemistry, fluency, and fabrication processes.

f) Requirement for Coolant Flow

The bottom nozzle shall provide adequate distribution of reactor coolant flow to the entrance of the flow channels between the fuel rods. It shall accomplish this without an unacceptable loss of pressure. When it is included as a feature of the design, the bottom nozzle shall provide a filtering action that minimises particles of debris that would cause fuel clad failure from entering the fuel flow channel. The uniformity of the pressures above the bottom nozzle (across the outlet of the nozzle structure) and the total pressure loss shall be within the appropriate design allowances for the particular core design.

The thermal and hydraulic design of the core is based on limiting the maldistribution and pressure loss to certain allowable values. In general, the two attributes are related such that the distribution is improved as the pressure losses increase; consequently, the design has to be properly balanced to meet this criterion.

g) Debris Effectiveness

The bottom nozzle in combination with the protective grid shall prevent metallic particles that could result in fuel clad failure from passing through the nozzle flow passages.

Experience with operating plants has shown that a high fraction of fuel failures can be traced to debris in the reactor coolant that becomes lodged in the grids and results in eventual perforation of the cladding.

Grids

The design bases and acceptance limits used by Westinghouse are described below (Reference 22.4 and 22.5):

a) Requirement for Positioning

The grid assemblies shall maintain the relative lateral position of fuel rods, guide thimbles, and the instrumentation tube; and provide structural support as part of the fuel assembly skeleton structure. This includes providing features that control the straightness and bowing of the assembly, including the fuel rods, guide thimbles, and instrumentation tube. The physical arrangement of the grid assembly shall satisfy nuclear, thermal and hydraulic, and reactor internals design requirements.

This criterion assures compliance with fuel assembly nuclear and thermal and hydraulic design requirements. It also ensures that RCCAs and core component assemblies can properly engage the guide thimbles, the instrumentation probes can be inserted into the instrumentation tube, and the fuel assembly is compatible with the reactor internals.

b) Requirement for Fuel Rod Support

The grids shall support individual fuel rods in a manner that permits the fuel to achieve its design lifetime. This includes features to avoid flow-induced vibration and clad wear (fretting) that could result in failure of the fuel cladding. Flow-induced fuel rod vibration can lead to fuel rod failures that can limit assembly lifetime and thus must be controlled and limited. Experience has shown that by meeting these support requirements, excessive fretting of the fuel rod clad is prevented.

The fuel assembly design shall prevent the amplitude of self-excited vibration at specific frequencies from exceeding amplitudes that are sufficient to cause fuel rod fretting [

]. In addition, the fuel assembly natural frequency shall not be in resonance with the frequency of the reactor coolant pumps. All grid assembly supports shall be designed to limit fuel rod clad fretting [ ], considering all pertinent factors such as worst-case tolerances, spring relaxation due to irradiation, and clad creepdown.

c) Thermal and Hydraulic Characteristics

The grid assemblies shall provide thermal and hydraulic characteristics that are consistent with the DB requirements. This includes features that determine the pressure loss in the grids and the character of the flow in the channels between the fuel rods. The grids shall maintain the lateral spacing of the fuel rods with respect to each other and with respect to the guide thimbles and the instrumentation tube within acceptable limits. The grid shall not permit or cause rod bowing that exceeds the allowable limits for channel closure for the fuel assembly lifetime. In the case of IFM or protective grids, the rod bowing in any span shall not be increased compared with fuel that does not incorporate those types of grids. The pressure loss coefficient of the grid assemblies shall be acceptable.

The allowable channel spacing deviations are determined by their effect upon a statistical evaluation of as-built channel spacing measurements. Spacing deviations beyond the values assumed in the fuel assembly thermal and hydraulic analyses can reduce the thermal margins. Channel spacing measurements are taken during manufacturing and are also used as a final quality control check to detect changes in fabrication.

Rod bow depends, in part, on the constraints (both lateral and axial) provided by the grids. The selection of incorrect grid parameters can result in increased rod bow under some circumstances.

d) Requirement for Structural Integrity

The grid assemblies shall maintain their structural integrity under design loadings so that the required functions such as the positioning of the fuel, guide thimbles, and the support of the fuel rods can be achieved, in particular as follows:

- For loadings expected during the life of the fuel assembly (normal operation and frequent faults), there shall be no permanent deformations or other effects that would prevent the use of the fuel assembly for its full design life.

- For loadings under accidents and other unanticipated events (infrequent faults), there shall be no deformation or other effects that would prevent effective emergency cooling of the fuel or safe reactor shutdown.

- For loadings during shipping and handling, there shall be no permanent deformations or other effects that would prevent the use of the fuel assembly for its full design life.

No normal operation event or frequent faults result in significant loads on the grid assembly. Accordingly, the mechanical strength requirements of the grid assembly are controlled by dynamic loadings resulting from infrequent faults, and no specific criteria are required for normal operation or frequent fault loads.

For infrequent faults, the grid assembly shall withstand the combined effects of the maximum design basis earthquake and the most adverse LOCA. To meet this criterion,

the following detailed criteria shall be met to confirm grid performance under infrequent fault loads:

- The grid deformation due to the most limiting horizontal impact load for infrequent faults shall not result in unacceptable fuel rod flow channel closure, that is, closure that could result in clad temperatures above those of a coolable geometry or unacceptable thimble tube deformation, which could impede control rod motion.

- The requirement may be satisfied by demonstrating that the calculated infrequent fault impact loads shall not exceed the lower 95 percent confidence limit calculated from the true mean grid crush strength at operating temperature, where the crush strength is defined as the dynamic impact load at which buckling just begins as determined by tests.

- The requirement may also be satisfied by showing that the calculated infrequent fault impact loads do not affect the coolable geometry of the grid and insertion of the control rods is not impacted for infrequent faults, excluding large-break LOCA events.

The mechanical strength requirements of grids are dictated by dynamic loadings resulting from infrequent faults. For an infrequent fault, the reactor must be able to be brought to a safe state with only a small fraction of fuel rods damaged, although sufficient damage might occur to preclude resumption of operation without considerable outage time. For an infrequent fault the reactor must also be able to be brought to a safe state and the core kept subcritical with acceptable heat transfer geometry.

It is not practical to apply stress limits to determine the stresses because of the complexity of the analysis. Since irradiation enhances the mechanical strength of **ZIRLO** (Reference 22.12) and the grid will be operating in essentially the elastic range with the above acceptance limit, it is conservative to use test results from unirradiated grids to establish the buckling strength of the grid assembly. The grids should be tested at operating temperature, however, to account for the adverse effect of temperature on grid strength.

It should be noted that an additional assessment was carried out to assess the structural and IFM grid response to the depressurisation of the primary circuit due to a DEG break of the RCS cold leg. This assessment, documented in Reference 22.97, concluded that the fuel assemblies will not preclude the reactor from being able to be brought to safe state or limit flow through the inboard fuel assemblies.

e) Requirement for Handling of Fuel Assemblies

The configuration of the grid assemblies shall be such that handling of the fuel assemblies, including insertion and removal from the core and the handling in and out of transfer, shipping, or storage facilities, does not result in damage to the fuel assembly itself, to neighbouring fuel assemblies, or to other reactor components and plant equipment.

The grid assembly peripheral dimensions shall be consistent with the overall fuel assembly envelope to ensure that the fuel assembly can be installed in the required shipping containers, fuel storage racks, fuel transfer mechanisms, fuel elevators, and spent fuel shipping casks. Also, the nominal cold grid-to-grid clearance in core shall be consistent with LOCA blowdown impact load analyses assumptions. [

] The grid assembly shall have suitable lead-in tabs and vanes on the outer straps to prevent fuel assembly hangup during insertion or removal operations considering possible fuel assembly distortion due to operation.

Compliance with this criterion ensures that fuel assembly interface compatibility requirements are met, and that the grid-to-grid spacing is sufficient for fuel handling operations and is not so large that it unduly increases LOCA blowdown impact loads.

f) Requirement for Materials

The materials used in the grid assemblies shall provide satisfactory strength and other mechanical properties, corrosion resistance, nuclear properties, dimensional stability, and fabrication characteristics for the range of environmental conditions that the grid assemblies will experience in service. This includes consideration of temperature, coolant chemistry, fluence, and fabrication processes.

Irradiation changes the physical properties of the grid material throughout life. The grid design must account for these changes to ensure that the grid physical requirements are met throughout the fuel lifetime. Grid corrosion must be limited to ensure that the grid maintains sufficient strength and grid growth does not impede fuel assembly handling operations to meet the design requirements throughout its lifetime.

Assembly Bow

The AP1000 reactor fuel assemblies shall be built with a high degree of resistance to assembly bowing, thus minimising or eliminating the potential for any impact on safety margins. This is accomplished through changes in the guide tube wall and dashpot mechanical design to increase lateral stiffness, selection of skeleton materials that minimise fuel assembly growth, and optimisation of the top nozzle hold-down spring forces. The relative resistance of the design to assembly bow is evaluated through comparison with existing Westinghouse fuel designs with known assembly bow characteristics.

22.5.1.2 Fuel Rod

Fuel Material

The fuel material is enriched uranium in the form of cylindrical pellets of uranium dioxide. The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5.

A summary of the individual criteria and design bases for the fuel material are discussed below.

a) Fuel Centreline Temperature

The centre temperature of the hottest pellet is below the melting temperature of the uranium dioxide. The melting temperature of unirradiated uranium dioxide, 2804.44°C (5080°F), decreases by 32.22°C (58°F) per 10,000 MWD/MTU (Reference 22.13).

The nominal design density of the fuel is approximately 95.5 percent of the theoretical density. This limit is discussed further in Section 3.7.2.1.1 of Reference 22.5.

b) Fuel Dimensional Changes

Once the fuel pellet and cladding are in contact, the fission product swelling of the fuel must not cause clad failure. [

]

[

] The criteria for internal fuel rod pressure and gap reopening are discussed in section 3.7.2.1.2 of Reference 22.5.

c) Fuel Chemical Properties

Due to the potential for adverse chemical reactions between the fuel pellet and the cladding the moisture content in the fuel pellets is controlled to minimise the potential for hydride induced failures of the cladding. The moisture content is limited as part of the total hydrogen requirement defined in the pellet production specification, Reference 22.101.

d) Zirconium Diboride Material Properties

There are manufacturing specifications on variability of the rod-by-rod ZrB_2 content within a region and the region average ZrB_2 loading. These specifications address total core reactivity and the impact on local radial power distribution changes. Further details on ZrB_2 loading specifications are provided in Reference 22.92.

Cladding

The cladding is made of **ZIRLO**, which combines neutron economy (low-absorption cross-section); high corrosion resistance to coolant, fuel, and fission products; and high strength and ductility at operating temperatures. **ZIRLO** is an advanced zirconium-based alloy that has the same or similar properties and advantages as Zircaloy-4 and was developed to support extended fuel burnup. A discussion of the chemical and mechanical properties of the **ZIRLO** cladding material and a comparison with Zircaloy-4 is provided in Reference 22.3.

The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5. A summary of the individual criteria and design bases for the fuel cladding is presented below.

a) Clad Stress

The volume average effective stress, considering interference due to uniform cylindrical pellet-clad contact caused by pellet thermal expansion, pellet swelling, uniform clad creep, and pressure differences, must be less than the 0.2 percent offset yield stress with due consideration of temperature and irradiation effects for normal operation and frequent faults. While the clad has some capability for accommodating plastic strain, the yield stress has been accepted as a conservative design limit. The stress calculations are conservative and take into account the effects of temperature and irradiation on the yield stress.

Excessive clad stress can arise because of local power increases of rapid rate such that the clad creep cannot accommodate the pellet thermal expansion. Limiting effective stress levels to the yield strength of the material is a well-accepted and conservative design practice since some ductility is available following yielding. This limit is discussed further in section 3.7.2.1.4 of Reference 22.5.

b) Clad Strain (Transient)

The acceptance limit for fuel clad strain during frequent faults is that the total tensile strain due to uniform cylindrical pellet thermal expansion should be less than 1 percent from the pre-transient value.

The intent of this criterion is to minimise the potential for clad failure due to excessive clad straining. The criterion addresses slow strain rate mechanisms where the clad effective stress never reaches the yield strength of the material because of stress relaxation. Fuel swelling can result in small clad strains (<1 percent) for expected discharge burnups, but the associated clad stresses are very low because of clad creep (thermal and irradiation-induced creep). Furthermore, the 1 percent strain criterion is extremely conservative for fuel-swelling-driven clad strain because the strain rate associated with solid fission products swelling is very slow. In-pile experiments have shown that the cladding exhibits "super-plasticity" at slow strain rates during neutron irradiation. In design, this criterion is currently interpreted in terms of a uniform circumferential strain. This limit is discussed further in section 3.7.2.1.5 of Reference 22.5.

c) Clad Strain (Steady-State)

For steady-state operation, the total plastic tensile creep strain due to uniform clad creep and cylindrical fuel pellet expansion associated with fuel swelling and thermal expansion is less than 1 percent from the unirradiated condition.

The intent of this criterion is to minimise the potential for clad failure due to excessive clad straining. The criterion addresses slow strain rate mechanisms where the clad effective stress never reaches the yield strength of the material because of stress relaxation. The present 1 percent limit on circumferential strain is based on the results of tensile and high strain rate biaxial tests on irradiated tubing as discussed in item (b) above. In design, this criterion is currently interpreted in terms of a uniform circumferential strain. This limit is discussed further in section 3.7.2.1.6 of Reference 22.5.

d) Clad Corrosion

An oxide thickness limit established to ensure the cladding integrity during normal operation and anticipated operational occurrences (AOOs).

A hydrogen pickup criterion is required to limit loss of ductility due to hydrogen embrittlement, which occurs as a portion of the free hydrogen is absorbed into the base metal as zirconium hydride precipitates or platelets. This limit precludes a condition of low-temperature embrittlement (Reference 22.89). Further details on clad corrosion are provided in section 3.7.2.1.7 of Reference 22.5.

e) Clad Flattening

The fuel rod design shall preclude clad flattening during the projected lifetime of the fuel. This criterion was established to prevent the long-term creep collapse of the fuel cladding into axial gaps that can form within the fuel column. This criterion is discussed further in section 3.7.2.1.8 of Reference 22.5.

f) Clad Fatigue

The fatigue usage factor shall be less than 1.0: that is, for a given strain range, the number of strain fatigue cycles is less than required for failure, considering a minimum safety factor of 2 on the stress amplitude or a minimum safety factor of 20 on the number of cycles, whichever is more conservative.

The concern of this criterion is the accumulated effect of short-term, cyclic cladding stress and strain that result primarily from daily load follow operation. The accumulated effects of cyclic strains associated with normal plant shutdowns and returns to full power are also considered. This criterion is discussed further in section 3.7.2.1.9 of Reference 22.5.

g) Clad Wall Thickness and Ovality

The clad wall thickness variations and initial ovality affect fuel rod bow, flattening, and clad stresses and therefore must be controlled to preclude incipient clad collapse during normal operation. The maximum-allowed clad wall thickness variation around the circumference at any location and the maximum allowed ovality shall be acceptable from a fuel performance standpoint. Limits on clad wall thickness and ovality are discussed further in section 3.7.2.3.1 of Reference 22.5.

h) Clad Scratch Limits

Scratches on the outside diameter of the clad shall be limited to depths that do not significantly affect clad integrity during the life of the fuel rod. [

]

Excessively deep or wide scratches could result in clad failures before fuel rod design life is reached. The scratch limits of the criterion have been found to be acceptable based on rod performance, fracture mechanics, and finite element analyses: that is, scratches of the size allowed do not degrade fuel rod performance. This limit is discussed further in section 3.7.2.3.2 of Reference 22.5.

i) Rod Bowing

The design of the fuel assembly shall not increase the rod bow penalty above acceptable limits. Further details on this criterion are provided in sections 3.4.1.2 and 3.4.2.3.2 of Reference 22.5. The effects of rod bow on DNB are discussed further in section 3.9.2.6 of Reference 22.5.

Fuel Rod

A summary of the individual criteria and design bases for the fuel rod are discussed below. These criteria are discussed in more detail in Reference 22.5.

a) Fuel Rod Internal Gas Pressure (Departure from Nucleate Boiling Propagation)

The fuel rod internal pressure will be limited to a value below that which could cause extensive propagation of DNB due to clad ballooning during transients. This limit is discussed further in section 3.7.2.1.3 of Reference 22.5.

b) Fuel Rod Internal Gas Pressure (Gap Reopening)

The fuel rod internal pressure will be limited to a value below that which could cause the fuel pellet-clad gap to increase because of outward cladding creep during steady-state operation. The limits and supporting analysis are provided in Reference 22.5. Restricting the fuel-clad gap from increasing will prevent accelerated fission gas release at high burnup and preclude high burnup fuel from becoming limiting from a LOCA viewpoint. This limit is discussed further in section 3.7.2.1.2 of Reference 22.5.

c) Fuel Axial Growth

The overall length of the fuel rod (over the end plugs) and the space between the nozzles (plate-to-plate) shall be such that the rod does not contact both nozzles. This includes the effects of fuel growth, guide tube growth and creep, and thermal expansion of the components.

This criterion should consider the effects of fuel growth, guide tube and instrumentation tube growth and creep, and thermal expansion of those members. To prevent overstressing guide thimble tubes and/or guide thimble tube-to-nozzle joints, excessive interference should not occur. This limit is discussed further in section 3.7.2.1.10 of Reference 22.5.

d) End Plug Weld Integrity

The fuel rod end plug shall maintain its integrity during normal operation and frequent faults and shall not contribute to any additional fuel failures above those already considered for infrequent faults.

The intent of this criterion is to ensure that fuel rod failures will not occur due to the tensile pressure differential loads that can exist across the weld. The current inspection limits for the end plug weld allows for the existence of small defects within the weld and under maximum tensile pressure differential, failure of the weld should not occur. This criterion is discussed further in section 3.7.2.1.12 of Reference 22.5.

e) Fuel Rod Straightness

The clad and fuel rod shall be straight within the limits defined in Reference 22.92.

Controlling fuel rod straightness ensures that fuel rod channel spacing is adequate throughout service life. This limit is discussed further in section 3.7.2.2.1 of Reference 22.5.

f) Hold-Down Spring Radial Support of Clad

The fuel rod in the plenum region shall not collapse during normal operating conditions for the fuel rod design lifetime.

This criterion precludes fuel rod collapse and associated failure in the plenum region of the fuel rod where the cladding is not supported by the presence of the fuel pellet stack. This criterion is discussed further in section 3.7.2.3.3 of Reference 22.5.

g) Axial Location of Fuel Pellet Stack

Prior to irradiation, the spring shall provide a minimum hold-down force on the fuel pellet stack of four times the nominal weight of the fuel stack.

Experience has shown that designing the hold-down force to meet this criterion will prevent any significant fuel pellet motion and chipping during shipping and handling. In addition, to ensure that the shipping loads do not exceed the hold-down force, accelerometers are mounted in the shipping package during transport. After the fuel is installed in the core and operation begins, a high spring force is no longer required because in-plant handling loads are expected to be low and because mechanical interaction between the pellet and cladding minimises the potential for pellet stack motion. This criterion is discussed further in section 3.7.2.5 of Reference 22.5.

h) Fuel Rod Outer Diameter at Weld

The maximum outer diameter of the fuel rod at the weld shall not cause the grid cell size to exceed the maximum allowable size for the particular grid design.

If the fuel rod maximum outer diameter at the weld significantly exceeds the clad outer diameter, it could result in unacceptable plastic setting of grid springs as the weld passes through a grid cell during loading of fuel rods into the skeleton. This condition could cause spring forces to be below the values established to avoid unacceptable fretting damage to the clad in service. This limit is discussed further in section 3.7.2.6.1 of Reference 22.5.

i) Standoff Tube Design

Fuel rod gases shall have access to communicate with the tube internal volume throughout life to provide greater fuel rod internal pressure margin. In addition, the standoff tube design shall prevent fuel pellets or large pellet fragments from entering the lower plenum space to maintain fuel stack integrity. This criterion is discussed further in section 3.7.2.7 of Reference 22.5.

j) Potentially Damaging Temperature Effects during Transients

Thermal expansion of the fuel rods should be considered in the fuel design so that the loads imposed on the fuel rods during a thermal transient will not result in unacceptable fuel performance or damage to the fuel. Further details on the criteria which limit the potential for stress due to thermal expansion are provided in sections 3.7.2.1.1, 3.7.2.1.4, 3.7.2.1.5, and 3.7.2.1.6 of Reference 22.5.

k) Fuel Element Burnout and Potential Energy Release

The AP1000 reactor core should be protected from DNB over the full range of possible operating conditions. Further details on the criteria and bases which provide controls to ensure the core is protected against DNB are provided in section 3.9.2 of Reference 22.5.

l) Fuel/Cladding Mechanical Interaction

One factor in fuel element duty is potential mechanical interaction of the fuel and clad. This fuel/clad interaction produces cyclic stresses and strains in the clad, which in turn reduce clad life. The reduction of fuel/clad interaction is therefore a design goal. This criterion is discussed further in section 3.7.2.1.9 of Reference 22.5.

22.5.1.3 In-Core Control Components

The in-core control components are subdivided into permanent and temporary devices. The permanent components are the RCCAs, GRCAs, thimble plugs, and secondary neutron source assemblies. The temporary components are the primary neutron source assemblies (normally used only in the initial core) and the BA assemblies. Note that for some reloads, the use of BA assemblies may be necessary for power distribution control and/or to achieve an acceptable moderator temperature coefficient throughout core life. Materials for both permanent and temporary devices are selected for the following features:

- Compatibility in the PWR environment
- Adequate mechanical properties at room and operating temperatures
- Resistance to adverse property changes in a radioactive environment
- Compatibility with interfacing components

The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5.

A summary of the individual criteria and design bases for evaluating the structural integrity are discussed below.

a) Control Rods

For normal operation and frequent faults, the stress categories and strength theory developed by ASME are used as a general guide in the design of the RCCA and GRCA structural parts in addition to absorber cladding.

The design bases are as follows:

- External pressure equal to the RCS operating pressure with appropriate allowance for overpressure transients
- Wear allowance equivalent to 1000 reactor trips
- Bending of the rod due to a misalignment in the guide thimble
- Forces imposed on the rods during rod drop
- Loads imposed by the accelerations of the CRDM
- Radiation exposure during maximum core life
- The absorber material temperature shall not exceed its melting temperature (790°C (1454°F) for silver-indium-cadmium (Reference 22.13), and 3380°C (6116°F) for tungsten [Reference 22.36]). Confirmation that the RCCA silver-indium-cadmium absorber material will not exceed the melting temperature is provided in the analysis

contained in References 22.102 and 22.103. The supporting analysis for the GRCA tungsten absorber is contained in References 22.104, 22.105, and 22.5.

- Temperature effects at operating conditions

b) Burnable Absorber Rods

For normal operation and frequent faults, the stress categories and strength theory developed by ASME are used as a general guide in the design of the BA cladding. For abnormal loads during infrequent faults, code stresses are not considered limiting. Failures of the BA rods during these conditions must not interfere with reactor shutdown or emergency cooling of the fuel rods. The BA material is non-structural. The structural elements of the BA rod are designed to maintain the absorber geometry even if the absorber material is fractured.

To reduce the dissolved boron requirement for control of excess reactivity, WABA rods have been incorporated in the core design. The WABA material is boron carbide contained in an alumina matrix. Thermal-physical and gas release properties of alumina-boron carbide are described in Westinghouse technical reports (References 22.13 and 22.15). Discrete BA rods are designed so that the absorber temperature does not exceed 649°C (1200°F) during normal operation or an overpower transient. The units maximum temperature helium gas release in a discrete BA rod will not exceed 30 percent of theoretical (Reference 22.15).

c) Neutron Source Rods

The neutron source rods are designed to withstand the following:

- The external pressure equal to RCS operating pressure with appropriate allowance for overpressure transients

- An internal pressure equal to the pressure generated by released gases over the source rod life

22.5.2 Design Evaluation

The fuel assemblies, fuel rods, and in-core control components are designed to satisfy the performance and safety criteria and the mechanical design bases described in Section 22.5.1 and Reference 22.4.

The PAD code is used to confirm the performance of the fuel. The design bases and acceptance limits used by Westinghouse are described in References 22.4 and 22.5. Fuel rod and assembly models used for the performance evaluations are documented and maintained under the Westinghouse Software Engineering Methodology and Quality Assurance process. This includes processes used to benchmark new data against the models used within the PAD code. Material properties used in the design evaluations are given in Reference 22.3.

With the development of PAD 5 a new topical report was created which consolidates the methodology, analysis, and results into one comprehensive report. While the AP1000 plant currently uses the PAD 4 model, it is anticipated that the transition will be made to PAD 5 for UK AP1000 plants. At that time the PAD 5 topical report, WCAP-17642-P, (Ref. 22.94) will be the reference for all relevant analysis and results using the PAD code.

22.5.2.1 Fuel Assembly

The fuel assembly component stress levels are limited by the design. For example, stresses in the fuel rod due to thermal expansion and **ZIRLO** irradiation growth are limited by the relative motion of the rod as it slips over the grid spring and dimple surfaces. Clearances between the fuel rod ends and nozzles are provided so that **ZIRLO** irradiation growth does not result in rod end interference. Stresses in the fuel assembly caused by tripping of the RCCA have little influence on fatigue usage margin because of the small number of events during the life of an assembly. Assembly components and prototype fuel assemblies made from production parts have been subjected to structural tests to verify that the DB requirements are met.

The fuel assembly design loads for shipping have been established at 4G axial and 6G lateral. Accelerometers are permanently placed in the shipping cask to monitor and detect fuel assembly accelerations that would exceed the criteria. Experience indicates that loads exceeding the allowable limits rarely occur. Exceeding the limits requires reinspection of the fuel assembly for damage. Tests on various fuel assembly components, such as the grid assembly, sleeves, inserts, and structure joints, have been performed to confirm that the shipping design limits do not impair fuel assembly function.

To demonstrate that the fuel assemblies will maintain a geometry capable of being cooled under the worst-case accident infrequent fault, a plant-specific or bounding seismic analysis is performed. The fuel assembly response resulting from safe shutdown earthquake condition is analysed using time-history numerical techniques. The vessel motion for this type of event primarily causes lateral loads on the reactor core. Consequently, the methodology and analytical procedures described in References 22.16, 22.17, and 22.18 are used to assess the fuel assembly deflections and impact forces.

The motions of the reactor internals upper and lower core plates and the core barrel at the upper core plate elevation, which are simultaneously applied to simulate the reactor core input motion, are obtained from the time-history analysis of the reactor vessel and internals. The fuel assembly response, namely the displacements and impact forces, is obtained with the reactor core model. Similar dynamic analyses of the core were performed using reactor internals motions indicative of the postulated pipe rupture. Scenarios regarding breaches in the pressure boundary have been investigated to determine the most limiting structural loads for the fuel assembly. The application of leak before break (LBB) limits the size of the pipe rupture loads for the fuel assembly. The pipe rupture used in the fuel assembly analysis is the largest pipe connected to the RCS that does not satisfy the LBB criteria. Mechanistic pipe break is discussed in Appendices 20D and 20E.

The maximum grid impact force obtained from seismic analyses is less than the allowable grid strength. Westinghouse has demonstrated that a simultaneous safe shutdown earthquake and pipe rupture event is highly unlikely. The fatigue cycles, crack initiation, and crack growth due to normal operating and seismic events will not realistically lead to a pipe rupture (Reference 22.19).

Based on the deterministic fracture mechanics evaluation of small flaws in piping components, Westinghouse has demonstrated that the dynamic effects of a large pipe rupture in the primary coolant piping system for the AP1000 design does not have to be considered.

A DB for the piping design in the AP1000 plant is that the reactor coolant loop and surge lines will satisfy the LBB criteria for mechanistic pipe break. In addition, the piping connected to the RCS that is 152.4-mm (6 inches) nominal diameter or larger is evaluated for LBB. The result of a pipe leakage event consistent with the mechanistic pipe break evaluation

would be to impose insignificant asymmetric loadings on the reactor core system. Thus, fuel assembly grid loads due to large pipe ruptures are unrealistic and, as such, are not included in the analysis.

The pressure boundary integrity for numerous branch lines is analysed to determine the most limiting break of a line not qualified for LBB for the dynamic loading of the reactor core. Grid loads resulting from a combined seismic and pipe rupture event do not cause unacceptable grid deformation as to preclude a core coolable geometry.

The stresses induced in the various fuel assembly nongrid components are assessed based on the most limiting seismic condition. The fuel assembly axial forces resulting from the hold-down spring load together with its own weight distribution are the primary sources of the stresses in the guide thimbles and fuel assembly nozzles. The fuel rod accident-induced stresses, which are generally very small, are caused by bending due to the fuel assembly deflections during a seismic event. The seismic-induced stresses are compared with the allowable stress limits for the fuel assembly major components. The component stresses, which include normal operating stresses, are below the established allowable limits. Consequently, the structural designs of the fuel assembly components are acceptable for the DB accident conditions for the AP1000 plant.

Localised yielding and slight deformation in some fuel assembly components are allowed to occur during an infrequent fault. The maximum permanent deflection, or deformation, does not result in any violation of the functional requirements of the fuel assembly. In the early phase of the transient following the coolant circuit break, the high axial loads (which could be generated by the difference in thermal expansion between fuel clad and thimbles) are relieved by slippage of the fuel rods through the grids. The relatively low drag force restraint on the fuel rods will induce only minor thermal bowing, which is insufficient to close the fuel rod to thimble tube gap.

It should be noted that an additional assessment was carried out to assess the structural and IFM grid response to the depressurisation of the primary circuit due to a DEG break of the RCS cold leg. This assessment, documented in Reference 22.97, concluded that the fuel assemblies will not preclude the reactor from being able to be brought to safe state or limit flow through the inboard fuel assemblies.

Westinghouse has developed and evolved the RFA design, adding features such as thicker guide tube walls, a stronger guide tube dashpot, optimised top nozzle hold-down springs, and the low-growth **ZIRLO** alloy in order to improve assembly stiffness characteristics and resistance to assembly bow and incomplete rod insertion. With the continued deployment of RFA, the occurrence of incomplete control rod insertion upon reactor trip has been eliminated and the occurrence of grid damage during fuel handling significantly reduced.

In the event that AP1000 plant fuel assembly bow measurements are inconsistent with RFA performance expectations, Westinghouse has developed detailed mechanical and nuclear methods for the modelling the effects of assembly bow on the core power distribution (Reference 22.20). Any potential peaking factor penalties would be expected to be small and available margins could be reallocated to accommodate these small penalties without affecting the conclusions of the AP1000 plant safety case.

Top Nozzle

A summary of the evaluation of the individual criteria and design bases for the top nozzle are discussed below.

a) Requirement for Normal Operation and Frequent Faults

Shipping and handling loads are more limiting than normal operation and frequent faults for the top nozzle, as an axial load equal to four times the weight of the fuel assembly plus an RCCA will bound all loads imposed on the top nozzle by those events. A verification test was performed in which the production nozzles were axially loaded (at room temperature) in both tension and compression to loads significantly greater than would be calculated for normal operation and frequent faults.

The resulting deformation of the adapter plate was then characterised and evaluated. The test results concluded that when the top nozzle was tested in tension (the largest load applied during testing) to represent handling conditions, [ ]. When the top nozzle was tested in compression to represent shipping conditions, [ ].

Along with these two tests, a test with a vertical load imposed by RCCA impact on the adaptor plate was performed. The adaptor plate was characterised after the test and there was no permanent displacement. After each test, the ability to remove and reinstall the top nozzle was not impaired and there was no difficulty installing the lock tubes in the inserts.

b) Requirement for Infrequent Faults

Shipping and handling loads are more limiting than Infrequent faults for the top nozzle, as an axial load equal to four times the weight of the fuel assembly plus an RCCA will bound all loads imposed on the top nozzle by those events. A verification test was performed in which production nozzles were axially loaded (at room temperature) in both tension and compression to loads significantly greater than would be calculated for infrequent faults, with results the same as those described in item a) above.

c) Requirement for Shipping and Handling

A verification test was performed in which production nozzles were axially loaded (at room temperature) in both tension and compression to loads greater than four times the weight of the fuel assembly plus an RCCA. The resulting deformation of the adapter plate was then characterised and evaluated. The test results concluded that when the top nozzle was tested in tension to represent handling conditions, [ ]. When the top nozzle was tested in compression to represent shipping conditions, [ ]. After each test, the ability to remove and reinstall the top nozzle was not impaired and there was no difficulty installing the lock tubes in the inserts. Thus, the loadings on the top nozzle during shipping and handling do not result in permanent deformation, loss of structural integrity, or any other damage that would prevent it from meeting all functional requirements during its design life.

d) Requirement for Cyclic Loads

Analyses performed on top nozzles representative of the AP1000 design have consistently yielded fatigue usage factors two orders of magnitude or more less than the ASME Code limit of 1.0.

e) Requirement for Materials

Materials used in the WIN design for the AP1000 plant have been used successfully in previous Westinghouse top nozzles. Calculations have been performed based on measurements reported in the literature to ensure that casting cracks smaller than those that can be detected by the nondestructive examination (NDE) programme will not propagate due to inherent notch sensitivity, SCC, or radiation- and corrosion-assisted fatigue (Reference 22.22).

f) Requirement for Coolant Flow

The top nozzle adaptor plate has a new flow pattern versus the 17×17 XL top nozzle, which has the typical flow pattern used in previous Westinghouse top nozzle designs. The flow pattern in the XL top nozzle consists of flow slots arranged in one direction, thus providing half-symmetry of the flow pattern. The new flow pattern has a quadrant symmetric pattern, thus providing quarter-symmetry of the flow pattern. As such, the top nozzle will provide a more uniform flow distribution in the fuel rod coolant channels from quadrant to quadrant than the XL top nozzle.

g) Requirement for Spring Containment

Confirmatory testing has demonstrated that if top, middle two, or bottom leaf springs are severed at the root bend, they remain captured in the top nozzle and have no range of motion (Reference 22.23). It should be noted that the lower bend for the bottom spring is constrained by the WIN pad gussets. For the extreme case where all four leaves were severed, the test showed a range of motion comparable to that observed in the previous WIN designs. This range of motion will not obstruct the movement of a core component.

Bottom Nozzle

A summary of the evaluation of the individual criteria and design bases for the bottom nozzle are discussed below.

a) Requirements for Normal Operation and Frequent Fault Loads

Design loads for normal operation and frequent faults include fuel assembly weight, hold-down spring force, and scram loads. These loads are bounded by the 4G shipping and handling loads. The evaluation of the shipping and handling loads described below shows that these loads are acceptable.

b) Requirements for Infrequent Fault Loads

The maximum axial loading on the bottom nozzle for infrequent faults is the sum of the vertical seismic (inertia) load, the LOCA load, and the fuel assembly and RCCA weight, plus the (hot) hold-down spring force. The resulting stresses are well below their corresponding allowable limits (Reference 22.5).

c) Requirements for Shipping and Handling Loads

The AP1000 plant fuel assembly [
]; therefore, [
]. The resulting primary membrane stress intensity and primary membrane plus bending stress intensity are well below the corresponding design limits for this criterion (Reference 22.5).

d) Requirement for Cyclic Loads

Previous analyses have consistently shown that the cumulative fatigue usage factor for bottom nozzles [ ] versus a limit of 1.0. This indicates that bottom nozzles can easily withstand the combined transients described without fatigue failure. Since the AP1000 design of the bottom nozzle is essentially unchanged from previous bottom nozzle designs and the cyclical loadings are also similar, the previous analysis results are used to show that it meets the requirements for cyclic loads.

e) Requirements for Materials

The AP1000 design incorporates the standard casting and adaptor plate material used in earlier fuel assembly designs and so the bottom nozzle is unchanged with respect to material requirements. The operating conditions and operational experience and testing performed on other Westinghouse fuel assembly designs shows that the materials will maintain their physical properties and other functional requirements over the full core lifetime.

f) Requirement for Coolant Flow

The bottom nozzle design is a combination of the low-profile type used in fuel assemblies for 3.65-m (12 foot) high cores and the tall leg type used in fuel assemblies for current (XL) 4.27-m (14 foot) high cores. One feature that is common to all three bottom nozzle designs is the flow hole design (bore diameter and hole pattern). This similarity minimises the pressure distribution difference between the nozzle designs, with the AP1000 plant pressure distribution bounded by the other two nozzle types.

In thermal design space, the maldistribution and pressure loss for the AP1000 design are within the experience base of current Westinghouse designs. Therefore, the existing thermal design methodology for Westinghouse designs can be applied to the AP1000 plant.

g) Debris Effectiveness

Debris filtering tests indicate that a typical DFBN, similar to the bottom nozzle in the AP1000 design, stops more than 70 percent of the debris, by weight, compared to a non-DBFN. In combination with the protective grid, nearly all metallic debris that could induce fuel rod failures is trapped by the nozzle.

Grids

A summary of the evaluation of the individual criteria and design bases for the grids are discussed below.

a) Requirement for Positioning

The 17×17 mid and IFM grid assemblies have drawing specifications describing features affecting this criterion that are consistent with a 17×17 RFA design. The top and bottom grid assemblies used on the AP1000 plant fuel assembly both have the same cell pitch, thimble cell array, and instrument cell position (centre location) as existing Westinghouse 17×17 grid designs.

b) Requirement for Fuel Rod Support

An unbalanced mixing vane pattern is the primary mechanism for self-excited fuel assembly vibration. The RFA and IFM grids include the standard RFA symmetric, balanced vane pattern, eliminating this known mechanism for fuel assembly vibration. Testing of the symmetric, balanced mixing vane pattern confirms that these assemblies are not subject to self-excited resonant vibration (Reference 22.5).

Most of the excitation energy from the pumps that could contribute to fuel vibration occurs at the vane passing frequencies. [

] At hot end-of-life (EOL) conditions, the fuel frequencies will be lower. Thus, the fuel assembly frequencies are well below the lowest pump frequencies and there is no direct correspondence between any of these fuel assembly modal and pump impellor vane passing frequencies.

There has been considerable post-irradiation examination (PIE) of the 17x17 RFA-type fuel assembly designs that demonstrates very good fretting performance [ ]. For the AP1000 design, test data shows significantly improved fuel rod cladding fretting performance relative to current RFA-type designs with sufficient margin to meet [ ] fretting wear criterion.

c) Thermal and Hydraulic Characteristics

The grid designs incorporate into the grid drawings the same tolerances and specifications as the drawings for current Westinghouse 17x17 standard grids to control the channel spacing. Thus, the as-built deviations of the fuel rods from nominal spacing will be consistent with that of current Westinghouse grid designs.

With four IFMs and an increased dimple-to-dimple span within the mid grid, fuel assembly span lengths are reduced in comparison with 17x17 XL RFA assemblies. The AP1000 plant top grid design incorporates the reduced rod bow spring design, which has a reduced grid spring force on the fuel rod. This reduces the potential for bowing, accommodating rod growth by allowing it to slip through the top grid. This end grid design has a satisfactory reactor operating history.

The pressure loss coefficients of the grids were determined by testing and an evaluation performed to demonstrate acceptability (Reference 22.5).

d) Requirement for Structural Integrity

Grid dynamic crush testing was performed to determine the dynamic impact characteristics of the RFA and IFM grid designs (References 22.24 and 22.25). The test results (crush strength and stiffness) compared with the calculated impact loads from the dynamic analysis show that the maximum calculated impact loads are less than the lower 95 percent confidence limit crush strengths for the mid and IFM grids.

Based on seismic and LOCA analyses, the lateral impact loads on the top and bottom end grids are negligible. This is consistent with results from previous analyses for current operating plants.

The fatigue of the mid grid has also been shown to be acceptable. The calculated fatigue usage factor is well below the allowable limit of 1.0.

Previous analyses have shown that the fatigue usage of end grids is very low. The end grid designs for the AP1000 plant are the same as those used on previous Westinghouse 17x17 fuel assemblies.

e) Requirement for Handling of Fuel Assemblies

The grid assembly peripheral dimensions are consistent with the overall fuel assembly envelope and identical to the peripheral dimensions of previous Westinghouse 17x17 fuel assembly grids. Operating experience with these grids has shown that the fuel assembly can be satisfactorily installed in shipping containers, fuel storage racks, fuel transfer mechanisms, fuel elevators, and spent fuel shipping casks.

The mid and IFM grid designs feature anti-snag outer strap designs, having guide vanes and guide tabs at each inner strap location. The mid grid guide tab and guide vane offsets have also been increased compared with those of the standard RFA design, reducing the potential of damaging grid-to-grid engagement. The IFM grid utilises the same guide vane and guide tab geometry as the current 17x17 RFA design. The inner-to-outer strap weld joints have been made more robust by moving them outward from the grid lateral centreline, in effect isolating the weld-created heat-affected zones from the thin inner strap ligaments. In summary, these changes both reduce the probability of grid-to-grid snagging occurring during fuel handling operations and minimise the probability of loose parts being created should snagging occur.

f) Requirement for Materials

Alloy-718 will be used to fabricate the top, bottom, and protective grids. **ZIRLO** will be used to fabricate all other grids. There is extensive satisfactory experience with the grid materials and their chemical properties (References 22.3 and 22.13).

Appropriate mechanical properties are specified in design documents (drawings and material specifications) to ensure that the grid assembly design loads can be satisfactorily accommodated and that satisfactory experience with previous grid designs remains applicable.

Material property changes due to irradiation are accounted for in the design of a grid. Successful operating experience with these grid materials (**ZIRLO** and Alloy-718) has shown that irradiation-induced creep and growth will not lead to fuel rod fretting or fuel handling problems.

A corrosion evaluation of the **ZIRLO** grids, based on typical power histories, [

]. The SCC resistance of welded Alloy-718 in the Westinghouse PWR coolant environment was verified during development of prior Westinghouse fuel assembly designs.

Effects of Assembly Bow on Safety Margin

The primary design features for the fuel assembly that provide resistance to fuel assembly bow are the following:

- Increased thickness of the guide tube wall

- Changing the dashpot region of the guide tube to a tube-in-tube design, effectively further increasing the guide tube wall thickness in this critical region

- Implementing **ZIRLO** as the grid and guide tube material to reduce neutron fluence induced growth

- Optimised top nozzle hold-down spring forces

Lateral stiffness experiments have been performed for the fuel assembly design and compared with the existing RFA designs. The results show that the fuel assembly lateral stiffness is the same as or better than the current RFA designs (Reference 22.20). The use of **ZIRLO** versus Zr-4 as the guide tube material will result in significantly less fuel assembly axial growth due to neutron fluence accumulation. This reduces the top nozzle hold-down spring compressive force and therefore reduces the risk of assembly bow for **ZIRLO**-based fuel relative to Zr-4.

Therefore, the fuel in the AP1000 design is not expected to suffer from excessive distortion.

Westinghouse has developed a methodology for predicting assembly bow (Reference 22.20). Given the initial bow conditions of the assemblies loaded into the core at the beginning of the cycle along with the depletion history and operating conditions of the cycle, a detailed mechanical model provides a good estimate of the fuel assembly bow expected at the end of the cycle. The model has been used to develop a cycle-independent set of in-core gap distributions for the purposes of developing a conservative set of cycle-independent peaking factor penalties. The predicted conservative peaking factor penalties are quite small and less than those observed for RFA fuel. In the event that the AP1000 plant fuel assembly bow measurements are inconsistent with RFA performance expectations, available margins could be reallocated to accommodate the small potential penalties without affecting the conclusions of the AP1000 plant safety case.

Another potential impact of assembly bow on the safety case is incomplete control rod insertion upon reactor trip, which would result in a reduction in available shutdown margin. The design features described above increase the lateral stiffness of the assembly, thus reducing the potential for guide tube distortion. As these features have been implemented within the current operating fleet of Westinghouse plants, the risk of incomplete rod insertion has been significantly reduced.

A surveillance programme will be conducted to confirm the dimensional stability of the fuel assembly. This programme will include pre- and post-irradiation measurements of fuel assembly length (to determine growth) and fuel assembly bow and twist. These measurements will be conducted on assemblies expected to have the highest burnups. In addition, RCCA drag force and RCCA drop time will be measured. Any unusual results that might indicate fuel assembly distortion beyond the expected limits will be evaluated as necessary.

22.5.2.2 Fuel Rod

Fuel Material

Sintered, high-density uranium dioxide fuel reacts only slightly with the clad at core operating temperatures and pressures. In the event of clad defects, the high resistance of uranium dioxide to attack by water protects against fuel deterioration, although limited fuel erosion can occur. The consequences of defects in the clad are greatly reduced by the ability

of uranium dioxide to retain fission products, including those that are gaseous or highly volatile.

The evaluation of the individual criteria and design bases for the fuel materials is summarised below.

a) Fuel Centreline Temperature

The Westinghouse standard methodology for the fuel temperature calculations was used to determine the allowed linear heat rate for the prevention of fuel centreline melt.

b) Fuel Dimensional Changes

Observations from several early Westinghouse PWRs have shown that fuel pellets can densify under irradiation to a density higher than the manufactured values (Reference 22.27). Fuel densification and subsequent settling of the fuel pellets can result in local and distributed gaps in the fuel rods. The densification process is related to the elimination of very small as-fabricated porosity in the fuel during irradiation. Early fuels were intentionally manufactured to low initial density and were under-sintered, which resulted in a large fraction of very small pores.

Densification behaviour in current fuel is controlled by improved manufacturing process controls and by specifying a nominal 95.5 percent initial fuel density, which results in reduced levels of small, densifying porosity. The evaluation of fuel densification effects and the treatment of fuel swelling and fission gas release are described in References 22.7 and 22.28.

c) Fuel Chemical Properties

Due to the potential for adverse chemical reactions between the fuel pellet and the cladding the moisture content in the fuel pellets is controlled to minimise the potential for hydride induced failures of the cladding. The moisture content is limited as part of the total hydrogen requirement defined in the pellet production specification, Reference 22.101.

d) Zirconium Diboride Material Properties

The rod average bias in the axial ZrB2 loading is monitored by manufacturing to identify and correct issues that would create significant variations in the axial loading caused by the manufacturing process.

The monitoring is performed using an active gamma scan of every fuel rod. [

]

[

]

Cladding

The evaluation of the individual criteria and design bases for the fuel cladding is summarised below.

a) Clad Stress

Cladding stress analyses are performed with a bounding methodology approach. Important fuel rod dimensions and models that can adversely affect the cladding stress analysis are all set to their limiting values in the same PAD code clad stress run.

Cladding stress analyses are performed to determine the allowable frequent fault local power as a function of initial local power and local burnup so that the cladding yield stress is not exceeded. Cladding stress analyses are performed for a large spectrum of possible steady-state rod power histories with the PAD code. This spectrum of power histories covers the entire range of possible rod powers from low to high and a range of rod burnups.

The most limiting final local power for a given initial local power and local burnup is provided to the core designer. The core designer then ensures that the final allowed local power as a function of initial local power and local burnup will not be exceeded based upon the normal operating range and on the plant protection system. If necessary, constraints on the normal operation range are imposed or more limiting plant trip setpoints are implemented so that the plant will trip prior to exceeding the allowed final local power allowed by the stress analysis.

Another fuel rod design criterion that sets limits on the allowed local power during frequent faults is the one to prevent the cladding total tensile strain due to uniform cylindrical pellet thermal expansion from exceeding 1 percent from the pre-transient value. The cladding stress criterion is more limiting than the 1 percent transient cladding strain criterion. That is, the allowed local power for meeting the stress criterion is less than that allowed for meeting the strain criterion. This cladding stress analysis is purely an analytical calculation to ensure that the yield stress is not exceeded during normal operation and frequent faults..

b) Clad Strain (Transient)

Based upon previous analysis experience and generic analyses, transient clad stress is always more limiting than transient clad strain for a frequent fault. That is, the cladding yield strength would be reached prior to the transient clad strain reaching 1 percent.

c) Clad Strain (Steady State)

The steady-state clad strain mechanism is controlled by the relatively slow processes of fuel swelling and densification and clad creep. Following pellet-clad contact, the clad strain is driven primarily by fuel solid swelling, which is a function of fuel burnup. Outward clad creep associated with operation with rod internal pressure greater than system pressure has only a second-order effect on clad steady-state strain. Since steady-state strain is controlled in large part by fuel behaviour, factors that affect fuel pellet geometry will also affect cladding strain.

d) Clad Corrosion

For the clad corrosion analyses, the best-estimate clad oxide thickness and hydrogen pickup remain less than the criteria limits (Reference 22.89).

e) Clad Flattening

Current fuel rod designs employ fuel with a nominal density of 95.5 percent theoretical density (TD) with improved in-pile stability and high helium backfill pressures that provide adequate assurance that no clad flattening will occur. Westinghouse has undertaken an evaluation of clad flattening based upon available post-irradiation and in-core flux trace data (Reference 22.28). These data confirm that significant axial gaps do not occur for current Westinghouse fuel and concluded that clad flattening will not occur.

According to the lower plenum design criteria, fuel cladding in the lower plenum region shall not be flattened due to creep (thermal- and irradiation-induced) ovalisation during normal operations for the fuel rod design life. This criterion was verified by performing autoclave tests and by operating experience. For the instantaneous and thermal creep collapse, two autoclave tests were performed. The test results (Reference 22.5) indicate that no collapse occurred and that none of the test samples show significant cladding creepdown or flattening.

For the irradiation creep collapse, even though the in-reactor irradiation creep part of the evaluation for the standoff tube was not included in the autoclave tests, the operating experience of the lower plenum standoff design has shown that no issues have ever been reported on the in-reactor irradiation creep effect. The lower plenum design has been used in multiple plant applications for more than three decades. A summary of operating experience is given in Reference 22.5.

f) Clad Fatigue

The fatigue analysis considered three-cycle fuel in 18-month cycles with load follow occurring over 100 percent of each cycle length. [

] Axial power shapes associated with all-rods-out operation were also assumed in the analysis. This spectrum of peaking factor assumptions, along with the load follow core power swing assumption [
] (assumed for fuel rod design purposes only) power provided a wide range of possible initial local powers for the analysis. Both the IFBA fuel rod and the non-IFBA fuel rod were analysed. The IFBA fuel rod was more limiting because of the ZrB_2 coating on the pellet, causing pellet-clad contact sooner than the non-IFBA fuel rod and resulting in more pellet-cladding contact and more strain cycles during load follow.

The standard fatigue methodology is to perform a best-estimate fatigue analysis for all the possible power histories and then to perform an uncertainty analysis for the limiting rod power histories to obtain the upper bound fatigue usage. The methodology includes the important parameters for determining cladding strains as part of the uncertainties consistent with References 22.4, 22.6, 22.30, and 22.5 [

].

The reference analysis in Reference 22.5 analysed a spectrum of power histories for three cycles worth of fuel. Typically, the three cycle is the limiting cycle with the longest pellet-clad contact pressure and resulting strain on the cladding to produce the highest fatigue considering load follow and no grid frequency control.

[

]

[

]

[

]

g) Clad Wall Thickness and Ovality

The fuel cladding wall thickness requirement and maximum-allowed ovality are specified and controlled through product drawings. These specified limits are the same as for previous Westinghouse designs and are acceptable based on successful operating history.

h) Clad Scratch Limits

Fuel cladding scratch limitation is specified and controlled through product drawings and specifications and inspected using visual standards. This specified limit is the same as for previous Westinghouse designs and is acceptable based on successful operating history.

i) Rod Bowing

Potential for rod bow is minimised by control of the fuel element design parameters identified below. Analyses have shown the following conditions to be influential in this context:

[

Rod bow observations have been evaluated for [ ] 14×14-, 15×15-, and 17×17-type cores [ ] (Reference 22.66). This large statistical base has been used to validate the model used for the evaluation of fuel rod bowing in the AP1000 design.

Fuel Rod

In the calculation of the steady-state performance of a nuclear fuel rod, the following interacting factors are considered:

- Clad creep and elastic deflection.
- Pellet density changes, thermal expansion, gas release, and thermal properties as a function of temperature and fuel burnup.
- Internal pressure as a function of fission gas release, rod geometry, and temperature distribution.

These effects are evaluated with PAD using fuel rod design models that include appropriate models for time-dependent fuel densification (Reference 22.7). With these interacting factors considered, the model determines the fuel rod performance characteristics for a given rod geometry, power history, and axial power shape. In particular, internal gas pressure, fuel and clad temperatures, and clad deflections are calculated. The fuel rod is divided into several axial sections and radially into a number of annular zones for the model. The parameters are reconfirmed every cycle using the PAD code to ensure that they remain below their respective limits.

The initial rod internal pressure is selected to delay fuel/clad mechanical interaction and to avoid the potential for clad flattening. It is limited, however, by the design criteria for the rod internal pressure.

The gap conductance between the pellet surface and the clad inner diameter is calculated as a function of the composition, temperature, and pressure of the gas mixture; and the gap size or contact pressure between the clad and pellet. After computing the fuel temperature for each pellet zone, the fractional fission gas release is assessed using an empirical model derived from experimental data (Reference 22.7). The total amount of gas released is based on the average fractional release within each axial and radial zone and the gas generation rate, which, in turn, is a function of burnup. Finally, the gas released is summed up over the zones and the pressure is calculated.

The model shows close agreement in fit for a variety of published and proprietary data on fission gas release, fuel temperatures, and clad deflections. These data include variations in power, time, fuel density, and geometry.

The evaluation of the individual criteria and design bases for the fuel rod performance are summarised below.

a) Fuel Rod Internal Gas Pressure (Departure from Nucleate Boiling Propagation)

Two methodologies exist for verifying this criterion: probabilistic (Reference 22.90) and mechanistic (Reference 22.91). The use of the mechanistic DNB methodology can provide additional flexibility in fuel management and peaking factor space by allowing the use of more IFBA rods and/or the use of nonstandard IFBA patterns. The acceptable strain value is one that ensures that the flow channel closure due to the cladding strain during the transient will not result in additional rods to experience DNB. It also ensures that cladding burst will not take place because of the strain that occurs while the rod is in DNB during the transient.

b) Fuel Rod Internal Gas Pressure (Gap Reopening)

The Westinghouse fuel performance model was used in the analysis of this criterion. The rod internal analysis considers a best estimate plus total uncertainty methodology to obtain the upper bound rod internal pressure. The IFBA rod is limiting because of the helium released from the ZrB_2 coating. For the standard rod internal pressure analysis, the limiting IFBA rod internal pressure was less than the gap-re-opening limit. Analysis of simulated MSHIM operation is necessary to determine the potential effects of local power peaking perturbations on rod internal pressure.

c) Fuel Axial Growth

The Westinghouse standard methodology for fuel rod growth has been used for the verification analysis. This analysis shows that contact will be precluded, conservatively assuming upper bound fuel rod growth, lower bound fuel assembly growth, minimum initial rod to nozzle gap, upper bound fuel rod fast fluence (E>1.0 MeV), and nominal differential thermal expansion between the fuel rod cladding and the fuel assembly structure. The analysis indicates that the design criterion is satisfied considering a lead rod burnup of 62 GWD/MTU.

d) End Plug Weld Integrity

For infrequent faults, the limit is that which produces the maximum tensile differential pressure loads. The limiting event is steam line break (SLB), which produces significant depressurisation of the primary system. This reduced system pressure, along with a return to power during the event (that concentrates the power under the worst-stuck RCCA) can result in high rod internal pressure and high differential pressure loads across the weld.

Generic end plug weld integrity analyses performed for standard fuel rod designs show that [

] the end plug weld integrity criterion would be met. The analysis for the SLB event in the AP1000 design shows a hot rod average power well below this limit for the initial core. The hot rod average power is calculated for each cycle and while the calculated value may vary for a given cycle, it must remain below the limit defined for SLB above.

e) Fuel Rod Straightness

The requirement for fuel cladding and fuel rod assembly straightness in the AP1000 design is specified and controlled through product drawings. This specified limit is the same as for previous Westinghouse designs and is acceptable based on successful operating history.

f) Hold-Down Spring Radial Support of Clad

Verification of this criterion is shown by demonstrating that the springs in the AP1000 design are bounded by previous spring designs. Previous standard pitch springs and variable pitch springs have undergone extensive autoclave testing and have demonstrated acceptable in-pile performance and so provide a sound DB for the design of the plenum springs in the AP1000 design. It has been verified that the wire diameter, the compressed spring midpitch, and the coil diameter of the springs are bounded by previous spring designs. On the basis of this evaluation (Reference 22.5), it is concluded that the fuel rod plenum spring design for the AP1000 plant is capable of providing sufficient radial support to the cladding in the plenum region to preclude collapse.

g) Axial Location of Fuel Pellet Stack

The minimum plenum spring hold-down force on the fuel pellet stack is greater than [ ] times the weight of the [ ] (Reference 22.5). Since the minimum spring force is greater than [ ] times the weight, this design criterion is satisfied.

h) Fuel Rod Outer Diameter at Weld

The fuel rod end plug design and fuel rod outer diameter at the weld are identical to those in previous Westinghouse fuel assembly designs. Successful operating experience with these previous designs and the testing performed on the AP1000 design shows that it will not cause unacceptable fretting damage to the clad in service.

i) Standoff Tube Design

The dimension and shape of the pellet stack base and standoff tube allow fission gases to communicate with the standoff tube internal volume through the centre hole on the pellet

stack base as shown in Figure 22-16. In addition, the hole diameter is designed to be smaller than the wall thickness of the annular pellet. The pellet stack base will therefore prevent fuel pellets or large pellet fragments from entering the lower plenum region.

j) Potentially Damaging Temperature Effects during Transients

The fuel rod experiences many operational transients (intentional manoeuvres) during its residence in the core. A number of thermal effects must be considered when analysing the fuel rod performance.

The clad can be in contact with the fuel pellet at some time in the fuel lifetime. Clad/pellet interaction occurs if the fuel pellet temperature is increased after the clad is in contact with the pellet. Clad/pellet interaction is discussed below.

Clad flattening is precluded during the fuel residence in the core by the use of stable fuel.

Potential differential thermal expansion between the fuel rods and the guide thimbles during a transient is considered in the design. Excessive bowing of the fuel rods is precluded because the grid assemblies allow axial movement of them relative to the grids. Specifically, thermal expansion of the fuel rods is considered in the grid design so that axial loads imposed on them during a thermal transient will not result in excessively bowed fuel rods.

k) Fuel Element Burnout and Potential Energy Release

The core is protected from DNB over the full range of possible operating conditions. In the extremely unlikely event that DNB occurs, the clad temperature will rise because of the steam blanketing at the rod surface and the consequent degradation in heat transfer. During this time, there is a potential for chemical reaction between the cladding and the coolant; however, because of the relatively sufficient film boiling heat transfer following DNB, the energy release resulting from this reaction is insignificant compared with the power produced by the fuel.

l) Fuel/Cladding Mechanical Interaction

The gap between the fuel and clad is initially sufficient to prevent hard contact between the two, but during power operation, a gradual compressive creep of the clad onto the fuel pellet occurs because of the external pressure exerted on the rod by the coolant. Clad compressive creep eventually results in fuel/clad contact. Once this contact occurs, changes in power level result in changes in clad stresses and strains. By using pre-pressurised fuel rods to partially offset the effect of the coolant external pressure, the rate of clad creep toward the surface of the fuel is reduced. Fuel rod pre-pressurisation delays the time at which fuel/clad contact occurs and hence significantly reduces the extent of cyclic stresses and strains experienced by the clad both before and after contact. These factors result in an increase in the fatigue life margin of the clad and lead to greater clad reliability.

22.5.2.3 In-Core Control Components

a) Internal Pressure and Cladding Stresses during Normal, Transient, and Accident Conditions

The designs of the BA, source, and gray rods provide a sufficient cold void volume to accommodate the internal pressure increase during operation. This is not a concern for

the RCCA absorber rod because no significant amount of gas is released by the silver-indium-cadmium absorber material.

For the discrete BA rod, there is sufficient cold void volume to limit the internal pressure to a value that satisfies the design criteria. For the source rods, a void volume is provided within the rod to limit the maximum internal pressure increase at EOL.

During normal transient and accident conditions, the void volume limits the internal pressures to values that satisfy the criteria in Section 22.5.1.3. These limits are established not only to prevent the peak stresses from reaching unacceptable values but also to limit the amplitude of the oscillatory stress component in consideration of the fatigue characteristics of the materials.

Rod, guide thimble, and dashpot flow analyses indicate that the flow is sufficient to prevent coolant boiling within the guide thimble.

b) Thermal Stability of the Absorber Material, Including Phase Changes and Thermal Expansion

The radial and axial temperature profiles within the source and absorber rods are determined by considering gap conductance, thermal expansion, neutron or gamma heating of the contained material, as well as gamma heating of the clad.

The maximum temperatures of the silver-indium-cadmium RCCA or tungsten GRCA absorber materials are calculated and found to be significantly less than the material melting point and to occur axially at only the highest flux region.

The maximum temperature of the alumina-boron carbide WABA pellet is expected to be less than 649°C (1200°F), which occurs following the initial power ascent. As the operating cycle proceeds, the BA pellet temperature decreases because of a reduction in heat generation from boron depletion and better gap conduction as the helium produced diffuses into the gap.

Sufficient diametral and end clearances have been provided in the neutron absorber, BA, and source rods to accommodate the relative thermal expansions between the enclosed material and the surrounding clad and end plug.

c) Irradiation Stability of the Absorber Material, Taking into Consideration Gas Release and Swelling

Irradiation produces no deleterious effects in the silver-indium-cadmium absorber material (Reference 22.13). As mentioned above, gas release is not a concern for the control rod material because no gas is produced by the absorber material. Sufficient diametral and end clearances are provided to accommodate any potential expansion and/or swelling of the absorber material for both RCCA and GRCA absorber rods. The irradiation stability of the tungsten absorber material is discussed in Reference 22.36.

Irradiation produces no deleterious effects in the tungsten absorber material of the gray rodlets. Some minor cracking of the tungsten material may occur, but this cracking does not affect the absorber column geometric stability due to the small clearance between the absorber and sleeve (Reference 22.36).

The alumina-boron carbide BA pellets are designed such that gross swelling or crumbling of the pellets is not predicted during reactor operation. Some minor cracking of the pellets may occur, but it should not affect the overall absorber and stack integrity.

d) Potential for Chemical Interaction, Including Possible Water-Logging Rupture

The structural materials selected have good resistance to irradiation damage and are compatible with the reactor environment. Corrosion of the materials exposed to the coolant is quite low, and proper control of chloride and oxygen in the coolant minimises the potential for stress corrosion. By controlling the coolant chemistry in accordance with the guidance provided in Reference 22.95, the potential for corrosion of components exposed to coolant is minimised and thus the potential for the interference with RCCA movement due to possible corrosion phenomena is very low.

Water-logging rupture is not a failure mechanism associated with the control rods in the AP1000 design. Furthermore, a breach of the cladding for any postulated reason does not result in serious consequences. The silver-indium-cadmium absorber material is relatively inert and will remain so even when subjected to high coolant velocity regions. Rapid loss of reactivity control material will not occur. Test results concluded that additions of indium and cadmium to silver, in the amounts to form the silver-indium-cadmium absorber material composition, result in small corrosion rates (Reference 22.13). In the unlikely event of a GRCA rod cladding breach, loss of absorber material will not occur because the inner sleeve encapsulates the tungsten absorber (Reference 22.36).

For the discrete BA, in the unlikely event that the zirconium alloy clad is breached, the boron carbide in the affected rods could be leached out by the coolant water. If this occurs, normal examination of primary chemistry would indicate presence of boron or in-core instruments would detect peaking factor changes, and corrective action would be taken if warranted. A postulated clad breach after substantial irradiation would have no significant effect on peaking factors since the boron will have been depleted. Breaching of the zirconium alloy clad by internal hydriding is not expected because of moisture controls employed during fabrication. The moisture content is limited as part of the total hydrogen requirement defined in the pellet production specification, Reference 22.101. Reference 22.110 provides the process and inspection requirements to achieve the design requirement during manufacturing. Rods of this design have performed very well with no failures observed.

22.5.3 Testing and Inspection Plan

Westinghouse fuel and core component manufacturing has an extensive amount of information available characterising the success in implementing quality assurance programmes over many years. As a result, the Westinghouse fuel and core components have an extremely high success rate in performing their function, thus demonstrating the robustness of meeting the design criteria described in this chapter. The Westinghouse quality assurance, development, testing, and inspection programmes are described briefly below.

22.5.3.1 Quality Assurance Programme

The Quality Assurance Programme Plan of the Westinghouse Commercial Nuclear Fuel Division provides for control over activities affecting product quality, commencing with design and development and continuing through procurement, materials handling, fabrication, testing and inspection, storage, and transportation. The programme also provides for the indoctrination and training of personnel and for the auditing of activities affecting product quality through a formal auditing programme.

Westinghouse drawings and product, process, and material specifications identify the inspections to be performed.

22.5.3.2 Quality Control

Quality control philosophy is generally based on the following inspections being performed to a 95 percent confidence level that at least 95 percent of the product meets specification, unless otherwise noted.

a) Fuel System Components and Parts

The characteristics inspected depend on the component parts. The quality control programme includes dimensional and visual examinations, check audits of test reports, material certification, and NDE such as X-ray and ultrasonic.

b) Fuel Pellets

Inspection is performed for dimensional characteristics such as diameter, density, length, and squareness of ends. Additional visual inspections are performed for cracks, chips, and surface conditions. Reference 22.111 provides the process and inspection requirements to achieve the design requirements during manufacturing.

Density is determined in terms of weight per unit length and is plotted on zone charts used in controlling the process. Chemical analyses are taken on a specified sample basis throughout pellet production.

c) Rod Inspection

Inspections of fuel rods, rod cluster control rods, discrete BA rods, and source rods consist of the following NDE techniques and methods, as applicable, as follows:

- Each rod is leak tested using a calibrated mass spectrometer, with helium being the detectable gas.
- Rod welds are inspected by ultrasonic test or X-ray in accordance with a qualified technique and Westinghouse specifications meeting the requirements of American Society for Testing Materials (ASTM)-E-142-86 (Reference 22.31).
- Rods are dimensionally inspected prior to final release. The requirements include such items as length, camber, and visual appearance.
- Fuel rods are inspected by gamma scanning to confirm proper plenum dimensions.
- Fuel rods are inspected by gamma scanning to confirm that no significant gaps exist between pellets.

- Fuel rods are actively and/or passively gamma-scanned to verify enrichment control prior to acceptance for assembly loading.

- Traceability of rods and associated rod components is established by quality control.

d) Fuel Assemblies

Each fuel rod, control rod, BA rod, and source rod assembly is inspected for compliance with drawing and/or specification requirements. Other in-core control component inspection and specification requirements are given in Section 22.5.3.3.

e) Other Inspections

The following inspections are performed as part of the routine inspection operation:

- Tool and gauge inspection and control, including standardisation to primary and/or secondary working standards. Tool inspection is performed at prescribed intervals on serialised tools. Complete records are kept of calibration and conditions of tools.

- Audits are performed of inspection activities and records to confirm that prescribed methods are followed and that records are correct and properly maintained.

- Surveillance inspection, where appropriate, and audits of outside contractors are performed to confirm conformance with specified requirements.

f) Process Control

Generally, all items used in fabrication of fuel assemblies and core components are tracked using a manufacturing execution system (MES) interfacing with a database. The local human-machine interfaces (HMIs) vary widely but all are "qualified" in accordance with the quality management system (QMS). The qualification process ensures that the HMI uses and transmits data as intended. Steps in the manufacturing procedures include activities with the HMIs. The HMIs mine the data for the particular items being used to make up the subsequent item or assembly and will only allow the use of items that meet expectations of the programme, or the operator will be unable to complete the operation.

To prevent the possibility of mixing enrichments during fuel manufacture and assembly, strict enrichment segregation and other process controls are exercised.

The uranium dioxide powder is kept in sealed containers. The contents are fully identified both by descriptive tagging and unique bar code numbers. A quality control identification tag completely describing the contents is affixed to the containers before transfer to powder storage. Isotopic content is confirmed by analysis.

Powder can be withdrawn from storage by only one authorised group, which directs the powder to the correct pellet production line. The pellet production lines are physically separated from each other, and pellets of only a single nominal enrichment and density are produced in a given production line at any given time.

Finished pellets are placed on trays identified with the same colour code as the powder containers and transferred to segregated storage racks within the confines of the pelleting area. Samples from each pellet lot are tested for isotopic content and impurity levels prior to acceptance by quality control. Physical barriers are used to prevent mixing of pellets of

different nominal densities and enrichments in the pellet storage area. Unused powder and substandard pellets are returned to storage in the original colour-coded containers.

Loading of pellets into the clad is performed in isolated production lines; only one density and enrichment (with possible exception of top and bottom (axial blanket) zones) are loaded on a line at a time.

A serialised traceability code is placed on each fuel tube, which identifies the contract and enrichment. The end plugs are inserted and then welded (in an inert gas atmosphere) to seal the tube. The fuel tube remains coded and traceability identified until just prior to installation in the fuel assembly.

Similar traceability is provided for WABA, source, and control rods, as required.

22.5.3.3 In-Core Control Component Testing and Inspection

Tests and inspections are performed on each reactivity control component to verify the mechanical characteristics. In the case of the RCCA, prototype testing has been conducted. Manufacturing tests and inspections and functional testing at the plant site are performed.

During the component manufacturing phase, the following requirements apply to the reactivity control components to provide proper functioning during reactor operation:

- Materials are procured to specifications to attain the desired standard of quality.
- Rods are checked for integrity by the applicable nondestructive methods.
- To confirm proper fit with the fuel assembly, the rod cluster control, discrete BA, and source assemblies are installed in the fuel assembly and checked for binding in the dry condition.

The RCCAs and GRCAs are also functionally tested following core loading but prior to criticality to demonstrate reliable operation of the assemblies. Each assembly is operated (and tripped) one time at full-flow/hot conditions. In addition, any assembly that has a drop time greater than a two-sigma limit from the average rod drop time is subjected to additional rod drops to confirm drop time. Thus, each assembly is sufficiently tested to confirm proper functioning and operation. [

]

To demonstrate continuous free movement of the RCCAs and GRCAs and to provide acceptable core power distributions during operations, partial movement checks are performed as required by the Tech Specs. [

] In addition, periodic drop tests of the assemblies are performed at each refuelling shutdown to demonstrate continued ability to meet trip time requirements.

If an RCCA cannot be moved by its mechanism and is determined to be untrippable, adjustments in the boron concentration of the coolant provide that adequate SDM will be achieved following a trip. Thus, inability to move one assembly can be tolerated until the

reactor can be safely taken to Mode 3. Short-term operation with more than one inoperable RCCA may be tolerated as well, depending on the amount of excess SDM initially available, but would impose additional demands on the plant operator.

Upon discovery of one or more inoperable RCCAs, the plant Tech Specs require the operator to confirm adequate SDM and adjust the boron concentration if necessary to achieve it, and then be in Mode 3 within 6 hours of discovery. No allowance is made for continued operation past 6 hours with one or more inoperable RCCAs even if adequate SDM can be maintained with adjustments to the boron concentration. The discovery of an inoperable GRCA is not associated with a requirement to shut down because rapid GRCA insertion is not currently credited for safety purposes. The operator can compensate for the operational effects of an inoperable GRCA by adjusting boron more often or by switching to an alternate GRCA bank.

22.5.3.4 In-Service Surveillance

Westinghouse has gained significant fuel assembly operating experience over many years by conducting a programme to examine detailed aspects of the 17x17 fuel assembly (Reference 22.32). This operating experience is periodically updated to provide recent results of operating experience with Westinghouse fuel and in-core control components. A surveillance programme similar to those conducted in the past will be performed on irradiated fuel assemblies and core components of the AP1000 plant.

22.5.3.5 Onsite Receipt Inspection

Written procedures are used for the post shipment inspection of the new fuel assemblies in addition to reactivity control and source components. Fuel handling procedures specify the sequence in which handling and inspection take place.

Loaded fuel containers, when received onsite, are externally inspected to confirm that labels and markings are intact and security seals are unbroken. After the containers are opened, the shock indicators attached to the suspended internals are inspected to determine whether movement during transit exceeded design limitations.

Following removal of the fuel assembly from the container in accordance with detailed procedures, the fuel assembly plastic wrapper is examined for evidence of damage. The polyethylene wrapper is then removed and a visual inspection of the entire fuel assembly is performed.

Control rod, gray rod, secondary source rod, and discrete BA rod assemblies are usually shipped in fuel assemblies. They are inspected prior to removal of the fuel assembly from the container. The control rod assembly is withdrawn a few inches from the fuel assembly to confirm free and unrestricted movement; the exposed section is visually inspected for mechanical integrity, replaced in the fuel assembly, and stored with the fuel assembly. Control rod, secondary source, or discrete BA assemblies may be stored separately or within fuel assemblies in the new fuel storage area.

Primary source rods will be shipped to site in separate containers because of the radioactive properties of the source material. Inspection of the rods will be carried out prior to fixing into the core component assemblies.

22.6 NUCLEAR DESIGN

22.6.1 Design Bases

This section describes the design bases and functional requirements used in the nuclear design of the fuel and reactivity control system. The design bases are the fundamental criteria that must be met using analytical techniques.

The initial fuel loading of the reactor and the nuclear performance during the first operating cycle are important periods of the nuclear design. This is because some of the safety-related nuclear parameters may assume their most extreme values during this period. Where subsequent operation is expected to produce more extreme values of any safety-related parameter, a representative reload core condition is derived to evaluate it.

Conservative upper and lower limits are specified for all safety-related parameters and a prime purpose of the nuclear design basis is to ensure that no safety parameter moves outside its permitted bandwidth. The safety case for the lifetime of the plant is based on these conservative limiting values and there is a high degree of confidence that these limits will not be exceeded during the operating lifetime of the plant.

The core design power distribution limits related to fuel integrity are met for frequent faults through conservative design and are maintained by the action of the control system.

The requirements for frequent faults are met by providing an adequate protection system that monitors reactor parameters.

The control and protection systems for core monitoring and control and for fuel handling and storage systems are described in Chapter 19.

The consequences of faults are described in appropriate sections of Chapter 9.

22.6.1.1 Fuel Burnup

A limitation on initial installed excess reactivity or average discharge burnup is not required other than as is quantified in terms of other design bases, such as overall negative power reactivity feedback discussed below. A maximum fuel rod average burnup of 62,000 MWD/MTU has been adopted for the core (Reference 22.29). Note that this is an extension of the original licensed limit of 60,000 MWD/MTU (Reference 22.4).

Burnup is a measure of fuel depletion that represents the integrated energy output of the fuel in MWD/MTU and is a useful means for quantifying fuel exposure criteria.

The core design lifetime, or design discharge burnup, is achieved by installing sufficient initial excess reactivity in each fuel region and subsequently following a fuel replacement programme that meets the safety-related criteria in each cycle of operation.

Initial excess reactivity installed in the fuel, although not a DB, must be sufficient to maintain core criticality at full-power operating conditions throughout cycle life with equilibrium xenon, samarium, and other fission products present. BAs, control rods, and/or chemical shim are used to compensate for the excess reactivity. The end of design cycle life is defined as occurring when the chemical shim concentration is essentially zero with control rods present to the degree necessary for operational requirements.

22.6.1.2 Reactivity Coefficients

For the initial fuel cycle, the fuel temperature coefficient must be negative and the moderator temperature coefficient of reactivity must also be negative for power operating conditions, thereby providing negative reactivity feedback characteristics.

When compensation for a rapid increase in reactivity is considered, there are two major effects: the resonance absorption (Doppler) effects associated with changing fuel temperature and the neutron spectrum and reactor composition change effects resulting from changing moderator density. These basic physics characteristics are often identified by reactivity coefficients. The use of slightly enriched uranium results in a Doppler coefficient of reactivity that is negative. This coefficient provides the most rapid reactivity compensation.

The initial core is also designed to have an overall negative moderator temperature coefficient of reactivity during power operation so that average coolant temperature changes or void content provides another, slower compensatory effect. For some core designs, if the compensation for excess reactivity is provided only by chemical shim, the moderator temperature coefficient could become positive. Nominal power operation is permitted only in a range of overall negative moderator temperature coefficient. The negative moderator temperature coefficient can be achieved through the use of discrete BAs and/or integral fuel BAs and/or control rods by limiting the reactivity controlled by soluble boron.

BA content (quantity and distribution) is not stated as a DB; however, for some initial core designs or subsequent reloads, the use of BAs may be necessary for power distribution control and/or to achieve an acceptable moderator temperature coefficient throughout core life. In any core design, a sufficient number of BAs are provided to achieve a negative moderator temperature coefficient at the conditions expected for initial criticality. Thus, there can be no significant transient due to moderator feedback during the initial startup of a cycle. During subsequent operation, the core reactivity may initially increase for the first few months of a cycle and will then begin to decrease after the majority of the BA absorber material has been depleted. Continued operation at or near full power will maintain the negative moderator temperature coefficient condition without any additional operating restrictions during the peak reactivity point in the cycle. If low power operations or a startup are required at the peak reactivity point in the cycle, however, it may be necessary to establish additional limits on control rod withdrawal or maximum soluble boron concentration to maintain the negative moderator temperature coefficient at low power levels. The establishment of such limits would not impact actual operation because the normal boron concentration and position of control rods during MSHIM operation would not challenge the limits required to ensure compliance with the moderator temperature coefficient (MTC) limit.

22.6.1.3 Control of Power Distribution

The nuclear DB is the following, with at least a 95 percent confidence level:

- The fuel will not operate with a power distribution that would result in exceeding the DNB DB (i.e., the DNBR shall be greater than the design limit DNBR) under normal operation and frequent faults, including the maximum overpower condition.

- Under abnormal conditions, including the maximum overpower condition, the peak linear heat rate (PLHR) will not cause fuel melting.

- Fuel management will be such as to produce values of fuel rod power and burnup consistent with the assumptions in the fuel rod mechanical integrity analysis in Section 22.5.

- The fuel will not be operated at PLHR values greater than those found to be acceptable within the body of the safety analysis under normal operating conditions, including an allowance of 1 percent for calorimetric error.

Calculation of extreme power shapes that affect fuel design limits are performed with proven methods. The conditions under which limiting power shapes are assumed to occur are chosen conservatively with regard to any permissible operating state. A nuclear uncertainty is applied to the calculated power distribution. Such margins are provided both for the analysis for normal operating states and for anticipated transients.

22.6.1.4 Maximum Controlled Reactivity Insertion Rate

The maximum reactivity insertion rate due to withdrawal of RCCAs or GRCAs or by boron dilution is limited by plant design, hardware, and basic physics. During normal power operation, the maximum controlled reactivity insertion rate is limited. The maximum reactivity change rate for accidental withdrawal of two control banks is set such that PLHR and the DNBR limitations are not challenged.

The maximum reactivity worth of control rods and the maximum rates of reactivity insertion employing control rods are limited to preclude rupture of the coolant pressure boundary or disruption of the core internals to a degree that would impair core cooling capacity because of a rod withdrawal or an ejection accident.

Following any infrequent fault, such as rod ejection or SLB, the reactor can be brought to the shutdown condition and the core maintains acceptable heat transfer geometry.

Reactivity addition associated with an accidental withdrawal of a control bank (or banks) is limited by the maximum rod speed (or travel rate) and by the worth of the banks. For the AP1000 reactor, the maximum control and gray rod speed is 1.14 m/minute (45 inches/minute).

The reactivity change rates are conservatively calculated, assuming unfavourable axial power and xenon distributions. The typical peak xenon burnout rate is significantly lower than the maximum reactivity addition rate for normal operation and for accidental withdrawal of two banks.

22.6.1.5 Shutdown Margins

The minimum shutdown margin as specified in the Tech Specs is required in all operating modes. In analyses involving reactor trip, the single highest-worth RCCA is postulated to remain untripped in its full-out position (stuck-rod criterion).

Two independent reactivity control systems are provided: control rods and soluble boron in the coolant. The control rods provide reactivity changes that compensate for the reactivity effects of the fuel and water density changes accompanying power level changes over the range from full load to no load. The control rods provide the minimum shutdown margin for normal operation; they are capable of making the core subcritical rapidly enough to prevent exceeding acceptable fuel damage limits (very small number of rod failures), assuming that the highest worth control rod is stuck-out upon trip.

The boron system can compensate for xenon burnout reactivity changes and maintain the reactor in the cold shutdown condition. Thus, backup and emergency shutdown provisions are provided by mechanical and chemical shim control systems that satisfy the design criteria. Reactivity changes due to fuel depletion are accommodated with the boron system.

When fuel assemblies are in the pressure vessel and the vessel head is not in place, k_{eff} will be maintained at or below 0.95 with control rods and soluble boron. Furthermore, the fuel will be maintained sufficiently subcritical that removal of the RCCAs will not result in criticality.

ANSI N18.2a (Reference 22.33) specifies a k_{eff} not to exceed 0.95 in spent fuel storage racks and transfer equipment flooded with pure water; and a k_{eff} not to exceed 0.98 in normally dry new fuel storage racks, assuming optimum moderation. This is an established criterion within the nuclear industry. No criterion is given for the refuelling operation; however, a 5 percent margin, which is consistent with spent fuel storage and transfer and the new fuel storage, is adequate for the controlled and continuously monitored operations involved.

The boron concentration required to meet the refuelling shutdown criteria is specified in the Core Operating Limits Report (COLR). Verification that these shutdown criteria are met, including uncertainties, is achieved using standard design methods. The subcriticality of the core is continuously monitored as described in the Tech Specs.

When considering maintaining shutdown margin in the long term following a trip, periodic calculations are made of the required RCS boron concentrations necessary to ensure the correct shutdown margin. These calculations will be based on conservative assumptions such as no-xenon conditions and limiting temperature for each applicable operating mode.

Calculations are also made by the online core monitoring system of the required RCS boron concentration to maintain shutdown margin immediately after a reactor trip. These calculations assume the current core xenon condition, that the highest-worth RCCA will remain stuck out of the core, and that the plant will reach the zero-power no-load temperature following the trip. When compared with the current operating boron concentration, these calculations are an indication of how much excess shutdown margin above the required Tech Spec limit will be available immediately after the reactor trip. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96.

Following trip, operations procedures will be initiated that will direct the operator to confirm or take action to ensure adequate SDM for the current condition and the anticipated final operating mode and the post-trip condition. When this step in the procedure is reached, the RCS boron concentration data will be readily available.

Assuming that the plant trips into a condition with the Tech Spec minimum-required SDM, the initial buildup of xenon following the trip will provide the operator with at least 8 hours to identify the expected final mode, borate the RCS to the required long-term boron concentration (if necessary), and confirm the concentration by sample. This is more than adequate time in present plants and the AP1000 plant is not substantially different in this matter.

22.6.1.6 Stability

The core will be inherently stable to power oscillations at the fundamental mode. Spatial power oscillations within the core with a constant core power output, should they occur, can be reliably and readily detected and suppressed.

Oscillations of the total power output of the core, from whatever cause, are readily detected by the loop temperature sensors and by the nuclear instrumentation. The core is protected by these systems; a reactor trip occurs if power increases unacceptably, thereby preserving the design margins to fuel design limits. The combined stability of the turbine, steam generator, and reactor power control systems are such that total core power oscillations are not normally possible. The redundancy of the protection circuits results in a low probability of exceeding design power levels.

The core is designed so that diametral and azimuthal oscillations due to spatial xenon effects are self-damping: no operator action or control action is required to suppress them. The stability to diametral oscillations is so great that this excitation is highly improbable. Convergent azimuthal oscillations can be excited by prohibited motion of individual control rods.

Indications of power distribution anomalies are continuously available from an online core monitoring system. The online monitoring and safety systems process information provided by the fixed in-core detectors, in-core thermocouples, and loop temperature measurements. Radial power distributions are therefore continuously monitored, thus power oscillations are readily observable and alarmed. The ex-core long ion chambers also provide surveillance and alarms of anomalous power distributions. In proposed core designs, these horizontal plane oscillations are self-damping by virtue of reactivity feedback effects inherent to the basic core physics.

Axial xenon spatial power oscillations may occur during core life, especially late in the cycle. The online core monitoring system provides continuous surveillance of the axial power distributions. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96. The control rod system provides both manual and automatic control systems for controlling the axial power distributions.

Confidence that fuel design limits are not exceeded is provided by reactor protection system overpower ΔT ($OP\Delta T$) and overtemperature ΔT ($OT\Delta T$) trip functions, which use the loop temperature sensors, pressuriser pressure indication, and measured axial offset as an input.

22.6.1.7 Anticipated Transients without Trip

The diverse reactor trip actuation system is independent of the reactor trip breakers used by the protection monitoring system. The diverse reactor trip reduces the probability and consequences of postulated anticipated transient without trip (ATWT). These effects are considered to be low probability design basis events which are considered using more realistic inputs and analysis methods and have more relaxed acceptance criteria than higher probability design basis events. Analysis has shown that the likelihood of such a hypothetical event is negligibly small. Furthermore, analysis of the consequences of a hypothetical failure to trip following anticipated transients has shown that no significant core damage would result, system peak pressures should be limited to acceptable values, and no failure of the RCS would result (Reference 22.34). A detailed discussion of ATWT is given in Chapter 9.

22.6.2 Design Description

22.6.2.1 Nuclear Design Description

The reactor core consists of a specified number of fuel rods held in bundles by spacer grids and top and bottom fittings. The fuel rods are fabricated from cylindrical tubes made of

zirconium based alloy(s) containing uranium dioxide fuel pellets. The bundles, known as fuel assemblies, are arranged in a pattern which approximates a right circular cylinder.

Each fuel assembly contains a 17 x 17 rod array composed nominally of 264 fuel rods, 24 rod cluster control thimbles, and an in-core instrumentation thimble. Figure 22-1 shows a cross-sectional view of a 17 x 17 fuel assembly and the related rod cluster control guide thimble locations. Detailed descriptions of the AP1000 fuel assembly design features are given in Section 22.5.

Both the initial and reload core loading patterns can employ various fuel management techniques including “low-leakage” designs, and are anticipated to operate approximately 18 months between refuelling. For reload core loading patterns, the initial and final positions of assemblies and the number of fresh assemblies and their placement are dependent on the energy requirement for the reload cycle and burnup and power histories of the previous cycles.

For the initial core loading, the fuel rods within certain assemblies contain varying uranium enrichments in both the radial and axial planes. Fuel containing up to five average enrichments will be used in the initial core load to establish a favourable radial power distribution simulating the reactivity distribution of a low leakage reload core. Figure 22-17 shows the fuel loading pattern used in the initial cycle. The higher enriched regions will be configured in the core interior consistent with the feed fuel placement in a reload core, and the lower enriched regions will approximate the reactivity of the burned fuel assemblies of a reload core. The enrichments for the initial cycle are shown in Table 22-2.

Reload core loading patterns can employ various fuel management techniques including “low-leakage” designs where the feed fuel is interspersed checkerboard-style in the core interior and depleted fuel is placed on the periphery. Low-leakage designs in general result in lower fuel cycle costs and reduced fluence accumulation on the reactor vessel internals. Regardless of the fuel management technique employed, the reactor vessel fluence is maintained below analysed limits. This is accomplished through metallurgical sampling, radiation analysis, and, if necessary, the implementation of loading pattern constraints on the peripheral core power distribution. Reload core designs, as well as the initial cycle design, are anticipated to operate approximately 18 months between refuelling, accumulating a cycle average burnup of approximately 21,000 MWD/MTU. The exact reloading pattern, the initial and final positions of assemblies, and the number of fresh assemblies and their placement depend on the energy requirement for the reload cycle and burnup and power histories of the previous cycles.

The core average enrichment is determined by the amount of fissionable material required to provide the desired energy requirements. The physics of the burnout process is such that operation of the reactor depletes the amount of fuel available because of the absorption of neutrons by the U-235 atoms and their subsequent fission. In addition, the fission process results in the formation of fission products, some of which readily absorb neutrons. These effects, the depletion and the buildup of fission products, are partially offset by the buildup of plutonium, which occurs due to the parasitic absorption of neutrons in U-238.

At the beginning of any cycle, therefore, a reactivity reserve equal to the depletion of the fissionable fuel and the buildup of fission product poisons, less the buildup of fissile fuel over the specified cycle life, is built into the reactor. This excess reactivity is controlled by removable neutron-absorbing material in the form of boron dissolved in the primary coolant, control rod insertion, BA rods, and/or IFBAs. The stack length of the BA rods and/or integral absorber bearing fuel may vary for different core designs, with the optimum length

determined on a design-specific basis. Figure 22-18 shows a plot of the initial core soluble boron concentration versus core depletion.

The concentration of the soluble neutron absorber is varied to compensate for reactivity changes due to fuel burnup; fission product poisoning, including xenon and samarium; BA depletion; and the cold-to-operating moderator temperature change. Throughout the operating range, the CVS is designed to provide changes in RCS boron concentration to compensate for the reactivity effects of fuel depletion, peak xenon burnout and decay, and cold shutdown boration requirements.

BA rods are strategically located to provide a favourable radial power distribution and provide for negative reactivity feedback. Figures 22-19 and 22-20 show the burnable absorber distributions within a fuel assembly for the several patterns used in a 17 x 17 array. The initial core burnable absorber loading pattern is shown in Figure 22-21.

Tables 22-3 and 22-4 contain summaries of reactor core design parameters including reactivity coefficients, delayed neutron fraction, and neutron lifetimes. Sufficient information is included to permit an independent calculation of the nuclear performance characteristics of the core.

22.6.2.2 Power Distribution

Relative power distributions within the reactor are quantified in terms of hot channel factors (Reference 22.35). These hot channel factors are normalised ratios of maximal absolute power generation rates and are a measure of the peak pellet power within the reactor core relative to the average pellet (F_Q) and the energy produced in a coolant channel relative to the core average channel ($F_{\Delta H}$). Absolute power generation rates are expressed in terms of quantities related to the nuclear or thermal design; more specifically, volumetric power density (q_{vol}) is the thermal power produced per unit volume of the core.

The **linear heat rate (LHR)** is the thermal power produced per unit length of active fuel (kW/m). Since the fuel assembly geometry is standardised, LHR is the unit of absolute power density most commonly used. For practical purposes, LHR differs from q_{vol} by a constant factor that includes geometry effects and the heat flux deposition fraction. The PLHR is defined as the maximum linear heat rate occurring throughout the reactor. It directly affects fuel temperatures and decay power levels and thus is a significant safety analysis parameter.

The **average linear heat rate (ALHR)** is the total thermal power produced in the fuel rods expressed as heat flux divided by the total active fuel length of the rods in the core.

The **local heat flux** is the heat flux at the surface of the cladding. For nominal rod parameters, this differs from LHR by a constant factor.

The **rod power** is the total power generated in one rod (kW).

The **average rod power** is the total thermal power produced in the fuel rods divided by the number of fuel rods.

The hot channel factors used in the discussion of power distributions in this section are defined below.

The **heat flux hot channel factor (F_Q)** is defined as the maximum local heat flux on the surface of a fuel rod divided by the average fuel rod heat flux, allowing for manufacturing tolerances on fuel pellets and rods.

The **nuclear heat flux hot channel factor (F_Q^N)**, is defined as the maximum local fuel rod linear heat rate divided by the average fuel rod linear heat rate, assuming nominal fuel pellet and rod parameters.

The **engineering heat flux hot channel factor (F_Q^E)**, is the allowance on heat flux required for manufacturing tolerances. The engineering factor allows for local variations in enrichment, pellet density and diameter, BA content, surface area of the fuel rod, and eccentricity of the gap between pellet and clad. Combined statistically, the net effect is a factor of 1.03 to be applied to the fuel rod surface heat flux.

The **nuclear enthalpy rise hot channel factor ($F_{\Delta H}^N$)**, is defined as the ratio of the maximum integrated rod power within the core to the average rod power.

Manufacturing tolerances, hot channel power distribution, and surrounding channel power distributions are treated explicitly in the calculation of the DNBR described in Section 22.7.

It is convenient for the purposes of discussion to define subfactors of F_Q; however, design limits are set in terms of the total peaking factor.

$$F_Q = \text{total peaking factor or heat flux hot channel factor} = \frac{PLHR}{ALHR}$$

Without densification effects:

$$F_Q = F_Q^N \times F_Q^E = F_{XY}^N \times F_Z^N \times F_U^N \times F_Q^E$$

where,

F_U^N = Factor for calculation uncertainty, assumed to be 1.05

F_{XY}^N = Ratio of peak power density to average power density in the horizontal plane of peak local power

F_Z^N = Ratio of the power per unit core height in the horizontal plane of peak local power to the average value of power per unit core height. If the plane of peak local power coincides with the plane of maximum power per unit core height, then F_Z^N is the core average axial peaking factor.

22.6.2.3 Radial Power Distribution

The power shape in horizontal sections of the core at full power is a function of the fuel assembly and BA rod loading patterns, the control rod pattern, and the fuel burnup distribution. Thus, at any time in the cycle, a horizontal section of the core can be characterised as being unrodded or being with control rods. These two situations combined with burnup effects determine the radial power shapes that can exist in the core at full power. Typical first cycle values of $F_{\Delta H}^N$, the nuclear enthalpy rise hot channel factors from BOL to EOL, are given in Table 22-3.

The effects on radial power shapes of power level, xenon, samarium, and moderator density are also considered, but these are quite small. The effect of non-uniform flow distribution is negligible. While radial power distributions in various planes of the core are often illustrated, since the moderator density is directly proportional to enthalpy, the core radial enthalpy rise distribution, as determined by the integral of power up each channel, is of greater interest. Figures 22-22 through 22-27 show typical normalised power density distributions for one-quarter of the core for representative operating conditions. These conditions are as follows:

- Hot full power (HFP) near beginning of life, unrodded, no xenon
- Hot full power near beginning of life, unrodded, equilibrium xenon
- Hot full power near beginning of life, gray bank MA+MB in, equilibrium xenon
- Hot full power near middle of life (MOL), unrodded equilibrium xenon
- Hot full power near end of life, unrodded, equilibrium xenon
- Hot full power near end of life, gray bank MA+MB in, equilibrium xenon

Since the position of the hot channel varies from time to time, a single-reference radial design power distribution is selected for DNB calculations. This reference power distribution is chosen conservatively to concentrate power in one area of the core, minimising the benefits of flow redistribution. Assembly powers are normalised to core average power. The radial power distribution within a fuel rod and its variation with burnup as utilised in thermal calculations and fuel rod design are discussed in Section 22.7.

22.6.2.4 Assembly Power Distribution

For the purpose of illustration, typical rodwise power distributions for the BOL and EOL conditions are given in Figure 22-28 and Figure 22-29, respectively. Since the detailed power distribution surrounding the hot channel varies from time to time, a conservatively flat radial assembly power distribution is assumed in the DNB analysis, described in Section 22.7, with the rod of maximum integrated power artificially raised to the design value of $F^N_{\Delta H}$. Care is taken in the nuclear design of the fuel cycles and operating conditions to confirm that a flatter assembly power distribution does not occur with limiting values of $F^N_{\Delta H}$.

22.6.2.5 Axial Power Distribution

The distribution of power in the axial or vertical direction is largely under the control of the operator through either manual operation of the control rods or the automatic motion of control rods in conjunction with manual operation of the CVS. The automated mode of operation is referred to as MSHIM and discussed in Section 22.6.2.12. The rod control system automatically modulates the insertion of the AO control bank controlling the axial power distribution simultaneous with the MSHIM gray and control rod banks to maintain programmed coolant temperature. Operation of the CVS is initiated manually by the operator to compensate for fuel burnup and maintain the desired MSHIM bank insertion. Nuclear effects that cause variations in the axial power shape include moderator density, Doppler effect on resonance absorption, spatial distribution of xenon, burnup, and axial distribution of fuel enrichment and BA. Automatically controlled variations in total power output and rod motion are also important in determining the axial power shape at any time.

The online core monitoring system provides the operator with detailed power distribution information in both the radial and axial sense, continuously using signals from the fixed in-core detectors. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96 Signals are also available to the operator from the ex-core ion chambers, which are long ion

chambers outside the reactor vessel running parallel to the axis of the core. Separate signals are taken from each ion chamber, then processed and calibrated against the in-core measurements such that an indication of the power in the top of the core less the power in the bottom of the core is derived. The calibrated difference in power between the core top and bottom halves, called the flux difference (ΔI), is derived for each of the four channels of ex-core detectors and is displayed on the control panel. The principal use of the flux difference is to provide the shape penalty function to the OTΔT DNB protection and the OPΔT protection.

22.6.2.6 Local Power Peaking

Fuel densification occurred early in the evolution of PWR fuel manufacture under irradiation in several operating reactors, causing the fuel pellets to shrink both axially and radially. The pellet shrinkage combined with random hang up of fuel pellets resulted in gaps in the fuel column when the pellets below the hung-up pellet settled in the fuel rod. The gaps varied in length and location in the fuel rod. Because of decreased neutron absorption in the vicinity of the gap, power peaking occurs in the adjacent fuel rods, resulting in an increased power peaking factor. A quantitative measure of this local peaking is given by the power spike factor S(Z), where Z is the axial location in the core (References 22.27 and 22.37).

Modern PWR fuel manufacturing practices have essentially eliminated significant fuel densification impact on reactor design and operation. It has since been concluded and accepted that a densification power spike factor of 1.0 is appropriate for Westinghouse fuel (Reference 22.28).

22.6.2.7 Limiting Power Distribution

High-Frequency, Low Consequence (HFLC) faults are those expected frequently or regularly in the course of power operation, maintenance, or manoeuvring of the plant (refer to Chapter 8 for a list of these faults). As such, HFLC faults are accommodated with margin between any plant parameter and the value of that parameter, which would require either automatic or manual protective action. HFLC faults are considered from the point of view of affecting the consequences of fault conditions. Analysis of each fault condition described is based on a conservative set of corresponding initial conditions.

The list of steady-state and shutdown conditions, permissible deviations, and operational transients is given in Chapter 9. Implicit in the definition of normal operation is proper and timely action by the reactor operator; that is, the operator follows recommended operating procedures for maintaining appropriate power distributions and takes any necessary remedial actions when alerted to do so by the plant instrumentation.

The analysis to support the online monitoring system evaluates the consequences of limiting power distributions based upon the conditions prevalent in the reactor at the current time. Operating space evaluations performed by the online monitoring system include the most limiting power distributions that can be generated by inappropriate operator or control system actions given the current core power level, xenon distribution, MSHIM or AO bank insertion, and core burnup. Thus, as stated, the worst or limiting power distribution that can occur during normal operation is considered as the starting point for analysis of faults.

Improper procedural actions or errors by the operator are assumed in the design as frequent faults. The limiting power shapes that result from frequent fault occurrences are those power distributions that deviate from the normal operating condition within the allowable operating space as defined in the core operating limits; e.g., because of lack of proper action by the

operator during a xenon transient following a change in power level brought about by control rod motion. Power distributions that fall in this category are used for determining the reactor protection system setpoints to maintain margin to overpower or DNB limits.

The means for maintaining power distributions within the required absolute power generation limits are described in the Technical Specifications (Tech Specs). The online core monitoring system provides the operator with the current allowable operating space, detailed current power distribution information, thermal margin assessment, and operational recommendations to manage and maintain required thermal margins. As such, the online monitoring system provides the primary means of managing and maintaining required operating thermal margins during normal operation. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96. The axial flux difference and quadrant power tilt ratio (QPTR) limits defined in the Technical specifications provide additional confirmation of acceptable margin during normal operation.

In the unlikely event that the online monitoring system is out of service, power distribution controls based on bounding, precalculated analysis are also provided to the operator such that the online monitoring system is not a required element for short-term reactor operation. Limits are placed on the axial flux difference so that the heat flux hot channel factor F_Q is maintained within acceptable limits. A discussion of pre-calculated power distribution control in Westinghouse PWRs is included in Reference 22.39. Detailed background information on the design constraints on local power density in a Westinghouse PWR, on the defined operating procedures, and on the measures taken to preclude exceeding design limits is presented in Reference 22.40. The following paragraphs summarise this report and describe the calculations used to establish the upper bound on peaking factors.

The calculations used to establish the upper bound on peaking factors, F_Q and $F_{\Delta H}^N$, include the nuclear effects that influence the radial and axial power distributions throughout core life for various modes of operation, including load follow, reduced power operation, and axial xenon transients. As described above, the online core monitoring system provides a means for monitoring of the peaking factors directly during operation to confirm that they remain below the acceptable levels defined in the Tech Specs.

Power distributions are calculated for the full-power condition. Fuel and moderator temperature feedback effects are included within these calculations in each spatial dimension. The steady-state nuclear design calculations are done for normal flow with the same mass flow in each channel and flow redistribution effects neglected. The effect of flow redistribution is calculated explicitly where it is important in the DNB analysis of accidents. The effect of xenon on radial power distribution is small (compare Figures 22-22 and 22-23) but is included as part of the normal design process.

The core axial profile can experience significant changes that occur rapidly as a result of rod motion and load changes and more slowly due to xenon distribution. Several thousand cases are examined for the study of points of closest approach to thermal margin limits. Since the properties of the nuclear design dictate what axial shapes can occur, boundaries on the limits of interest can be set in terms of the parameters readily observed on the plant. Specifically, the nuclear design parameters significant to the axial power distribution analysis are as follows:

- Core power level
- Core height
- Coolant temperature and flow

- Coolant temperature programme as a function of reactor power
- Fuel cycle lifetimes
- Rod bank worth
- Rod bank overlaps

Normal operation of the plant assumes compliance with the following conditions:

- Control rods in a single bank move together with no individual rod insertion differing from the bank demand position by more than the number of steps identified in the Tech Specs.
- Control banks are sequenced with overlapping banks.
- The control bank insertion limits are not violated.
- Axial power distribution control procedures, which are given in terms of flux difference control and control bank position, are observed.

The axial power distribution procedures referred to above are part of the required operating procedures followed in normal operation with the online monitoring system out of service. In service, the online core monitoring system provides continuous indication of power distribution, SDM, and margin-to-design limits.

The relaxed axial offset control (RAOC) procedures were developed to provide wide control band widths and, consequently, more operating flexibility (Reference 22.41). These wide operating limits, particularly at lower power levels, increase plant availability by allowing quicker plant startup and increased manoeuvring flexibility without trip.

This procedure has been modified to accommodate MSHIM operation in the AP1000 plant. It is applied to analysis of axial power distributions under MSHIM control for the purpose of defining the allowed normal operating space such that thermal margin limits are maintained and frequent fault occurrences are adequately protected by the reactor protection system when the online monitoring system is out of service.

The purpose of this analysis is to find the widest permissible ΔI versus power operating space by analysing a wide range of achievable xenon distributions, MSHIM/ axial offset (AO) bank insertion, and power level.

The bounding analyses performed offline in anticipation of the online monitoring system being out of service are similar to those based on the RAOC analysis, which uses a xenon reconstruction model (Reference 22.41). This is a practical method used to define the power operating space allowed with MSHIM operation. Each resulting power shape is analysed to determine if LOCA constraints are met or exceeded.

The online monitoring system evaluates the effects of radial xenon distribution changes due to operational parameter changes continuously and therefore eliminates the need for overly conservative bounding evaluations when the system is available. The calculated values have been increased by a factor of 1.05 for method uncertainty and a factor of 1.03 for the engineering factor F_Q^E.

The envelope drawn in Figure 22-30 represents an upper bound envelope on local power density versus elevation in the core. This envelope is a conservative representation of the bounding values of local power density.

The online monitoring system measures the core condition continuously and evaluates the thermal margin condition directly in terms of PLHR and margin to DNB limitations directly.

Allowing for fuel densification effects, the average linear power at 3400 MW is 18.76 kW/m (5.72 kW/ft). The conservative upper bound value of normalised local power density, including uncertainty allowances, is 2.60 corresponding to a PLHR of 49.26 kW/m (15.0 kW/ft) for each core elevation at 101 percent power.

To determine reactor protection system setpoints with respect to power distributions, three categories of events are considered: rod control equipment malfunctions and operator errors of commission or omission. In evaluating these three categories, the core is assumed to be operating within the four constraints described above.

The first category comprises uncontrolled rod withdrawal (with rods moving in the normal bank sequence) for both AO and MSHIM banks. Also included are motions of the AO and MSHIM banks below their insertion limits, which could be caused, for example, by uncontrolled dilution or primary coolant cooldown. Power distributions are calculated throughout these occurrences, assuming short-term corrective action; that is, no transient xenon effects are considered to result from the malfunction. The event is assumed to occur from typical normal operating situations, which include normal xenon transients. It is further assumed in determining the power distributions that total core power level would be limited by reactor trip to below the overpower protection setpoint of nominally 118 percent rated thermal power (RTP). Since the study is to determine protection limits with respect to power and AO, no credit is taken for OTΔT or OPΔT trip setpoint reduction due to flux difference. The peak power density that can occur in such events, assuming reactor trip at or below 118 percent, is less than that required for fuel centreline melt, including uncertainties and densification effects.

The second category assumes that the operator mispositions the AO and/or MSHIM rod banks in violation of the insertion limits and creates short-term conditions not included in normal operating conditions.

The third category assumes that the operator fails to take action to correct a power distribution limit violation (such as boration and dilution transient) assuming automatic operation of the rod control system, which will maintain constant reactor power.

For each of the above categories, the trip setpoints are designed so as not to exceed fuel centreline melt criteria as well as fuel mechanical design criteria.

The appropriate hot channel factors F_Q and $F^N_{\Delta H}$ for peak local power density and for DNB analysis at full power are based on analyses of possible operating power shapes and are addressed in the Tech Specs. The methodology for the power shape analysis is described in Reference 22.41. The maximum allowable F_Q can be increased with decreasing power. Increasing $F^N_{\Delta H}$ with decreasing power is permitted by the DNB protection setpoints and allows radial power shape changes with rod insertion to the insertion limits. The allowance for the increased $F^N_{\Delta H}$ permitted is addressed in the Tech Specs.

This becomes a design basis criterion used for establishing acceptable control rod patterns and control bank sequencing. Likewise, fuel loading patterns for each cycle are selected with consideration of this design criterion. The worst values of $F^N_{\Delta H}$ for possible rod configurations occurring in normal operation are used in verifying that this criterion is met.

The worst values generally occur when the rods are assumed to be at their insertion limits. Operation with rod positions above the allowed insertion limits provides increased margin to

the $F^N_{\Delta H}$ criterion. It has been determined that the Tech Specs' limits are met, provided the above conditions are observed (Reference 22.42). These limits are taken as input to the thermal-hydraulic DB as described in Section 22.7.

In normal operation, when a situation could result in local power densities in excess of those assumed as the precondition for a subsequent hypothetical accident but would not itself cause fuel failure, administrative controls and alarms are provided for returning the core to a safe condition.

The independence of the various individual uncertainties constituting the uncertainty factor on F_Q enables the uncertainty (F^U_Q) to be calculated by statistically combining the individual uncertainties on the limiting rod. The standard deviation of the resultant distribution of F^U_Q is determined by taking the square root of the sum of the variances of each of the contributing distributions (Reference 22.35). The values for F^E_Q and F^N_U are 1.03 and 1.05, respectively. The value for the rod bow factor, F^B_Q, is 1.056, which accounts for the maximum F_Q penalty as a function of burnup due to rod bow effects.

22.6.2.8 Experimental Verification of Power Distribution Analysis

This subject is discussed in References 22.35 and 22.43. A summary of these reports and the extension to include the fixed in-core instrumentation system is given below. Power-distribution-related measurements are incorporated into the evaluation of calculated power distribution information using the in-core instrumentation processing algorithms contained within the online monitoring system.

The processing algorithms contained within the online monitoring system are functionally identical to those historically used for the evaluation of power distribution measurements in Westinghouse PWRs. Advances in technology allow a complete functional integration of reaction rate measurement algorithms and the expected reaction rate predictive capability within the same software package. The predictive software integrated within the online monitoring system supplies accurate, detailed information about current reactor conditions (Reference 22.43).

The measured versus calculation comparison is performed continuously by the online monitoring system throughout the core life. The online monitoring system operability requirements are specified in the Tech Specs.

In a measurement of the reactor power distribution and the associated thermal margin limiting parameters, with the in-core instrumentation system, the following uncertainties must be considered:

1. Reproducibility of the measured signal

2. Errors in the calculated relationship between detector current and local power generation within the fuel bundle

3. Errors in the detector current associated with the depletion of the emitter material, manufacturing tolerances, and measured detector depletion

4. Errors due to the inference of power generation some distance from the measurement thimble.

The appropriate allowance for Category A has been accounted for through the imposition of strict manufacturing tolerances for the individual detectors. This approach is accepted industry practice and has been used in PWRs with fixed in-core instrumentation worldwide.

Errors in Category B are quantified by calculation and evaluation of critical experiment data on arrays of rods with simulated guide thimbles, control rods, and BAs. These critical experiments provide the quantification of errors of categories A and D.

Errors in Category C have been quantified through direct experimental measurement of the depletion characteristics of the detectors being used, including the precision of the in-core instrumentation system's measurement of the current detector depletion. The description of the experimental measurement of detector depletion can be found in Reference 22.38.

Critical experiments have been performed at the Westinghouse Reactor Evaluation Centre and measurements have been taken on two Westinghouse plants with movable fission chamber in-core instrumentation systems (Reference 22.35). The measurement aspects of the movable fission chamber share the previous uncertainty categories less Category C, which is independent of the other sources of uncertainty. It is concluded that the uncertainty associated with PLHR ($F_Q \cdot P$) is less than 5 percent at the 95 percent confidence level with only 5 percent of the measurements greater than the inferred value.

In comparing measured power distributions (or detector currents) with calculations for the same operating conditions, it is not possible to isolate the detector reproducibility. Thus, a comparison between measured and predicted power distributions includes some measurement error. Such comparisons are given in Reference 22.35. Since the first publication of Reference 22.35, hundreds of measurements have been taken on reactors all over the world. These results confirm the adequacy of the 5 percent uncertainty allowance on the calculated PLHR ($ALHR \cdot F_Q \cdot P$).

A similar analysis for the uncertainty in hot rod integrated power ($F_{\Delta H} \cdot P$) measurements results in an allowance of 4 percent at the equivalent of a 95 percent confidence level.

A measurement in the fourth cycle of a 157-assembly, 3.66-m (12 foot) core is compared with a simplified 1-D core average axial calculation in Figure 22-22. This calculation does not give explicit representation of the fuel grids.

The accumulated data on power distributions in actual operation are basically of three types:

- Much of the data is obtained in steady-state operation at constant power in the normal operating configuration

- Data with unusual values of AO are obtained as part of the ex-core detector calibration exercise performed monthly

- Special tests performed in load follow and other transient xenon conditions that have yielded useful information on power distributions

These data are presented in detail in Reference 22.42.

22.6.2.9 Testing

A series of physics tests are planned to be performed on the first core. These tests and the criteria for satisfactory results are described in Chapter 7. Since not all limiting situations can be created at BOL, the main purpose of the tests is to provide a check on the calculation methods used in the predictions for the conditions of the test. Tests performed at the beginning of each reload cycle are limited to verification of the selected safety-related parameters of the reload design.

22.6.2.10 Monitoring Instrumentation

The adequacy of instrument numbers, spatial deployment, required correlations between readings and peaking factors, calibration, and errors are described in Reference 22.43. The core monitoring system, utilising signals from the fixed in-core detectors, allows for an online measurement of the 3-D power distribution and core reactivity condition and an accurate assessment of available margins to reactor thermal and shutdown reactivity limits (PLHR, DNBR, and SDM).

The online core monitoring system also incorporates features that allow for the analysis and prediction of core behaviour. The margin to actual reactor operational thermal and shutdown reactivity limits is monitored using the same 3-D nodal and thermal hydraulic methods of the Westinghouse codes licensed for core design and safety analysis.

The online 3D monitoring licensed for control room Tech Spec power distribution surveillance provides many benefits over traditional core monitoring, including the following:

- Direct continuous monitoring of DNB, PLHR, and nuclear hot channel or nuclear enthalpy rise hot channel factors

- Direct monitoring of margin results in a Tech Spec so that there is a continuous display of the minimum margin available in any of the monitored parameters (PLHR, nuclear hot channel power, and DNBR).

- In addition, online confirmation of SDM and some associated relaxation of rod insertion limits is also provided.

Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96.

Provided that the limitations on rod insertion and flux difference are observed, the in-core and ex-core detector systems provide adequate monitoring of power distributions when the online monitoring system is out of service. Further details about specific limits on the observed rod positions and flux difference, along with a discussion of their bases, are given in the Tech Specs. Limits for alarms and reactor trip are also given in the Tech Specs.

22.6.2.11 Reactivity Coefficients

The kinetic characteristics of the reactor core determine its response to changing plant conditions or to operator adjustments made during normal operation, as well as its response during abnormal or accidental transients. These kinetic characteristics are quantified in reactivity coefficients.

The reactivity coefficients reflect the changes in the neutron multiplication due to varying plant conditions, such as thermal power, moderator and fuel temperatures, coolant pressure, or void conditions. Since reactivity coefficients change during the life of the core, ranges of coefficients are employed in transient analysis to determine the response of the plant throughout life. The results of such simulations and the reactivity coefficients used are presented in Chapter 9. The reactivity coefficients used in transient simulations are summarized in the Safety Analysis Checklist (SAC) (Reference 22.99). The reactivity coefficient limits are divided between those used for the standard safety case and those used for the diverse ATWT case. The latter set of limits are calculated based on better estimate assumptions consistent with analysis of the ATWT case.

The reactivity coefficients are calculated with approved nuclear methods. The analytical methods and calculation models are provided in Section 22.6.3. The effect of the radial and axial power distribution on core average reactivity coefficients is not significant under normal operating conditions. For example, a skewed axial xenon distribution that results in changing AO by 5 percent typically changes the moderator and Doppler temperature coefficients by less than 0.018 pcm/°C (0.01 pcm/°F). An artificially skewed radial xenon distribution that results in changing the radial $F^N_{\Delta H}$ by 3 percent typically changes the moderator and Doppler temperature coefficients by less than 0.054 pcm/°C (0.03 pcm/°F) and 0.0018 pcm/°C (0.001 pcm/°F), respectively. The spatial effects are accentuated in some transient conditions, for example, in postulated rupture of the main steam line and rupture of an RCCA mechanism housing.

The analytical methods and calculation models used in calculating the reactivity coefficients are given in Section 22.6.3. These models have been confirmed through extensive qualification efforts performed for core and lattice designs.

Quantitative information is given below for calculated reactivity coefficients including fuel-Doppler coefficient, moderator coefficients (density, temperature, pressure, and void), and power coefficient.

a) Fuel Temperature (Doppler) Coefficient

The fuel temperature (Doppler) coefficient is defined as the change in reactivity per degree change in effective fuel temperature and is primarily a measure of the Doppler broadening of U-238 and Pu-240 resonance absorption peaks. Doppler broadening of other isotopes is also considered but their contribution to the Doppler effect is small. An increase in fuel temperature increases the effective resonance absorption cross-sections of the fuel and produces a corresponding reduction in reactivity.

The fuel temperature coefficient is calculated using approved nuclear methods. The moderator temperature is held constant and the power level is varied. Spatial variation of fuel temperature is taken into account by calculating the effective fuel temperature as a function of power density.

A typical Doppler temperature coefficient is shown in Figure 22-32 as a function of the effective fuel temperature (at BOL and EOL conditions). The effective fuel temperature is lower than the volume-averaged fuel temperature since the neutron flux distribution is non-uniform through the pellet and gives preferential weight to the surface temperature.

A typical Doppler-only contribution to the power coefficient, defined later, is shown in Figure 22-33 as a function of relative core power. The integral of the differential curve in Figure 22-33 is the Doppler contribution to the power defect and is shown in

Figure 22-34 as a function of relative power. The Doppler temperature coefficient becomes more negative as a function of life as the Pu-240 content increases, thus increasing the Pu-240 resonance absorption. The upper and lower limits of Doppler coefficient used in accident analyses are given in Chapter 9.

b) Moderator Coefficients

The moderator coefficient is a measure of the change in reactivity due to a change in specific coolant parameters, such as density/temperature, pressure, or void.

The moderator temperature (density) coefficient is defined as the change in reactivity per degree change in the moderator temperature. Generally, the effects of the changes in moderator density and the temperature are considered together.

The soluble boron used in the reactor as a means of reactivity control also has a secondary effect on the moderator density coefficient, since the soluble boron density and the water density are decreased when the coolant temperature rises. A decrease in the soluble boron density introduces a positive component in the moderator coefficient. If the concentration of soluble boron is large enough, the net value of the coefficient may be positive.

The initial core hot boron concentration is sufficiently low that the moderator temperature coefficient is negative at operating temperatures with the BA loading specified. Discrete or IFBA rods can be used in reload cores to confirm that the moderator temperature coefficient is negative over the range of power operation. The effect of control rods is to make the moderator coefficient more negative, since the thermal neutron mean free path, and hence the volume affected by the control rods, increases with an increase in temperature.

With burnup, the moderator coefficient becomes more negative, primarily as a result of boric acid dilution but also to a significant extent from the effects of the buildup of plutonium and fission products. In the first few months of a cycle, however, the moderator coefficient can become less negative as the BA is depleted and core reactivity and soluble boron concentration increases. The moderator temperature coefficient is maintained at a negative value during power operation.

The moderator coefficient is calculated for a range of plant conditions by performing two group two- or 3-D calculations, in which the moderator temperature is varied by about ±2.8°C (5°F) around each of the mean temperatures, resulting in density changes consistent with the temperature change.

The moderator temperature coefficient is shown as a function of core temperature and boron concentration for the core in Figure 22-35 to Figure 22-37. The temperature range covered is from cold (about 21.1°C(68°F)) to about 287.8°C (550°F). The contribution due to Doppler coefficient (because of change in moderator temperature) has been subtracted from these results.

Figure 22-38 shows the unrodded, hot, full-power MTC plotted as a function of burnup for the initial cycle. The temperature coefficient corresponds to the unrodded critical boron concentration present at hot full-power operating conditions.

The moderator coefficients presented here are calculated to describe the core behaviour in normal and accident situations when the moderator temperature changes can be considered to affect the entire core.

The moderator pressure coefficient relates the change in moderator density resulting from a reactor coolant pressure change to the corresponding effect on neutron production. This coefficient is much less significant than the MTC because pressure changes have a much smaller effect on the moderator density over the normal range of operation in a PWR. This is due to the relative incompressibility of liquid water under high pressure. A change of 0.345 MPa (50 psi) in pressure has approximately the same effect on reactivity as a 0.28ºC (0.5°F) change in moderator temperature. This coefficient can be determined from the MTC by relating change in pressure to the corresponding change in density. The typical moderator pressure coefficient may be negative over a portion of the moderator temperature range at BOL (-0.58 pcm/MPa) (-0.004 pcm/psi) but is always positive at operating conditions and becomes more positive during life (+43.5 pcm/MPa (+0.3 pcm/psi) at EOL).

The moderator void coefficient relates the change in neutron multiplication to the presence of voids in the moderator. In a PWR, this coefficient is not very significant because of the low void content in the coolant. The core void content is less than one-half of one percent and is due to local or statistical boiling. The typical void coefficient varies from 50 pcm/percent void at BOL and at low temperatures to -250 pcm/percent void at EOL and at operating temperatures. The void coefficient is always negative during power operation and becomes more negative with fuel burnup.

c) Power Coefficient

The combined effect of moderator temperature and fuel temperature change as the core power level changes is called the total power coefficient and is expressed in terms of reactivity change per percent power change. Since a 3-D calculation is performed in determining total power coefficients and total power defects, the axial redistribution reactivity component is implicitly included. A typical power coefficient at BOL and EOL conditions is given in Figure 22-39. The total power coefficient becomes more negative with burnup, reflecting the combined effect of moderator and fuel temperature coefficients with burnup. The power defect (integral reactivity effect) at BOL and EOL is given in Figure 22-40.

d) Reactivity Coefficients Used in Transient Analysis

Table 22-3 gives the limiting values as well as typical best-estimate values for the reactivity coefficients for the initial cycle. The limiting values are used as design limits in the standard safety case transient analysis. The exact values of the coefficient used in the analysis depend on whether the transient of interest is examined at the BOL or EOL, whether the most negative or the most positive (least negative) coefficients are appropriate, and whether spatial non-uniformity must be considered in the analysis. Conservative values of coefficients, considering various aspects of analysis, are used in the transient analysis. This is described in Chapter 9.

The reactivity coefficients used in transient simulations are summarized in the Safety Analysis Checklist (SAC) (Reference 22.99). The reactivity coefficient limits are divided between those used for the standard safety case and those used for the diverse ATWT case. The latter set of limits are calculated based on better estimate assumptions consistent with analysis of the ATWT case.

The reactivity coefficients shown in Figure 22-32 to Figure 22-40 are typical best-estimate values calculated for the initial cycle. Limiting values are chosen to encompass the best-estimate reactivity coefficients, including the uncertainties over appropriate operating conditions. The most positive, as well as the most negative, values are selected to form the DB range used in the transient analysis.

In many instances, the most conservative combination of reactivity coefficients is used in the transient analysis even though the extreme coefficients assumed may not simultaneously occur at the conditions assumed in the analysis. The need for a re-evaluation of any accident in a subsequent cycle is contingent upon whether the coefficients for that cycle fall within the identified range used in the analysis presented in Chapter 9 with due allowance for the calculation uncertainties.

Section 22.6.3 describes the comparison of calculated and experimental reactivity coefficients in detail. Experimental evaluation of the reactivity coefficients will be performed during the physics startup tests described in Chapter 7.

22.6.2.12 Shutdown Requirements and Reactivity Control

22.6.2.12.1 Shutdown Requirements

To establish the required shutdown margin stated in the COLR under conditions where a cooldown to ambient temperature is required, concentrated soluble boron is added to the coolant. Boron concentrations for several core conditions are listed in Table 22-3 for the initial cycle. For core conditions including refuelling, the boron concentration is well below the solubility limit. The rod cluster control assemblies are employed to bring the reactor to the shutdown condition. The minimum required shutdown margin is given in the COLR.

The ability to meet the shutdown margin requirements for hot conditions is demonstrated for the initial cycle and for an equilibrium reload cycle by performing a bounding calculation, the results of which are shown in Table 22-4. Table 22-4 compares the difference between the rod cluster control assembly reactivity available with an allowance for the worst stuck rod with that required for control and protection purposes. The shutdown margin includes an allowance of seven percent for analytic uncertainties which assumes the use of silver-indium-cadmium rod cluster control assemblies. Use of a seven percent uncertainty allowance on rod cluster control assembly worth is discussed and shown to be acceptable in Reference 22.45. The largest reactivity control requirement appears at the EOL when the moderator temperature coefficient reaches its peak negative value as reflected in the larger power defect.

Any available negative reactivity insertion from withdrawn tungsten GRCAs is conservatively excluded when determining the available shutdown margin at hot operating conditions, even though all GRCAs are released into the core on a reactor trip (Reference 22.36). Only silver-indium-cadmium control rods are assumed to insert when the reactor is tripped for purposes of demonstrating that adequate shutdown margin is available at hot operating conditions. As such, the use of a seven percent uncertainty allowance for the credited trip rod worth remains appropriate in Table 22-4. After the reactor is brought to a shutdown condition, the presence of GRCAs which are confirmed to be inserted and which have met the applicable physics testing acceptance criteria may be credited in confirming that the required shutdown margin is maintained during any cooldown period and as the result of long term xenon decay (Reference 22.36).

During plant operation, the available shutdown margin for hot operating conditions is continuously confirmed by the online monitoring system, by comparing the operating soluble boron concentration at current core conditions to the shutdown boron concentration that would be required immediately following a reactor trip from those conditions. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96. The required shutdown boron concentration used in this type of calculation is conservatively determined at the target shutdown reactivity condition, assuming that all control rods insert except for the 16 tungsten GRCAs and the highest worth silver-indium-cadmium RCCA.

The control rods are required to provide sufficient reactivity to account for the power defect from full power to zero power and to provide the required shutdown margin. The reactivity addition resulting from power reduction consists of contributions from Doppler effect, moderator temperature, flux redistribution, and reduction in void content as discussed below.

Doppler Effect

The Doppler effect arises from the broadening of U-238 and Pu-240 resonance cross-sections with an increase in effective pellet temperature. This effect is most noticeable over the range of zero power to full power due to the large pellet temperature increase with power generation. The Doppler effect is implicitly included in the total power defects shown in Table 22-4.

Variable Average Moderator Temperature

When the core is shut down to the hot zero-power condition, the average moderator temperature changes from the equilibrium full-load value determined by the steam generator and turbine characteristics (such as steam pressure, heat transfer, tube fouling) to the equilibrium no-load value, which is based on the steam generator shell side design pressure. The design change in temperature is conservatively increased to account for the control system dead band and measurement errors.

When the moderator coefficient is negative, there is a reactivity addition with power reduction. The moderator coefficient becomes more negative as the fuel depletes because the boron concentration is reduced. This effect is the major contributor to the increased requirement at EOL. The change in average moderator temperature is implicitly included in the total power defects shown in Table 22-4.

Redistribution

During full-power operation, the coolant density decreases with core height. This, together with partial insertion of control rods, results in less fuel depletion near the top of the core. Under steady-state conditions, the relative power distribution will be slightly asymmetric toward the bottom of the core. On the other hand, at hot zero-power conditions, the coolant density is uniform up the core, and there is no flattening due to Doppler effect. The result will be a flux distribution which at zero power can be skewed toward the top of the core. Since a three-dimensional calculation is performed in determining total power defect, flux redistribution is implicitly included in this calculation. The three-dimensional total power defects specified in Table 22-4 were calculated including the use of a conservatively skewed adverse axial xenon distribution which increases the redistribution effect.

Void Content

A small void content in the core is due to nucleate boiling at full power. The void collapse coincident with power reduction makes a small positive reactivity contribution which has been added to the calculated total power defects shown in Table 22-4.

Rod Insertion Allowance

The MSHIM and AO banks are operated within a prescribed band of travel to compensate for changes in temperature and axial offset which are caused by fuel depletion and power manoeuvres. In calculating the available shutdown margin at hot operating conditions, the pre-trip control rod insertion can affect both the available trip rod worth and the total power defect control requirements. In addition, since the tungsten GRCAs are assumed not to insert on a reactor trip (Reference 22.36), the initial gray rod positions assumed prior to the trip can also have a small effect on the worth of the silver-indium-cadmium control rods that insert after the trip. In the bounding calculations shown in Table 22-4, the effect of the most limiting allowed control rod insertion is implicitly included in the calculated trip rod worth and total power defect values reported in the table. The most limiting allowed control rod insertion was determined by performing a series of three-dimensional shutdown margin calculations over the range of allowed control rod motion, and selecting the conditions which resulted in the minimum calculated shutdown margin.

Installed Excess Reactivity for Depletion

Excess reactivity is installed at the beginning of each cycle to provide sufficient reactivity to compensate for fuel depletion and fission product buildup throughout the cycle. This reactivity is controlled by the addition of soluble boron to the coolant, control rod insertion, and by burnable absorbers when necessary. The soluble boron concentration for several core configurations and the unit boron worth are given in Table 22-3 for the initial cycle. Since the excess reactivity for burnup is balanced during operation by negative reactivity from the above sources, it is not included in control rod requirements.

Xenon and Samarium Poisoning

Changes in xenon and samarium concentrations in the core occur at a sufficiently slow rate, even following rapid power level changes, so that the resulting reactivity change can be controlled by changing the gray and/or control rod insertion.

pH Effects

Changes in reactivity due to a change in coolant pH, if any, are sufficiently small in magnitude and occur slowly enough to be controlled by the boron system (Reference 22.44).

22.6.2.12.2 Reactivity Control

Core reactivity is controlled by means of a chemical poison dissolved in the coolant, rod cluster control assemblies, gray rod cluster assemblies and burnable absorbers as described below.

Chemical Shim

Boron in solution as boric acid is used to control relatively slow reactivity changes associated with:

- The moderator temperature defect in going from cold shutdown at ambient temperature to the hot operating temperature at zero power
- Transient xenon and samarium reactivity effects, following power changes
- The reactivity effects of fissile inventory depletion and buildup of long-life fission products
- The depletion of the burnable absorbers

The boron concentrations for various core conditions are presented in Table 22-3 for the initial cycle.

Rod Cluster Control Assemblies

The number of rod cluster control assemblies is given in Table 22-2. The rod cluster control assemblies are used for shutdown and control purposes to offset fast reactivity changes associated with:

- The required shutdown margin in the hot zero power, stuck rod condition
- The reactivity compensation as a result of an increase in power above hot zero power (power defect, including Doppler and moderator reactivity changes)
- Unprogrammed fluctuations in boron concentration, coolant temperature, or xenon concentration (with rods not exceeding the allowable rod insertion limits)
- Reactivity changes resulting from load changes

The allowed control bank reactivity insertion is limited at full power to maintain shutdown capability. As the power level is reduced, control rod reactivity requirements are also reduced, and more rod insertion is allowed. The control bank position is monitored, and the operator is notified by an alarm if the limit is approached. The determination of the insertion limit uses conservative xenon distributions and axial power shapes. In addition, the rod cluster control assembly withdrawal pattern determined from the analyses is used in determining power distribution factors and in determining the maximum worth of an inserted rod cluster control assembly ejection accident. For further discussion, refer to the technical specifications on rod insertion limits.

Power distribution, rod ejection, and rod misalignment analyses are based on the arrangement of the shutdown and control groups of the rod cluster control assemblies shown in Figure 22-41. Shutdown rod cluster control assemblies are withdrawn before withdrawal of the control and AO banks is initiated. The approach to critical is initiated by using the chemical and volume control system to establish an appropriate boron concentration based upon the estimated critical condition then withdrawing the AO bank above the zero power insertion limit and finally withdrawing the control banks sequentially. The limits of rod insertion and further discussion on the basis for rod insertion limits are provided in the COLR.

Gray Rod Cluster Assemblies

The rod cluster control assembly control banks include four gray rod banks consisting of gray rod cluster assemblies (GRCAs). Gray rod cluster assemblies consist of 24 rodlets fastened at the top end to a common hub or spider. Geometrically, it is the same as an RCCA except that the GRCA design uses tungsten encapsulated in an Alloy 718 sleeve as an absorber. The term gray rod refers to the reduced reactivity worth relative to that of an RCCA consisting of 24 silver-indium-cadmium rodlets. The GRCAs are used in base load operation and load follow maneuvering and provide a mechanical shim reactivity mechanism which reduces the need for changes to the concentration of soluble boron (that is, chemical shim).

Burnable Absorbers

Discrete burnable absorber rods and integral fuel burnable absorber rods will be used to provide partial control of the excess reactivity available during the first operating cycle. In doing so, the burnable absorber loading controls peaking factors and prevents the moderator temperature coefficient from being positive at normal operating conditions. The burnable absorbers perform this function by reducing the requirement for soluble boron in the moderator at the beginning of the fuel cycle. For purposes of illustration, the initial cycle burnable absorber pattern is shown in Figure 22-21. Figures 22-19 and 22-20 show the burnable absorber distribution within a fuel assembly for several burnable absorber patterns used in the 17 x 17 array. The boron in the rods is depleted with burnup but at a slow rate so that the peaking factor limits are not exceeded and the resulting critical concentration of soluble boron is such that the moderator temperature coefficient remains within the limits stated above for power operating conditions.

Peak Xenon Startup

Compensation for the peak xenon buildup may be accomplished using the boron control system. Startup from the peak xenon condition is accomplished with a combination of rod motion and boron dilution. The boron dilution can be made at any time, including during the shutdown period, provided the shutdown margin is maintained.

Load Follow Control and Xenon Control

During load follow manoeuvres, power changes are primarily accomplished using control rod motion alone, as required. Control rod motion is limited by the control rod insertion limits as provided in the COLR. The power distribution is maintained within acceptable limits through limitations on control rod insertion. Reactivity changes due to the changing xenon concentration are also controlled by rod motion. The soluble boron concentration may also be changed during large load change manoeuvres or during extended reduced power operation to maintain the control rods in a more optimum range for power distribution control.

Rapid power increases (five percent/min) from part power during load follow operation are accomplished with rod motion.

The rod control system is designed to automatically provide the power and temperature control described above 30 percent rated power for most of the cycle length without the need to change boron concentration as a result of the load manoeuvre. The automated mode of operation is referred to as MSHIM because of the usage of mechanical means to control reactivity and power distribution simultaneously. MSHIM operation allows load manoeuvring without boron change because of the degree of allowed insertion of the control banks in conjunction with the independent power distribution control of the AO control bank. The worth and overlap of the MA, MB, MC, MD, M1, and M2 control banks are designed

such that their movement will not result in drastic fluctuations in AO. The AO control bank insertion limit versus power level is designed such that AO bank insertion will always result in a monotonically decreasing axial offset; the AO bank cannot be inserted to the point of concentrating the neutron flux to the bottom of the core such that further AO bank insertion results in the flux suddenly shifting towards the top of the core. MSHIM operation uses the MA, MB, MC, MD, M1, and M2 control banks to maintain the programmed coolant average temperature throughout the operating power range. The AO control bank is independently modulated by the rod control system to maintain a nearly constant axial offset throughout the operating power range.

While the primary means for controlling the coolant average temperature is the M banks, the movement of the AO bank also results in some adjustment of coolant temperature. In the event that both the M and AO banks are demanded to move in the same direction the M banks will be paused to allow the AO bank to adjust AO and coolant temperature. Should the M and AO banks be demanded to move in opposite directions, the movement of the M banks are moved to their demand position at an accelerated rate to restore the coolant average temperature quickly and then the AO bank is moved. This provides efficient management of both coolant average temperature and AO. The target axial offset used during MSHIM operation is established at a more negative value than the axial offset associated with the all rods out condition. The negative bias is necessary to maintain both positive and negative axial offset control effectiveness by the AO-bank. Operation with gray control rod banks (MA, MB, MC, and MD) inserted has less of an effect on the core axial power distribution than insertion of the black control rods banks (M1 and M2) and results in a smaller negative bias in the target axial offset. Load change operations that are large enough to require a black control rod bank to enter the core may require a more negative target axial offset to accomplish. However, the boron system can optionally be used to maintain operation in the more optimum range of gray rod motion during such manoeuvres. The degree of control rod insertion under MSHIM operation allows rapid return to power without the need to change boron concentration.

Extended base load operation is performed by controlling axial offset to the target value using the AO control bank, and by controlling the coolant average temperature to the programmed value with the M-banks. Boron concentration changes are made periodically as the fuel depletes to reposition the M-banks and allow for a periodic exchange of the gray rod bank insertion sequence. MSHIM load follow and base load operations (including the gray rod bank insertion sequence exchanges) are considered normal operations.

Burnup

Control of the excess reactivity for burnup is accomplished using soluble boron, control rod insertion, and/or burnable absorbers. The boron concentration is limited during operating conditions to maintain the moderator temperature coefficient within its specified limits. A sufficient burnable absorber loading is installed at the beginning of a cycle to give the desired cycle lifetime, without exceeding the boron concentration limit. The end of a fuel cycle is reached when the soluble boron concentration approaches the practical minimum boron concentration in the range of 0 to 10 ppm.

Rapid Power Reduction System

The reactor power control system is designed with the capability of responding to full load rejection without initiating a reactor trip using the normal rod control system, reactor control system, and the rapid power reduction system. Load rejections requiring greater than a fifty percent reduction of rated thermal power initiate the rapid power reduction system. The rapid power reduction system utilizes preselected control rod groups and/or banks which are

intentionally tripped to rapidly reduce reactor power into a range where the rod control and reactor control systems are sufficient to maintain stable plant operation. The consequence of accidental or inappropriate actuation of the rapid power reduction system is included in the cycle specific safety analysis and licensing process.

22.6.2.13 Control Rod Patterns and Reactivity Worth

The RCCAs are designated by function as the control groups and the shutdown groups. The terms group and bank are used synonymously to describe a particular grouping of control assemblies. The control banks are labelled MA, MB, MC, MD, M1, M2, and AO (Figure 22-41) with the MA, MB, MC, and MD banks comprising GRCAs; the shutdown banks are labelled SD1, SD2, SD3, and SD4. Each bank of more than four RCCAs, although operated and controlled as a unit, is composed of two or more subgroups. The axial position of the RCCAs may be controlled manually or automatically. All control rods are dropped into the core following actuation of reactor trip signals.

Two criteria have been employed for selection of the control groups. First, the total reactivity worth must be adequate to meet the requirements specified in Table 22-4. Second, in view of the fact that these rods may be partially inserted at power operation, the total power peaking factor should be low enough to meet the power capability requirements.

Analyses indicate that the first requirement can be met either by a single group or by two or more banks whose total worth equals at least the required amount. The axial power shape is more peaked following movement of a single group of rods worth 3 to 4 percent $\Delta\rho$; therefore, control bank RCCAs have been separated into several bank groupings. Typical control bank worths for the initial cycle are shown in Table 22-3.

The position of control banks for criticality under any reactor condition is determined by the concentration of boron in the coolant. On an approach to criticality, boron is adjusted so that criticality will be achieved with control rods above the insertion limit set by shutdown and other considerations. Early in the cycle, there may also be a withdrawal limit at low power or a limitation on the maximum-allowed RCS boron concentration to maintain the MTC within the specified limits for that power level. The current nuclear design philosophy is to provide a sufficient number of BAs to achieve a negative MTC at the conditions of the initial criticality for a cycle. The MTC becomes more negative as the power level is increased and xenon builds in, so operation during the initial startup and power escalation occurs with an increasingly negative MTC. During the first few months of the cycle, the BA absorber depletes significantly and the reactivity of the core may slowly increase before it starts to decrease due to fuel burnup. This is observable in the soluble boron concentration curve as shown for example in Figure 22-18. As long as the core is operating at or near RTP, the moderator temperature coefficient remains negative. If, however, reduced power operation should occur or if a startup is required during these first few months of increased core reactivity, it may be necessary to establish limits on the maximum boron concentration or control rod withdrawal limits for the low power conditions. This would only be the case if the core reactivity increase due to BA depletion is large enough to cause a non-negative MTC at the low power condition. This would also be the case if the MTC were mistakenly predicted at the beginning of the cycle so that a positive MTC was measured during startup physics testing. The establishment of such limits would not impact actual operation because the normal boron concentration and position of control rods during MSHIM operation would not challenge the limits required to ensure compliance with the MTC limit. A restriction on the maximum boron concentration or a rod withdrawal limit would maintain compliance with the MTC technical specification and is comparable to the establishment of rod insertion limits

and minimum boron concentration requirements to maintain compliance with other core-related Tech Specs.

Allowable deviations due to misaligned control rods are discussed in the Tech Specs.

A representative differential rod worth calculation for two banks of control rods withdrawn simultaneously (rod withdrawal accident) is given in Figure 22-42.

Calculation of control rod reactivity worth versus time following reactor trip involves both control rod velocity and differential reactivity worth. For nuclear design purposes, the reactivity worth versus rod position is calculated by a series of steady-state calculations at various control positions, assuming the rods out of the core as the initial position to minimise the initial reactivity insertion rate. Also, to be conservative, the rod of highest worth is assumed to be stuck out of the core, and the flux distribution (and thus reactivity importance) is assumed to be skewed to the bottom of the core.

The shutdown groups provide additional negative reactivity to establish adequate SDM. SDM is the amount by which the core would be subcritical at hot shutdown if the RCCAs were tripped, but assuming that the highest-worth assembly remained fully withdrawn and no changes in xenon or boron took place. The loss of control rod worth due to the depletion of the absorber material is negligible.

The results in Table 22-4 show that the available reactivity in withdrawn RCCAs provides the design bases' minimum SDM, allowing for the highest-worth cluster to be at its fully withdrawn position. An allowance for the uncertainty in the calculated worth of N-1 rods is made before determining the SDM.

22.6.2.14 Core Loading Procedure

During the initial core loading, only fresh fuel is used to construct the core as detailed in a fuel loading sequence procedure. As the core is being loaded, three nuclear monitoring channels of temporary core loading instrumentation are used in addition to the two plant-installed source range instrumentation system detectors. The temporary core loading instrumentation detectors are positioned in the reactor vessel at predetermined locations and are monitored by instrumentation located in the reactor building on the operating deck.

Data from all the nuclear monitoring channels are used to calculate the inverse count rate ratio, which in turn is used to assess the safety of the core loading operations. During the core loading operations, the response of at least one responding detector shall be displayed continuously on a strip chart recorder at all times when fuel is being added to the reactor vessel.

22.6.2.15 Core Reload Safety

Since the late 1960s and early 1970s, Westinghouse has used a safety analysis checklist for first cores and a reload safety analysis checklist for reload cores to document and track the core parameters utilised in the transient analysis.

The safety analysis checklist has one column of parameters that may include the maximum and minimum values, depending on the sensitivity of the transient to the parameter. Reference 22.100 provides information about how the values of these parameters are determined.

The reload safety analysis checklist is the same as the safety analysis checklist, except that transient statepoint information from the safety analysis of record are also included. The first column is the value of the parameter that has been used in the safety analysis of record; the second column is the value of the parameter as determined for the reload core. The safety analysis then determines if the reload parameter is bounded by the parameter for the safety analysis of record.

The reload safety analysis checklist is recalculated for each cycle. With the exception of rod ejection, for the hundreds of reload cores evaluated, it has rarely been necessary to perform the transients again, unless a new fuel design is incorporated.

22.6.2.16 Criticality of Fuel Assemblies during Refuelling

The basis for maintaining the reactor subcritical during refuelling is presented in Section 22.6.1.5; a discussion of how control requirements are met is in Sections 22.6.2.12 and 22.6.2.13.

Criticality of fuel assemblies outside the reactor is precluded by adequate design of fuel transfer, shipping, and storage facilities and by administrative control procedures. The two principal methods of preventing criticality are limiting the fuel assembly array size and limiting assembly interaction by fixing the minimum separation between assemblies and/or inserting neutron poisons between assemblies.

The design criteria and requirements are as follows:

- The maximum K-effective value, including all biases and uncertainties, must be less than 0.95 with for normal operation and less than 0.98 for credible abnormal operation. If no credit for soluble boron is taken, the K-effective of the spent fuel storage racks loaded with fuel of the maximum fuel assembly reactivity must not exceed 0.95, at a 95/95 confidence level during normal operation.

- The maximum enrichment of fresh fuel assemblies must be less than or equal to 5 weight-percent U-235. The maximum nominal U-235 enrichment of the fresh fuel assemblies is limited to 5 weight-percent.

The following conditions are assumed in meeting these design bases:

- The fuel assembly contains the highest enrichment authorised without any control rods or nonintegral BA rods and is at its most reactive point in life.

- For flooded conditions, the moderator is pure water at the temperature within the design limits that yields the largest reactivity.

- The array is either infinite in lateral extent or is surrounded by a conservatively chosen reflector, whichever is appropriate for the design.

- Mechanical uncertainties are treated by combining both the worst-case bounding value and sensitivity study approaches.

- Credit is taken for the neutron absorption in structural materials and in solid materials added specifically for neutron absorption (Reference 22.46).

22.6.2.17 Stability

The stability of PWR cores against xenon-induced spatial oscillations and the control of such transients has been discussed extensively (References 22.21, 22.39, 22.47, and 22.48). A summary of these reports is given below, and the design bases are given in Section 22.6.1.6.

In a large reactor core, xenon-induced oscillations can take place with no corresponding change in the total power of the core. The oscillation may be caused by a power shift in the core that occurs rapidly by comparison with the xenon-iodine time constants. Such a power shift occurs in the axial direction when a plant load change is made by control rod motion and results in a change in the moderator density and fuel temperature distributions. Such a power shift could occur in the diametral plane of the core as a result of abnormal control action.

Due to the negative power coefficient of reactivity, PWR cores are inherently stable to oscillations in total power. Protection against total power instabilities is provided by the control and protection system.

The core in the AP1000 reactor has an active fuel length that is 0.6096 m (2 foot) longer (nominal) than that for previous Westinghouse PWRs licensed in the US with 157 fuel assemblies. For this reason, it is expected that this core will be as stable as the 3.658-m (12 foot) designs with respect to radial and diametral xenon oscillations since the radial core dimensions have not changed.

This core will be slightly less stable than the 3.658-m (12 foot), 157-assembly cores with respect to axial xenon oscillations because the active core height has been increased by 0.6096 m (2 foot). The effect of this increase will be to decrease the burnup at which the axial stability index becomes zero.

The MTCs and the Doppler temperature coefficients of reactivity will be similar to those of previous designs. Control banks included in the core design are sufficient to dampen any xenon oscillations that may occur.

22.6.2.18 Vessel Irradiation

A review of the methods and analyses used in the determination of neutron and gamma ray flux attenuation between the core and the pressure vessel is provided below. A more complete discussion on the pressure vessel irradiation and surveillance program is given in Chapter 20.

The materials that serve to attenuate neutrons originating in the core and gamma rays from both the core and structural components consist of the core shroud, core barrel, and associated water annuli. These are within the region between the core and the pressure vessel.

In general, few group neutron diffusion theory codes are used to determine fission power density distributions within the active core, and the accuracy of these analyses is verified by in-core measurements on operating reactors. Region and rodwise power-sharing information from the core calculations is then used as source information in two-dimensional transport calculations which compute the flux distributions throughout the reactor.

The neutron flux distribution and spectrum in the various structural components vary significantly from the core to the pressure vessel. Representative values of the neutron flux distribution and spectrum are presented in Table 22-7.

As discussed in Chapter 20, the irradiation surveillance program utilises actual test samples to verify the accuracy of the calculated fluxes at the vessel.

22.6.3 Analytical Codes and Methods

Calculations required in nuclear design consist of the following three distinct types, which are performed in sequence:

- Determination of effective fuel temperatures
- Generation of microscopic few-group parameters
- Space-dependent, few-group diffusion calculations

These calculations are carried out by computer codes that can be executed individually. Most of the codes required have been linked to form an automated design sequence that minimises design time, avoids errors in transcription of data, and standardises the design methods.

22.6.3.1 Fuel Temperature (Doppler) Calculations

Temperatures vary radially within the fuel rod, depending on the heat generation rate in the pellet; the conductivity of the materials in the pellet, gap, and clad; and the temperature of the coolant.

The fuel temperatures for use in most nuclear design Doppler calculations are obtained from a simplified version of the Westinghouse fuel rod design model, which considers the effect of radial variation of pellet conductivity; expansion coefficient and heat generation rate; elastic deflection of the clad; and a gap conductance that depends on the initial fill gas, the hot open-gap dimension, and the fraction of the pellet over which the gap is closed. The fraction of the gap assumed closed represents an empirical adjustment used to produce close agreement with observed reactivity data at beginning of life. Further gap closure occurs with burnup and accounts for the decrease in Doppler defect with burnup which has been observed in operating plants. For detailed calculations of the Doppler coefficient, such as for use in xenon stability calculations, a more sophisticated temperature model is used that accounts for the effects of fuel swelling, fission gas release, and plastic clad deformation.

Radial power distributions in the pellet as a function of burnup are obtained from LASER calculations (Reference 22.49).

The effective U-238 temperature for resonance absorption is obtained from the radial temperature distribution by applying a radially dependent weighing function. The weighing function was determined from REPAD Monte Carlo calculations of resonance escape probabilities in several steady-state and transient temperature distributions (Reference 22.50). In each case, a flat pellet temperature that produced the same resonance escape probability as the actual distribution was determined. The weighing function was empirically determined from these results.

The effective Pu-240 temperature for resonance absorption is determined by a convolution of the radial distribution of Pu-240 densities from LASER burnup calculations and the radial weighing function. The resulting temperature is burnup-dependent but the difference between U-238 and Pu-240 temperatures, in terms of reactivity effects, is small.

The effective pellet temperature for pellet dimensional change is that value that produces the same outer pellet radius in a virgin pellet as the one obtained from the temperature model. The effective clad temperature for dimensional change is its average value.

The temperature calculation model has been validated by plant Doppler defect data and Doppler coefficient data, as shown in Figure 22-43. Stability index measurements also provide a sensitive measure of the Doppler coefficient near full power (Section 22.6.2.17).

22.6.3.2 Macroscopic Group Constants

PHOENIX-P (Reference 22.51) and PARAGON (Reference 22.58) have been used for generating the macroscopic cross-sections needed for the spatial few group codes (Reference 22.51). Both codes can be used for reload designs for the AP1000 plant.

PHOENIX-P is a 2-D, multigroup, transport-based lattice code capable of providing necessary data for PWR analysis. Since it is a dimensional lattice code, PHOENIX-P does not rely on predetermined spatial/spectral interaction assumptions for the heterogeneous fuel lattice and can therefore provide an accurate multigroup spatial flux solution.

The solution for the detailed spatial flux and energy distribution is divided into two major steps in PHOENIX-P. First, a 2-D fine energy group nodal solution is obtained, coupling individual subcell regions (e.g., pellet, clad, and moderator) as well as surrounding pins, using a method based on Carlvik's collision probability approach and heterogeneous response fluxes that preserve the heterogeneous nature of the pin cells and their surroundings. The nodal solution provides an accurate and detailed local flux distribution, which is then used to homogenise the pin cells spatially to few groups.

Next, a standard S4 discrete ordinates calculation solves for the angular distribution based on the group-collapsed and homogenised cross-sections from the first step. These S4 fluxes normalise the detailed spatial and energy nodal fluxes, which are then used to compute reaction rates and power distributions and to deplete the fuel and BA rods. A standard B1 calculation evaluates the fundamental mode critical spectrum, providing an improved fast diffusion coefficient for the core spatial codes.

PHOENIX-P employs a 70-energy group library derived mainly from the ENDF/B-VI files. This library was designed to capture the integral properties of the multigroup data properly during group collapse and to model important resonance parameters properly. It contains neutronics data necessary for modelling fuel, fission products, cladding and structural materials, coolant, and control and BA rod materials present in PWRs.

Group constants for BA cells, control rod cells, guide thimbles and instrumentation thimbles, or other nonfuel cells, can be obtained directly from PHOENIX-P without any adjustments such as those required in the cell or 1D lattice codes.

PHOENIX-P has been validated through an extensive qualification effort that includes calculation-measurement comparison of the Strawbridge-Barry critical experiments (Reference 22.52), the KRITZ high-temperature criticals (Reference 22.53), the Babcock and Wilcox criticals (References 22.54, 22.76, and 22.77) sponsored by the Atomic Energy Commission (AEC), and measured actinide isotopic data from fuel pins irradiated in the Saxton and Yankee Rowe cores (References 22.55 and 22.78 through 22.81). In addition, calculation-measurement comparisons have been made to operating reactor data measured during startup tests and normal power operation.

Confirmatory critical experiments on burnable absorber rods are described in WCAP-7806 (Reference 22.82).

Group constants for tungsten GRCAs are generated using the PARAGON lattice code. Like PHOENIX-P, PARAGON is a two-dimensional, multi-group, transport-based lattice code

capable of providing necessary data for PWR (Reference 22.58). Reference 22.36 contains a description of the nuclear methods for modelling tungsten and PARAGON benchmark results to Monte-Carlo simulations for assemblies containing tungsten GRCAs.

The PARAGON lattice code is also capable of generating all of the group constants generated by PHOENIX-P, and has been benchmarked and qualified to the same degree as PHOENIX-P. The primary difference between PARAGON and PHOENIX-P is that PARAGON uses Collision Probability theory with the interface current method to solve the integral transport equation. PARAGON also allows increased flexibility in modelling the exact assembly and pin cell geometry. The group constants generated by PARAGON are coupled to the spatial few-group code using the NEXUS nuclear data methodology (Reference 22.83).

22.6.3.3 Spatial Few Group Diffusion Calculations

The 3D ANC code permits the introduction of advanced fuel designs with axial heterogeneities, such as axial blankets and part-length BA rods, and allows such features to be modelled explicitly (References 22.56 and 22.84). The 3-D nature of this code provides both radial and axial power distribution.

Spatial few-group calculations are performed to determine the critical boron concentrations and power distributions. The moderator coefficient is evaluated by varying the inlet temperature in the same kind of calculations used for power distribution and reactivity predictions.

Validation of the reactivity calculations is associated with validation of the group constants themselves, as discussed in Section 22.6.3.2. Validation of the Doppler calculations is associated with the fuel temperature validation discussed in Section 22.6.3.1. Validation of the moderator coefficient calculations is obtained by comparison with plant measurements at hot zero-power conditions.

Axial calculations may be used in place of the full 3D model to determine differential control rod worth curves (reactivity versus rod insertion) and to demonstrate load follow capability. Group constants are obtained from the 3-D nodal model by flux-volume weighing on an axial slicewise basis. Radial bucklings are determined by varying parameters in the buckling model while forcing the 1-D model to reproduce the axial characteristics (AO, midplane power) of the 3-D model.

Validation of the spatial codes for calculating power distributions involves the use of in-core and ex-core detectors and is discussed in Section 22.6.2.8.

Calculation-measurement comparisons have been made with operating reactor data measured during startup tests and normal power operation. These comparisons include a variety of core geometries and fuel loading patterns and incorporate a reasonably extreme range of fuel enrichment, BA rod loading, and cycle burnup. Qualification data indicates small mean and standard deviations relative to measurement that are equal to or less than those found in previous reviews of similar or parallel methodologies (References 22.51, 22.58, and 22.83). For the reload designs, the spatial codes described above are used.

22.7 THERMAL AND HYDRAULIC DESIGN

The thermal and hydraulic design of the reactor core provides adequate heat transfer compatible with the heat generation distribution in the core. This provides adequate heat

removal by the RCS, the normal residual heat removal system, or the passive core cooling system.

22.7.1 Design Bases

To satisfy the heat transfer performance requirements for all modes of operation the following design bases have been established for the thermal and hydraulic design of the reactor core.

22.7.1.1 Departure from Nucleate Boiling Design Basis

There is at least a 95 percent probability at a 95 percent confidence level that DNB does not occur on the limiting fuel rods during normal operation and operational transients and any transient conditions arising from faults of moderate frequency (frequent faults).

With the Revised Thermal Design Procedure (RTDP) (Reference 22.64) uncertainties in plant operating parameters, nuclear and thermal parameters, fuel fabrication parameters, computer codes, and DNB correlation predictions are considered statistically to obtain DNB uncertainty factors. Based on the DNB uncertainty factors, RTDP design limit DNBR values are determined such that there is at least a 95 percent probability at a 95 percent confidence level that DNB will not occur on the most limiting fuel rod during normal operation and operational transients and during transient conditions arising from faults of moderate frequency (frequent faults).

Assumed uncertainties in the plant operating parameters (pressuriser pressure, primary coolant temperature, reactor power, and RCS flow) are evaluated. Only the random portion of the plant operating parameter uncertainties is included in the statistical combination. Instrumentation bias is treated as a direct DNBR penalty. Since the parameter uncertainties are considered in determining the RTDP design limit DNBR values, the plant safety analyses are performed using input parameters at their nominal values.

For those transients that use the VIPRE-01 computer program (subsection 22.7.1) and the WRB-2M correlation, the RTDP design limits are 1.25 for the typical cell and 1.25 for the thimble cell. These values may be revised (slightly) when plant specific uncertainties are available.

To maintain DNBR margin to offset DNB penalties such as those due to fuel rod bow, the safety analyses are performed to DNBR limits higher than the design limit DNBR values. The difference between the design limit DNBRs and the safety analysis limit DNBRs results in DNBR margin. A portion of this margin is used to offset the rod bow and or other DNBR penalties not directly modelled in the DNBR calculation.

The Standard Thermal Design Procedure (STDP) is used for [
] analyses where RTDP is not applicable. Rod withdrawal from subcritical must be analysed using STDP since this transient is initiated at zero power and the plant-specific uncertainties are not available at this power. Steamline break at hot-zero power is always analysed using STDP since the statepoints are out of the range of applicability of RTDP. In the STDP method, the parameters used in the analysis are treated in a conservative way from a DNBR standpoint. The parameter uncertainties are applied directly to the plant safety analyses input values to give the lowest minimum DNBR. The DNBR limit for STDP is the appropriate DNB correlation limits increased to give sufficient margins to cover any DNBR penalties associated with the analysis.

By preventing DNB, adequate heat transfer is provided from the fuel clad to the reactor coolant, thereby preventing clad damage from inadequate cooling. Maximum fuel rod surface temperature is not a DB, since it is within a few degrees of coolant temperature during operation in the nucleate boiling region. Limits provided by the nuclear control and protection systems are such that this DB is met for transients associated with frequent faults, including overpower transients. There is an additional large DNBR margin at rated power operation and during normal operating transients.

22.7.1.2 Fuel Temperature Design Basis

During modes of operation associated with normal operation and frequent faults, there is at least a 95 percent probability at a 95 percent confidence level that the peak linear heat rate fuel rods will not exceed the uranium dioxide melting temperature. The melting temperature of uranium dioxide is 2804.44°C (5080°F) (Reference 22.85) unirradiated, decreasing by 32.22°C (58°F) per 10,000 MWD/MTU. By precluding uranium dioxide melting, the fuel geometry is preserved and possible adverse effects of molten uranium dioxide on the cladding are eliminated. Design evaluations for normal operation and frequent faults have shown that fuel melting will not occur for achievable local burnups up to 75,000 MWD/MTU (Reference 22.89).

Fuel rod thermal evaluations are performed at rated power and maximum overpower and during transients at various burnups. These analyses confirm that this DB and the fuel integrity design bases given in Section 22.5 are met. They also provide input for the evaluation of infrequent faults given in Chapter 9.

The centreline temperature limit has been applied to reload cores with an extended burnup limit of 62,000 MWD/MTU. For higher burnups, the peak linear heat rate experienced during normal operation and frequent faults is limited to that maximum value sufficient to provide that the fuel centreline temperatures remain below the melting temperature for the fuel rods. Thus, the fuel rod DB that fuel rod damage due to fuel melting does not occur continues to be met.

22.7.1.3 Core Flow Design Basis

The maximum bypass flow fraction of 5.9 percent is calculated [

].

The 5.9 percent bypass flow fraction assumes the use of thimble plugging devices in the rod cluster control guide thimble tubes that do not contain any other core components.

Subtracting the 5.9 percent bypass flow fraction from the total thermal flow rate provides a minimum value of 94.1 percent that is assumed to pass through the fuel rod region of the core and is effective for fuel rod cooling. Coolant flow through the thimble and instrumentation tubes and the leakage between the core barrel and core shroud, head cooling flow, and leakage to the vessel outlet nozzles are not considered effective for heat removal. The shroud core cavity flow is considered as active flow effective for fuel rod cooling.

22.7.1.4 Hydrodynamic Stability Design Basis

Modes of operation associated with normal operating transients and frequent faults do not lead to hydrodynamic instability.

22.7.2 Design Description

22.7.2.1 Summary Comparison

Table 22-5 provides a comparison of the design parameters for the AP1000 and AP600 plants and a licensed Westinghouse-designed plant using standard XL RFA fuel.

22.7.2.2 Critical Heat Flux Ratio or Departure from Nucleate Boiling Ratio and Mixing Technology

The minimum DNBRs for the rated power and anticipated transient conditions are given in Table 22-5. The minimum DNBR in the limiting flow channel is typically downstream of the peak heat flux location (hot spot) due to the increased downstream enthalpy rise.

DNBRs are calculated by using the correlation and definitions described below. The VIPRE-01 computer code described is used to determine the flow distribution in the core and the local conditions in the hot channel for use in the DNB correlation.

The primary DNB correlation used for the analysis of the fuel is the WRB-2M correlation (Reference 22.57). The WRB-2M correlation was developed specifically for the RFAs, which are planned to be used in the AP1000 reactor core. This correlation applies to most AP1000 plant conditions. The applicable range of parameters for the WRB-2M correlation is as follows (SI units):

Pressure (P)	10.308 to 16.720 MPa abs
Local mass velocity (G_{loc})	4.74 to 15.1 x 10^6 kg/(m² hr)
Local quality (X_{loc})	-0.1 to 0.29
Heated length, inlet to CHF location (L_h)	≤ 426.72 cm
Grid spacing (g_{sp})	25.4 to 52.32 cm
Equivalent hydraulic diameter (D_e)	9.4 to 11.7 mm
Equivalent heated hydraulic diameter (D_h)	11.7 to 13.7 mm

The applicable range of parameters for the WRB-2M correlation is as follows (Imperial units):

Pressure (P)	1495 to 2425 psia
Local mass velocity (G_{loc})	0.97 to 3.1 x 10^6 lb/(ft² hr)
Local quality (X_{loc})	-0.1 to 0.29
Heated length, inlet to CHF location (L_h)	≤ 14 feet
Grid spacing (g_{sp})	10 to 20.6 inches
Equivalent hydraulic diameter (D_e)	0.37 to 0.46 inches
Equivalent heated hydraulic diameter (D_h)	0.46 to 0.54 inches

The WRB-2 (Reference 22.16), ABB-NV (Reference 22.86) or WLOP (Reference 22.87) correlation is used whenever the WRB-2M correlation is not applicable The WRB-2 correlation 95/95 limit is 1.17.

The applicable range of parameters for the WRB-2 correlation is as follows (SI units):

Pressure (P)	9.928 to 17.168 MPa abs
Local mass velocity (G_{loc})	4.4 to 18.1 x 10^6 kg/(m^2 hr)
Local quality (X_{loc})	-0.1 to 0.3
Heated length, inlet to CHF location (L_h)	≤ 426.7 cm
Grid spacing (g_{sp})	25.4 to 66.04 cm
Equivalent hydraulic diameter (D_e)	9.4 to 13.0 mm
Equivalent heated hydraulic diameter (D_h)	11.7 to 15.0 mm

The applicable range of parameters for the WRB-2 correlation is as follows (Imperial units):

Pressure (P)	1440 to 2490 psia
Local mass velocity (G_{loc})	0.9 to 3.7 x 10^6 lb/(ft² hr)
Local quality (X_{loc})	-0.1 to 0.3
Heated length, inlet to CHF location (L_h)	≤ 14 feet
Grid spacing (g_{sp})	10 to 26 inches
Equivalent hydraulic diameter (D_e)	0.37 to 0.51 inches
Equivalent heated hydraulic diameter (D_h)	0.46 to 0.59 inches

In the heated region below the first mixing vane grid, the ABB-NV correlation, References 22.86 and 22.87, which is based on CHF data from fuel assemblies without mixing vane grids, is used to calculate DNBR values. For system pressures and flow rates where the above correlations are not applicable, the WLOP correlation, Reference 22.87, is used to calculate DNBR values.

The DNB heat flux ratio, DNBR, as applied to typical cells (flow cells with all walls heated) and thimble cells (flow cells with heated and unheated walls), is defined as follows:

$$DNBR = \frac{q''_{DNB,predicted}}{q''_{actual}}$$

where,

$$q''_{DNB,predicted} = \frac{q''_{WRB-2M}}{F} \quad \text{or} \quad q''_{DNB,predicted} = \frac{q''_{WRB-2}}{F}$$

q''_{WRB-2M} = Uniform DNB heat flux as predicted by the WRB-2M DNB correlation

q''_{WRB-2} = Uniform DNB heat flux as predicted by the WRB-2 DNB correlation

F = Flux shape factor to account for non-uniform axial heat flux distributions (Reference 22.88) with the term "C" modified as in Reference 22.59

q''_{actual} = Actual local heat flux

Thermal Diffusion Coefficient

The rate of heat exchange by mixing between flow channels is proportional to the difference in the local mean fluid enthalpy of the respective channels, the local fluid density, and the flow velocity. The proportionality is expressed by the dimensionless thermal diffusion coefficient (TDC), which is defined as:

$$TDC = \frac{w'}{\rho V a}$$

where,

w' = Flow exchange rate per unit length (kg/m-s)
ρ = Fluid density (kg/m^3)
V = Fluid velocity (m/s)
a = Lateral flow area between channels per unit length (m^2/m)

A series of tests, using the "R" mixing vane grid design on 33.02 cm, 66.04 cm, and 81.28 cm (13 inch, 26 inch, and 32 inch)grid spacing, were conducted in pressurised water loops at Reynolds numbers similar to those of the AP1000 reactor core under the following single- and two-phase (subcooled boiling) flow conditions (Reference 22.26) as follows (in SI units):

Pressure	10.342 to 16.547 MPa abs
Inlet temperature	166.67 to 338.89°C
Mass velocity	4.9 to 17.1 x 10^6 kg/(m^2 hr)
Reynolds number	1.34 to 7.45 x 10^5
Bulk outlet quality	-52.1 to -13.5 percent

and in Imperial units:

Pressure	1500 to 2400 psia
Inlet temperature	332 to 642°F
Mass velocity	1.0 to 3.5 x 10^6 lbm/(hr-ft^2)
Reynolds number	1.34 to 7.45 x 10^5
Bulk outlet quality	-52.1 to -13.5 percent

The TDC is determined by comparing subchannel code predictions with the measured subchannel exit temperatures. The TDC is found to be independent of the Reynolds number, mass velocity, pressure, and quality over the ranges tested. The two-phase data (local, subcooled boiling) falls within the scatter of the single-phase data. In the subcooled boiling

region, the values of the TDC are indistinguishable from the single-phase values. In the quality region, in the case with rod spacing similar to that in the AP1000 reactor core geometry, the value of the TDC increased with quality to a point and then decreased, but never below the single-phase value.

The data from these tests on the "R" mixing vane grid show that a design TDC value of 0.038 (for 66.04 cm (26 inch) grid spacing) can be used in determining the effect of coolant mixing in the THINC analysis. An equivalent value of the mixing coefficient is used in the VIPRE-01 evaluations (Reference 22.61). A mixing test programme similar to the one just described was conducted for the current 17x17 geometry and mixing vane grids on a 66.04 cm (26 inch) spacing (Reference 22.62). The mean value of the TDC obtained from these tests is 0.059.

Including the IFM grids in the upper spans of the AP1000 plant fuel assembly results in grid spacing of approximately 25.4 cm (10 inch), giving higher values of the TDC. A conservative value of the TDC, 0.038, is used to determine the effect of coolant mixing in the core thermal performance analysis.

The total hot channel factors for heat flux and enthalpy rise are defined as the maximum-to-core-average ratios of these quantities. The heat flux hot channel factor considers the local maximum linear heat generation rate at a point (the hot spot), and the enthalpy rise hot channel factor involves the maximum integrated value along a channel (the hot channel).

Each total hot channel factor is composed of a nuclear hot channel factor describing the neutron power distribution and an engineering hot channel factor, which allows for variations in flow conditions and fabrication tolerances. The engineering hot channel factors are made up of subfactors that account for the influence of the variations of fuel pellet diameter, density, enrichment, eccentricity, inlet flow distribution, flow redistribution and flow mixing.

Heat Flux Engineering Hot Channel Factor, F_Q^E

The heat flux engineering hot channel factor is used to evaluate the maximum linear heat generation rate in the core. This subfactor is determined by statistically combining the fabrication variations for fuel pellet diameter, density, and enrichment. No DNB penalty need be taken for the short, relatively low-intensity heat flux spikes caused by variations in the above parameters, as well as fuel pellet eccentricity and fuel rod diameter variation (Reference 22.63).

Enthalpy Rise Engineering Hot Channel Factor, $F_{\Delta H}^E$

The effect of variations in flow conditions and fabrication tolerances on the hot channel enthalpy rise is directly considered in the VIPRE-01 core thermal subchannel analysis under any reactor opening condition. The following items are considered as contributors to the enthalpy rise engineering hot channel factor:

Pellet Diameter, Density, and Enrichment

Variations in pellet diameter, density, and enrichment are considered statistically in establishing the limit DNBRs for the Revised Thermal Design Procedure (Reference 22.64). Uncertainties in these variables are determined from sampling manufacturing data.

Inlet Flow Mal-distribution

A DB of 5 percent reduction in coolant flow to the hot assembly is used in the VIPRE-01 analyses. [

]

Flow Redistribution

The flow redistribution accounts for the reduction in flow in the hot channel resulting from the high-flow resistance in it due to the local or bulk boiling. The effect of the non-uniform power distribution is inherently considered in the VIPRE-01 analyses for every operating condition evaluated.

Flow Mixing

The subchannel mixing model incorporated in the VIPRE-01 code and used in reactor design is based on experimental data. The mixing vanes incorporated in the spacer grid design induce additional flow mixing between the various flow channels in a fuel assembly as well as between adjacent assemblies. This mixing reduces the enthalpy rise in the hot channel resulting from local power peaking or unfavourable mechanical tolerances.

Effects of Rod Bow on DNBR

The phenomenon of fuel rod bowing is accounted for in the DNBR safety analysis of frequent faults for each plant application. Applicable generic credits for margin resulting from retained conservatism in DNBR limit and/or margin in the core design parameter ([ ]), can be used to offset the effect of rod bow.

For the safety analysis of the AP1000 design, sufficient DNBR margin was maintained to accommodate the full- and low-flow rod bow DNBR penalties. The penalties are applicable to the analyses using the WRB-2M or WRB-2 DNB correlations.

The maximum rod bow penalties (less than about 2 percent DNBR) accounted for in the design safety analysis are based on an assembly average burnup of 24,000 MWD/MTU. At burnups greater than 24,000 MWD/MTU, credit is taken for the effect of $F^N_{\Delta H}$ burndown because of the decrease in fissionable isotopes and the buildup of fission product inventory, and no additional rod bow penalty is required.

In the upper spans of the fuel assembly, additional restraint is provided with the IFM grids such that the grid-to-grid spacing in those spans with IFM grids is approximately 25.4 cm (10 inch) compared with approximately 50.8 cm in the other spans. The use of a scaling factor (Reference 22.66) results in predicted channel closure in the limiting 25.4 cm (10 inch) spans of less than 50 percent closure; therefore, no rod bow DNBR penalty is required in the 25.4 cm (10 inch) spans in the safety analyses.

22.7.2.3 Linear Heat Generation Rate

The core average and maximum linear heat generation rates are given in Table 22-5.

22.7.2.4 Void Fraction Distribution

The calculated core average and the hot subchannel maximum and average void fractions are presented in Table 22-5 for operation at full power. The void models used in the VIPRE-01 code are described in Section 22.7.2.7.

22.7.2.5 Core Coolant Flow Distribution

The VIPRE-01 code is used to calculate the flow and enthalpy distribution in the core for use in safety analysis.

22.7.2.6 Core Pressure Drops and Hydraulic Loads

The core pressure drop includes those in the fuel assembly, lower core plate, and upper core plate. The full-power operation pressure drop values shown in Table 22-5 are the unrecoverable pressure drops across the vessel, including the inlet and outlet nozzles, and across the core. Since the best-estimate flow is that flow most likely to exist in an operating plant, the calculated core pressure drops in Table 22-5 are based on this best-estimate flow rather than the thermal design flow. The uncertainties associated with the core pressure drop values are presented in Section 22.7.2.7.

The fuel assembly hold-down springs are designed to keep the fuel assemblies in contact with the lower core plate under normal operation and frequent faults, except for the turbine overspeed transient associated with a loss of external load. The hold-down springs are designed to tolerate the possibility of an overdeflection associated with fuel assembly lift-off for this case and to provide contact between the fuel assembly and the lower core plate following this transient. More adverse flow conditions occur during a LOCA.

Hydraulic loads at normal operating conditions are calculated considering the best-estimate flow, accounting for the minimum core bypass flow based on manufacturing tolerances. Core hydraulic loads at cold plant startup conditions are based on the cold best-estimate flow but are adjusted to account for the coolant density difference. Conservative core hydraulic loads for a pump overspeed transient, which could possibly create a flow rate 18 percent greater than the best-estimate flow, are evaluated to be approximately twice the fuel assembly weight.

22.7.2.7 Correlation and Physical Data

Forced convection heat transfer coefficients are obtained from the Dittus-Boelter correlation with the properties evaluated at bulk fluid conditions. This correlation has been shown to be conservative for rod bundle geometries with pitch-to-diameter ratios in the range used by PWRs. The onset of nucleate boiling occurs when the clad wall temperature reaches the amount of superheat predicted by Thom's correlation. The justification of the Westinghouse VIPRE-01 modelling for PWR applications and related correlation choices is documented in Reference 22.61.

The analytical model used in the VIPRE-01 code (Reference 22.67) and the experimental data used to calculate the pressure drops shown in Table 22-5 are described below. Unrecoverable pressure losses occur as a result of viscous drag (friction) and/or geometry changes (form) in the fluid flow path. The flow field is assumed to be incompressible, turbulent, single-phase water. Those assumptions apply to the core and vessel pressure drop calculations for the purpose of establishing the primary loop flow rate. Two-phase considerations are neglected in the vessel pressure drop evaluation because the core average

void is negligible, as shown in Table 22-5. Two-phase flow considerations in the core thermal subchannel analysis are considered in the calculation of the core and vessel pressure losses.

Fluid density is assumed to be constant at the appropriate value for each component in the core and vessel. Because of the complex core and vessel flow geometry, precise analytical values for the form and friction loss coefficients are not available; therefore, experimental values for these coefficients are obtained from geometrically similar models.

Values are quoted in Table 22-5 for unrecoverable pressure loss across the reactor vessel, including the inlet and outlet nozzles, and across the core. The results of full-scale tests of core components, and fuel assemblies are used in developing the core pressure loss characteristic.

Tests of the primary coolant loop flow rates are made prior to initial criticality to verify that the flow rates used in the design, which are determined in part from the pressure losses calculated by the method described here, are conservative.

VIPRE-01 considers two-phase flow in two steps: first, a quality model is used to compute the flowing vapour mass fraction (true quality), including the effects of subcooled boiling; then given the true void quality, a bulk void model is applied to compute the vapour volume fraction (void fraction).

VIPRE-01 uses a profile fit model for determining subcooled quality. It calculates the local vapour volumetric fraction in forced convection boiling by: 1) predicting the point of bubble departure from the heated surface and 2) postulating a relationship between the true local vapour fraction and the corresponding thermal equilibrium value.

The void fraction in the bulk boiling region is predicted by using homogeneous flow theory and assuming no slip (Reference 22.61). The void fraction in this region is therefore a function only of the thermodynamic quality.

22.7.2.8 Thermal Effects of Operational Transients

DNB core safety limits are generated as a function of coolant temperature, pressure, core power, and axial power imbalance. Steady-state operation within these safety limits provides that the DNB design basis is met. The OTΔT trip provides protection against anticipated operational transients that are slow with respect to fluid transport delays in the primary system. In addition, for fast transients (such as uncontrolled rod bank withdrawal at power incident), specific protection functions are provided. The use of these protection functions is described in Chapter 9.

22.7.2.9 Uncertainties in Estimates

a) Uncertainties in Fuel and Clad Temperatures

The fuel temperature is a function of crud, oxide, clad, pellet-clad gap, and pellet conductances. Uncertainties in the fuel temperature calculation are essentially of two types: fabrication uncertainties, such as variations in pellet and clad dimensions and pellet density; and model uncertainties, such as variations in pellet conductivity and gap conductance.

These uncertainties have been quantified by comparison of the thermal model with the in-pile thermocouple measurements, by out-of-pile measurements of the fuel and clad properties, and by measurements of the fuel and clad dimensions during fabrication. The

resulting uncertainties are then used in the evaluations involving the fuel temperature. The effect of densification on fuel temperature uncertainties is also included in the calculation of the total uncertainty.

In addition to the temperature uncertainty described above, the measurement uncertainty in determining the local power and the effect of density and enrichment variations on the local power are considered in establishing the heat flux hot channel factor.

Reactor trip setpoints, as specified in the Tech Specs, include allowance for instrument and measurement uncertainties such as calorimetric error, instrument drift and channel reproducibility, temperature measurement uncertainties, noise, and heat capacity variations.

Uncertainty in determining the cladding temperature results from uncertainties in the crud and oxide thicknesses. Because of the adequate heat transfer between the surface of the rod and the coolant, the film temperature drop does not appreciably contribute to the uncertainty.

b) Uncertainties in Pressure Drops

Core and vessel pressure drops based on the best-estimate flow are quoted in Table 22-5. The uncertainties quoted are based on the uncertainties in both the test results and the analytical extension of these values to the reactor application.

A major use of the core and vessel pressure drops is to determine the primary system coolant flow rates. In addition, tests on primary system prior to initial criticality are conducted to verify that a conservative primary system coolant flow rate has been used in the design and analysis of the plant.

c) Uncertainties due to Inlet Flow Maldistribution

The effects of uncertainties in the inlet flow maldistribution criteria used in the core thermal analyses are described in Section 22.7.2.2.

d) Uncertainty in Departure from Nucleate Boiling Correlation

The uncertainty in the DNB correlation is written as a statement on the probability of not being in DNB based on the statistics of the DNB data.

e) Uncertainties in Departure from Nucleate Boiling Ratio Calculations

The uncertainties in the DNBRs calculated by the VIPRE-01 analyses due to uncertainties in the nuclear peaking factors are accounted for by applying conservatively high values of the nuclear peaking factors. Measurement error allowances are included in the statistical evaluation of the DNBR limit. In addition, conservative values for the engineering hot channel factors are used. The results of a sensitivity study with THINC-IV, a VIPRE-01 equivalent code, show that the minimum DNBR in the hot channel is relatively insensitive to variations in the corewide radial power distribution (for the same value of $F^N_{\Delta H}$) (Reference 22.65).

Studies have been performed to determine the sensitivity of the minimum DNBR to the void fraction correlation and the inlet flow distributions (Reference 22.67). The results of these studies show that the minimum DNBR is relatively insensitive to variation in these

parameters. Furthermore, the VIPRE-01 flow field model for predicting conditions in the hot channels is consistent with that used in the derivation of the DNB correlation limits, including void and quality modelling, turbulent mixing, cross-flow, and two-phase flow.

f) Uncertainties in Flow Rates

A thermal design flow is defined for use in core thermal performance evaluations accounting for both prediction and measurement uncertainties. In addition, another 5.9 percent of the thermal design flow is assumed to be ineffective for core heat removal capability because it bypasses the core through the various available vessel flow paths.

g) Uncertainties in Hydraulic Loads

Hydraulic loads on the fuel assembly are evaluated for a pump overspeed transient that creates flow rates 18 percent greater than the best-estimate flow. The best-estimate flow is the most likely flow rate value for the actual plant operating condition.

h) Uncertainties in Mixing Coefficient

A conservative value of the mixing coefficient, that is, the TDC, is used in the VIPRE-01 analyses.

22.7.2.10 Flux Tilt Considerations

Significant quadrant power tilts are not anticipated during normal operation since this phenomenon is caused by some asymmetric perturbation. A dropped or misaligned RCCA could cause changes in hot channel factors. These events are analysed separately in Chapter 9.

Other possible causes for quadrant power tilts include X-Y xenon transients, inlet temperature mismatches, enrichment variations within tolerances, and so forth.

In addition to unanticipated quadrant power tilts as described above, other readily explainable asymmetries may be observed during calibration of the ex-core detector quadrant power tilt alarm. During operation, in-core maps are taken at least one per month and additional maps are obtained periodically for calibration purposes. Each of these maps is reviewed for deviations from the expected power distributions.

Asymmetry in the core, from quadrant to quadrant, is frequently a consequence of the design when assembly and/or component shuffling and rotation requirements do not allow exact symmetry preservation. In each case, the acceptability of an observed asymmetry, planned or otherwise, depends solely on meeting the required accident analyses assumptions. In practice, once acceptability has been established by review of the in-core maps, the quadrant power tilt alarms and related instrumentation are adjusted to indicate zero quadrant power tilt ratio as the final step in the calibration process. This action confirms that the instrumentation is correctly calibrated to alarm in the event that an unexplained or unanticipated change occurs in the quadrant-to-quadrant relationships between calibration intervals.

Proper functioning of the quadrant power tilt alarm is significant. No allowances are made in the design for increased hot channel factors due to unexpected developing flux tilts, since likely causes are presented by design or procedures or are specifically analysed.

Finally, in the event that unexplained flux tilts do occur, the Tech Specs provide appropriate corrective actions to provide continued safe operation of the reactor.

22.7.2.11 Fuel and Cladding Temperatures

Consistent with the thermal hydraulic design bases described in Section 22.7.1, the following discussion pertains mainly to fuel pellet temperature evaluation.

The thermal hydraulic design provides that the maximum fuel temperature is below the melting point of uranium dioxide. To preclude centre melting and to serve as a basis for overpower protection system setpoints, a calculated centreline fuel temperature of 2593.33°C (4700°F) is selected as the overpower limit. This provides sufficient margin for uncertainties in the thermal evaluations.

The temperature distribution within the fuel pellet is predominantly a function of the local power density and the uranium dioxide thermal conductivity, but the computation of radial fuel temperature distributions combines crud, oxide, clad gap, and pellet conductances. The factors that influence these conductances, such as gap size (or contact pressure), internal gas pressure, gas composition, pellet density, and radial power distribution within the pellet, have been combined into a semiempirical thermal model that includes a model for time-dependent fuel densification. See Reference 22.7 for the section on "Revised PAD Thermal Model Calibration and Verification" for the statistics from the thermal calibration and verification of this model. This thermal model enables the determination of these factors and their net effects on temperature profiles. The temperature predictions have been compared with in-pile fuel temperature measurements and melt radius data with good results.

Fuel rod thermal evaluations (fuel centreline and average and surface temperatures) are performed at several times in the fuel rod lifetime (with consideration of time-dependent densification) to determine the maximum fuel temperatures.

The principal factors used in determining the fuel temperature are as follow:

a) Uranium Dioxide Thermal Conductivity

The thermal conductivity of uranium dioxide was evaluated from published data (Reference 22.68). At the higher temperatures, thermal conductivity is best obtained by using the integral conductivity to melt. From an examination of the data, it has been concluded that the best estimate is the following:

$$\int_0^{2800} \mathrm{KDT} = 93\ \mathrm{W/cm}$$

The design curve for the thermal conductivity is shown in Figure 22-44. The section of the curve at temperatures between 0° and 1300°C is in agreement with the recommendation of the International Atomic Energy Agency (IAEA). The section of the curve above 1300°C is derived for an integral value of 93 W/cm.

Thermal conductivity for uranium dioxide at 95 percent theoretical density can be represented by the following equation:

$$\mathrm{K} = \frac{1}{11.8 + 0.0238\mathrm{T}} + 8.775 \times 10^{-13}\,\mathrm{T}^3$$

where,

K = W/cm-°C
T = °C

b) Radial Power Distribution in Uranium Dioxide Fuel Rods

An accurate description of the radial power distribution as a function of burnup is needed for determining the power level for incipient fuel melting and other important performance parameters, such as pellet thermal expansion, fuel swelling, and fission gas release rates. Radial power distribution in uranium dioxide fuel rods is determined with the neutron transport theory code, LASER.

The LASER code has been validated by comparing the code predictions on radial burnup and isotopic distributions with measured radial microdrill data (Reference 22.69). A radial power depression factor, f, is determined using radial power distributions predicted by LASER. The factor, f, enters into the determination of the pellet centreline temperature, T_c, relative to the pellet surface temperature, T_g, through the expression:

$$\int_{T_i}^{T_c} K(T)dT = \frac{q''f}{4\pi}$$

where,

K(T) = Thermal conductivity for uranium dioxide with a uniform density distribution
q″ = Linear power generation rate

c) Gap Conductance

The temperature drop across the pellet-clad gap is a function of the gap size and the thermal conductivity of the gas in the gap. The gap conductance model is selected so that when combined with the uranium dioxide thermal conductivity model, the calculated fuel centreline temperatures reflect the in-pile temperature measurements. A more detailed description of the gap conductance model is presented in Reference 22.7.

d) Fuel Clad Temperatures

The outer surface of the fuel rod at the hot spot operates at a temperature a few degrees above fluid temperature for steady-state operation at rated power throughout core life because of the onset of nucleate boiling. At BOL, this temperature is the same as the clad metal outer surface.

During operation over the life of the core, the buildup of oxides and crud on the fuel rod surface causes the clad surface temperature to increase. To preclude fuel centre melting and to serve as a basis for overpower protection system setpoints, a calculated centreline fuel temperature of 2593.33°C (4700°F) is selected as the limit. This provides sufficient margin for uncertainties in the thermal evaluations. The temperature distribution within the fuel pellet is predominantly a function of the local power density and the uranium dioxide thermal conductivity, however, the computation of radial fuel temperature distributions combines crud, oxide, clad gap, and pellet conductances. The factors that influence these conductances, such as gap size (or contact pressure), internal gas pressure, gas composition, pellet density, and radial power distribution within the pellet,

have been combined into a semiempirical thermal model that includes a model for time-dependent fuel densification. This thermal model enables the determination of these factors and their net effects on temperature profiles.

Since the thermal hydraulic DB limits DNB, adequate heat transfer is provided between the fuel clad and the reactor coolant so that the core thermal output is not limited by considerations of clad temperature.

e) Treatment of Peaking Factors

The design value of the total heat flux hot channel factor F_Q is 2.6 for normal operation.

The centreline fuel temperature must be below the uranium dioxide melt temperature over the lifetime of the rod, including allowances for uncertainties. The fuel temperature DB results in a maximum allowable calculated centreline temperature of 2593.33°C (4700°F). The peak linear power for prevention of centreline melt is 73.82 kW/m (22.5 kW/ft). The centreline temperature at the peak linear power resulting from overpower transients and operator errors (assuming a maximum overpower of 118 percent) is below that required to produce melting. This is ensured for each operating cycle as part of the nuclear design reload safety analysis and the confirmation of the adequacy of the OPΔT and OTΔT trip setpoints (Reference 22.74).

22.7.3 Evaluation of the Validity of Thermal Hydraulic Design Techniques

22.7.3.1 Critical Heat Flux

The CHF correlations used in the core thermal analysis are explained in Section 22.7.2.

22.7.3.2 Core Hydraulics

The following flow paths for core bypass are considered:

1. Flow through the spray nozzles into the upper head for head cooling purposes
2. Flow entering the rod cluster control and gray rod cluster guide thimbles
3. Leakage flow from the vessel inlet nozzle directly to the vessel outlet nozzle through the gap between the vessel and the barrel
4. Flow between the core barrel and the core shroud for the purpose of cooling and not considered available for core cooling

The above contributions are evaluated to confirm that the design value of the core bypass flow is met. Of the total allowance, one part is associated with the core (item 2 above) and the rest is associated with the internals (items 1, 3 and 4 above). Calculations have been performed using drawing tolerances in the worst direction and accounting for uncertainties in pressure losses. Based on these calculations, the core bypass is no greater than the 5.9 percent design value.

A reduction in core inlet flow distribution of 5 percent to the hot assembly inlet is used in the VIPRE-01 analyses of DNBR in the AP1000 reactor core. Studies made with THINC-IV, a VIPRE-01 equivalent code, show that flow distributions significantly more non-uniform than 5 percent have a very small effect on DNBR (Reference 22.65).

The friction factor for VIPRE-01 in the axial direction, parallel to the fuel rod axis, is evaluated using a correlation for a smooth tube (Reference 22.67). The effect of two-phase flow on the friction loss is expressed in terms of the single-phase friction pressure drop and a two-phase friction multiplier. The multiplier is calculated using the homogenous equilibrium flow model (Reference 22.61).

The flow in the lateral directions, normal to the fuel rod axis, views the reactor core as a large tube bank. This correlation is of the form:

$$FL = A\,Re_L^{-0.2}$$

where,

A = Function of the rod pitch and diameter a
Re_L = Lateral Reynolds number based on the rod diameter

22.7.3.3 Influence of Power Distribution

The core power distribution, which is largely established at BOL by fuel enrichment, loading pattern, and core power level, is also a function of variables such as control rod worth and position, and fuel depletion through lifetime. Radial power distributions in various planes of the core are often illustrated for general interest; however, the core radial enthalpy rise distribution, as determined by the integral of power up each channel, is of greater importance for DNBR analyses. These radial power distributions, characterised by $F_{\Delta H}^N$, as well as axial heat flux profiles, are discussed below.

Given the local power density q′ (kW/m) at a point *x, y,* and *z* in a core with *N* fuel rods and height H, then:

$$F_{\Delta H}^N = \frac{\text{hot rod power}}{\text{average rod power}} = \frac{\underset{0}{\overset{H}{\text{Max}\int}} q'(x_0 y_0 z_0)dz}{\frac{1}{N}\sum_{\text{all rods}} \int_0^H q'(x_0 y_0 z_0)dz}$$

The way in which $F_{\Delta H}^N$ is used in the DNBR calculation is important. The location of minimum DNBR depends on the axial profile, and the value of DNBR depends on the enthalpy rise to that point. Basically, the maximum value of the rod integral power is used to identify the most likely rod for minimum DNBR. An axial power profile is obtained that, when normalised to the design value of $F_{\Delta H}^N$, recreates the axial heat flux along the limiting rod. The surrounding rods are assumed to have the same axial profile with rod average powers that are typical distributions found in hot assemblies. In this manner, worst-case axial profiles can be combined with worst-case radial distributions for reference DNBR calculations.

It should be noted again that $F_{\Delta H}^{N}$ is an integral and is used as such in DNBR calculations. Local heat fluxes are obtained by using hot channel and adjacent channel explicit power shapes that take into account variations in horizontal power shapes throughout the core. For operation at a fraction of full power, the design $F_{\Delta H}^{N}$ used is given by:

$$F_{\Delta H}^{N} = F_{\Delta H}^{RTP}\left[1 + 0.3\left(1 - P\right)\right]$$

where,

$F_{\Delta H}^{RTP}$ = Limit at RTP
P = Fraction of RTP

The permitted relaxation of $F_{\Delta H}^{N}$ is included in the DNB protection setpoints and allows radial power shape changes with rod insertion to the insertion limits. This allows greater flexibility in the nuclear design.

The axial heat flux distribution can vary as a result of rod motion or power change, or of a spatial xenon transient that may occur in the axial direction. The ex-core nuclear detectors are used to measure the axial power imbalance. The information from the ex-core detectors is used to protect the core from excessive axial power imbalance. The reactor trip system provides automatic reduction of the trip setpoints on excessive axial power imbalance. To determine the magnitude of the setpoint reduction, the reference shape is supplemented by other axial shapes skewed to the bottom and top of the core.

The course of those accidents in which DNB is a concern is analysed in Chapter 9, assuming that the protection setpoints have been set on the basis of these shapes. In many cases, the axial power distribution in the hot channel changes throughout the course of the accident because of rod motion, coolant temperature, and power level changes.

The initial conditions for the accidents that require DNB protection are assumed to be those permissible within the specified AO control limits. In the case of the loss-of-flow accident, the hot channel heat flux profile is very similar to the power density profile in normal operation preceding the accident. It is therefore possible to illustrate the calculated minimum DNBR for conditions representative of the loss-of-flow accident as a function of the flux difference initially in the core. The power shapes are evaluated with a full-power radial peaking factor ($F_{\Delta H}^{N}$). The radial contribution to the hot rod power shape is conservative both for the initial condition and for the condition at the time of minimum DNBR during the loss-of-flow transient. The minimum DNBR is calculated for the design power shape for non-overpower/overtemperature DNB events. This design shape results in calculated DNBR that bounds the normal operation shapes.

22.7.3.4 Core Thermal Response

A general summary of the steady-state thermal hydraulic design parameters, including thermal output and flow rates, is provided in Table 22-5.

As stated in Section 22.7.1, the design bases of the application are to prevent DNB and to prevent fuel melting for frequent faults. The AP1000 plant protective systems are designed to meet these bases. The response of the core to frequent faults is given in Chapter 9.

22.7.3.5 Codes and Analytical Techniques

The objective of reactor core thermal design is to determine the maximum heat removal capability in all flow subchannels and to show that the core safety limits, as presented in the Tech Specs, are not exceeded while combining engineering and nuclear effects. The thermal design takes into account local variations in dimensions, power generation, flow redistribution, and mixing.

The Westinghouse version of VIPRE-01 contains a 3-D subchannel code that has been developed to account for hydraulic and nuclear effects on the enthalpy rise in the core and hot channels (Reference 22.67). VIPRE-01 modelling of a PWR core is based on a one-pass modelling approach. In this one-pass modelling, hot channels and their adjacent channels are modelled in detail, while the rest of the core is modelled simultaneously on a relatively coarse mesh.

The behaviour of the hot assembly is determined by superimposing the power distribution upon the inlet flow distribution while allowing for flow mixing and flow distribution between flow channels. Local variations in fuel rod power, fuel rod and pellet fabrication, and turbulent mixing are also considered in determining conditions in the hot channels. Conservation equations of mass, axial and lateral momentum, and energy are solved for the fluid enthalpy, axial flow rate, lateral flow, and pressure drop.

The VIPRE-01 core model is used with the applicable DNB correlations to determine DNBR distributions along the hot channels of the reactor core under all expected operating conditions. The effect of crud on the flow and enthalpy distribution in the core is not directly accounted for in the VIPRE-01 evaluations. However, conservative treatment by the Westinghouse VIPRE-01 modelling method has been demonstrated to bound this effect in DNBR calculations (References 22.61 and 22.86).

Westinghouse is very familiar with the Electric Power Research Institute (EPRI) guidelines for fuel cladding crud and corrosion, however, since it originally started the development of the methodology and associated computer codes and is one of the key contributors to the guidelines. Westinghouse and EPRI then worked jointly with the utilities and consultants to finalise the supporting methodology and resulting codes associated with these guidelines.

Using these guidelines and computer codes, Westinghouse has performed an initial assessment for the AP1000 design of crud formation effects on core power distribution, also known as crud-induced power shift (CIPS) (Reference 22.70). Burnup-dependent core power distributions are predicted by the Westinghouse 3-D neutronics code ANC. These power distributions are then input to the Westinghouse version of the EPRI VIPRE thermal and hydraulic code (VIPRE-01) to calculate the local thermal hydraulic conditions in three dimensions.

The local thermal hydraulic conditions from VIPRE and relevant coolant chemistry data such as boron concentration and pH levels are then input to the EPRI BOA code[1] to calculate the local subcooled boiling rates, deposition of crud on the fuel clad surface, and the deposition of boron from the coolant into the crud layer throughout the cycle. This assessment has determined that the AP1000 plant will have a low risk of operational issues due to crud formation on the fuel cladding surface. Conservative treatment by the Westinghouse

1. The Boron-induced Offset Anomaly Risk Assessment Tool (BOA) is a widely used industry code.

VIPRE-01 modelling method has been demonstrated to bound this effect in DNBR calculations (Reference 22.67).

To reduce the amount of crud being deposited on the fuel clad surface and hence the risk of operational issues, Westinghouse is implementing zinc injection for the AP1000 plant. Zinc injection has been shown to reduce the corrosion rate of primary system surfaces in operating PWRs. This will reduce the source of material available to deposit on the core as crud.

EPRI guidelines will also be followed to minimise corrosion of system surfaces, release of corrosion products to the coolant, corrosion product transport, and corrosion product deposition on the fuel. Reduced crud formation is expected in AP1000 plant because of the use of zinc addition. Plants that have implemented zinc addition following steam generator replacement have reported much less crud deposition on the fuel, which is attributed to the effect of zinc addition reducing corrosion rates from fresh metal surfaces.

For the AP1000 plant, zinc addition will commence with the initial hot functional testing and continue thereafter. The EPRI guidelines recommend zinc addition for plants replacing steam generators to reduce the risk of crud formation. This recommendation is also applicable to new plants. Core designs can also influence crud deposition by changing the amount and distribution of subcooled boiling on fuel cladding surfaces. Westinghouse applies the VIPRE BOA crud risk evaluation methods to minimise the risk of crud deposition for first core and reload designs. The use of these tools helps in developing designs that are more tolerant of crud deposits. Specifically, the tools can be used to avoid core designs that result in thick local crud deposits.

Estimates of uncertainties are discussed in Section 22.7.2.9.

Extensive additional experimental verification of VIPRE-01 has been undertaken (Reference 22.67). The VIPRE-01 analysis is based on a knowledge and understanding of the heat transfer and hydrodynamic behaviour of the coolant flow and the mechanical characteristics of the fuel elements. The use of the VIPRE-01 analysis provides a realistic evaluation of the core performance and is used in the thermal hydraulic analyses as described above.

VIPRE-01 is capable of transient DNB analysis. The conservation equations in the VIPRE-01 code contain the necessary accumulation terms for transient calculations. The input description can include one or more of the following time-dependent arrays:

- Inlet flow variation
- Core heat flux variation
- Core pressure variation
- Inlet temperature or enthalpy variation

At the beginning of the transient, the calculation procedure is carried out as in the steady-state analysis. The time is incremented by an amount determined either by the user or by the time-step control options in the code itself. At each new time step, the calculations are performed with the addition of the accumulation terms that are evaluated using the information from the previous time step. This procedure is continued until a preset maximum time is reached.

At time intervals selected by the user, a complete description of the coolant parameter distributions as well as DNBR is printed out. In this manner, the variation of any parameter with time can be readily determined.

22.7.3.6 Flow Instability

Boiling flow may be susceptible to thermohydrodynamic instabilities (Reference 22.71). These instabilities are undesirable in reactors since they may cause a change in thermal hydraulic conditions that may lead to a reduction in the DNB heat flux relative to that observed during a steady flow condition or to undesired forced vibrations of core components. A thermal hydraulic design criterion was therefore developed: it states that modes of operation under normal operation and frequent faults shall not lead to thermohydrodynamic instabilities.

Two specific types of flow instabilities are considered for AP1000 plant operation: the Ledinegg (or flow excursion) type of static instability and the density wave type of dynamic instability.

The Ledinegg instability involves a sudden change in flow rate from one steady state to another. This instability occurs when the scope of the RCS pressure drop-flow rate curve,

$$\left(\frac{\partial \Delta P}{\partial G} \bigg| \text{int ernal} \right)$$

becomes algebraically smaller than the loop supply (pump head) pressure drop-flow rate curve,

$$\left(\frac{\partial \Delta P}{\partial G} \bigg| \text{external} \right)$$

The criterion for stability is thus:

$$\left(\frac{\partial \Delta P}{\partial G} \bigg| \text{int ernal} \geq \frac{\partial \Delta P}{\partial G} \bigg| \text{external} \right)$$

The reactor coolant pump head curve has a negative slope ($\partial \Delta P/\partial G$ external less than zero), whereas the RCS pressure drop-flow curve has a positive slope ($\partial \Delta P/\partial G$ internal greater than zero) over the normal and frequent fault operational ranges. Thus, the Ledinegg instability does not occur.

The mechanism of density wave oscillations in a heated channel is such that an inlet flow fluctuation produces an enthalpy perturbation. This perturbs the length and the pressure drop of the single-phase region and causes quality or void perturbations in the two-phase regions that travel up the channel with the flow. The quality and length perturbations in the two-phase region create two-phase pressure drop perturbations; however, since the total pressure drop across the core is maintained by the characteristics of the fluid system external to the core, the two-phase pressure drop perturbation feeds back to the single-phase region. These resulting perturbations can be either attenuated or self-sustained.

A simple method has been developed for parallel closed-channel systems to evaluate whether a given condition is stable with respect to the density wave type of dynamic instability. This

method had been used to assess the stability of typical Westinghouse reactor designs in normal operation and frequent faults. The results indicate that a large margin-to-density-wave instability exists. Increases on the order of 150 percent of rated reactor power would be required for the predicted inception of this type of instability.

The application of this method to Westinghouse reactor designs is conservative because of the parallel open-channel feature of Westinghouse PWR cores. For such cores, there is little resistance to lateral flow leaving the flow channels of high-power density. There is also energy transfer from channels of high-power density to lower-power density channels. This coupling with cooler channels leads to the conclusion that an open-channel configuration is more stable than the above closed-channel analysis under the same boundary conditions.

Flow stability tests have been conducted where the closed channel systems were shown to be less stable than when the same channels were cross-connected at several locations. The cross-connections were such that the resistance to channel crossflow and enthalpy perturbations would be greater than those in a PWR core that has a relatively low resistance to crossflow.

Flow instabilities that have been observed have occurred almost exclusively in closed-channel systems operating at low pressures relative to the Westinghouse PWR operating pressures. Evidence that flow instabilities do not adversely affect thermal margin is provided by data from rod bundle DNB tests. Many Westinghouse rod bundles have been tested over wide ranges of operating conditions for the mixing vane DNB correlations with no evidence of premature DNB or inconsistent data that might indicate flow instabilities in the rod bundle.

In summary, it is concluded that thermohydrodynamic instabilities will not occur under normal operation and frequent faults for Westinghouse PWR designs. A large power margin, greater than 150 percent of rated power, exists to predicted inception of such instabilities. Analysis has shown that minor plant-to-plant differences in Westinghouse reactor designs such as fuel assembly arrays, power-to-flow ratios, and fuel assembly length do not result in gross deterioration of the above power margins.

22.7.3.7 Fuel Rod Behaviour Effects from Coolant Flow Blockage

Coolant flow blockages can occur within the coolant channels of a fuel assembly or external to the reactor core. The effects of fuel assembly blockage within the assembly on fuel rod behaviour are more pronounced than external blockages of the same magnitude. In both cases, the flow blockages cause local reductions in coolant flow. The amount of local flow reduction, where the reduction occurs in the reactor, and how far along the flow stream the reduction persists are considerations that will influence the fuel rod behaviour.

The effects of coolant flow blockages in terms of maintaining rated core performance are determined both by analytical and experimental methods. The experimental data are usually used to augment analytical tools such as computer programmes similar to the VIPRE-01 programme. Inspection of the DNB correlation shows that the predicted DNBR depends upon the local values of quality and mass velocity.

The VIPRE-01 code is capable of predicting the effects of local flow blockages on DNBR within the fuel assembly on a subchannel basis, regardless of where the flow blockage occurs (Reference 22.67). For a fuel assembly similar to the Westinghouse design, VIPRE-01 accurately predicts the flow distribution within the fuel assembly when the inlet nozzle is completely blocked. Full recovery of the flow was found to occur about 76.20 cm (30 in)

downstream of the blockage. With the reactor operating at the nominal full-power conditions specified in Table 22-4, the effects of an increase in enthalpy and decrease in mass velocity in the lower portion of the fuel assembly would not result in the fuel rods reaching the DNBR limit.

The open literature supports the conclusion that flow blockage in open-lattice cores, similar to the Westinghouse cores, causes flow perturbations that are local to the blockage. For example, A. Ohstubo and S. Uruwashi show that the mean bundle velocity is approached asymptomatically about 10.2 cm (4 in) downstream from the flow blockage in a single-flow cell (Reference 22.72).

Similar results were also found for two and three cells completely blocked, tested on an open-lattice fuel assembly in which 41 percent of the subchannels were completely blocked in the centre of the test bundle between spacer grids. These results show that the stagnant zone behind the flow blockage essentially disappears after 1.65 L/De or about 12.70 cm (5 in) for their test bundle. It was also found that leakage flow through the blockage tended to shorten the stagnant zone or, in essence, the complete recovery length.

Thus, local flow blockages within a fuel assembly have little effect on subchannel enthalpy rise and rod bundle test results showed no adverse effect on DNB (Reference 22.73).

Coolant flow blockages induce local crossflows as well as promote turbulence. Fuel rod behaviour is changed under the influence of a sufficiently high crossflow component. Fuel rod vibration could occur, caused by this crossflow component, through vortex shedding or turbulent mechanisms. If the crossflow velocity exceeds the limit established for fluid elastic stability, large amplitude whirling results.

The limits for a controlled vibration mechanism are established from studies of vortex shedding and turbulent pressure fluctuations. The crossflow velocity required to exceed fluid elastic stability limits depends on the axial location of the blockage and the characterisation of the crossflow (jet flow or not). These limits are greater than those for vibratory fuel rod wear. Crossflow velocity above the established limits can lead to mechanical wear of the fuel rods at the grid support locations. Fuel rod wear due to flow-induced vibration is considered in the fuel rod fretting evaluation as discussed in Section 22.5.

22.7.4 Testing and Verification

22.7.4.1 Tests prior to Initial Criticality

A reactor coolant flow test is performed following fuel loading but prior to initial criticality. Coolant loop pressure data is obtained in this test. This data allows determination of the coolant flow rates at reactor operating conditions. This test verifies that proper coolant flow rates have been used in the core thermal and hydraulic analysis.

22.7.4.2 Initial Power and Plant Operation

Core power distribution measurements are made at several core power levels. These tests are used to confirm that conservative peaking factors are used in the core thermal and hydraulic analysis.

Additional demonstration of the overall conservatism of the THINC analysis was obtained by comparing THINC predictions with in-core thermocouple measurements (Reference 22.65). VIPRE-01 has been confirmed to be as conservative as the THINC code (Reference 22.67).

22.7.4.3 Components and Fuel Inspections

Inspections performed on the manufactured fuel are described in Section 22.5.3. Fabrication measurements critical to thermal and hydraulic analysis are obtained to verify that the engineering hot channel factors in the design analyses are met.

22.7.5 Instrumentation Requirements

22.7.5.1 In-core Instrumentation

The primary function of the in-core instrumentation system is to provide a 3-D flux map of the reactor core. This map is used to calibrate neutron detectors used by the protection and safety monitoring system as well as to optimise core performance.

A secondary function of the in-core instrumentation system is to provide the protection and safety monitoring system with the signals necessary for monitoring core exit temperatures. This secondary function is the result of the mechanical design that groups the detectors used for generating the flux map in the same thimble as the core exit thermocouples.

The in-core instrumentation system consists of in-core instrument thimble assemblies that house fixed in-core detectors, core exit thermocouple assemblies contained within an inner and outer sheath assembly, and associated signal processing and data processing equipment. There are 42 in-core instrument thimble assemblies, each composed of multiple fixed in-core detectors and one thermocouple.

The thimbles are inserted into the active core through the upper head and internals of the reactor vessel. The signals output from the fixed in-core detectors are digitised inside containment and multiplexed out of the containment. The signal processing software integral to the in-core instrumentation system allows the fixed in-core detector signals to be used to calculate an accurate 3-D core power distribution suitable for developing calibration information for the ex-core nuclear instrumentation input to the OTΔT and OPΔT reactor trip setpoints. This calibration information is developed using the online core monitoring system and confirmed via the Data Display and Processing System prior to entry into the Plant Monitoring and Safety System. The system is also capable of accurately determining whether the reactor power distribution is currently within the operating limits defined in the Tech Specs while the reactor is operating above approximately 20 percent of RTP.

The in-core instrument system data processor receives the transmitted digitised fixed in-core detector signals from the signal processor and combines the measured data with analytically derived constants and certain other plant instrumentation sensor signals to generate a full 3-D indication of nuclear power distribution in the reactor core. It also edits the 3-D indication of power distribution to extract pertinent power distribution parameter outputs for use by the plant operators and engineers. The data processor also generates hardcopy representations of the detailed 3-D nuclear power indications.

The hardware and software that calculate the 3-D power distribution are capable of executing the calculation algorithms and constructing graphical and tabular displays of core conditions at intervals of 1 minute or less. The software provides information to enable the reactor operator to ascertain how the measured peaking factor performance agrees with the peaking factor performance predicted by the design model used to determine the acceptability of the fuel loading pattern. The analysis software provides information required to activate a visual alarm display to alert the reactor operator about the current existence of, or the potential for, reactor operating limit violations.

The calculation algorithms are capable of determining the three-dimensional reactor core power distribution using a minimum set of the total 42 in-core instrumentation thimble assemblies. Each in-core instrumentation thimble assembly consists of multiple fixed in-core detector elements that start at the top of the active fuel and have sequentially increasing lengths such that the longest element reaches the bottom of the active fuel in the fuel assembly. The calculation algorithms use the measured signal from detectors of different lengths within the assembly. The difference in signal from two operable detectors in the same assembly is defined as a detector segment. The minimum number of in-core detectors required for operability of the system is at least 75 percent operating detector segments during the initial power distribution measurement required in each operating cycle, and at least 40 percent operating detector segments following the cycle initial power distribution measurement. A minimum of 15 operating detector segments in each quadrant (with at least six detector segments per quadrant below the core midplane and six per quadrant above the core midplane) is required both prior to and following the cycle initial power distribution measurement. The hardware that performs the online power distribution monitoring is configured so that a single hardware failure will not necessitate a reactor maximum power reduction or restrict normal reactor operations.

During plant operation, the in-core instrument thimble assembly is positioned within the fuel assembly and exits through the top of the reactor vessel seal connection. The fixed in-core detector and core exit thermocouple signal exit the detector through a multi-pin connector to the in-core instrument thimble tube cables. The fixed in-core detector and core exit thermocouple cables are then routed to different data conditioning and processing stations. The data is processed and the results are available for display in the main control room (MCR).

22.7.5.2 Departure from Nucleate Boiling and High Power Instrumentation

The OTΔT trip protects the core against low DNBR. The OPΔT trip protects against excessive power (fuel rod rating protection). Factors included in establishing the OTΔT and OPΔT trip setpoints include the reactor coolant temperature in each loop and the axial distribution of core power as seen by ex-core neutron detectors.

22.7.5.3 Instrumentation to Limit Maximum Power Output

The signals from the three ranges (source, intermediate, and power) of neutron flux detectors are used to limit the maximum power output of the reactor within their respective ranges.

There are eight radial locations containing a total of 12 neutron flux detectors installed around the reactor between the vessel and the primary shield. Four proportional counters for the source range are located at the highest fluence portions of the core containing the primary startup sources at an elevation approximately one-fourth of the core height.

Four pulse fission chambers for the intermediate range, located in the same instrument wells as the source range detectors, are positioned at an elevation corresponding to one-half of the core height.

Four uncompensated ionisation chamber assemblies for the power range are installed vertically at the four corners of the core. These assemblies are located equidistant from the reactor vessel along the length and, to minimise neutron flux pattern distortions, within approximately 1 foot of the reactor vessel. Each power range detector provides two signals corresponding to the neutron flux in the upper and lower sections of a core quadrant.

The three ranges of detectors are used as inputs to monitor neutron flux from a completely shutdown condition to 120 percent of full power, with the capability of recording overpower excursions up to 200 percent of full power.

The output of the power range channels is used for the following:

- Protecting the core against the consequences of rod ejection accidents
- Protecting the core against the consequences of adverse power distributions resulting from dropped rods
- Rod speed control function
- Alerting the operator to an excessive power imbalance between the quadrants

The intermediate range detectors also provide signals for the post-accident monitoring system. Details about the neutron detectors, nuclear instrumentation design, and control and trip logic are contained in Sections 19.1.2.7, 19.2.2, 19.2.3, 19.2.5, and 19.12. The limits on neutron flux operation and trip setpoints are given in the Tech Specs.

22.8 FUNCTIONAL DESIGN OF REACTIVITY CONTROL SYSTEMS

22.8.1 Information for Control Rod Drive System

The CRDM and operation of the control rod drive system are described in Reference 22.2. No hydraulic system is associated with the functioning of the control rod drive system. The instrumentation and controls for the reactor trip system and the reactor control system are described here in Sections 19.1.4, 19.2.2, 19.2.3.1, 19.2.5, and 19.3.6.

The parts of the CRDMs and control rod drive line exposed to reactor coolant are made of metals that resist the corrosive action of the coolant. Three types of metals are used exclusively: stainless steels; nickel-chromium-iron alloys; and, to a limited extent, cobalt-based alloys. These materials have provided many years of successful operation in similar CRDMs. In the case of stainless steels, only austenitic and martensitic stainless steels are used.

The material selection is based in part on the duty cycle specified for the CRDMs and control rods. The materials are specified so that the components do not suffer adverse effects, such as excessive wear or galling, as a result of a minimum 300 trips from full power and 60 coupling and decoupling cycles of the drive rod coupling assembly.

The material for the CRDMs and the control rod assemblies is selected for acceptable performance, that is, the design goal is to achieve a service life of 9×10^6 full-step cycles. Inspection or changes in operation indicate the need for replacement or refurbishment.

The worst-case result of undetected wear of a CRDM or drive rod is a rod assembly drop or a failure to drop an assembly during a trip. Both events are accounted for in safety analyses. The pressure boundary components are not subject to significant wear due to stepping cycles.

The drive rod assembly is also immersed in the reactor coolant and uses a Type 410 stainless-steel drive rod. The drive rod coupling is machined from Type 403 stainless steel. Other parts are Type 304 stainless steel with the exception of the springs, which are nickel-chromium-iron alloy, and the locking button, which is fabricated of cobalt-alloy bar stock or a qualified substitute.

The absorber rodlets in the RCCAs and the GRCAs are closed stainless-steel tubes (cladding) containing absorber material. The stainless-steel cladding isolates from the reactor coolant, the absorber material, and other substances inside the tubes. The containment function of the control rod cladding and the effects of neutron flux in the control rod materials are addressed in Section 22.5.

The CRDMs are contained within an integrated head package located on top of the reactor vessel head. This assembly provides the support required for seismic restraint in conjunction with the attachment of the CRDMs to the reactor vessel head. An outer shroud and the seismic restraint structure isolate the CRDMs from the effects of ruptures of high-energy lines outside the shroud and from missiles.

The shroud also is used to direct air from the cooling fans past the CRDMs. The cooling system maintains the temperatures of the coils in the CRDMs below the design operating temperature. The integrated head package provides the proper support and required separation for electrical lines providing power to the CRDMs and signals from the rod position sensors.

The line for the reactor head vent system is located among the CRDMs and is supported by the integrated head package. This line is pressurised to RCS pressure and considered to be a high-energy line; it is constructed to the appropriate requirements of the ASME Code.

22.8.2 Evaluation of the Control Rod Drive System

Rod control systems of the type used in the AP1000 design have been analysed in detailed reliability studies. These studies include fault tree analysis and failure mode and effects analyses. These studies, and the analyses presented in Chapter 9, demonstrate that the control rod drive system performs its intended safety-related function: a reactor trip. The control rod drive system puts the reactor in a subcritical condition when a safety-related system setting is reached with an assumed credible failure of a single active component.

The essential elements of the control rod drive system (those required to provide reactor trip) are isolated from nonessential portions of the rod control system by the reactor trip switchgear. The essential portion of the control rod drive system is shielded from the direct effects of postulated moderate- and high-energy line breaks by the integrated head package. The dynamic effects of pipe ruptures do not have to be considered for those pipes that satisfy the requirements for mechanistic pipe break.

The reactor vessel head vent lines and instrumentation conduits are 25.4-mm (1 inch) nominal diameter or smaller. Breaks in lines of this size do not have to be postulated for dynamic effects, pressurisation, and spray wetting. The pressure boundary housing of the CRDMs is constructed to ASME requirements and a break in this pressure boundary is not credible.

The only instrumentation required of the CRDM and supporting systems to operate safely is the rod position indicator. A break in the cables connected to the rod position indicators would neither preclude a reactor trip nor result in an unplanned withdrawal of a rod assembly. A break in the power cable to the CRDM coils results in a drop of the rod assembly.

Information on the pressure and temperature of the CRDMs and surrounding areas is not required for safe operation. The design pressure and temperature of the CRDM housing is the same as the RCS, which is protected by safety valves. Overheating of the CRDM coils caused by a failure of the cooling system would in the worst case result in a drop of one or more rod

assemblies. The reactor and reactor protection system are designed to accommodate and protect against rod drop events.

22.8.3 Testing and Verification of the Control Rod Drive System

The control rod drive system is extensively tested prior to its operation. These tests may be subdivided into the following five categories:

- Prototype tests of components
- Prototype control rod drive system tests
- Production tests of components following manufacture and prior to installation
- Onsite preoperational and initial startup tests
- Periodic in-service tests

These tests are conducted to verify the operability of the control rod drive system when called upon to function.

22.8.4 Evaluation of Combined Reactivity Control Performance

The evaluations of the SLB, the feedwater line break, and the small-break LOCA, which presume the combined actuation of the reactor trip system, the control rod drive system, and the passive safety injection, are presented in Chapter 9, Sections 9.1.5, 9.1.6, 9.2.8, and 9.6. Reactor trip signals and signals to actuate passive safety features for these events are generated from functionally diverse sensors. These signals actuate diverse means of reactivity control, i.e., control rod insertion and injection of soluble neutron absorber.

Nondiverse but redundant types of equipment are used only in processing the incoming sensor signals into appropriate logic, which initiates the protective action. In particular, protection from equipment failures is provided by redundant equipment and periodic testing. Reliability studies, including failure mode and effects analysis for this type of equipment, verify that a single failure does not have an adverse effect upon the engineered safety features actuation system.

In addition to providing automatic actuations, the diverse actuation system (DAS) also provides for manual actuation of the reactor trip.

The probability of a common mode failure impairing the ability of the reactor trip system to perform its safety-related function is extremely low (see Chapters 10, 26 and 27). For all frequent faults an analysis is performed which considers failure of the reactor trip system, as presented in Chapter 9. The large-break LOCA is analysed assuming a failure of rod insertion, due to hydrodynamic effects. The evaluation of the large-break LOCA in Section 9.9 demonstrates that voiding in combination with borated injection water shuts down the reactor with no rods required. Decay heat is removed via passive injection and venting through the break and ADS valves.

22.9 REACTOR OPERATION

22.9.1 Operating Constraints

The fuel system requires constraints on the operating regime of the reactor to continue to meet the safety criteria defined in Section 22.2. Operational constraints are initially defined in the safety analysis of the first core design and then are either validated or modified for reload cores in the reload safety analysis. The key operational parameters that are constrained and the associated required corrective actions are defined in the plant Tech Specs. The specific numerical limits associated with the constrained parameters for each core design are provided in the COLR. Periodic surveillance measurements are also implemented in the plant Tech Specs to confirm that the plant is operating within the allowed constraints and that the fuel system is performing within DB limits.

Some of the fuel DB limits are monitored directly through the on-line core monitoring system. These limits include F_Q and $F_{\Delta H}^N$, DNBR, and SDM. The core monitoring system provides alarms upon approaching or exceeding these parameters and the Tech Specs define requirements for corrective actions should the limits ever be exceeded. Additional information on the online core monitoring system including the safety claims, arguments, and evidence for the system are provided in Reference 22.96.

In the unlikely event the core monitoring system becomes nonfunctional during a cycle, the axial flux difference and QPTR Tech Specs which are confirmed using the Data Display and Processing System remain applicable and contingency Tech Specs become applicable to ensure that fuel design limits and operating constraints continue to be met. Specifically, the rod insertion limits become more restrictive to ensure that the power distribution and SDM limits will be met in all normal operating scenarios. The axial flux difference and QPTR limits will remain applicable to ensure that the F_Q limit is met. The contingency Tech Spec limits are more restrictive because they are developed under the assumption that the plant is operating with limiting transient xenon conditions and because the surveillance requirements on the DB limits are performed only periodically as opposed to continuously by the core monitoring system.

Plant trip setpoints on OPΔT and OTΔT also define operating constraints that protect the fuel DB limits under frequent fault conditions. The trip setpoints are independent of core monitoring system operation. Continued applicability of the trip setpoints is confirmed prior to each operating cycle.

The design analysis performed for the fuel system prior to each operating cycle in conjunction with the operating constraints defined by the plant Tech Specs ensures that the fuel safety criteria defined in Section 22.2 will continue to be met.

22.10 CONCLUSIONS

This chapter provides a safety justification of the fuel elements in the AP1000 reactor. For normal operation, this means that all reasonable steps should be taken to minimise the failure of the fuel rod cladding and thus minimise the release of radioactive fission products into the coolant. For fault conditions, the definition of satisfactory performance depends on the frequency with which the fault is expected to occur.

The limits within which the fuel can operate safely during both normal and fault conditions have been defined and justified to demonstrate safe operation of the fuel. To achieve this, safety design bases and design limiting criteria have been defined, leading to the

establishment of mechanical, nuclear, and thermal hydraulic design bases inherent in the safety design approach. It is demonstrated that none of the design bases or limiting criteria is exceeded when the fuel is subjected to the full range of operational and fault conditions.

Table 22-1. Fuel Rod Secondary Limits

Type of Fault	Limits	Degradation Mechanisms to which Limits Relate
LOCA	Peak clad temperature ≤1204°C (2200°F) local clad oxidation ≤17%	Remaining below limits ensures that embrittlement of the fuel clad will not occur so that loss of coolable geometry or escape of pellets into the coolant circuit would occur.
RIA	Radial average peak fuel enthalpy rise at hot spot during transients ≤628 J/g (150 cal/g) Peak clad temperature ≤1482°C (2700°F)	Remaining within these limits ensures that disruption of the clad by interaction with the pellet will not occur so that coolable geometry would be lost or fuel pellets could escape into the coolant circuit. Remaining within this limit ensures that embrittling of the fuel clad will not occur so that loss of coolable geometry or escape of pellets into the coolant circuit would occur.
PCM accidents	Peak clad temperature ≤1204°C (2200°F) for boiling times <350 s. For longer boiling times, the allowable peak clad temperature is reduced linearly with log (time) being 875°C (1607°F) at 10,000 s.	Remaining within this limit ensures that embrittling of the fuel clad will not occur so that loss of coolable geometry or escape of pellets into the coolant circuit would occur.

Table 22-2. Reactor Core Description (First Cycle)

Active Core	
Equivalent diameter	304.0 cm (119.7 in)
Active fuel height first core (cold)	426.7 cm (168 in)
Height-to-diameter ratio	1.40
Total cross-section area	7.26 m^2 (78.14ft^2)
H_2O/U molecular ratio (cell, cold)	2.40
Reflector Thickness and Composition	
Top – water plus steel	~25.4 cm (10 in)
Bottom – water plus steel	~25.4 cm (10 in)
Side – water plus steel	~38.1 cm (15 in)
Fuel Assemblies	
Number	157
Rod array	17x17
Rods per assembly	264
Rod pitch	1.26 cm (0.496 in)
Overall transverse dimensions	21.402 x 21.402 cm (8.426 x 8.426 in)
Fuel weight, as uranium dioxide	95,975 kg (211,588 lb)
ZIRLO clad weight	19,552 kg (43,105 lb)
Number of grids per assembly	
Top and bottom	2 Alloy 718
Intermediate	8 **ZIRLO**
IFM	4 **ZIRLO**
Protective	1 Alloy 718
Number of guide thimbles per assembly	24
Composition of guide thimbles	**ZIRLO**
Diameter of guide thimbles – upper part	1.123 cm ID x 1.224 cm OD (0.442 in ID x 0.482 in OD)
Diameter of guide thimbles – lower part	1.008 cm ID x 1.224 cm OD (0.397 in ID x 0.482 in OD)
Diameter of instrument guide thimbles	1.123 cm ID x 1.224 cm OD (0.442 in ID x 0.482 in OD)

Table 22-2. Reactor Core Description (First Cycle) (cont.)

Fuel Rods	
Number	41,448
Outside diameter	0.950 cm (0.374 in)
Diameter gap	0.0165 cm (0.0065 in)
Clad thickness	0.0572 cm (0.225 in)
Clad material	**ZIRLO**
Fuel Pellets	
Material	Uranium dioxide sintered
Density (% of theoretical) (nominal)	95.5
Fuel enrichments, first core (average w/o midzone/blanket)	
Region 1	0.74 / ---
Region 2	1.58 / ---
Region 3	3.20 / 1.58
Region 4	3.776 / 3.20
Region 5	4.376 / 3.20
Diameter	0.81915 cm (0.3225 in)
Length	0.983 cm (0.387 in)
Mass of uranium dioxide per unit length of fuel rod	0.545 kg/m (0.366 lb/ft)
RCCAs	
Neutron absorber	Ag-In-Cd
Diameter	0.866 cm (0.341 in)
Density	10.16 g/cm^3 (0.367 lb/in^3)
Cladding material	Type 304 or 304L, cold-worked SS
Cladding OD	0.968 cm (0.381 in)
Cladding thickness	0.047 cm (0.0185 in)
Number of clusters – full length	53
Number of absorber rods per cluster	24

Table 22-2. Reactor Core Description (First Cycle) (cont.)

GRCAs	
Neutron absorber	Tungsten / Alloy 718
Diameter	Tungsten 0.500 cm (0.197 in) / Alloy 718 0.787 cm (0.310 in)
Density	Tungsten 19.24 g/cm^3 (0.695 lb/in^3) / Alloy 718 8.19 g/cm^3 (0.296 lb/in^3)
Cladding material	Type 304 or 304L, cold-worked SS
Clad thickness	0.065 cm (0.0255 in)
Number of clusters – full length	16
Number of absorber rods per cluster	24
Discrete BA Rods (First Core)	
Number	592
Material	Alumina Boron-Carbide
Outer diameter	0.968 cm (0.381 in)
Inner tube, outer diameter	0.678 cm (0.267 in)
Clad material	Zircaloy
Inner tube material	Zircaloy
B-10 content	6.03 mg/cm (0.0004 lb/ft)
Absorber length	See Figure 22.20
IFBAs (First Core)	
Number	5632
Type	IFBA
Material	Boride coating
B-10 content	0.773 mg/cm (0.000052 lb/ft)
Absorber length	386.1 cm (152 in)
Excess Reactivity	
Maximum fuel assembly K∞ (cold, clean, unborated water)	1.392
Maximum core reactivity k_{eff} (cold, zero power, beginning of cycle, zero soluble boron)	1.201

Table 22-3. Nuclear Design Parameters (First Cycle)

Core average linear power, including densification effects	18.76 kW/m (5.72 kW/ft)	
Total heat flux hot channel factor, F_Q	≤2.60	
Nuclear enthalpy rise hot channel factor, $F^N_{\Delta H}$	≤1.72	
Reactivity coefficients	Design Limits	Typical Best Estimate
Doppler-only power coefficients (see Figure 9.0-3) (pcm/% power)(1)		
Upper curve	-19.4 to -12.6	-14.6 to -9.0
Lower curve	-10.2 to -6.7	-12.4 to -8.9
Doppler temperature coefficient (pcm/°C)(1)	-6.3 to -1.8	-3.8 to -2.5
(Doppler temperature coefficient (pcm/°F)(1)	-3.5 to -1.0	-2.1 to -1.4)
Moderator temperature coefficient (pcm/°C)(1)	0 to -72	0 to -63
(Moderator temperature coefficient (pcm/°F)(1)	0 to -40	0 to -35)
Boron coefficient (pcm/ppm)(1)	-13.5 to -5.0	-11.3 to -7.2
Rodded moderator density coefficient (pcm/g/cm^3)(1)	≤ 0.47x10^5	≤ 0.45x10^5
Delayed neutron fraction and lifetime, β_{eff}	0.0075(0.0044)(2)	
Prompt Neutron Lifetime, ℓ^*, μs	19.8	
Control rods		
Rod requirements	See Table 22-4	
Maximum ejected rod worth	See Chapter 9	
Typical Bank worth HZP no overlap (pcm)(1)	BOL, Xe Free	EOL, Eq. Xe
MA Bank	238	257
MB Bank	248	327
MC Bank	232	194
MD Bank	239	271
M1 Bank	686	757
M2 Bank	1363	1031
AO Bank	1627	1544

Table 22-3. Nuclear Design Parameters (First Cycle) (cont.)

Typical Hot Channel Factors $F^N_{\Delta H}$ [6]	BOL	EOL
Unrodded	1.44	1.38
MA bank	1.48	1.44
MA + MB banks	1.51	1.43
MA + MB + MC banks	1.51	1.42
MA + MB + MC + MD banks	1.54	1.47
MA + MB + MC + MD + M1 banks	1.63	1.53
AO bank	1.68	1.61
Typical Boron concentrations (ppm)		
Zero power, k_{eff} = 0.99, cold[3] RCCAs out		1427
Zero power, k_{eff} = 0.99, hot[4] RCCAs out		1429
Design basis refuelling boron concentration		2700
Zero power, $k_{eff} \leq 0.95$, cold[3] RCCAs in		1061
Zero power, k_{eff} = 1.00, hot[4] RCCAs out		1321
Full power, no xenon, k_{eff} = 1.0, hot RCCAs out		1160
Full power, equilibrium xenon, k = 1.0, hot RCCAs out		844
Reduction with fuel burnup		
First cycle (ppm)/(GWD/MTU)[5]		See Figure 22-17
Reload cycle (ppm)/(GWD/MTU)		~40

Notes:

1. 1 pcm = 10^{-5} $\Delta\rho$ where $\Delta\rho$ is calculated from two statepoint values of k_{eff} by ln (k_1/k_2).
2. Bounding lower value used for safety analysis.
3. Cold means 20°C (68°F), 0.1 MPa (14.7 psia).
4. Hot means 291.7°C (557°F), 15.5 MPa (2250 psia).
5. 1 GWD = 1000 MWD.
6. Rodded hot channel factors reflect full insertion of each bank at hot full power conditions. Rod Insertion limits for the first cycle prohibit full insertion of the M1 and AO-banks during full power operation. The Rodded hot channel factors for these conditions are therefore not indicative of permitted operating conditions at full rated thermal power.

Table 22-4. Reactivity Requirements for RCCAs

Requirement	First Cycle BOL Worths (%Δρ)	First Cycle EOL Worth (%Δρ)	Equilibrium Cycle EOL Representative Worths (%Δρ)
(1) Total power defect (%Δρ)[1]	1.66	3.14	3.50
Trip rod worth [2]	7.24	6.02	6.41
(2) Less 7% [3]	6.73	5.60	5.96
Shutdown Margin			
Calculated margin (2) – (1)	5.07	2.46	2.46
Required shutdown margin [4]	1.60	1.60	1.60

Notes:

1. Includes Doppler, Moderator Temperature, Redistribution, and Void collapse reactivity effects associated with reducing power from full power to zero. Also includes the effect of inserted control rods at the most limiting allowed insertion point on the total power defect.
2. Negative reactivity inserted by RCCAs on the reactor trip. Assumes RCCAs start at the most limiting allowed insertion point and fully insert on the reactor trip except for the highest worth stuck RCCA. Also conservatively excludes negative reactivity from withdrawn GRCAs which are designed to insert on the reactor trip.
3. 7 percent adjustment to accommodate uncertainties (this assumes the use of Ag-In-Cd RCCAs).
4. The design basis minimum shutdown margin is 1.60 percent.

Table 22-5. Thermal and Hydraulic Comparison (SI units)

Design Parameters	AP1000	AP600	Typical XL Plant
Reactor core heat output (MWt)	3,400	1,933	3800
Reactor core heat output (E+6 BTU/hr)	11,601	6596	12,969
Heat generated in fuel (%)	97.4	97.4	97.4
System pressure, nominal (MPa abs)	15.513	15.513	15.513
System pressure, minimum (MPa abs)	15.100	15.168	15.196
Minimum DNBR at Nominal Conditions			
Typical flow channel	2.59	3.48	2.20
Thimble (cold wall) flow channel)	2.60	3.48	2.12
Minimum DNBR for design transients			
Typical flow channel	>1.25	>1.23	>1.26
Thimble (cold wall) flow channel)	>1.25	>1.22	>1.24
DNB correlation	WRB-2M	WRB-2	WRB-1
Coolant Conditions			
Vessel minimum measured flow rate (t/hr)	52412.6	33747.3	67,539.9
Vessel thermal design flow rate (t/hr)	51482.7	33066.9	65,770.9
Effective flow rate for heat transfer (t/hr)	48443.7	30073.2	60,191.7
Effective flow area for heat transfer (m^2)	3.88	3.58	4.75
Average velocity along fuel rods (m/s)	4.816	3.231	5.060
Average mass velocity (kg/(m^2 hr))	12.45 E+6	8.40 E+6	12.69 E+6
Coolant Temperature			
Nominal inlet (°C)	279.44	278.22	294.00
Average rise in vessel (°C)	42.89	38.67	35.33
Average rise in core (°C)	45.22	42.11	38.17

23 CONTAINMENT AND NUCLEAR VENTILATION SYSTEMS

23.1 Introduction

This chapter provides the evidence that the design of the containment and nuclear ventilation systems in the AP1000 design is adequate to meet the safety claims placed upon these systems in other parts of the safety case, both for normal operations and under fault conditions. System Specification Documents (SSD) are referenced for each relevant mechanical system. The SSD provides addition details and evidence for the safety claims placed upon systems, structures, and components (SSCs). Each SSD identifies the specific design requirements for the system and documents the system design that satisfies the requirements. SSD delineate the following:

- Summarises the functions, design criteria, and design data of system
- Describes system layout, instrumentation and control, interfacing systems, and environmental requirements.
- Describes system operations and identifies examination, maintenance, inspection, and testing (EMIT) guidelines.
- Listing of the pertinent Piping and Instrumentation Diagrams for the system.
- Lists supporting references

The containment and nuclear ventilation systems largely support the primary safety functions of the containment of radioactive substances, heat transfer/residual heat removal and provide environmental support to SSCs that, in turn contribute to primary safety functions. Analysis of the containment and ventilation systems has therefore been carried out to review their requirements against the primary safety functions. The intention of the justification against these safety functions is to demonstrate how the risks have been reduced to a level that can be considered as low as reasonably practicable (ALARP).

Generic component failure data parameters for the SSCs discussed in Chapter 23 are shown in Table 10-34 and Table 10-35. The component failure data is used as an input to the AP1000 plant Probabilistic Safety Assessment (PSA) discussed in Chapter 10. Justification against the containment primary safety function considers how the mechanical design of plant systems ensures that the containment provided by the containment vessel (CV) and other SSCs is protected.

Justification against the heat transfer/residual heat removal primary safety function considers the way in which the mechanical design of plant systems influences the management of decay heat within the CV.

Justification of the support provided by the ventilation systems to other SSCs considers how the ventilation systems maintain the internal building conditions within design limits with regards to temperature, hydrogen concentrations, and other factors.

The report against each of the relevant systems is structured in the following way:

- Its role in normal and abnormal operation is discussed and the primary safety functions to which the system contributes are identified and discussed.

- A description of the relevant SSCs that contribute to provision of the system function is provided.

- Classification and categorisation of these components and identification of what they must do to meet any safety requirements.

- A justification to support the claims that are made.

Plant response to loss of heating, ventilation, and air conditioning (HVAC) events are discussed in Chapter 6 and Chapter 8 respectively. Section 6.6.3 describes design features to maintain the Main Control Room habitable if normal HVAC is lost. Chapter 8 describes the design basis for loss of normal HVAC to the balance of auxiliary building. Active HVAC is not required for containment during a design basis accident.

The contribution of the ventilation systems to radiation protection is discussed further in Chapter 24 of this Pre-Construction Safety Report (PCSR).The AP1000 plant ventilation systems are designed to United States (US) codes and standards. The design satisfies the with United Kingdom (UK) practice as described in References 23.1 and 23.2. This is discussed further in Appendix 23A. A justification for the acceptability of United States standards for use in the UK is provided in UKP-GW-GL-045 (Reference 23.44).

23.2 SCOPE

23.2.1 Scope of Ventilation Systems

The CV is supported in its containment function by the following ventilation systems:

- Containment air filtration system (VFS)
- Containment recirculation cooling system (VCS)
- Containment leak rate test system (VUS)
- Containment hydrogen control system (VLS)

The passive containment cooling system (PCS), which provides the principal post-accident means of removing decay heat from the containment to the ultimate heat sink, the atmosphere, is not discussed in this chapter, but a detailed discussion of the safety claims and supporting evidence is provided in Section 17.6.1.

The support of other SSCs is provided outside the CV by the following:

- Main control room emergency habitability system (VES)
- Radiologically controlled area ventilation system (VAS)
- Radwaste building HVAC system (VRS)
- Health physics and hot machine shop HVAC system (VHS)
- Nuclear island nonradioactive ventilation system (VBS)
- Annex/auxiliary building nonradioactive ventilation system (VXS)
- Turbine building ventilation system (VTS)
- Diesel generator building heating and ventilation system (VZS)

The AP1000 design safety case presented in this PCSR makes a number of claims on the containment and ventilation systems. These claims in Chapter 14 are detailed in the relevant parts of this chapter.

23.2.2 Maritime Weather Conditions

The hardening of ventilation external features in respect to the maritime climate is a site-specific design change, while the standard design ventilation (assessed in the generic design assessment) is not salt-hardened. However, Westinghouse recognises that if the AP1000 design is selected for construction in the UK, it will be most likely for a coastal site. In that case, the following changes may be necessary depending on the sea salt aerosol concentrations:

- The majority of AP1000 plant ventilation systems includes filtration of air intakes and will remove any sea salt aerosols or particulates at the first, coarse filter and the higher efficiency second filter. Air passing through the remainder of the HVAC system will be essentially salt-free. It is only the portions of the HVAC components and structures upstream of the filters that will be exposed to potential salt corrosion, Therefore, salt-resistant materials will be added to ducts and air handling units so that all material upstream of high-efficiency filters is salt-hardened.

- The remaining HVAC systems are portions of the VTS, VBS (PCS valve room), and VZS. The aforementioned systems do not provide any air conditioning. At coastal sites, the portions of the turbine building served by the unfiltered VTS ventilation subsystem will be exposed to unmodified outside salt air. Those portions of the building, all of the HVAC ducting, components, and structures are exposed to salt, therefore:

  – Salt-resistant coatings will be added for equipment, components, piping, and exposed structural steel located in the nonconditioned areas of the turbine building, including ducts and equipment.

  – Fan-ventilated electrical cabinets in nonconditioned areas will be required to have inlet air filters to remove salt spray and particles. This additional cabinet filtration will add to the normal maintenance inspection and replacement schedule.

The VCS, VES, and the VLS are not affected by coastal site conditions because they are not exposed to salt-laden air.

23.3 CONTAINMENT AIR FILTRATION SYSTEM

23.3.1 Role

The VFS contributes to the containment primary safety function by providing containment isolation and filtered extract from the fuel handling area, the radiologically controlled area (RCA) of the annex/auxiliary buildings and the hot machine shop, and other areas served by the VHS following detection of high radiation by the VAS or VHS. Further design details of this system and its constituent components are delineated in Reference 23.5. This system is also discussed in Chapter 6.

The plant design makes provision for two supply air handling units (AHUs) and two air filtration exhaust units and fans. The filtration units include high-efficiency particulate air (HEPA) filters and charcoal adsorbers. Containment isolation valves (CIVs) are provided on either side of the containment penetrations for the supply and extract air pipework.

During normal intermittent purge operation, only one supply and exhaust system is required to operate. The standby supply and exhaust units can be started manually by the operator if the operating train fails. Prior to and during plant shutdown, one or both exhaust filtration trains can be operated to remove airborne radioactivity for personnel access.

A number of systems support the function of the VFS. These include, but are not limited to the following:

- Compressed air system (CAS)
- VCS recirculation coolers.
- Protection and safety monitoring system (PMS)
- Diverse actuation system (DAS)
- Plant control system (PLS)
- Fire protection system (FPS)

The PMS and radiation monitoring system (RMS) are supported by the VFS through the provision of appropriate sensors within the system.

23.3.2 System Components and Equipment Contributing to Safety Function[2]

The following components provide key contributions to the ability of the VFS to perform its safety function.

- **CIVs (VFS-PL-V003, V004, V009, V010)** – The CIVs are metal seated butterfly valves. The valves are designed and constructed to American Society of Mechanical Engineers (ASME) Code, Section III-2 (Reference 23.4) and are Seismic Category I (C-I) as detailed in the VFS system specification document (Reference 23.5, Appendix F2). Each valve is provided with a pneumatically operated spring return actuator that fails safe in a closed position on a loss of electrical power or instrument air. The isolation valves have manual manipulation devices to verify proper operation of the valves and/or to override their fail safe position.

  Automatic closure of the CIVs in response to the DAS or PMS is necessary to maintain the leaktight integrity of the CV. The CIVs are designed to Class 1 as they are the principal means of Containment Isolation which is a Category A safety function.

  CIVs (VFS-PL-V800A, V800B, V803A, 803B) – The vacuum relief portion of the VFS provides a relief path into containment to relieve excessive negative pressure caused by cold weather. Containment isolation valves (VFS-PL-V800A and V800B) are metal seated butterfly valves. The valves are designed and constructed to ASME Code III-2 (Reference 23.4) and are Seismic C-I. Containment isolation valves VFS-PL-V803A and V803B are check valves. The valves are designed and constructed to ASME Code, Section III-2 (Reference 23.4) and are Seismic C-I. The CIVs are designed to Class 1 as they are the principal means of Containment Isolation which is a Category A safety function.

  Manual CIV (V007, V008, V101, V202, V587) – The Integrated Leak Rate Test (ILRT) test connection valves (VFS-PL-V008, V101) are manual globe valves. The containment isolation block valves **(**VFS-PL-V202, V587) are manual butterfly valves. The Reactor Coolant System (RCS) vacuum ejector discharge air isolation valve (VFS-PL-V007) is a manual butterfly valve. The valves are designed and constructed to ASME Code, Section III-2 (Reference 23.4) and are Seismic C-I. The CIVs are designed to Class 1 as they are the principal means of Containment Isolation which is a Category A safety function.

- **HEPA filter** – HEPA filters are constructed, qualified, and tested in accordance with the nuclear air and gas treatment code (Reference 23.6, Section FC). Each HEPA filter cell is individually shop tested to verify an efficiency of at least 99.97 percent using a

monodisperse 0.3-µm (1.18e-5 inch) aerosol in accordance with Reference 23.6, Section TA.

The HEPA filters in the VFS work to remove particulate present in extract air from the containment, fuel handling area and auxiliary/annex buildings to minimise the offsite release of contamination to a level that is ALARP and within the regulatory limits.

HEPA filters are passive components, and as such, no actuation signal is required. Ensuring a particulate filtration efficiency of 99.97 percent of 0.3-µm (1.18e-5 inch) particles is a Category B safety function and thus the component is designed to Class 3.

- **Charcoal adsorber** – Each charcoal adsorber is designed, constructed, qualified, and tested in accordance with ASME AG-1 (Reference 23.6, Section FE) and Regulatory Guide 1.140 (Reference 23.7). This guide describes the design, inspection, and testing criteria for air filtration and adsorption units of normal atmosphere cleanup systems in light-water-cooled nuclear power plants. Each charcoal adsorber is a single assembly with welded construction and 102 mm (4 inches) deep Type III rechargeable adsorber cell. Reference 23.7 indicates that a charcoal adsorber of this type should have a decontamination efficiency of 99 percent using the appropriate test methodology.

  The charcoal adsorbers in the VFS work to remove radiation present in extract air from the containment, fuel handling area and auxiliary/annex buildings to minimise the offsite release of radiation to a level that is ALARP and within the regulatory limits.

  Charcoal adsorbers are passive components, and as such, no actuation signal is required. Ensuring a decontamination efficiency of 99 percent is a Category B safety function and is designed to Class 3.

- **Supply and exhaust fans** – The supply and exhaust air fans are centrifugal type, single-width single-inlet, with high-efficiency wheels and backward-inclined blades to produce non-overloading characteristics. Fan performance is rated in accordance with American National Standards Institute (ANSI)/Air Movement and Control Association (AMCA) Standards 210 [1] (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

  Operation of the supply and exhaust fans ensures that a suitable airflow can be achieved through the containment during purge operations to reduce the radiation levels in the containment environment. The exhaust fans also provide a filtered exhaust route from the fuel handling area and annex/auxiliary buildings, maintaining a depression relative to the surrounding areas.

  The supply/exhaust fans operate in response to signals from the PLS. They are manually operated for containment purge functions. The exhaust fans respond automatically to signals that include high/low pressure differential in the fuel handling area, RCAs of the annex/auxiliary buildings, or high radiation in these areas.

  Failure of the supply fans would not result in the VFS being unable to fulfil its primary safety function; therefore, no further analysis is required. Failure of the exhaust fans when demanded to extract from the fuel handling area and annex/auxiliary buildings

1. The AP1000 design ventilation systems are designed to US codes and standards. The design satisfies the UK practice as described in References 23.1 and 23.2. This is discussed further in Appendix 23A. A justification for the acceptability of United States standards for use in the UK is provided in UKP-GW-GL-045 (Reference 23.44).

may prevent the maintenance of a depression in those areas and lead to an unmonitored release of air to the environment or surrounding areas. Therefore, operation of the exhaust fans is a Category C safety function and the component is designed to Class 3.

- **Isolation, balancing, and shutoff dampers** – Isolation dampers are bubble-tight, single- or parallel-blade type. The isolation dampers have spring return actuators that fail closed on loss of electrical power or instrument air. The design and construction of the isolation dampers is in accordance with ANSI/AMCA Standard 500 (Reference 23.12) or ASME AG-1 (Reference 23.6). Multi-blade, two-position, remotely operated shutoff dampers are parallel-blade type. AHU and fan shutoff dampers are designed for maximum fan static pressure at shutoff flow and meet the performance requirements of ANSI/AMCA Standard 500 (Reference 23.12). The containment exhaust air dampers meet the design and construction criteria of ASME AG-1 (Reference 23.6, Section DA). Multi-blade, balancing dampers are of single or opposed-blade type.

  The isolation and shutoff dampers operate in response to signals from the PLS.

  The dampers are manufactured to appropriate industrial or nuclear standards to ensure a high reliability. Balancing dampers are set during commissioning and are not required to actuate during operation. In the main ductwork, active dampers are located in redundant supply/extract lines such that failure of a damper will not prevent the VFS from performing its safety function. The exception to this is on the extract lines from the areas served by the VAS. However, it is considered that the likelihood of coincident failure of an isolation damper and the occurrence of an event leading to a release of contamination is very low. As such, no further analysis is required.

- **Ductwork and accessories** – Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressures is structurally designed to accommodate these pressures. The system air ductwork inside containment is constructed from pipe, and meets Seismic Category II (C-II) criteria so that it will not fall and damage any safety equipment following a safe shutdown earthquake. Ductwork, supports, and accessories meet the design and construction requirements of the Sheet Metal and Air Conditioning Contractors' National Association (SMACNA) Rectangular and Round Industrial Duct Construction Standards (References 23.13 and 23.14) and HVAC Duct Construction Standard – Metal and Flexible (Reference 23.15). The exhaust air ductwork and supports meet the design and construction requirements of ASME AG-1 (Reference 23.6, Article SA-4500). The ductwork low leakage rate will be tested as necessary in accordance with SMACNA HVAC Duct Leakage Test Manual (Reference 23.16) and/or ASME N510 (Reference 23.17, Section 6) to verify that the leak tightness meets the design requirements (Reference 23.5, Section 5.1).

  The ductwork is required to contain potentially contaminated air within the VFS. It is considered that the tests and standards outlined above are adequate to allow the ductwork to meet its safety function and as such no further analysis is required.

- **Fire dampers** – Fire dampers are provided at duct penetrations through fire barriers to maintain the fire resistance rating of the barriers. The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blade when the air temperature reaches 74°C (165°F) (Reference 23.5, Section 5.1). The damper blades close via a spring mechanism. Additionally some VFS fire dampers are provided with position indication. The fire dampers meet the design, testing and installation requirements of Underwriters Laboratories (UL) 555 (Reference 23.18).

The fire dampers are passive components operated by temperature and an internal spring mechanism. As such, no actuation signal is required.

The fire damper rating will be at least equal to the fire barrier that it penetrates, up to a maximum 3-hour rating. This is essential to maintain the integrity of fire barriers discussed in the internal fire hazard section of Chapter 11 and is Category B Class 3 equipment.

23.3.3 Claims on Components and Equipment

23.3.3.1 Containment Isolation Valves (VFS-PL-V003, V004, V009, V010, V800A, V800B, V803A, 803B)

Containment isolation maintains the integrity of the CV in the event of a loss-of-coolant accident (LOCA), thus minimising the release of radioactive material from the containment. This is a Category A safety function. The CIVs are fundamental to maintaining the containment boundary, and failure to operate could result in a significant release of radioactive material from the containment. The CIVs are the primary means of fulfilling the containment isolation function and hence are Class 1 components. The UK safety categorisation and classification methodology is discussed in further detail in Chapter 5 and Appendix 15A.

CIVs are provided in series with one valve inside containment and one valve outside containment. It is claimed that at least one CIV will close to successfully isolate the containment.

The design of CIVs are very similar to other air-operated valves (AOVs) installed in pressurised water reactors (PWRs) already operating.

23.3.3.2 High-Efficiency Particulate Air Filter and Charcoal Adsorber

The HEPA filters and charcoal adsorbers in the VFS minimise the radiation released to the environment during containment purging operations and extract from the fuel handling area and annex/auxiliary building. As such, the HEPA filters and charcoal adsorbers provide a Category B safety function. Failure of either the HEPA filters or the charcoal adsorbers will result in the potential for a release of contamination and radioactivity to the environment. The HEPA filters and charcoal adsorbers provide a contribution to the VFS primary safety function and are Class 3 equipment. See Appendix 15A.

There is one HEPA filter bank and one charcoal adsorber in each exhaust air filtration unit, and there are two exhaust air filtration units. Only one filtration unit is required to operate for the VFS to deliver its safety function. Therefore, it is claimed that one HEPA filter bank and one charcoal adsorber will filter the exhaust air to ensure air discharged to atmosphere is below preset radiation limits.

23.3.3.3 Exhaust Fans

The exhaust fans are not required to operate to support the containment following an event. However, they do maintain a depression in the fuel handling area and annex/auxiliary building areas served by the VAS following detection of high radiation. This prevents an unmonitored release of air to the environment and surrounding areas. In doing this, the fans control the level of radioactivity released to the environment, which is a Category C safety

function. The exhaust fans provide a contribution to nuclear safety and are Class 3 equipment. See Appendix 15A.

There are two exhaust fans installed, and it is claimed that one fan will start and operate to extract air from the fuel handling area, the RCA of the annex/auxiliary buildings and the hot machine shop, and other areas served by the VHS following detection of high radiation by the VAS or VHS.

23.3.3.4 Fire Dampers

Fire dampers are installed where ductwork passes through fire barriers.

The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. As the fire dampers provide a contribution to achieving this safety function, they are deemed to be Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit.

23.3.4 Justification of Claims on Components and Equipment

23.3.4.1 Containment Isolation Valves (VFS-PL-V003, V004, V009, V010)

The CIVs are of a spring return design such that no external power source is required to close the valve. This passive approach offers a high degree of inherent safety and high reliability.

The CIVs are Seismic C-I and are to be designed and constructed to the ASME Code, Section III-2 (Reference 23.4) design code. This code has been specifically developed to qualify pressure retaining components in safety significant applications on nuclear power stations. The code, with the testing and examination that supports it, provides the foundations for claims made on the CIVs.

The isolation valve design is fail safe such that a loss of pneumatic or electrical power will cause the valve to fail closed. The valves are very similar to those already in service to provide the same function on many operating power stations. As a result, the information from testing of these in-service valves offers a high degree of confidence about the reliability to be expected from the valves proposed for the AP1000 design. The AOV component boundary includes the valve, valve operator (including the associated solenoid operated valves), local circuit breaker, and local control and instrumentation (C&I) circuitry (Reference 23.21). It is reasonable to assume that a large proportion of these failures will be associated with moves to an energised position.

The operating mechanism for the valve is simple, and aside from gross mechanical failure, the principal mechanisms for valve failure, is considered to be some form of adhesion preventing the valve closing, or leakage of the valve under pressure when in the closed position. These failures are considered to be unlikely because of a combination of good design and a robust maintenance, inspection, and testing regime. The valve is a metal seated butterfly type with double seals around the periphery of the disk to reduce leakage past the valve. CIVs will be leak tested at a suitable frequency in accordance with the primary containment leakage rate test programme (Reference 23.5, Appendix I-2.2). The materials of the valve have been selected to minimise the risk of corrosion interfering with valve

operation. In-service testing (IST) will include the following (Reference 23.5, Appendix I-2.2):

- Movement of the valve through its full stroke every quarter to verify operation
- Demonstration of valve closure times and valve position sensor testing by cycling and monitoring valve position every 2 years
- Containment isolation leak testing

23.3.4.2 Containment Isolation Valves (VFS-PL-V800A, V800B, V803A, V803B)

CIVs VFS-PL-803A/B are of a check valve design such that no external power source is required to close the valve. This passive approach offers a high degree of inherent safety and high reliability.

CIVs 803A/B are Seismic C-I and are to be designed and constructed to the ASME Code, Section III-2 (Reference 23.4) design code. The code, with the testing and examination that supports it, provides the foundations for claims made on the CIVs.

The operating mechanism for the valve is simple, and aside from gross mechanical failure, the principal mechanisms for valve failure, are considered to be some form of adhesion preventing the valve from closing, or leakage of the valve under pressure when in the closed position. These failures are considered to be unlikely because of a combination of good design and a robust maintenance, inspection, and testing regime. The valve is a metal seated butterfly type with double seals around the periphery of the disk to reduce leakage past the valve. CIVs will be leak tested at a suitable frequency in accordance with the primary containment leakage rate test programme (Reference 23.5, Appendix I-2.2). The materials of the valve have been selected to minimise the risk of corrosion interfering with valve operation. IST) will include the following (Reference 23.5, Appendix I-2.2):

- Movement of the valve through its full stroke every refuelling outage to verify operation
- Containment isolation leak testing

CIVs VFS-PL-800A/B are of a motor operated butterfly valve design. The valves are powered by the Class 1 electrical system. They are fail-as-is since both opening and closing is a safety function.

CIVs 800A/B are Seismic C-I and are to be designed and constructed to the ASME Code, Section III-2 (Reference 23.4). The code, with the testing and examination that supports it, provides the foundations for claims made on the CIVs.

The operating mechanism for the valve is simple, and aside from gross mechanical failure, the principal mechanisms for valve failure, are considered to be some form of adhesion preventing the valve from closing, or leakage of the valve under pressure when in the closed position. These failures are considered to be unlikely because of a combination of good design and a robust maintenance, inspection, and testing regime. The valve is a metal seated butterfly type with double seals around the periphery of the disk to reduce leakage past the valve. CIVs will be leak tested at a suitable frequency in accordance with the primary containment leakage rate test programme (Reference 23.5, Appendix I-2.2). The materials of the valve have been selected to minimise the risk of corrosion interfering with valve operation. IST will include the following (Reference 23.5, Appendix I-2.2):

- Movement of the valve through its full stroke every refuelling outage to verify operation

- Containment isolation leak testing

23.3.4.3 High-Efficiency Particulate Air Filter and Charcoal Adsorber

HEPA filters and charcoal adsorbers are passive components with a high degree of inherent safety. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.3.2). There is a large amount of experience with using HEPA filters and charcoal adsorbers designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety function.

A pressure differential sensor is installed across the HEPA filter to measure the pressure drop across it as an indication of its performance. Upon detection of a high-pressure drop across the HEPA filter, an indicator and alarm are activated.

A particle penetration of the HEPA filter unit (including through any bypass routes) that is greater than the design limit will be detected by the radiation sensor downstream of the filter bank. This would enable operator action to take place, such as shutting down the exhaust filtration system or switching to the alternative exhaust filtration unit, if it is not in operation.

The claimed efficiency of the HEPA filters and charcoal adsorbers will be demonstrated in situ upon installation of a new filter/adsorber and through periodic testing in accordance with ASME N510 throughout the plant life (Reference 23.17, Table 1).

23.3.4.4 Exhaust Fans

Primary containment of radioactive substances is provided by the building structure, and the VFS provides a defence in depth function. The fan design includes backward-inclined blades to produce nonoverloading characteristics. This will prevent overpressurisation of the ventilation distribution system if a damper in the system closes. This is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

The exhaust fans are to be designed and constructed to normal industrial standards that are suitable for Class 3 equipment.

Redundant fans are provided in the design to further reduce the risk of a total failure of the VFS extract from the fuel handling area and annex/auxiliary building areas.

Conceivable failure modes for this type of fan include, for example, a failed bearing, failed drive belt, etc. These types of mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified.

Maintenance will be carried out in line with the manufacturer’s information. There is extensive experience of operating this type of fan, designed and constructed to similar standards, to give confidence that if they are adequately maintained they will have a good reliability in service and be able to meet their safety functions.

23.3.4.5 Fire Dampers

The design of fire damper used in the VFS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and a spring mechanism closing the damper. Additionally some VFS fire dampers are provided with position indication. This provides a high degree of inherent safety and high reliability. The fire load in the served areas will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire dampers is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.4 CONTAINMENT RECIRCULATION COOLING SYSTEM

23.4.1 Role

The primary safety function of the VCS is heat transfer/residual heat removal. The safety function of the system is to support the containment structure and equipment by maintaining the containment thermal environment within appropriate limits for normal operation (below 49°C (120°F)) and during refuelling and shutdown (10° to 21°C (50° to 70°F)). The VCS also makes a contribution to the containment primary safety function with the provision of a steam generator (SG) maintenance space ventilation subsystem. This is for use during shutdown designed to protect maintenance personnel and control the spread of airborne contamination from the SG compartments to the other containment areas. Further design details of this system and its constituent components are delineated in Reference 23.3. This system is also discussed in Chapter 6.

The VCS makes provision for four 50-percent-capacity skid-mounted fan coil unit (FCU) assemblies to a common supply duct ring header and distribution system. The SG maintenance space ventilation subsystem consists of permanently installed exhaust ductwork with flexible hose connectors in the vicinity of the SG channel heads. The other end of the ductwork can be connected to a portable exhaust air filtration unit. During operation of the subsystem, flexible hosing can be used to exhaust localised contaminated air from the SG.

Cooling water is supplied to the FCUs by the central chilled water system (VWS). During cold weather conditions, while the plant is in an outage, the Hot Water Heating System (VYS) can be manually aligned to supply hot water to the VCS for containment heating purposes to keep piping and components from freezing as well as for personnel comfort. Control of the VCS is provided by the PLS with flow and temperature sensors. The FCUs are powered from the main ac power system (ECS) with redundant supply coming from the onsite standby power system (ZOS).

The VCS supports the VFS by helping to mix and distribute the VFS supply air within the containment. The VCS includes three containment atmosphere temperature sensors that provide input to the DAS for actuation of the PCS.

23.4.2 System Components and Equipment Contributing to Safety Function

Ductwork, accessories, and duct supports are constructed of galvanised steel and are structurally designed to accommodate fan shutoff pressures. The ductwork meets the design, testing, and construction requirements of SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15). Ductwork and connectors are the only components in the SG space ventilation subsystem that contribute to the containment primary safety function. The standards described above are adequate to ensure that the subsystem will deliver its safety function, and no further analysis is required.

The following components provide key contributions to the ability of the VCS to perform its safety functions.

- **Fan coil units** – Each FCU has a return air mixing plenum for each assembly and cooling coils for each FCU. The cooling coils are counterflow finned tubular type. The cooling coils are rated and meet the performance requirements in accordance with ANSI/Air Conditioning and Refrigeration Institute (ARI) 410 (Reference 23.22) for forced-circulation air cooling and air heating coils and the American Society of Heating, Refrigerating and Air Conditioning Engineers (ASHRAE) 33 (Reference 23.23) for the testing methods for rating of forced circulation air cooling and air heating coils. Each FCU includes a recirculation fan. The fans are a vane axial upblast type, direct driven with high-efficiency wheel, adjustable blades, and an inlet bell. The fans are designed with a nonoverloading, two-speed motor. The fans are designed, factory-tested and rated for performance in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

  The initiating signal for each FCU is from the PLS. The FCUs are required to operate to maintain the temperature in the containment within preset limits, and correct operation is therefore a safety function.

23.4.3 Claims on Components and Equipment

The VCS recirculation FCU assemblies and ductwork are classified as Seismic C-II such that it cannot adversely affect operation of Class 1 equipment inside containment. See Chapter 5 and Appendix 15A.

23.4.3.1 Fan Coil Units

The FCUs provide an alternative containment heat removal path for heat released to containment by the primary equipment. This is a Category B safety function. The FCUs provide an alternative role as the primary system for containment cooling is the PCS. As such, the FCUs are Category B Class 3 equipment. See Appendix 15A.

Two FCUs are required to start and operate to remove nuclear heat from the containment atmosphere during normal operation.

23.4.4 Justification of Claims on Components and Equipment

23.4.4.1 Fan Coil Units

The FCUs are standard components designed and manufactured to normal industrial codes that are appropriate for Class 3 equipment.

Redundant FCUs are provided in the VCS (4x50 percent).

FCU assemblies. They are connected to the ECS with backup supply from the ZOS. This redundancy provides further confidence that the FCUs will be able to meet the required reliability.

The Technical Specification (Tech Spec) surveillance requirement associated with the VCS is SR 3.6.5.1, which requires verification every 24 hours that the containment average air temperature is within limits (Reference 23.46). Specific maintenance requirements for the FCUs will be taken from the component manufacturer's information. There is extensive experience of operating this type of FCU to give confidence that if they are adequately maintained, they will have a good reliability in service.

23.5 CONTAINMENT LEAK RATE TEST SYSTEM

23.5.1 Role

The reactor containment, containment penetrations, and isolation barriers are designed to permit periodic leak rate testing. The VUS is designed to verify that leakage from the containment remains within limits established in the Tech Specs. Containment isolation is discussed further in Chapter 17.

The VUS verifies that containment isolation components are capable of performing their safety functions. It does not in itself perform a safety function. Any faults associated with the VUS will not result in the loss of function of other equipment. Therefore, substantiation of the system is not required.

Further design details of this system and its constituent components are delineated in Reference 23.19. This system is also discussed in Chapter 6.

23.5.2 System Components and Equipment Contributing to Safety Function

- **Manual CIV (V015, V016, Personnel Hatch Test Connections, V023 Electrical Penetration Test Isolation Valves Spare Penetration Test Connection) –** The ILRT test connection valves are manual globe valves. These valves are ASME III seismic C-I.

23.5.3 Claims on Components and Equipment

- **Manual CIV (V015, V016, Personnel Hatch Test Connections, V023 Electrical Penetration Test Isolation Valves Spare Penetration Test Connection) –** The ILRT test connection valves are manual globe valves. These valves are Category A Class 1 because they form part of the containment boundary.

23.5.4 Justification of Claims on Components and Equipment

Not applicable.

23.6 CONTAINMENT HYDROGEN CONTROL SYSTEM

23.6.1 Role

The VLS supports the containment primary safety function. Detonation of hydrogen is a hazard that could challenge containment integrity. The VLS acts to limit the hydrogen concentration in the containment so that containment integrity is not endangered.

The system consists of the following three subsystems:

- Hydrogen concentration monitoring
- Hydrogen recombination
- Hydrogen ignition

The hydrogen concentration monitoring subsystem consists of three hydrogen monitors to inform personnel of hydrogen levels in the containment building. The hydrogen recombination subsystem makes provision for two passive autocatalytic recombiners (PARs) inside the containment building to accommodate hydrogen released following a LOCA. The hydrogen ignition subsystem makes provision for 66 hydrogen igniters to accommodate the potential for release of large quantities of hydrogen during and following a degraded core or core melt scenarios.

The hydrogen ignition elements are supported by the ECS, ZOS, and Class 2 dc and uninterruptible power supply system (EDS) for electrical supplies.

The VLS supports the containment system by preventing the build-up of a hazard.

Further design details of this system and its constituent components are delineated in Reference 23.24. This system is also discussed in Chapter 6.

23.6.2 System Components and Equipment Contributing to Safety Function

There are construction and layout features to enhance the atmospheric natural circulation within containment and prevent the buildup of hydrogen pockets. All compartments below deck include openings through the top of the compartments to prevent dead-pockets of high hydrogen concentration.

The following components provide key contributions to the ability of the VLS to perform its safety function.

- **PARs** – The PARs consist of a stainless steel enclosure containing the catalyst material. There is space between the catalyst material to permit through flow of air and a chimney to the top of the enclosure to enhance the efficiency and ventilation of the device. The PARs are passive devices with no moving parts and no requirement for electrical supply or other support systems. The PARs are effective over a wide range of temperatures and hydrogen levels. The safety function of the PARs is to prevent the buildup of hydrogen within the containment building.

- **Hydrogen igniters** – The hydrogen igniters are of the heated coil type that is designed to maintain a minimum surface temperature of 927°C (1700°F) in the anticipated containment environment following a severe accident. The igniters burn hydrogen in the vicinity once the gas concentration reaches flammability conditions. The igniters are normally de-energised and are energised manually from the main control room (MCR)

when required via the PLS or DAS. The safety function of the hydrogen igniters is to burn off hydrogen in a controlled fashion if the containment hydrogen concentration exceeds flammability limits.

23.6.3 Claims on Components and Equipment

23.6.3.1 Passive Autocatalytic Recombiners

The PARs prevent the build-up of a hazard that could compromise the integrity of the containment for design basis accidents. Functions provided to reach and maintain safe state for design basis are Category B safety functions. The PARs provide a defence in depth function to protect containment against the build-up of hydrogen following a LOCA. Therefore, the PARs are Category B Class 3 equipment. See Appendix 15A.

Two PARs are provided in the VLS, and it is claimed that at least one will operate to prevent the build-up of hydrogen in the containment, as identified in the VLS system specification document (Reference 23.24, Section 3.1.2).

23.6.3.2 Hydrogen Igniters

The igniters prevent the build-up of a hazard that could compromise the integrity of the containment for severe accidents (see Section 10). Functions provided to reach and maintain safe state for beyond design basis are Category B safety functions. The igniters provide protection against a build-up of hydrogen following a degraded core or core melt accident (severe accident scenario) and therefore are Class 2 equipment. See Appendix 15A.

A total of 66 hydrogen igniters are provided in the VLS, and it is claimed that only 33 are needed to be operable to prevent the buildup of hydrogen in the containment (Chapter 10).

23.6.4 Justification of Claims on Components and Equipment

23.6.4.1 Passive Autocatalytic Recombiners

The PARs are passive components with no moving parts and no requirement for electrical power or other support systems. As such, they offer a high degree of inherent safety and high reliability.

The PARs are designed and constructed to the manufacturer’s standards in line with good engineering practice. This is suitable for Class 3 equipment.

The PARs are very similar to those already in service to provide the same function on many operating power stations. As a result, the information from testing these in-service recombiners offers a high degree of confidence about the reliability to be expected from the components proposed for the AP1000 design.

Redundant PARs are provided in the VLS. Since the PARs are passive devices with no moving parts or power supplies, there are no active failures associated with them. One possible failure mechanism is blockage of the airflow route through the device; however, the location of the PARs is such that the units are not susceptible to debris blockage.

There are Operating Rules associated with the PARs. Periodic inspection and testing of a sample of the catalytic material will be carried out to provide further confidence in the reliability of the PARs and their ability to perform their safety function.

23.6.4.2 Hydrogen Igniters

The hydrogen igniters are designed and constructed to the manufacturer's standards in line with good engineering practice. There are no nuclear-specific standards available for the design of hydrogen igniters, which is what would usually be expected for Class 2 equipment. Therefore, these are the most suitable standards to use.

The igniters are very similar to those already in service to provide the same function on many operating power stations. As a result, the information from testing these in service igniters offers a high degree of confidence about the reliability to be expected from the components proposed for the AP1000 design.

A total of 66 hydrogen igniters are provided in the VLS, and these are divided into two groups. Each group is normally powered by offsite power, with standby power supplied by a separate nonessential diesel generator. If the diesels fail, igniter operation is supported by Class 2 batteries. These three power supply sources provide the confidence that the VLS is able to maintain operation of at least 33 hydrogen igniters to meet the claim. The grouping of the igniters has been defined so that each containment compartment and hydrogen pathway has igniter coverage provided by at least one igniter in each group.

The hydrogen igniters provide the primary protection against the build-up of hydrogen in the containment following degraded core or core melt scenarios (severe accident). A hazardous concentration of hydrogen will not develop immediately, and in the unlikely event that the three electrical supplies available to the igniters fail, there would be time available to reinstate them. For this reason, it is appropriate for the hydrogen igniters not to be supplied by the essential electrical system.

The igniters are actuated manually, by MCR personnel, on receiving an elevated core exit temperature in excess of 649°C (1200°F). This will occur well in advance of the hydrogen concentration reaching the flammability limit (Reference 23.24, Section 3.1.3) and provides further assurance that a dangerous containment atmosphere will not develop.

Periodic inspection and testing is to be performed to confirm the continued operability of the hydrogen ignition system. Operability testing consists of energising the igniters and confirming the surface temperature exceeds 927°C (1700°F).

23.7 MAIN CONTROL ROOM EMERGENCY HABITABILITY SYSTEM

23.7.1 Role

The safety function of the VES is to maintain the MCR environment such that it is suitable for prolonged occupancy throughout the duration of a postulated accident involving the release of radioactivity. A maximum of 11 people can be accommodated for up to 72 hours. This is achieved by providing ventilation, pressurisation, filtration, and cooling to the MCR.

In the unlikely event that the VBS is still unavailable after 72 hours, there are provisions for supplying the required cooling of the MCR by operating one of the two VBS MCR ancillary fans to supply outside air to the MCR. A Class 1 connection provides means to supply air to VES for continued operation.

The VES supplies air to the MCR from four banks of compressed air storage tanks (32 tanks in total) using the stored energy of the compressed air. This provides fresh breathing air and maintains the positive pressure in the MCR envelope. The flow of compressed air passes

through an eductor, which induces a recirculating flow of the MCR air through HEPA filtration and charcoal adsorption. The pressure and flow rate of compressed air is controlled by pressure-regulating valves and flow metering orifices located in the main and eductor-bypass supply lines. Air delivery main isolation valves are remotely operated valves arranged in parallel and located in the main supply line inside the MCR envelope. A manual isolation valve is provided within the MCR to open the alternate supply line.

The VES operates upon detection of high particulate or iodine radioactivity in the MCR supply air duct of the VBS or upon loss of ac power for more than 10 minutes. The VBS also supports the VES by providing isolation of the MCR from the surrounding areas and outside environment.

The PMS provides control of specific VES components following certain accidents and abnormal events. The CAS is used to refill the air storage tanks when required, and the VAS maintains the VES air storage/operating deck staging area within temperature limits.

Further design details of this system and its constituent components are delineated in Reference 23.27. This system is also discussed in Chapter 6.

23.7.2 System Components and Equipment Contributing to Safety Function

The following components provide key contributions to the ability of the VES to perform its safety function.

- **Emergency air storage tanks** – There are a total of 32 air storage tanks. The air storage tanks are constructed of forged, seamless pipe, with no welds, and conform to the ASME Boiler and Pressure Vessel Code, Section VIII (Reference 23.25) and Appendix 22 (Reference 23.26). The design pressure of the air storage tanks is 28 MPa (4000 psi). The storage tanks collectively contain a minimum storage capacity of 9,276 m^3 (327,574 scf). The tanks are Seismic C-I. See Appendix 15A.

  The air storage tanks are required to maintain and deliver a store of breathing air to the MCR. The air storage tanks are simple pressure vessels, and their structural integrity is a Category A safety function and are thus Category A Class 1 equipment.

- **Pressure-regulating valves (VES-PL-V002A/B)** – These are 25-mm DN (1-inch) normally open, pressure-reducing, process-controlled globe valves designed to ASME Code III-3 (Reference 23.4) as detailed in the VES system specification document (Reference 23.27, Section 5.2.2, Appendix B-4.2). Each self-contained pressure-regulating valve is located downstream of the common header for the associated compressed air tanks.

  The valves maintain a constant pressure in their outlet line upstream of the eductor or the eductor bypass flow orifice in order to ensure a constant airflow rate to the MCR.

  The valve operates by its internal mechanism, and no external actuation or control signal is required. Correct operation of the pressure-regulating valves is a Category A safety function and are thus Category A Class 1 equipment.

- **Eductor bypass flow orifice (VES-PY-R02)** – An orifice designed to ASME Code, Section III-3 (References 23.4 and 23.27, Appendix F-1) is placed downstream of the pressure-regulating valves to control the airflow rate delivered to the MCR following a passive single failure in the passive air filtration line. No initiating signal is required. The combination of pressure-regulating valve and flow control orifice provides a

constant air addition flow rate regardless of the air pressure in the tanks (Reference 23.27). Correct flow control is a Category A function and thus the component is Category A Class 1 equipment.

- **Air delivery main isolation valves (VES-PL-V005A/B)** – These 25 mm DN (1 inch), normally closed, fail-open, solenoid-operated globe valves are designed to ASME III-3 (Reference 23.4) and have a soft elastomeric seat material to have a low leak rate (Reference 23.27, Appendix B-4.2). These valves are equipped with manual isolation capability to allow manual valve stem closure operation in the event of solenoid operator malfunction.

  The valves are located downstream of the pressure-regulating valve and orifice in the main supply line and are actuated by signals from the PMS or PLS. The valves are designed to Class 1 as they are the principal means to isolate the compressed emergency air supply lines from the MCR when the VES is not in operation and to permit airflow to the MCR when the VES is activated which is a Category A safety function.

- **Main airflow path isolation valve (VES-PL-V044)** – This is a 25-mm DN (1-inch), normally open, manual globe valve designed to ASME Code, Section III-3 (References 23.4 and 23.27, Appendix F-2). The valve is located within the MCR pressure boundary, downstream of the remotely operated air delivery main isolation valves.

  The actuation of the valve isolates the main air supply path and preserves the air storage tanks' contents if the pressure regulator in the main path malfunctions. This valve is Category A Class 1 equipment.

  As it is a manual valve no actuation signal is required. The main air flow path isolation valve is required to be able to be manually closed to isolate the main air supply line in the event of failure of the pressure-regulating valve. As this is a simple manual globe valve that is to be designed to an appropriate code (ASME Code, Section III-3) no further analysis or justification is required.

- **Air delivery alternate isolation valve (VES-PL-V001)** – This is a 25-mm DN (1-inch), normally closed, manual globe valve designed to ASME Code, Section III-3 (References 23.4 and 23.27, Appendices B-4.1, F-2). The valve is located within the MCR and is required to manually activate the alternate delivery airflow path in the event the main delivery airflow path is inoperable.

  As it is a manual valve no actuation signal is required. The air delivery alternate isolation valve is required to have a low leak rate when closed to prevent depletion of the emergency air storage tanks and must also be able to be manually opened to activate the alternate air supply line in the event of failure of the main line pressure-regulating valve. As this is a simple manual globe valve that is to be designed to an appropriate code (ASME Code, Section III-3) no further analysis or justification is required. This valve Category A Class 1 equipment.

- **MCR Eductor/Air Amplifier** – The eductor is a passive component that has no electrical or C&I power requirements, contains no moving parts, and requires no maintenance such as adjusting set points or lubricating bearings. It directs the compressed air from the VES makeup line through a nozzle that contains a flow control orifice to generate a vacuum that draws air from the MCR through connected ductwork into the passive air filtration line. The eductor must generate a sufficient vacuum to draw

the appropriate flow into the passive air filtration system. This is a Category A safety function and thus these components are Category A Class 1 equipment.

- **HEPA filters** – HEPA filters are constructed, qualified, and tested in accordance with UL 586 (Reference 23.28) and ASME AG-1 (Reference 23.6, Section FC). Each HEPA filter cell is individually shop tested to verify an efficiency of at least 99.97 percent using a mono-disperse 0.3-micron aerosol in accordance with ASME AG-1 (Reference 23.6, Section TA). The HEPA filter is in the MCR passive filtration flow path and works to remove particulate from the air to reduce potential control room dose during VES operation. HEPA filters are passive components, and as such, no actuation signal is required. The HEPA filters is designed to Class 1 as it is the principal means of ensuring a particulate filtration efficiency of 99.97 percent or 0.3-micron particles which is a Category A safety function. The VES air filtration unit includes a shield plate underneath to provide radiation attenuation to minimize accident condition radiation emissions in the break room. The shield plate is a Class 1 component.

- **Charcoal adsorber** – The charcoal adsorber is designed, constructed, qualified, and tested in accordance with ASME AG-1 (Reference 23.6, Section FD) and Regulatory Guide 1.52 (Reference 23.29). Each charcoal adsorber is an assembly with 51 mm (2 inch) deep Type II adsorber cells. Reference 23.29 indicates that a charcoal adsorber of this type should have a decontamination efficiency of 99 percent using the appropriate test methodology.

  The charcoal adsorber in the MCR passive filtration flow path works to remove iodine from the air to reduce potential control room dose during VES operation. The charcoal adsorber is a passive component; therefore, no actuation signal is required. The charcoal adsorber is designed to Class 1 as it is the principal means of ensuring a decontamination efficiency of 99 percent is a Category A safety function.

- **Passive Filtration Ducting and Components** – The components that make up the passive filtration ducting and components (dampers, registers, silencers) that provide flow through the HEPA filters and charcoal adsorber are designed in accordance with ASME N509 or ASME N509/N510 as delineated in Appendix 15A.

- **Manual and Tank Pressure Relief Valves** – The various manual valves and tank pressure relief valves are designed in accordance with ASME III. These valves allow for isolation of portions of the system for operation and maintenance. The pressure relief precludes over pressure of the system.

23.7.3 Claims on Components and Equipment

All the components and equipment in the VES act to maintain the habitability of the MCR. This is identified as a Category A safety function. See Appendix 15A.

23.7.3.1 Emergency Air Storage Tanks

The emergency air storage tanks provide the principal means of fulfilling the safety function of the system and therefore are Category A Class 1 equipment. See Appendix 15A.

It is claimed that the air storage tanks will contain a sufficient quantity of air to accommodate up to 11 people for 72 hours in the MCR and that this air can be delivered to the MCR.

23.7.3.2 Pressure-Regulating Valves (VES-PL-V002A/B)

The pressure-regulating valves in the air supply lines provide the principal means of fulfilling the safety function of the system and therefore are Category A Class 1 equipment. See Appendix 15A. It is claimed that the pressure-regulating valves will modulate appropriately to maintain a constant air pressure downstream of the valve. This will ensure that the correct airflow is provided to the MCR.

23.7.3.3 Eductor Bypass Flow Control Orifice (VES-PY-R02)

The eductor bypass flow control orifice, located in the alternate air supply, provides the principal means of fulfilling the safety function of the system and therefore is Category A Class 1 equipment. See Appendix 15A.

It is claimed that the flow control orifice will control the flow rate of air supplied to the MCR to the design flow. The orifice works together with the pressure-regulating valve to preserve the air storage tanks' contents such that they will be able to support the MCR for 72 hours at the design flow rate.

23.7.3.4 Air Delivery Main Isolation Valves (VES-PL-V005A/B)

The air delivery main isolation valves provide the principal means of fulfilling the safety function of the system and therefore are Category A Class 1 equipment. See Appendix 15A.

Two isolation valves are provided in parallel in the main air supply line, and it is claimed that at least one of these valves will open upon receipt of a signal to operate the VES. There is also an implied claim that the valves will have a low leak rate when closed to prevent depletion of the emergency air storage tanks.

23.7.3.5 MCR Eductor/Air Amplifier

The eductor provides the principal means of controlling the flow rate with an internal flow control orifice and inducing a flow through the passive air filtration line in the VES and therefore is Category A Class 1 equipment. See Appendix 15A.

It is claimed that the eductor will induce a vacuum sufficient to draw the designed flow rate of air from the MCR through the passive air filtration line.

23.7.3.6 High-Efficiency Particulate Air Filters

The HEPA filters provide the principal means of removing particulate from the MCR atmosphere and therefore are Category A Class 1 equipment.

It is claimed that the HEPA filters will have an efficiency of not less than 99.97 percent using a mono-disperse 0.3-micron aerosol (the most penetrating particle size).

23.7.3.7 Charcoal Adsorber

The charcoal adsorber provides the principal means of removing radioactive iodine from the MCR atmosphere and therefore is Category A Class 1 equipment.

It is claimed that the charcoal adsorber will have a decontamination efficiency of not less than 99 percent.

23.7.3.8 Passive Filtration Ducting and Components

The components that make up the passive filtration ducting and components (dampers, registers, silencers) that provide flow through the HEPA filters and charcoal adsorber maintain the habitability of the MCR and are thus Category A Class 1 Components.

23.7.3.9 Manual and Tank Pressure Relief Valves

The various manual valves and tank pressure relief valves maintain MCR habitability in the event of an accident and are thus Category A Class 1.

23.7.4 Justification of Claims on Components and Equipment

23.7.4.1 Emergency Air Storage Tanks

The emergency air storage tanks are simple components and have a high degree of inherent safety. The tanks are Class 1 equipment and have been designed to an appropriate ASME standard for pressure vessels (Reference 23.25). Class 1 equipment is normally constructed to nuclear-specific standards; initially, it may be thought that ASME Code, Section III would be a more appropriate standard to use for the emergency air storage tanks, but there is a vast amount of experience to support the reliability of air cylinders designed to ASME Code, Section VIII. This allows the evidence for the emergency air storage tanks to be based on the service experience of other air tanks in operation. As such, it is not considered that construction to ASME Code, III would ensure that the risk of failure was ALARP.

There are 32 tanks arranged in four banks. The emergency air storage tanks have been sized to ensure the volume of air stored is sufficient and the capacity is to be verified during preoperational testing.

Surveillance Requirement SR 3.7.6.2 requires verification that the compressed air storage tanks contain more than 9276 m^3 (327,574 scf) of compressed air every 24 hours. This ensures the air storage tanks will contain sufficient air to support 11 people in the MCR for 72 hours.

23.7.4.2 Pressure-Regulating Valves (VES-PL-V002A/B)

The pressure-regulating valves rely on their internal mechanisms and not on any external powered actuation to perform their function, providing a high degree of inherent safety. Pressure-regulating valves are common components in pressurised gas systems and as such a lot of knowledge exists about their design and operation. The valves have been designed to the ASME Code, Section III-3 design code (Reference 23.4), which has been specifically developed to qualify components suitable for nuclear power stations. The code, with the testing and examination that support it, provides the foundations for claims made on the pressure-regulating valves.

Pressure-regulating valves are present in the main and alternative supply lines, thus providing redundancy if one valve fails. Also, the valves have two stages that reduce the chance of a total valve failure. The pressure-regulating valves could either fail open or fail closed. If the main pressure-regulating valve fails open, airflow greater than the design value would result. Air supplies would not last for the required 72 hours, but the main supply line could be manually isolated and the alternative line manually activated. If the main pressure-regulating valve fails closed, the alternative line could be manually activated and the minimum flow rate would be met.

Surveillance Requirement (SR) 3.7.6.9 requires periodic verification that the self-contained pressure-regulating valve in each VES delivery airflow path is operable in accordance with the IST programme.

23.7.4.3 Eductor Bypass Flow Control Orifice (VES-PY-R02)

The flow control orifice is a simple component with no moving parts and is inherently safe. The orifice has been designed to the ASME Code, Section III-3 design code (Reference 23.4), which has been specifically developed to qualify components suitable for nuclear power stations. The code, with the testing and examination that support it, provides the foundations for claims made on the flow control orifice.

It is expected that the VES will operate very infrequently, and as such, wear should not be a significant failure mechanism. Preoperational testing will verify that the design flow rate of 110.4 ±8.5 m^3/hr (65 ±5 scfm) is achieved.

There is extensive experience of operating flow metering orifices, designed and constructed to similar standards, to give confidence that they will have a good reliability in service.

23.7.4.4 Air Delivery Main Isolation Valves (VES-PL-V005A/B)

The air delivery main isolation valves have been designed and manufactured to the ASME Code, Section III-3 design code (Reference 23.4), which has been specifically developed to qualify components suitable for nuclear power stations. The code, with the testing and examination that support it, provides the foundations for claims made on the air delivery main isolation valves.

The isolation valves are normally closed but designed to fail open. Redundant air delivery main isolation valves are provided in parallel on the main supply line and are sized such that one valve is allowed to fail closed and the other will still allow the required flow rate to pass. If both isolation valves fail closed, the alternative supply line provides a redundant route for supplying air to the MCR.

Surveillance requirement SR 3.7.6.3 requires periodic verification that each VES air delivery isolation valve is operable in accordance with the IST programme. There is extensive experience of operating this type of valve, designed and constructed to similar standards, to give confidence that if they are adequately maintained they will have a good reliability in service.

23.7.4.5 MCR Eductor/Air Amplifier

The eductor is a passive component with no moving parts, no electrical power requirements and no requirement for maintenance such as adjusting set points or lubricating bearings. Its function relies solely on the design of the eductor and an adequate flow of compressed air. This approach offers a high degree of inherent safety and high reliability.

As this is a passive component that will be called on very infrequently over the life of the AP1000 Plant, there is no credible mechanism for failure. Additionally, there is extensive experience on operating eductors designed and constructed to similar standards. This gives confidence that it will have good reliability in service. Preoperational testing will verify that the eductor is capable of inducing the design flow rate into the passive air filtration line.

23.7.4.6 High-Efficiency Particulate Air Filters and Charcoal Adsorbers

HEPA filters and charcoal adsorbers are passive components. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.7.2). There is a large amount of experience in using HEPA filters and charcoal adsorbers designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety function.

HEPA filter damage could occur during installation. However, in situ penetration testing is to be carried out after every filter change to demonstrate that the filter is achieving the correct efficiency.

The claimed efficiencies will be demonstrated through periodic testing under the ventilation filter testing programme.

23.8 RADIOLOGICALLY CONTROLLED AREA VENTILATION SYSTEM

23.8.1 Role

The primary safety functions of the VAS are the containment of radioactive substances and the provision of support to other safety systems.

The VAS consists of the following two subsystems:

- Auxiliary/annex building ventilation
- Fuel handling area ventilation

Further design details of this system and its constituent components are delineated in Reference 23.30. This system is also discussed in Chapter 6.

23.8.1.1 Auxiliary/Annex Building Ventilation Subsystem

The safety function of the auxiliary/annex building ventilation subsystem is to control the spread of any potential contamination through maintaining appropriate negative pressures with respect to surrounding spaces, maintaining contamination levels below set limits, and monitoring the radiation in the extract air from the served areas. Upon detection of high radiation levels the VAS subsystem is isolated and the VFS is initiated to provide a charcoal and HEPA filtered extract route from the area.

HEPA filtration is provided for the spent fuel pool relief panel. In the unlikely case of spent fuel pool boiling, the HEPA filters ducted to the relief panel will remove particulates from the discharged air-steam mixture.

The served areas are split into two zones and each zone can be isolated independently of the other upon detection of high radiation. The subsystem also extracts from the radwaste effluent holdup tanks to prevent the potential build-up of airborne radioactivity or hydrogen gas.

An additional safety function of the auxiliary/annex building ventilation subsystem is to provide cooling to plant rooms that contain equipment contributing to the safety functions of other systems.

The auxiliary/annex building ventilation subsystem makes provision for two 50-percent-capacity supply AHUs, two 50-percent-capacity exhaust air fans and standalone unit coolers in the normal residual heat removal system (RNS) and chemical and volume control system (CVS) pump rooms. Isolation dampers provide isolation of the subsystem upon detection of high radiation.

The subsystem is supported by the PLS, VWS, and ZOS.

The auxiliary/annex building ventilation subsystem of the VAS supports the CVS through heat removal from the CVS makeup pump rooms, the RNS through heat removal from the RNS pump rooms, and the spent fuel pool cooling system (SFS) through heat removal from the SFS pump rooms. The subsystem maintains the VES air storage/operating deck staging area within design temperature limits during normal plant operation to ensure that the storage capacity of the VES pressurised air storage tanks is unaffected. The subsystem supports the RMS through the provision of radiation monitors in the extract ductwork and provides high radiation signals to the VFS filtered exhaust subsystem when high airborne radioactivity is detected in the VAS exhaust ducts or in the rooms served by the subsystem (using area monitors). The use of the exhaust radiation monitor and local area monitors to detect high levels of radiation ensures a rapid containment of the radiation (in less than 15 seconds).

23.8.1.2 Fuel Handling Area Ventilation Subsystem

The safety function of the fuel handling area ventilation subsystem is to control the spread of any potential contamination through maintaining appropriate depressions, diluting any contamination to maintain the concentration below set limits and monitoring the radiation in the extract air from the served areas. HEPA filtration is included in the VAS extract subsystem serving the fuel handling area. Upon detection of high radiation levels, the VAS subsystem is isolated and the VFS is initiated to provide a charcoal and HEPA filtered extract route from the area.

HEPA filtration is provided for the spent fuel pool relief panel. In the unlikely case of spent fuel pool boiling for a time sufficient to actuate the relief panel, the HEPA filters ducted to the relief panel will remove particulates from the discharged air stream.

The supply and exhaust ductwork is arranged to exhaust the spent fuel pool (SFP) area and to provide directional airflow from the rail car bay/filter storage area into the spent resin equipment rooms.

The fuel handling area ventilation subsystem makes provision for two 50-percent-capacity supply AHUs and two 50-percent-capacity exhaust air fans. Isolation dampers provide isolation of the subsystem upon detection of high radiation.

The subsystem's safety function is supported by the PLS and ZOS.

The subsystem supports the RMS through the provision of radiation monitors in the extract ductwork and provides high radiation signals to the VFS filtered exhaust subsystem when high airborne radioactivity is detected in the VAS exhaust ducts or in the rooms served by the subsystem (using area monitors). The use of the exhaust radiation monitor and local area monitors to detect high levels of radiation ensures a rapid containment of the radiation (in less than 15 seconds).

23.8.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressure is structurally designed for fan shutoff pressures. Ductwork, supports and accessories meet the design and construction requirements of SMACNA Rectangular and Round Industrial Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standard – Metal and Flexible (Reference 23.15).

The following components make key contributions to the ability of the VAS to perform its safety function.

- **Passive Filtered Relief –** a passive damper is provided in the fuel handling building area to provide a path for steam during spent fuel pool boiling. The damper is constructed of stainless steel or suitable material and actuated by fusible links designed to melt and release the damper when the air temperature reaches 74°C (l65°F). HEPA filtration of the exhaust flow path is provided.

- **Supply and exhaust air fans and CVS and RNS pump room coolers** – The supply and exhaust air fans are centrifugal type, single-width single-inlet, or double-width double-inlet, with high-efficiency wheels and backward-inclined blades to produce nonoverloading characteristics. The fans are designed and rated in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

  The supply fans in the supply AHUs are required to operate to dilute any contamination maintaining the concentration below set limits, and to meet the cooling requirements of areas containing safety equipment not supplied with unit coolers, e.g., the SFS pump rooms and the VES air storage/operating deck staging area.

  The supply fans in the unit coolers are required to operate to meet the cooling requirements of areas containing safety equipment, i.e., the CVS makeup pump rooms and the RNS pump rooms.

  The exhaust fans are required to operate to control the spread of any potential contamination by maintaining appropriate depressions and to provide a constant airflow in the extract duct, which is monitored for radiation. They are also required to prevent the potential build-up of hydrogen gas in the radwaste effluent holdup tanks.

  The fans operate in response to signals from the PLS, which include flow rate, temperature, and shutoff damper positions.

  Detection of radiation in the exhaust ductwork will result in the exhaust fans being shut down and initiation of the VFS. Failure of the exhaust fans and an increase or decrease in differential pressure in the served areas will also isolate the VAS subsystem and initiate the VFS extract system. This is a safe condition; therefore, no further analysis is required for the exhaust fans (see Section 23.3 for justification of the VFS).

  The supply fans are designed to Class 3 as they are the principal means of generation of the required airflows which is a Category B safety function.

  The CVS and RNS Pump Room Coolers are designed to Class 3 as they are the principal means of maintaining the rooms within their design temperature range which is a Category C safety function.

- **Cooling coils** – The chilled water cooling coils are counterflow, finned tubular type. Each cooling coil is constructed with copper tubes and fins and a galvanised steel casing. Large cooling coil banks that are constructed from multiple cooling coils are provided with coil holding racks designed to allow each coil to be independently removed (side pull) from the housing. The cooling coils are designed and rated in accordance with ASHRAE 33 (Reference 23.23) and ANSI/ARI 410 (Reference 23.22). The cooling capacity of the coils includes a 15 percent margin. This 15-percent margin accounts for uncertainties in the calculated cooling loads, as detailed in the VAS system specification document (Reference 23.30, Section 5.1). Coils are designed to withstand a working pressure of 1.03 MPa (150 psig) at 93.3°C (200°F) and are leak tested with 2.07 MPa (300 psig) air under water (Reference 23.30, Section 5.1).

  The cooling coils in the auxiliary/annex building ventilation subsystem AHUs and unit coolers obtain a flow of cooling water through activation of the chilled water control valves in response to signals from the PLS. The cooling coils are designed to Class 3 as it is the principal means to permit the flow of cooling water through the copper tubes and maintain an adequate surface for heat transfer between the air and cooling water in order to meet air temperature control requirements for the Air Handling Units which is a Category B safety function.

- **Isolation dampers** – Isolation dampers are bubble-tight, single- or parallel-blade type. The isolation dampers have spring return actuators that fail closed on loss of electrical power or loss of air pressure. The isolation dampers are constructed, qualified, and tested in accordance with ANSI/AMCA Standard 500 (Reference 23.12).

  The isolation dampers are required to operate to prevent the unfiltered release of potentially contaminated air from the served areas to the environment.

  Actuation of the isolation dampers is via the PLS in response to signals such as high radiation, high/low pressure differential, or one of the VFS dampers opening. The isolation dampers are designed to Class 3 as it is the principal means of isolation of individual airflows which is a Category B safety function.

- **Fire dampers** – Fire dampers are provided at duct penetrations through fire barriers to maintain the fire resistance rating of the barriers. Additionally some VAS fire dampers are provided with position indication. The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blade when the air temperature reaches 74°C (165°F) (Reference 23.30, Section 5). The damper blades close via a spring mechanism. The fire dampers meet the design, testing, and installation requirements of UL 555 (Reference 23.18).

  The fire dampers are passive components operated by temperature and an internal spring mechanism. As such, no actuation signal is required.

  The fire damper rating will be at least equal to the fire barrier that they penetrate, up to a maximum UL 555 3-hour rating. This is essential to maintain the integrity of fire barriers discussed in the internal fire hazard section of Chapter 11 and the dampers are Category B Class 3 equipment.

- **HEPA filters –** HEPA filtration is located on the VAS subsystem serving the fuel handling area to capture potential airborne particulates containing radioactivity. HEPA filters are constructed, qualified, and tested in accordance with ANSI N509.

23.8.3 Claims on Components and Equipment

23.8.3.1 Passive Filtration

Although not credited in the dose analysis, the passive filtration flow path is designed to remove particulate material from steam generated during spent fuel pool boiling.

23.8.3.2 Supply Air Fans and CVS and RNS pump room coolers

The supply fans make a minor contribution to the containment of radioactive substances through diluting the concentration of contamination in the air. The more significant function is providing cooling to equipment important to the safety functions of other systems. The RNS, CVS, and SFS pumps and the VES air storage area are all supported by the VAS supply air fans.

Failure of the fans supplying the VES air storage area could potentially lead to an increase in temperature of the air storage tanks and consequently a reduction in the mass of air stored within them. However, unlike the pump rooms, there is no significant heat load in this area, and the supply fans would have to be inoperable for a prolonged period of time to have an effect on the stored mass of air. This time period would be sufficient for operator intervention.

Failure of the supply fans will only be an issue after at least 8 hours of operation and until that time will be certain not to prevent the RNS, CVS, and SFS from providing their safety functions. Table 8A-4 identifies the need for HVAC to support these systems functionality. The RNS pumps provide a Category A safety function and are Class 2 equipment (see Chapter 17), the CVS pumps provide a Category A safety function and are Class 2 equipment and the SFS pumps provide a Category A safety function and are Class 2 equipment (see Chapter 17).

- RNS pump room unit cooler fans – Category C safety function, Class 3
- CVS pump room unit cooler fans – Category C safety function, Class 3
- Auxiliary/annex building ventilation subsystem supply AHU fans (which support the SFS pumps) – Category B safety function, and are thus Class 3 equipment

One supply fan is installed in each supply AHU of the auxiliary/annex building ventilation subsystem. The subsystem makes provision for 2- x 50-percent supply AHUs. Therefore, it is claimed that both fans will continue to operate to meet the VAS safety functions. However, as maintenance will be required on the system, the VAS is designed such that:

- The radiation chemistry laboratory and security rooms are provided with sufficient ventilation that design room temperatures can be maintained while one 50-percent-capacity supply air subsystem is shut down for maintenance.
- The system provides sufficient ventilation airflow to plant areas enclosing Class 1 qualified CIVs so that the ambient design temperatures can be maintained while one 50-percent-capacity supply air subsystem is shut down for maintenance.
- The auxiliary/annex building and fuel handling area will be ventilated with two, 50-percent-capacity supply and exhaust air subsystems so that a single train may be

taken out of service while the operating train maintains a negative pressure differential and ALARP airflow directions.

It is desirable to perform routine maintenance of the fuel handling area building isolation dampers and radiation monitors while there are no refuelling activities so that VAS isolation capability is available during fuel handling activities.

It is desirable to perform routine maintenance of the auxiliary building isolation dampers and radiation monitors while the plant is in cold shutdown so that VAS isolation capability is available during normal plant operation, when the probability for an abnormal release of airborne radioactivity is greatest.

Isolation dampers located at the inlet to the exhaust fans are designed to be closed to isolate the equipment from the process flow during maintenance activities. The damper blades will be repositioned to their normal open position when restoring equipment operation.

One supply fan is installed in each unit cooler in the RNS pump rooms, and one unit cooler is located in each of the two RNS pump rooms. It is claimed that each unit cooler will start on demand to meet the cooling requirements of the associated RNS pump.

One supply fan is installed in each of the two unit coolers in the CVS pump room. The CVS pump room contains two CVS pumps, and only one pump is required to operate at any time. Therefore, it is claimed that one unit cooler fan will start on demand to meet the cooling requirements of the CVS pump.

23.8.3.3 Cooling Coils

As with the fans, the cooling coils provide the primary means of cooling the areas that contain safety equipment. The cooling coils should have the same classification as their associated fans. Therefore, the following equipment categorisation and classifications apply to the cooling coils in the VAS:

- RNS pump room unit cooler chilled water cooling coils – Category C safety function, Class 3
- CVS pump room unit cooler chilled water cooling coils – Category C safety function, Class 3
- Auxiliary/annex building ventilation subsystem supply AHU chilled water cooling coils – Category B safety function, and are thus Class 3 equipment

Each RNS pump room unit cooler includes two chilled water cooling coil banks: one supplied from train A of the chilled water system and the other supplied from train B. Only one cooling coil bank on each unit cooler is required to operate to meet the 100 percent cooling demand of the RNS pump associated with each unit cooler. Both pumps and therefore both unit coolers may operate at the same time.

Each unit cooler in the CVS pump room makes provision for a single cooling coil bank. One cooling coil bank is supplied by train A of the chilled water system and the other bank is supplied by train B. One unit cooler can meet 100 percent of the cooling demand from a CVS pump. Only one CVS pump is in operation at any time; therefore, it is claimed that one CVS pump room unit cooler and cooling coil bank will operate on demand.

Each auxiliary/annex building ventilation subsystem supply AHU makes provision for a single chilled water cooling coil bank. The AHUs are 2- x 50-percent duty; therefore, it is claimed that both AHUs and both cooling coil banks will operate to meet the cooling demand.

23.8.3.4 Isolation Dampers

The VAS isolation dampers operate to prevent an unfiltered release of contamination when high levels of radiation are detected in the extract duct. Failure of the isolation dampers will not result in a design basis accident (DBA); therefore, this is a Category B safety function, and the dampers are Class 3 equipment. See Appendix 15A.

Single isolation dampers are provided in the duct branches where isolation is required. It is claimed that the isolation dampers will close on demand.

23.8.3.5 Fire Dampers

Fire dampers are installed where ductwork passes through fire barriers.

The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. As the fire dampers provide a contribution to achieving this safety function they are deemed to be Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit.

23.8.3.6 HEPA Filters

HEPA filtration is located on the VAS subsystem serving the fuel handling area to capture potential airborne particulates containing radioactivity and thus are Category B Class 3 equipment.

23.8.4 Justification of Claims on Components and Equipment

23.8.4.1 Passive Filtered Filtration

The design of damper used in the VAS does not require any external power source or actuation signals. Actuation is achieved by heat from the air melting the fusible link and a gravity opening the damper. This provides a high degree of inherent safety and high reliability.

The flow path components are designed and manufactured to standards that are suitable for Class I equipment, but some components are Class 2.

At least on redundant path is provided to prevent impact from the failure of a single path. Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating similar dampers to give confidence that if they are adequately maintained they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.8.4.2 Supply Air Fans

The fan design includes backward-inclined blades to produce nonoverloading characteristics. This will prevent overpressurisation of the ventilation distribution system if a damper in the system closes. This is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

The highest classification of supply air fan in the VAS is Class 3. The supply fans are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

The fans are very similar to those already in service to provide the same function on many operating power stations. As a result, the information from testing these in service fans offers a high degree of confidence about the reliability to be expected from the fans proposed for the AP1000 design.

Conceivable failure modes for this type of fan include, for example, a failed bearing or failed drive belt. These types of mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of fan, designed and constructed to similar standards, to give confidence that if they are adequately maintained they will have a good reliability in service.

23.8.4.3 Cooling Coils

The highest classification of cooling coil in the VAS is Class 3. The coils are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Redundant cooling coils are included in the RNS pump room unit coolers and these are supplied from diverse trains of the chilled water system. Redundant unit coolers are provided in the CVS pump room, and the cooling coil in each unit cooler is supplied from diverse trains of the chilled water system. This redundancy and diversity provides further confidence that the cooling coils will be able to deliver the reliability required to ensure the VAS meets its safety functions.

Possible failure mechanisms include the following:

- Failure of the chilled water control valves. If the control valves on the unit coolers fail and the supply temperature start to rise, sensors will activate the redundant coil or unit cooler. If the valves fail on the cooling coils in one of the AHUs, the other AHU will continue to provide cooling. Depending on ambient temperatures, this may be sufficient to maintain the area temperatures within the design limits. If it is not, then a temperature rise in the served areas would be detected and allow operator intervention.

- Failure of the complete chilled water system. If chilled water is lost to both AHUs of the auxiliary/annex building ventilation subsystem, the AHU may not be capable of maintaining design indoor temperatures, based on the outdoor temperature. Operator intervention may be required.

  Chilled water is supplied to the unit coolers in the RNS and CVS pump rooms from redundant VWS trains. As such, loss of a single train should ensure that one CVS pump and the RNS pumps can be supported.

- Structural failure of the coils. The use of suitable design standards and appropriate in service maintenance is deemed sufficient to reduce the risk of structural failure of the cooling coils.

In addition, the RNS pump motors could operate for at least 8 hours without room cooling . This would provide sufficient time for operator intervention following total failure of cooling in that area.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of cooling coil to give confidence that if they are adequately maintained they will have a good reliability in service.

23.8.4.4 Isolation Dampers

The isolation dampers are designed such that they fail safe. The spring return pneumatic design ensures that a loss of electrical power or pneumatic air will cause the dampers to close, isolating the ductwork and preventing any unfiltered release of air from the supplied areas. This provides a high degree of inherent safety. Spurious operation of the isolation damper in the supply duct serving the auxiliary building will prohibit the flow of cooling air to the SFS pump rooms. This will raise an alarm in the MCR and allow operator intervention to occur before the pump room temperature rises to a level that would prevent operation of the SFS pumps. The probability of spurious failure is considered to be sufficiently low based on the design and maintenance requirements of the damper. In addition, diverse cooling is available to the SFP via the RNS pumps, which are not affected by spurious operation of an isolation damper.

The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment. The dampers are of a low leakage design to minimise the passing of any air when the dampers are shut. This in turn prevents leakage of contamination from the area when the VAS is isolated.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained they will not seize or jam and will move to the closed position if demanded.

23.8.4.5 Fire Dampers

The design of fire damper used in the VAS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and a spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. The fire load in the areas served by VAS will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are

adequately maintained they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.8.4.6 HEPA Filters

HEPA filters are passive components. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards. There is a large amount of experience in using HEPA filters designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety functions. HEPA filter damage could occur during installation. However, in situ penetration testing is to be carried out after every filter change to demonstrate that the filter is achieving the correct efficiency.

The claimed efficiencies will be demonstrated through periodic testing under the ventilation filter testing programme.

23.9 RADWASTE BUILDING HEATING, VENTILATION, AND AIR CONDITIONING SYSTEM

23.9.1 Role

The VRS contributes to the containment primary safety function by controlling the spread of airborne contamination within the radwaste building and preventing the unmonitored release of potentially contaminated air. The VRS provides cooling to a number of processes in the radwaste building, but if the ventilation system is unavailable, the processes can be suspended. This does not impact on safe operation of the plant; therefore, cooling is not considered a safety function of the VRS.

The VRS is a once-through ventilation system that consists of two integrated subsystems: the radwaste building supply air system and the radwaste building exhaust air system.

The VRS makes provision for two 50-percent-capacity supply AHUs and two 50-percent-capacity exhaust fans. A radiation monitor is included in the exhaust duct to detect radioactivity. Exhaust connection points are provided to allow the direct exhaust of equipment located on the mobile systems. Mobile systems are where potential for significant airborne release exists; mobile systems include HEPA filtration. Backdraft dampers are provided at each mobile system connection to prevent blowback through the equipment in the event of exhaust system trip.

If a single component in either one of the supply AHUs or an exhaust fan is inoperable due to maintenance, failure, or repair, the VRS can operate with one supply AHU in conjunction with its associated exhaust fan, reducing the overall system capacity to 50 percent. In this mode of operation, airflow directions and building negative pressure still can be maintained. However, design indoor temperature may or may not be maintained within limits depending on the levels of radwaste process activities taking place and the outdoor conditions at the time.

The VRS operates continuously. It is recommended that filter replacement or other routine maintenance activities that require VRS components to be shut down be scheduled when radwaste activities are not required. Maintenance on unit heaters should be performed during warm weather. This will minimise temperature transients that will occur when VRS equipment is temporarily shut down for maintenance.

There is a low risk of airborne contamination being present within the radwaste building. HEPA filters are provided in the radwaste building exhaust system. Upon detection of radiation in the extract duct the operator in the MCR is alerted and can take appropriate action, such as sending maintenance personnel to investigate and shutting down the VRS.

Fire dampers are provided at duct penetrations through fire barriers to maintain the fire resistance ratings of the barriers.

The VRS is supported by the PLS for control functions and the FPS, which trips fans in the VRS on detection of fire in the served areas.

The VRS supports the RMS through the provision of radiation monitors in the exhaust ductwork and supports processes carried out by the gaseous and solid radwaste systems.

Further design details of this system and its constituent components are delineated in Reference 23.31. This system is also discussed in Chapter 6.

23.9.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressures is structurally designed to accommodate fan shutoff pressures. Ductwork, supports, and accessories meet the design and construction requirements of SMACNA Industrial Rectangular and Round Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15).

Multi-blade, two-position remotely operated shutoff dampers are parallel-blade type. Multi-blade, control and balancing dampers are opposed-blade type. AHU and fan shutoff dampers are designed for maximum fan static pressure at shutoff flow. Dampers meet the performance requirements of ANSI/AMCA Standard 500 (Reference 23.12).

The following components make key contributions to the ability of the VRS to perform its safety function.

- **Radwaste building exhaust radiation package –** Provides radiation monitoring of all potentially contaminated exhaust air prior to release to the plant vent. This monitoring is a Category C Class 3 function.

- **Fire dampers** – Fire dampers are provided at duct penetrations through fire barriers to maintain the fire resistance rating of the barriers. The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blades when the air temperature reaches 74°C (165°F), as detailed in the VRS system specification document (Reference 23.31, Section 5.2.1.3). The fire damper design has parallel blades and uses a spring mechanism to close. The fire dampers meet the design, testing, and installation requirements of UL555 (Reference 23.18).

- **HEPA filters** – HEPA filters are provided in the VRS extract. The filters provide protection to minimise particulate releases. The filters remove 99.97% of all particles 0.3 microns in diameter from the exhaust.

  A pressure differential sensor is installed across the HEPA filter to measure the pressure drop across it as an indication of its performance. Upon detection of a high pressure drop across the HEPA filter, an indicator and alarm are activated. They are designed per ANSI N509.

The fire damper rating will be at least equal to the fire barrier that they penetrate, up to a maximum UL 555 3-hour rating. Fire dampers are passive components operated by temperature and a spring mechanism. As such, no actuation signal is required. The fire dampers are essential to maintain the integrity of fire barriers discussed in the internal fire hazard section in Chapter 11. These fire dampers are Category B Class 3 equipment.

23.9.3 Claims on Components and Equipment

23.9.3.1 Fire Dampers

Fire dampers are installed where ductwork passes through fire barriers.

The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. See Appendix 15A. As the fire dampers assist in achieving this safety function, they are deemed to be Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit and maintain the integrity of the fire barrier.

23.9.3.2 High-Efficiency Particulate Air Filters

HEPA filters are passive components with a high degree of inherent safety. They will meet their claimed efficiency through being constructed, qualified and tested in accordance with appropriate standards (detailed in Section 23.3.2 above). There is a large amount of experience in using HEPA filters designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety function.

A particle penetration of the HEPA filter unit (including through any bypass routes) that is greater than the design limit will be detected by the radiation sensor downstream of the filter bank. This would enable operator action to take place, such as shutting down the exhaust filtration system.

The claimed efficiency of the HEPA filters will be demonstrated in situ upon installation of a new filter and through periodic testing.

The HEPA filters in the VRS minimise the radiation released to the environment during operation. As such, the HEPA filters provide a Category B safety function. Failure of either the HEPA filters will result in the potential for a release of contamination and radioactivity to the environment. The HEPA filters provide a contribution to the VRS's primary safety function and are Class 3 equipment. See Appendix 15A.

23.9.4 Justification of Claims on Components and Equipment

23.9.4.1 High-Efficiency Particulate Air Filters

HEPA filters are passive components. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.7.2). There is a large amount of experience in using HEPA filters designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety functions.

HEPA filter damage could occur during installation. However, in situ penetration testing is to be carried out after every filter change to demonstrate that the filter is achieving the correct efficiency.

The claimed efficiencies will be demonstrated through periodic testing under the ventilation filter testing programme.

23.9.4.2 Fire Dampers

The design of fire damper used in the VRS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and a spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. The fire load in the radwaste building will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire dampers in the system is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Category B Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.10 HEALTH PHYSICS AND HOT MACHINE SHOP HEATING, VENTILATION, AND AIR CONDITIONING SYSTEM

23.10.1 Role

The safety function of the VHS in support of the containment of radioactive substances is to control the spread of airborne contamination within the served areas and provide for radiation monitoring of the exhaust air prior to discharge. The VHS is designed to operate continuously.

The areas served by the VHS are the annex building stairwell, personnel decontamination area, frisking and monitoring facilities, containment access corridor, health physics facility, and hot machine shop in the annex building.

The plant design makes provision for two 100-percent-supply AHUs and two 100-percent-centrifugal exhaust fans. An additional exhaust fan and HEPA filter provide extract from machine tools and other localised areas in the hot machine shop. Radiation monitoring is installed in the exhaust ductwork.

The VHS is capable of maintaining a negative pressure in the health physics/controlled access area and hot machine shop with one active component out of service for maintenance or repair.

There is a low risk of airborne contamination being present within the areas served by the VHS. Upon detection of high radiation levels the VHS subsystem is isolated, and the VFS is initiated to provide a charcoal and HEPA filtered extract route from the area. The use of the exhaust radiation monitor and local area monitors to detect high levels of radiation ensures a rapid containment of the radiation (in less than 15 seconds).

The airflow pattern is controlled to minimise the spread of airborne contamination. Signals from differential pressure sensors in the served rooms modulate control dampers in the supply system to maintain an appropriate depression. The differential pressure sensor in the health physics area modulates the inlet vane dampers of the supply fans and the sensor in the hot machine shop modulates the control damper in the supply line to that area (VHS-MD-D008).

Low flow signals from the PLS for either the supply or extract fan will trip both the operating supply and extract fans. In addition, control signals from the PLS will close the outside air inlet damper of the operating AHU, the supply isolation damper and the extract isolation damper.

The VHS supports the RMS through the provision of the radiation monitor in the exhaust ductwork and is supported by the PLS through the control of the differential pressure in the served areas and the fan and damper controls.

Further design details of this system and its constituent components are delineated in Reference 23.45. This system is also discussed in Chapter 6.

23.10.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressure is structurally designed for fan shutoff pressures. Ductwork, supports, and accessories meet the design and construction requirements of SMACNA Rectangular and Round Industrial Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15).

The following components provide contributions to the ability of the VHS to perform its function.

- **Annex building exhaust radiation package –** Provides radiation monitoring of all potentially contaminated exhaust air prior to release to the plant vent. This monitoring is a Category C Class 3 function.

- **Fire dampers** – Fire dampers are provided at duct penetrations through fire barriers to maintain the fire resistance rating of the barriers. The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blades when the air temperature reaches 74°C (165°F). The fire damper design has parallel blades and uses a spring mechanism to close. The fire dampers meet the design, testing, and installation requirements of UL555 (Reference 23.18).

- **HEPA filters** – HEPA filters are provided in the VHS extract from individual machine tools. The filters provide protection to minimise particulate releases. The filters remove 99.97 percent of all particles 0.3 microns in diameter from the exhaust. They are designed in accordance with ANSI N509.

  A pressure differential sensor is installed across the HEPA filter to measure the pressure drop across it as an indication of its performance. Upon detection of a high-pressure drop

across the HEPA filter, an indicator and alarm are activated.

- **Shutoff dampers** – These are low leakage, gasket, parallel-blade dampers with manual manipulation devices to verify proper operability of the dampers and to manipulate the blade from its fail safe closed position. The shutoff damper actuators are of the spring return pneumatic type complete with solenoid valves that close the damper when there is a loss of pneumatic air or electrical power. The dampers meet the performance requirements of ANSI/AMCA Standard 500 [Reference 23.12]. The outside air inlet dampers of the AHUs, the supply isolation dampers, and the extract isolation dampers are of this type and act to isolate the supply and extract line upon failure of the operating system. The control signal comes from the PLS. Isolation of air supplies is does not contribute to maintaining nuclear safety as determined by the safety case and are thus classified as general non-safety (GNS).

23.10.3 Claims on Components and Equipment

Components and equipment in the VHS control and monitor the level of radioactivity released to the environment. As such, they provide a contribution to nuclear safety, but failure to maintain the safety function does not have the potential to result in a DBA.

23.10.3.1 Fire Dampers

Fire dampers are installed where ductwork passes through fire barriers. The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. See Appendix 15A. Because the fire dampers assist in achieving this safety function, they are deemed to be Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit and will maintain the integrity of the fire barrier.

23.10.3.2 High-Efficiency Particulate Air Filters

HEPA filters are passive components with a high degree of inherent safety. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.3.2 above). There is a large amount of experience with using HEPA filters designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety function.

A particle penetration of the HEPA filter unit (including through any bypass routes) that is greater than the design limit will be detected by the radiation sensor downstream of the filter bank. This would enable operator action, such as shutting down the exhaust filtration system, to take place.

The claimed efficiency of the HEPA filters will be demonstrated in situ upon installation of a new filter and through periodic testing.

The HEPA filters in the VHS minimise the radiation released to the environment during operation. As such, the HEPA filters provide a Category B safety function. Failure of either the HEPA filters will result in the potential for a release of contamination and radioactivity to

the environment. The HEPA filters provide a contribution to the VHS's primary safety function and are Category B Class 3 equipment. See Appendix 15A.

23.10.3.3 Shutoff Dampers

Operation of the shutoff dampers provides a non-safety function.

It is claimed that they will close on demand from the PLS to prevent an unmonitored release of air from the supplied areas when the VHS has failed. If they do not close, the VFS will still be capable of maintaining a negative pressure in the VHS area.

23.10.4 Justification of Claims on Components and Equipment

23.10.4.1 High-Efficiency Particulate Air Filters and Charcoal Adsorbers

HEPA filters are passive components. They will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.7.2). There is a large amount of experience in using HEPA filters designed to these codes in operating nuclear power stations around the world, which gives confidence in their ability to meet their safety function.

HEPA filter damage could occur during installation. However, in situ penetration testing is to be carried out after every filter change to demonstrate that the filter is achieving the correct efficiency.

The claimed efficiencies will be demonstrated through periodic testing under the ventilation filter testing programme.

23.10.4.2 Fire Dampers

The design of fire damper used in the VHS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and a spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. The fire load in the radwaste building will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire dampers in the system is Category B Class 3. The dampers are to be designed and manufactured to normal industrial standards suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper were to seize or jam in the open position.

Maintenance will be performed in line with the manufacturer's information. The extensive experience of operating this type of damper gives confidence that if adequately maintained, they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.10.4.3 Shutoff Dampers

The shutoff dampers are designed such that they fail to safety. The spring return pneumatic design ensures that a loss of electrical power or pneumatic air will cause the dampers to close, isolating the ductwork and preventing any unmonitored release of air from the supplied areas. This provides a high degree of inherent safety. If they do not close, and there is a radioactive release, the VFS will actuate to maintain a negative pressure in the VHS area, even if the dampers fail to close.

The shutoff dampers are to be designed to normal industrial standards. The dampers are of a low leakage design to minimise the passing of any air when the dampers are shut. This in turn prevents leakage of contamination from the area when the VHS is isolated.

Periodic inspection of the dampers will be undertaken to ensure that they have not seized or jammed and maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained they will not seize or jam and will move to the closed position if demanded.

23.11 NUCLEAR ISLAND NONRADIOACTIVE VENTILATION SYSTEM

23.11.1 Role

The VBS contributes to the containment primary safety function and provides support to other safety systems. The VBS consists of the following three subsystems:

- MCR/control support area (CSA), HVAC
- Essential electrical system equipment room, remote shutdown room (RSR) HVAC
- PCS valve room heating and ventilation

If complete ac power is lost, in the post-72-hour period, division B and C C&I room temperature is maintained by operating their respective ancillary fans to supply outside air to the C&I rooms. The air flow rate design basis is to maintain the C&I rooms below the qualification temperature of the C&I equipment (below 48.8°C (120°F)). Loss of normal HVAC is discussed in Chapter 8.

If complete ac power is lost, in the post-72-hour period, MCR habitability is maintained by operating one of the two MCR ancillary fans to supply outside air to the MCR.

Further design details of this system and its constituent components are delineated in Reference 23.33 and Chapter 6.

23.11.1.1 Main Control Room/Control Support Area Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the MCR/CSA HVAC subsystem is to contribute to maintaining the MCR environment in a habitable condition. This is achieved through monitoring the MCR supply air for radioactive particles and iodine concentrations and maintaining the space at a positive pressure to prevent unmonitored infiltration of air. The subsystem isolates the HVAC penetrations upon detection of high-high particulate or iodine concentrations in the MCR supply air or upon loss of ac power for more than 10 minutes or low MCR differential pressure with respect to the surrounding rooms for 10 minutes. This supports the function of the VES described in Chapter 6. In addition, the MCR/CSA HVAC subsystem provides a

defence in depth safety function through the filtration of MCR/CSA air during conditions of high airborne radioactivity in the supply air. The subsystem maintains the VES passive cooling heat sink below its initial design temperature and can operate in a recirculation mode when smoke is detected outside or provide smoke removal capabilities from the supplied areas.

The MCR/CSA HVAC subsystem makes provision for two 100-percent-capacity supply AHUs, return/exhaust air fans, supplemental air filtration units, associated dampers, C&I, and common ductwork. The supply AHUs and return/exhaust air fans are connected to common ductwork, which distributes air to the MCR and CSA areas. Each supplemental air filtration unit includes a supply fan, HEPA filter bank, and charcoal adsorber. Ancillary fans provide post-72-hour ventilation to the MCR and C&I rooms.

The MCR pressure boundary penetrations include isolation valves and isolation dampers. These are provided to isolate the normal outside air intake such that the outside air passes through the supplemental air filtration. Combination fire/smoke dampers are provided at duct penetrations through fire barriers to maintain the fire resistance ratings of the barriers and prevent the migration of smoke.

Stairwell pressurisation fans are provided where required to prevent smoke from entering stairwells during a fire.

The subsystem is supported by the PMS for MCR pressure boundary isolation and actuation of supplemental air filtration and the PLS for other control functions, the FPS for activation signals to the fire/smoke dampers, the VWS to supply the AHU cooling coils, and the ZOS for the standby power supply.

The MCR/CSA HVAC subsystem supports the FPS through the provision of smoke detection and deluge connections on the supplemental filtration units, the RMS through the provision of radiation monitors and the VES through the maintenance of the MCR passive heat sink initial design temperature and isolation of the MCR pressure boundary.

23.11.1.2 Essential Electrical System Equipment Room Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the essential electrical system equipment room HVAC subsystem is to maintain the essential electrical system equipment room passive cooling heat sink below its initial design ambient air temperature limit and provide post-72-hour cooling to the room. It is also required to exhaust air from the essential electrical system battery rooms to prevent the buildup of hydrogen gas and provide smoke removal capabilities from the essential electrical system equipment rooms and battery rooms.

The A and C electrical divisions, spare battery room, and reactor coolant pump trip switchgear rooms are served by one ventilation subsystem; the B and D electrical divisions and remote shutdown room are served by a second ventilation subsystem. Each subsystem makes provision for two 100-percent-supply AHUs that include both supply and return/exhaust fans and a chilled water cooling coil bank. Ancillary fans provide post-72-hour ventilation to the division B and C C&I room. Each subsystem for the essential electrical system battery rooms is provided with two 100-percent-capacity exhaust fans. Combination fire/smoke dampers are provided for essential electrical system equipment rooms, including the remote shutdown room, to isolate each fire area and block the migration of smoke and hot gases to or from adjacent fire areas.

The subsystem is supported by the PLS for control functions, the FPS for activation signals to the fire/smoke dampers, the VWS to supply the AHU cooling coils and the ZOS.

The main essential electrical system room HVAC subsystem supports the FPS through the provision of smoke detection. It also supports the essential electrical supply system (IDS) through the provision of battery room and electrical equipment room ventilation.

23.11.1.3 Passive Containment Cooling System Valve Room Heating and Ventilation Subsystem

The safety function of the PCS valve room heating and ventilation subsystem is to maintain the temperature of the valve room within predefined limits.

The subsystem includes one 100-percent-ventilation fan, two 100-percent-capacity electric unit heaters, and an air intake louver damper. The PCS valve room is not expected to exceed its upper temperature limit based on maximum ambient conditions and internal heat sources. Therefore, the ventilation fan does not provide a safety function.

The subsystem is supported by the PLS and ZOS.

The PCS valve room heating and ventilation subsystem supports the PCS through maintaining the PCS valve room temperature within pre-defined limits.

23.11.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressures is structurally designed to accommodate fan shutoff pressures. Ductwork, supports, and accessories meet the design and construction requirements of SMACNA Industrial Rectangular and Round Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15). The MCR/CSA HVAC subsystem's ductwork, including the air filtration units and the portion of the ductwork located outside of the MCR envelope that maintains the integrity of the MCR/CSA pressure boundary, are designed in accordance with ASME AG-1 (Reference 23.6, Article SA-4500). This ensures the ductwork is of a low leakage construction to maintain MCR/CSA habitability.

The ancillary fans provide post 72-hour cooling to the MCR and Division B and C C&I rooms with power from the ancillary diesel generators. They are centrifugal type with nonoverloading characteristics. Each can provide a minimum of 2718 m^3/hr (1600 cfm). The fans are designed and rated in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

Multi-blade, two-position remotely operated shut off dampers are parallel-blade type. Multi-blade, balancing dampers are opposed-blade type. AHU and fan shutoff dampers are designed for maximum fan static pressure at shutoff flow and meet the performance requirements in accordance with ANSI/AMCA Standard 500 (Reference 23.12). The supplemental air filtration subsystem dampers are constructed, qualified, and tested in accordance with ANSI/AMCA Standard 500 or ASME AG-1 (Reference 23.6, Section DA).

The following components make key contributions to the ability of the VBS to perform its safety function.

- **Air handling units supply and return/exhaust fans** – These are centrifugal type, single-width single-inlet or double-width double-inlet, with high-efficiency wheels and backward-inclined blades to produce nonoverloading characteristics. The fans are

designed and rated in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

The supplemental air filtration unit fans are provided with fan shaft seals to reduce external leakage as identified in the VBS system specification document (Reference 23.33, Section 5.1.2.1). This is to be done in accordance with requirements of the Utility Requirements Document (URD) (Reference 23.34, Chapter 9, Paragraph 8.2.1.1.13) and Information Notice 93-06[2] regarding potential bypass leakage paths in ventilation systems (Reference 23.35).

The essential electrical system battery room exhaust fans are of a spark proof design.

The supply and return/exhaust air fans in the MCR/CSA HVAC subsystem AHUs are required to operate to provide cooling to the MCR passive heat sink.

The supplemental air filtration unit fans are required to operate to provide the MCR/CSA with filtered air and prevent the ingress of unfiltered air.

The supply and return/exhaust air fans in the essential electrical system equipment room HVAC subsystem AHUs are required to operate to provide cooling to the essential electrical system equipment room emergency passive heat sink.

The essential electrical system battery room exhaust fans are required to operate to prevent the build-up of hydrogen in the battery rooms.

The fans all operate in response to signals from the PLS that include flow rate, temperature, and shutoff damper positions.

The Battery Exhaust Fans are designed to Class 2 as they are the principal means of proper airflow in the battery rooms to prevent hydrogen accumulation above the design limit during battery charging which is a Category B safety function.

The MCR/CSA Supplemental Air Filtration Units are designed to Class 2 as they are the principal means to provide supplementary ventilation function to preserve the habitability of MCR/CSA which is a Category A safety function.

The Other Air Handling Units are designed to Class 2 as they are the principal means to maintain design temperatures in the Class 1 electrical and C&I rooms which is a Category A safety function.

- **HEPA filters and charcoal adsorbers** – HEPA filters are constructed, qualified, and tested in accordance with UL 586 (Reference 23.28) and ASME AG-1 (Reference 23.6, Section FC). Each HEPA filter cell is individually shop tested to verify an efficiency of at least 99.97 percent using a monodisperse 0.3-micron aerosol in accordance with ASME AG-1 (Reference 23.6, Section TA). The HEPA filters in the supplemental air filtration units work to remove particulate from the outside supply air to reduce potential control room dose during high radiation levels. They also filter a proportion of recirculation air from the served areas. This is a Class 2 safety requirement.

2. Information Notice 93-06 represents good industry practice to prevent potential bypass leakage paths in ventilation systems and is therefore applicable to UK power stations.

Each charcoal adsorber is designed constructed, qualified, and tested in accordance with ASME AG-1 (Reference 23.6, Section FE) and Regulatory Guide 1.140 (Reference 23.7). Each charcoal adsorber is a single assembly with welded construction and 102 mm (4 inch) deep Type III rechargeable adsorber cell, conforming to IE Bulletin 80-03 (Ref. 23.8). Reference 23.7 indicates that a charcoal adsorber of this type should have a decontamination efficiency of 99 percent using an appropriate test methodology. The charcoal adsorbers in the supplemental air filtration units work to remove radiation from the outside supply air to reduce potential control room dose during high radiation levels. They also treat a proportion of recirculation air from the served areas. This is a Class 2 safety requirement.e HEPA filters and charcoal adsorbers are designed to Class 2 as they are the principal means to provide supplementary ventilation function to preserve the habitability of MCR/CSA which is a Category A safety function.

- **Electric unit heaters** – The electric unit heaters are forced-air, finned-tubular type, factory assembled, integral package units with single-stage or two-stage heating. Electric unit heater casings will be constructed of heavy gauge steel with a fan section and electric heating coil section. The electric unit heaters are UL-listed and meet the requirements of UL 1996 (Reference 23.36) and the National Electrical Code (Reference 23.37).

  The electric unit heaters operate in response to temperature signals from the PLS to maintain the temperature in the PCS valve room above the predefined lower limit in order to support valve operation. The PCS Room Heaters are designed to Class 3 as they are the principal means to maintain the temperature of the PCS valve room above freezing during normal operation which is a Category C safety function.

- **Cooling coils** – The chilled water cooling coils are counterflow, finned-tubular type. Each cooling coil is constructed with copper tubes and fins. Large cooling coil banks that are constructed from multiple cooling coils are provided with coil holding racks designed to allow each coil to be independently removed (side pull) from the housing. The cooling coils are designed and rated in accordance with ASHRAE 33 (Reference 23.23) and ANSI/ARI 410 (Reference 23.22). The cooling capacity of the coils includes a 15 percent margin. Coils are designed to withstand a working pressure of 1.03 MPa (150 psig) at 7.2°C (45°F) and leak tested with 2.07 MPa (300 psig) of air under water (Reference 23.33, Section 5.1.1.4.2).

  The cooling coils obtain a flow of cooling water through activation of the chilled water control valves in response to signals from the PLS. The cooling coils are designed to Class 2 as they are the principal means to permit the flow of cooling water through the copper tubes and maintain an adequate surface for heat transfer between the air and cooling water in order to meet air temperature control requirements which is a Category A safety function.

- **Isolation valves** – The MCR envelope isolation valves are rotary, double-seat, butterfly valves. The valves are designed to ASME Code, Section III, Class 3, and Seismic C-I (References 23.4 and 23.33, Appendix F2). The valve actuators are motor operated. The actuators are two-position type and fail in place upon electrical and control power failures. The actuators are designed to provide at least 1.5 times the torque required to meet the specific dynamic requirements and leakage rates. The actuators are designed with position switches to verify proper operation of the valves and manual manipulation devices to move the valve position, if necessary. The allowable leakage rate of the

isolation valves meets the testing and performance requirements of the Manufacturers Standardisation Society (MSS) SP-61 (References 23.38 and 23.33, Section 5.2.1).

The valves are required to operate to maintain the low leak rate integrity of the MCR envelope when the MCR emergency habitability system is operating. The valves operate in response to manual actuation signals from the PLS or automatic signals from the PMS. These MCR Isolation Valves are designed to Class 1 as they are the principal means for MCR isolation which is a Category A safety function.

- **Isolation dampers** – Isolation dampers are bubble-tight, single- or parallel-blade type. The isolation dampers have spring return actuators that fail closed on loss of electrical or control power. The isolation dampers are constructed, qualified and tested in accordance with ANSI/AMCA Standard 500 (Reference 23.12) or ASME AG-1 (Reference 23.6, Section DA).

  The isolation dampers are required to operate in response to signals from the PLS to prevent the infiltration of unfiltered supply air into the MCR/CSA AHU when high radiation has been detected. These Isolation Dampers are designed to Class 2 as they are the principal means for MCR/CSA isolation which is a Category A safety function.

- **Combination fire/smoke dampers** – Combination fire/smoke dampers are all galvanised construction, low leakage with parallel blades, suitable for vertical or horizontal mounting, and listed for dynamic closure. Damper blades are designed to close against the subsystem pressure and flow condition at the duct section in which they are located. The fire damper frame is continuously welded into a galvanised steel sleeve to minimise air leakage when the damper is closed. Combination fire/smoke dampers meet the requirements of UL 555 (Reference 23.18) and UL 555S (Reference 23.39) and bear a UL label. UL 555S is suitable for leakage rated dampers for use in smoke control systems. The fire rating of the combination fire/smoke damper is at least equal to the fire barrier that it protects, up to a maximum of three hours. The combination fire/smoke dampers are installed in accordance with the manufacturer's recommendations (Reference 23.33, Section 5.2.6). The fire/smoke damper closes under the action of a spring mechanism. The design includes a hold-open actuator, which releases and closes the damper in response to a control signal to prevent smoke migration.

  The combination fire/smoke dampers are required to operate to maintain the integrity of a fire barrier within which they are located and prevent the spread of smoke to other fire compartments. They respond to either the air temperature in the duct where no actuation signal is required or a smoke detection signal via the PLS. These combination fire/smoke dampers are Category A Class 2 equipment.

- **Ancillary fan –** Reduces the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident. The ancillary fans provide ventilation beginning 72 hours after an accident. They are required to operate to provide cooling to essential equipment. They are designed to meet the requirements of ANSI/AMCA standards.

- **VBS radiation package –** VBS contains two skid mounted MCR radiation monitoring packages consisting of radiation detectors, local radiation processors, and sampling components to continuously measure and record the radioactive materials in the MCR main supply air duct and actuate VBS supplemental air filtration and VES operation. They are designed to meet the requirements of applicable manufacturing standards and are seismic C-I.

23.11.3 Claims on Components and Equipment

23.11.3.1 Supply and Return/Exhaust Air Fans

- The supply and return/exhaust air fans in the MCR/CSA HVAC subsystem AHUs and the supplemental air filtration unit fans maintain the MCR habitability, and as such provide a Category A safety function. See Appendix 15A. They provide a defence in depth function as the primary system to maintain the MCR habitability is the VES. Therefore, the fans are Category A Class 2 equipment. See Appendix 15A.

  There are two 100-percent-capacity AHUs in the MCR/CSA HVAC subsystem with one supply and one return/exhaust air fan in each AHU. It is claimed that the fans in one of the AHUs will start on demand and continue to operate to provide cooling to the MCR passive heat sink and supply recirculation air to the supplemental air filtration units.

  There are two supplemental air filtration unit fans, and it is claimed that at least one of the fans will start on demand to supply the MCR/CSA with filtered air preventing the infiltration of potentially contaminated air. It is also claimed that they will recirculate air from the MCR/CSA through the filtration units.

- The essential electrical system battery room exhaust fans, in the essential electrical system equipment room HVAC subsystems, prevent the build-up of hydrogen in the battery rooms, which would directly and inevitably result in loss of other Category A safety functions. As such, the battery room exhaust fans provide a Category B safety function. See Appendix 15A. Hydrogen detectors in the battery rooms provide additional protection against hydrogen build-up. Also, the volume of air in the battery rooms effectively provides a delay between the failure of the exhaust fans and the hazard developing. The essential electrical system equipment room emergency passive heat sink controls the battery room temperature ensure that the batteries maintain their design capacity. The exhaust fans provide a significant contribution to preventing the build-up of hydrogen and are therefore Category B Class 3 equipment.

  There are two 100-percent-capacity essential electrical system battery room exhaust fans in each subsystem, and it is claimed that one fan from each battery room will start and continue to operate to prevent the build-up of hydrogen in the battery rooms.

- The supply and return/exhaust air fans in the essential electrical system equipment room HVAC subsystem AHUs support the essential electrical system equipment, including supplying the essential electrical system battery rooms. Failure of the ventilation system will not inevitably lead to the loss of the essential electrical system equipment room emergency passive heat sinks. Temperature sensors in the essential electrical system equipment rooms would alert MCR personnel if the room temperatures started to rise and allow them to take appropriate action to ensure that the passive heat sink temperatures did not rise above a predefined limit. The ancillary fans support the Category A safety functions provided by the essential electrical system equipment after 72 hours following an accident, and that is a Category B safety function. See Appendix 15A.The fans in the AHUs are required to operate to ventilate the battery rooms and failure of the supply will start the standby air handling unit fans. The fans in the AHUs should be of the same categorisation as the exhaust fans. Therefore, the supply and return/exhaust air fans in the essential electrical system equipment room HVAC subsystem AHUs provide a Category A safety function. See Appendix 15A. The fans provide a significant contribution to nuclear safety and are Class 2 equipment. See Appendix 15A.

There are two 100-percent-capacity AHUs in each essential electrical system equipment room HVAC subsystem with one supply and one return/exhaust air fan in each AHU. The fans in one of the AHUs in each subsystem are required to start on demand and continue to operate to provide cooling to the essential electrical system equipment rooms and ventilation to the battery rooms.

23.11.3.2 High-Efficiency Particulate Air Filters and Charcoal Adsorbers

HEPA filters and charcoal adsorbers in the MCR/CSA HVAC subsystem maintain the MCR habitability and as such provide a Category A safety function. See Appendix 15A. They provide a defence in depth function, as the primary system to maintain the MCR habitability is the VES. Therefore, the HEPA filters and charcoal adsorbers are Category A Class 2 equipment. See Appendix 15A.

There are two 100-percent-capacity supplemental air filtration units each containing a HEPA filter bank and charcoal adsorber. Only one unit is required to operate.

It is claimed that the HEPA filter banks and charcoal adsorbers will filter the supply and recirculation air to maintain the atmosphere in the MCR below pre-defined radiation limits.

23.11.3.3 Electric Unit Heaters

The electric unit heaters in the PCS valve room heating and ventilation subsystem support the PCS valves by ensuring that the temperature does not fall below a pre-determined limit. However, failure of the heaters will not inevitably lead to the loss of function of the PCS valves. Temperature sensors in the PCS valve room would alert MCR personnel if the room temperature started to fall below pre-set limits and allow them to take appropriate action to ensure the room temperature did not compromise PCS valve function. Failure of the electric unit heaters may reduce safety margins but would not lead to a DBA; therefore, the heaters provide a Category C safety function. See Appendix 15A. The electric unit heaters provide a minor contribution to nuclear safety and are Class 3 equipment. See Appendix 15A.

There are two 100-percent-capacity electric unit heaters, and it is claimed that one will start on demand to maintain the temperature in the PCS valve room.

23.11.3.4 Cooling Coils

The cooling coils in the MCR/CSA HVAC subsystem AHUs maintain the temperature in the MCR. Failure of the ventilation system will not inevitably lead to the loss of the MCR passive heat sink. Temperature sensors in the MCR would alert personnel if the room temperature started to rise and allow them to take appropriate action to ensure that the passive heat sink temperature did not rise above a predefined limit. The cooling coils support the Category A safety function of maintaining MCR habitability after 72 hours following an accident. They also function to maintain the room temperature at or below the set point temperature to support the VES. It is therefore concluded that the cooling coils in the MCR/CSA HVAC subsystem AHUs provide a Category A safety function. See Appendix 15A. The cooling coils provide a significant contribution to nuclear safety and are Class 2 equipment. See Appendix 15A.

There are two 100-percent-capacity AHUs in the MCR/CSA HVAC subsystem, with one cooling coil bank in each AHU. It is claimed that the cooling coil in one of the AHUs will continue to operate to provide cooling to the MCR passive heat sink.

The cooling coils in the essential electrical system equipment room HVAC subsystem AHUs support the essential electrical system equipment. Failure of the ventilation system will not inevitably lead to the loss of the essential electrical system equipment room emergency passive heat sinks. Temperature sensors in the essential electrical system equipment rooms would alert MCR personnel if the room temperatures started to rise and allow them to take appropriate action to ensure the passive heat sink temperatures did not rise above a predefined limit. It is therefore concluded that the cooling coils in the essential electrical system equipment room HVAC subsystem AHUs provide a Category A safety function. See Appendix 15A. The cooling coils provide a contribution to nuclear safety and are Class 2 equipment. See Appendix 15A.

There are two 100-percent-capacity AHUs in each essential electrical system equipment room HVAC subsystem, with one cooling coil bank in each AHU. It is claimed that the cooling coils in one of the AHUs will continue to operate to provide cooling to the essential electrical system equipment rooms.

23.11.3.5 Isolation Valves

The isolation valves in the MCR/CSA HVAC subsystem supply and extract ductwork close upon activation of the VES. They maintain the habitability of the MCR by preventing the ingress of potentially contaminated air into the MCR. This is a Category A safety function. See Appendix 15A. The isolation valves provide the principal means of ensuring the integrity of the MCR envelope therefore they are deemed to be Category A Class 1 equipment. See Appendix 15A.

Two isolation valves are provided in series for each of the penetrations. It is claimed that one valve will close to form a low leak rate seal.

23.11.3.6 Isolation Dampers

The VBS dampers in lines isolating radioactive contamination close to prevent an unfiltered supply of air into the MCR/CSA AHUs following detection of high radiation levels in the supply air. They act to maintain the MCR habitability and as such provide a Category A safety function. See Appendix 15A. They provide a secondary function, because primary isolation of the MCR is provided by the isolation valves. Therefore, the VBS isolation dampers are Category A Class 2 equipment. See Appendix 15A.

Two isolation dampers are provided in series in the MCR/CSA HVAC subsystem AHU normal outside air intake duct. It is claimed that one damper will close to form a low leak rate seal and prevent the supply of unfiltered outside air to the MCR/CSA AHUs.

23.11.3.7 Combination Fire/Smoke Dampers

Combination fire/smoke dampers are installed in the VBS where ductwork passes through fire barriers. Some VBS dampers are provided with position indication.

The fire/smoke dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category A safety function. See Appendix 15A. As the fire/smoke dampers provide a contribution to achieving this safety function, they are deemed to be Class 2 equipment. See Appendix 15A.

23.11.3.8 Ancillary Fans – Reduces the probability of requiring the use of offsite SSCs to maintain Category A safety functions after 72 hours following an accident. Therefore, this component is Category B Class 2 equipment.

23.11.3.9 VBS Radiation Package – VBS contains two skid mounted MCR radiation monitoring packages consisting of radiation detectors, local radiation processors, and sampling components to continuously measure and record the radioactive materials in the MCR main supply air duct and actuate VBS supplemental air filtration and VES operation. Therefore, this component is Category A Class 1.

23.11.4 Justification of Claims on Components and Equipment

23.11.4.1 Supply and Return/Exhaust Air Fans

The fan design includes backward-inclined blades to produce nonoverloading characteristics. This will prevent overpressurisation of the ventilation distribution system if a damper in the system closes. This is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

Hydrogen detectors in the battery rooms and redundant fans provide additional protection against hydrogen build-up. Also, the volume of air in the battery rooms provides a delay between the failure of the exhaust fans and the hazard developing to permit operator intervention. The essential electrical system equipment room emergency passive heat sink controls the battery room temperature to maintain battery capacity.

The supply and return/battery exhaust air fans in the VBS are Class 2 equipment. The fans are to be designed and manufactured to normal industrial standards that are suitable for Class 2 equipment. The battery room exhaust fans include enhancements to the design to ensure they are spark proof. This protects against the risk of ignition of any hydrogen in the rooms.

Redundant fans are included with the provision of standby supply AHUs for both the MCR/CSA HVAC subsystem and the essential electrical system equipment room HVAC subsystem and standby battery room exhaust fans. This redundancy provides further confidence that the fans will be able to deliver the reliability required to ensure the VBS meets its safety functions.

The fan motors and their lubricants are designed to withstand the environmental effects over the design life of the plant. The battery room fans are provided with direct-driven motors and self-lubricating seal bearings to minimise maintenance efforts (Reference 23.33).

Conceivable failure modes for these types of fans include, for example, a failed bearing, excessive vibration, etc. Such mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. MCR operators will be alerted to failure of any of the fans that will enable them to take appropriate action.

Maintenance will be carried out in line with the manufacturer's information. It is recognised that reliability of the battery room exhaust fans is very important, and any further maintenance requirements will be identified in the site-specific PCSR. There is extensive experience of operating these types of fans to give confidence that if adequately maintained they will have good reliability in service.

23.11.4.2 High-Efficiency Particulate Air Filters and Charcoal Adsorbers

HEPA filters and charcoal adsorbers are passive components and have a high reliability in service. They are Category A Class 2 equipment and will meet their claimed efficiency through being constructed, qualified, and tested in accordance with appropriate standards (detailed in Section 23.11.2 above). There is a large amount of experience in using HEPA filters and charcoal adsorbers designed to these codes in operating nuclear power stations. This gives confidence in their ability to meet their safety function.

A pressure differential sensor is installed to measure the pressure drop across the filter as an indication of its performance. Upon detection of a high pressure drop across the HEPA filter, an indicator and alarm are activated.

A filtration/adsorption efficiency lower than or approaching the design limit will be detected by periodic testing. The radiation sensors in the MCR supply duct will sense any high radiation level, and automatically actuate the supplemental AHU and if necessary the VES.

The claimed efficiency of the HEPA filters and charcoal adsorbers will be demonstrated in situ through periodically testing each operating cycle and after each replacement of a HEPA filter or charcoal adsorber (Reference 23.33, Table 9-2).

23.11.4.3 Electric Unit Heaters

The electric unit heaters are classified as Class 3. The heaters are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Redundant electric unit heaters are included with the provision of two 100-percent-heaters in the PCS valve room. This redundancy provides further confidence that the electric unit heaters will be able to deliver the reliability required to ensure the VBS meets its safety functions.

Failure of the unit heaters will not lead to an immediate loss of PCS valve function. The operators would be alerted to unit heater failure and a reduction in temperature below pre-set limits. This would enable them to take appropriate action to ensure the PCS valves can maintain their safety function.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of electric unit heater to give confidence that if they are adequately maintained, they will demonstrate good reliability in service.

23.11.4.4 Cooling Coils

The highest classification of cooling coil in the VBS is Class 2. The coils are to be designed and manufactured to normal industrial standards that are suitable for Class 2 equipment.

Redundant cooling coils are included with the provision of standby supply AHUs for both the MCR/CSA HVAC subsystem and the essential electrical system equipment room HVAC subsystem. This redundancy provides further confidence that the cooling coils will be able to deliver the reliability required to ensure the VBS meets its safety functions.

Possible failure mechanisms include:

- Failure of the chilled water control valves. If the chilled water control valves on the operating AHU fail, leading to an increase in supply air temperature, then an alarm would annunciate in the MCR. The temperature in the served area can be maintained by operation of the standby AHU.

- Failure of the complete chilled water system. If chilled water is lost to both AHUs in each subsystem, leading to an increase in supply air temperature, then an alarm would annunciate in the MCR. It may, in these circumstances, not be possible to maintain design indoor temperatures, based on the outdoor temperature. Thermal inertia will provide a time delay before room temperature exceeds design limits, and this would enable operator intervention to occur.

- Structural failure of the coils. The use of suitable design standards and appropriate in service maintenance is deemed sufficient to reduce the risk of structural failure of the cooling coils.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of cooling coil to give confidence that if they are adequately maintained, they will have good reliability in service.

23.11.4.5 Isolation Valves

The MCR isolation valves are battery operated and fail in place. This offers a high degree of inherent safety and high reliability because each redundant valve is connected to a different battery.

The MCR isolation valves are Seismic C-I and are to be designed and constructed to the ASME Code, Section III-3 design code (Reference 23.33, Appendix F2). This code has been specifically developed to qualify components in safety significant applications on nuclear power stations. The code, with the testing and examination that supports it, provides the foundation for claims made on the MCR isolation valves.

The valves are very similar to those already in service, providing the same function on many operating power stations. As a result, the information from the testing of these in service valves offers a high degree of confidence regarding the reliability of the valves proposed for the AP1000 design.

The operating mechanism for the valve is relatively simple, and aside from gross mechanical failure, the principal mechanisms for valve failure are considered to be some form of adhesion preventing the valve closing, or leakage of the valve under pressure when in the closed position. These failures are considered to be unlikely because of a combination of good design and a robust maintenance, inspection, and testing regime. The valve is of a double-seat butterfly type. The materials of the valve have been selected to minimise the risk of corrosion interfering with valve operation.

IST of the VBS MCR isolation valves is included in surveillance requirement SR 3.7.6.6. This requires verification that all VBS MCR isolation valves are operable and will close upon receipt of an actual or simulated actuation signal every 24 months. Periodic pneumatic leakage testing is also performed.

23.11.4.6 Isolation Dampers

The isolation dampers are designed such that they fail safe to the closed position. The spring-return actuator design ensures that a loss of electrical or control power will cause the dampers to close, isolating the ductwork and preventing any unfiltered supply of air to the MCR AHUs. This provides a high degree of inherent safety. Spurious operation of the isolation dampers in the AHU supply duct puts the ventilation system in a safe condition and can be manually reset.

The dampers in lines isolating radioactive contamination are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment. The dampers are of a low leakage design to minimise the passing of any air when the dampers are shut. This in turn prevents the supply of unfiltered air when the main AHU supply duct is isolated.

Redundant isolation dampers are included in the design such that only one is required to operate. This gives further assurance that the isolation dampers will be able to meet their safety function.

Periodic inspection of the dampers will be undertaken to ensure that they have not seized or jammed and maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will return to the closed position if demanded.

23.11.4.7 Combination Fire/Smoke Dampers

The design of the combination fire/smoke damper used in the VBS actuates in response to one of two signals: direct heat from a fire or upon receipt of a smoke signal from one of the area smoke detectors. For the damper to close in response to heat from a fire, it does not require any external power source or actuation signals. This provides a high degree of inherent safety and high reliability. The fire load in the served areas will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system. Some VBS dampers are provided with position indication.

The fire/smoke dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 2 equipment.

The combination fire/smoke dampers fail closed using a spring mechanism. Any failure that causes the fire/smoke damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will move to the closed position when required.

23.12 ANNEX/AUXILIARY BUILDING NONRADIOACTIVE HEATING, VENTILATION, AND AIR CONDITIONING SYSTEM

23.12.1 Role

The VXS consists of the following six subsystems:

- General area HVAC
- Mechanical equipment areas HVAC
- Switchgear room HVAC
- Equipment room HVAC
- Main steam line isolation valve (MSIV) compartment HVAC
- Valve/piping penetration room HVAC
- Annex building offices (area 4)

The general area and annex building offices HVAC subsystems do not provide a contribution to nuclear safety and, therefore, are not discussed in this section.

The mechanical equipment areas HVAC subsystem serves the ancillary diesel generator room, demineralised water deoxygenating room, boric acid batching room, upper south air handling equipment room, and air handling equipment room in the annex building. Ventilation and cooling for the ancillary diesel generator room when the ancillary diesel generators operate is provided by means of manually operated dampers and opening doors to allow radiator discharge air to be exhausted direct to outdoors. The equipment in the other rooms does not perform a safety function. The mechanical equipment areas HVAC subsystem does not perform a safety function and is not discussed further in this section.

The other subsystems of the VXS make a contribution to nuclear safety with their primary safety function being the provision of support to other safety systems.

To protect the power generation design basis, the VXS is provided with redundant equipment to limit temperature excursions in mechanical and electrical equipment areas resulting from the failure or the shutdown of HVAC equipment for maintenance.

Further design details of this system and its constituent components are delineated in Reference 23.40 and Chapter 6.

23.12.1.1 Switchgear Room Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the switchgear room HVAC subsystem is to support the diesel bus switchgear in the electrical switchgear rooms 1 and 2 through the provision of ventilation cooling and maintaining a minimum temperature during cold ambient conditions.

The subsystem consists of two 100-percent AHUs with integral supply and exhaust fans, cooling and heating coils. Mixing dampers are used to control the proportion of exhaust air that is recirculated. Combination fire/smoke dampers are installed at ductwork penetrations through fire barriers to the switchgear rooms.

The switchgear room HVAC subsystem is supported by the FPS that shuts the fire/smoke dampers on detection of fire in the served areas, the PLS that provides control functions, the ZOS to provide standby power to the VXS in the event of loss of offsite power, and the VWS and VYS for chilled and hot water, respectively.

The switchgear room HVAC subsystem supports operation of the ZOS through the provision of ventilation and cooling of the diesel bus switchgear.

23.12.1.2 Equipment Room Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the equipment room HVAC subsystem is to support equipment in the electrical and mechanical rooms. These rooms include the standby electrical system battery charger rooms 1 and 2, the standby electrical system battery rooms 1 and 2, the reactor trip switchgear rooms 1 and 2, and the standby electrical system penetration rooms. The equipment is supported by the provision of ventilation cooling and maintaining a minimum temperature during cold ambient conditions. In addition, the subsystem prevents the build-up of hydrogen through the continuous exhaust of the battery rooms.

The subsystem consists of two 100-percent-capacity AHUs with integral supply and exhaust fans, cooling and heating coils. Mixing dampers are used to control the proportion of exhaust air that is recirculated. An exhaust fan serves each of the standby electrical system battery rooms. Fire dampers or combination fire/smoke dampers are installed at ductwork penetrations through fire barriers.

The equipment room HVAC subsystem is supported by the FPS, which trips the fans on detection of fire in the served areas; the PLS, which provides control functions; the ZOS, which provides standby power to the VXS in the event of loss of offsite power; and the VWS and VYS, which provide chilled and hot water, respectively.

The equipment room HVAC subsystem supports operation of the ECS, the EDS, and the reactor trip switchgear.

23.12.1.3 Main Steam Isolation Valve Compartment Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the MSIV compartment HVAC subsystem is to support the MSIVs through the provision of ventilation cooling. Operation of the MSIVs will be required when the steam legs are hot; therefore, heating is not required to maintain safe operation of the valves.

The subsystem consists of separate heating and cooling equipment for each MSIV compartment. Two 100-percent-capacity AHUs are included within each MSIV compartment. Each AHU includes a fan and cooling coil.

The MSIV compartment HVAC subsystem is supported by the PLS for control functions, the VWS for chilled water, and the ZOS for standby power to the VXS in the event of loss of offsite power.

The MSIV compartment HVAC subsystem supports operation of the steam generator system (SGS) through the provision of heating and cooling of the MSIV compartment.

23.12.1.4 Valve/Piping Penetration Room Heating, Ventilation, and Air Conditioning Subsystem

The safety function of the valve/piping penetration room HVAC subsystem is to support equipment in the valve/piping penetration room through the provision of cooling and maintaining a minimum temperature during cold ambient conditions.

The subsystem consists of two 100-percent-capacity AHUs with integral supply fans, heating and cooling coils. Fire dampers are installed at ductwork penetrations through fire barriers.

The valve/piping penetration room HVAC subsystem is supported by the FPS, which trips the fans on detection of fire in the served areas; the PLS, which provides control functions; the ZOS, which provides standby power to the VXS in the event of loss of offsite power; and the VWS and VYS, which provide chilled and hot water, respectively.

The valve/piping penetration room HVAC subsystem supports equipment in the valve/piping penetration room.

23.12.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressure is structurally designed for fan shutoff pressures. Ductwork, supports, and accessories meet the design and construction requirements of SMACNA Rectangular and Round Industrial Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15).

Isolation dampers are single- or parallel-blade type. The isolation dampers have spring return actuators, which fail closed on loss of electrical power or loss of air pressure. The isolation dampers are constructed, qualified, and tested in accordance with ANSI/AMCA Standard 500 (Reference 23.12).

The following components make key contributions to the ability of the VXS to perform its safety function.

- **Supply and exhaust air fans** – The supply and exhaust fans are centrifugal type, single-width single-inlet, or double-width double-inlet. Most of the fans have backward-inclined blades to produce nonoverloading characteristics. However, those fans installed in AHUs that have little or no ductwork may utilise forward curved blades. The fan operating conditions will be selected to ensure smooth stable operation over the specified operating range without fan surging or instability. The fans are isolated from the AHU casing with spring-type vibration isolators. The fans are designed and rated in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

  In addition, the exhaust fans from the battery rooms in the equipment room HVAC subsystem have nonsparking wheels.

  The supply and exhaust air fans in the switchgear room HVAC subsystem AHUs are required to operate to provide long-term cooling to the diesel bus switchgear.

  The supply and exhaust air fans in the equipment room HVAC subsystem AHUs are required to operate to provide long-term cooling to the electrical equipment including the reactor trip switchgear.

The battery room exhaust air fans in the equipment room HVAC subsystem are required to operate to prevent the build-up of hydrogen in the battery rooms in the long term.

The supply fans in the MSIV compartment room HVAC subsystem AHUs are required to operate to provide long-term cooling to the MSIVs.

The supply fans in the valve/piping penetration room HVAC subsystem AHUs are required to operate to provide long-term cooling to components in the valve/piping penetration room.

All the fans operate in response to signals from the PLS that include flow rate, temperature, and fire protection signals. These supply and exhaust fans which provide required supply and extract airflows are Category C Class 3 equipment.

- **Cooling coils** – The chilled water cooling coils are counterflow, finned-tubular type. Each cooling coil is constructed with finned tubes. Large cooling coil banks that are constructed from multiple cooling coils are provided with coil holding racks designed to allow each coil to be independently removed (side pull) from the housing. The cooling coils are designed and rated in accordance with ASHRAE 33 (Reference 23.23) and ANSI/ARI 410 (Reference 23.22).

  The cooling coils in the ventilation subsystems obtain a flow of cooling water through activation of the chilled water control valves in response to signals from the PLS. The cooling coils are designed to Class 3 as they are the principal means to permit the flow of cooling water through the tubes and maintain an adequate surface for heat transfer between the air and cooling water which is a Category C safety function.

- **Heating coils** – The hot water heating coils are of the face and bypass type with counterflow, finned tubes. Large heating coil banks that are constructed from multiple heating coils are provided with coil holding racks designed to allow each coil to be independently removed (side pull) from the housing. The heating coils are designed and rated in accordance with ASHRAE 33 (Reference 23.23) and ANSI/ARI 410 (Reference 23.22).

  The heating coils in the valve/piping penetration room HVAC subsystem are required to permit the flow of hot water through the tubes and maintain an adequate surface for heat transfer between the air and hot water. Also, the face and bypass dampers operate to control the temperature of the supply air.

  The heating coil dampers operate in response to temperature signals from the PLS. Thes heating coils are designed to Class 3 as they are the principal means to maintain a minimum temperature in the served areas which is a Category C safety function.

- **Combination fire/smoke dampers** – Combination fire/smoke dampers are all galvanised construction, low leakage with parallel blades, suitable for vertical or horizontal mounting and listed for dynamic closure. Damper blades are designed to close against the subsystem pressure and flow condition at the duct section in which they are located. The fire/smoke damper frame is continuously welded into a galvanised steel sleeve to minimise air leakage when the damper is closed. Combination fire/smoke dampers meet the requirements of UL 555 and UL 555S and bear a UL label (References 23.18 and 23.39). The fire rating of the combination fire/smoke damper is at least equal to the fire barrier that it protects up to a maximum of three hours. The combination fire/smoke dampers are installed in accordance with the manufacturer's recommendations. The fire/smoke damper closes under the action of a spring

mechanism. The design includes a hold-open actuator, which releases and closes the damper in response to a control signal to prevent smoke migration.

The combination fire/smoke dampers respond to either the air temperature in the duct where no actuation signal is required or a smoke detection signal via the PLS. These dampers are designed to Class 3 as they are the principal means to operate in order to maintain the integrity of a fire barrier within which they are located and prevent the spread of smoke to other fire compartments which is a Category B safety function.

- **Fire dampers** – The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blades when the air temperature reaches 74°C (165°F). The damper blades close via a spring mechanism. Additionally some VXS fire dampers are provided with position indication. The fire dampers meet the design, testing, and installation requirements of UL 555 (Reference 23.18).

  The fire dampers are passive components operated by temperature and a spring mechanism. As such, no actuation signal is required. There is a Category B safety function that the fire damper rating will be at least equal to the fire barrier that they penetrate, up to a maximum 3-hour rating. These dampers are Category B Class 3 equipment.

23.12.3 Claims on Components and Equipment

23.12.3.1 Supply and Exhaust Air Fans and Dampers

- AHUs and dampers that support operation of ZOS by maintaining the diesel bus switchgear rooms and battery charger rooms (containing dc switchgear) within their design temperature range. The supply and exhaust air fans in the switchgear room HVAC subsystem AHUs support operation of the diesel bus switchgear. The onsite diesel generator system, including the diesel bus switchgear, supports a number of Category A safety functions and therefore provide a Category C safety function (see Appendix 15A). The diesel generators have a defence in depth role and are classified as Class 2 equipment. The switchgear ventilation system is therefore a Category C safety function system and is classified as Class 3 equipment.

  There are two 100-percent-capacity AHUs in the switchgear room HVAC subsystem with one supply and one exhaust air fan in each AHU. It is claimed that the fans in one of the AHUs will start on demand and continue to operate to provide cooling to the diesel bus switchgear.

- The standby electrical system battery room exhaust fans in the equipment room HVAC subsystem prevent the build-up of hydrogen in the battery rooms. Significant build-up can only occur during charging, when ac electrical power is available. At that point in time, the batteries are not required to operate. As such, the battery room exhaust fans provide a Category C safety function. Hydrogen detectors are used in battery rooms to protect against hydrogen build-up by alerting operators that hydrogen levels are building. Also, the volume of air in the battery rooms provides a delay between the failure of the exhaust fans and the hazard developing. The exhaust fans provide a minor contribution to nuclear safety and are therefore Class 3 equipment. See Appendix 15A.

There is one standby electrical system battery room exhaust fan extracting from each battery room. It is claimed that each fan will continue to operate to help prevent the build-up of hydrogen in the battery rooms when the batteries are being charged.

- The supply and exhaust air fans in the equipment room HVAC subsystem AHUs support electrical equipment, including the reactor trip switchgear and the nonessential electrical system battery rooms. The fans provide long-term support for the reactor trip switchgear. Failure of the ventilation system will not inevitably lead to the loss of reactor trip switchgear function. Low flow sensors in the ductwork would alert MCR personnel if the ventilation failed and allow them to take appropriate action to ensure that the room temperatures did not rise above a predefined limit. The fans contribute to delivering this safety function and are Class 3 equipment. See Appendix 15A.

  There are two 100-percent-capacity AHUs in the equipment room HVAC subsystem, with one supply and one exhaust air fan in each AHU. It is claimed that the fans in one of the AHUs will start on demand and continue to operate to provide cooling to the equipment, including the reactor trip switchgear, and ventilation to the battery rooms.

- The supply air fans in the MSIV compartment HVAC subsystem AHUs support operation of the MSIVs. The MSIVs provide a number of Category A safety functions and are classified as Class 1 equipment (see Chapter 17 for details). The fans support the Category A safety functions provided by the MSIVs. The AP1000 has the capability of using natural ventilation to cool these spaces. Therefore, the MSIV fans provide a Category C safety function. Failure of the ventilation system will not inevitably lead to the loss of MSIV function. Low flow sensors in the ductwork would alert MCR personnel if the ventilation failed and allow them to take appropriate action to ensure the compartment temperatures did not rise above a predefined limit. The fans contribute to delivering this safety function and are Class 3 equipment. See Appendix 15A.

  There are two 100-percent-capacity AHUs in each MSIV compartment, with one supply fan in each AHU. It is claimed that the fan in one of the AHUs in each compartment will start on demand and continue to operate to provide cooling to the MSIVs.

- The supply air fans in the valve/piping penetration room HVAC subsystem AHUs support the safety equipment in the valve/piping penetration room. Failure of the ventilation system will not inevitably lead to the loss of safety equipment function. Temperature sensors in the room will alert MCR personnel if the ventilation failed and allow them to take appropriate action to ensure that the room temperatures did not rise above a predefined limit. The fans support the pumps and piping that refill and heat the passive cooling water storage tank. This is a Category C function. The fans provide a minor contribution to delivering the safety function and are Class 3 equipment. See Appendix 15A.

  There are two 100-percent-capacity AHUs in the valve/piping penetration room HVAC subsystem, with one supply air fan in each AHU. It is claimed that the fan in one of the AHUs will start on demand and continue to operate to provide cooling to the room.

- Exhaust fan providing ancillary diesel room ventilation within their design temperature range. The supply and exhaust air fans in the switchgear room HVAC subsystem AHUs support operation of the ancillary diesel generator. The ancillary diesel generator supports a number of Category B safety functions. Therefore, the exhaust fan is Category C Class 3 equipment (see appendix 15A).

23.12.3.2 Cooling Coils

The cooling coils provide the same contribution to safety as the AHU supply and exhaust fans discussed above (Section 23.12.3.1). For the same reasons, the cooling coils in the subsystems of the VXS under discussion provide a Category C safety function. Similarly, all the cooling coils are Class 3 equipment. See Appendix 15A.

In each subsystem there are two 100-percent-capacity AHUs, with one cooling coil bank in each AHU. It is claimed that the chilled water control valves in one of the AHUs per subsystem will modulate to control the flow of chilled water and will therefore provide the cooling required to the served areas.

23.12.3.3 Heating Coils

The heating coils provide the same contribution to safety as the AHU supply and exhaust fans in the switchgear room, equipment room, and valve/piping penetration room HVAC subsystems discussed in Section 23.12.3.1. For the same reasons, the heating coils in the switchgear room, equipment room, and valve/piping penetration room HVAC subsystems provide a Category C safety function and are classified as Class 3 equipment.

In each subsystem there are two 100-percent AHUs, with one heating coil in each AHU. It is claimed that the heating coil dampers in one of the AHUs per subsystem will modulate to control the flow of air across the heating coil and hence provide the heating required to the served areas.

23.12.3.4 Combination Fire/Smoke Dampers

Fire dampers or combination fire/smoke dampers are installed in the VXS where ductwork passes through fire barriers.

The combination fire/smoke dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. See Appendix 15A. As the fire/smoke dampers contribute to achieving this safety function, they are deemed to be Class 3 equipment. See Appendix 15A.

Single combination fire/smoke dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire/smoke dampers will close when the air temperature in the duct reaches the design limit or upon a fire detection signal from the PLS to maintain the integrity of the fire barrier.

23.12.3.5 Fire Dampers

Included in discussion of “Combination Fire/Smoke Dampers” in section 23.12.3.4.

23.12.4 Justification of Claims on Components and Equipment

23.12.4.1 Supply and Exhaust Air Fans

The fan design for subsystems with a significant amount of ductwork includes backward-inclined blades to produce nonoverloading characteristics. This will prevent overpressurisation of the ventilation distribution system if a damper in the system closes. This

is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

Hydrogen detectors protect against hydrogen build-up by alerting operators that hydrogen concentrations are increasing. Also, the volume of air in the battery rooms effectively provides a delay between the failure of the exhaust fans and the hazard developing to permit operator intervention.

The highest classification of supply and return/exhaust air fans in VXS AHUs is Class 3. The fans are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

The battery room exhaust fans are also Class 3 equipment. They are designed and manufactured to normal industrial standards with enhancements to the design such as nonsparking wheels and motors. This protects against the risk of ignition of any hydrogen in the room.

Redundant fans are included with the provision of standby AHUs in the switchgear room, equipment room, MSIV compartment, and valve/piping penetration room HVAC subsystems. This redundancy provides further confidence that the fans will be able to deliver the reliability required to ensure that the VXS meets its safety functions. No redundancy is provided for the standby electrical system battery room exhaust fans. This is appropriate because the fans provide a Category C safety function, and the hydrogen levels are monitored.

The fan motors and their lubricants are designed to withstand the environmental effects over the design life of the plant. The battery room fans are provided with direct-driven motors, as are the AHU fans and self-lubricating seal bearings, to minimise maintenance effort.

Conceivable failure modes for these types of fans include, for example, a failed bearing, excessive vibration, etc. Such mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. MCR operators will be alerted to failure of any of the fans, which will enable them to take appropriate action.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of fan, which gives confidence that if they are adequately maintained, they will have good reliability in service.

23.12.4.2 Cooling Coils

The highest classification of cooling coils is Class 3. The coils are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Redundant cooling coils are included with the provision of standby AHUs in the switchgear room, equipment room, MSIV compartment and valve/piping penetration room HVAC subsystems. This redundancy provides further confidence that the cooling coils will be able to deliver the reliability required to ensure the VXS meets its safety functions.

Possible failure mechanisms include:

- Failure of the chilled water control valves. If the control valves on a cooling coil fails and the room temperature start to rise, this would be detected by the room temperature sensor and the standby AHU would be started.

- Failure of the complete chilled water system. If chilled water is lost to both AHUs of the switchgear room and equipment room HVAC subsystems, the subsystems may be operated in a once-through mode to maintain air circulation. The VXS system specification document (Reference 23.40, Section 4.3) identifies that, in this mode of operation, design indoor temperatures may not be capable of being maintained, based on the outdoor temperature. Some operations may have to be suspended in the affected areas.

  If chilled water is lost to both AHUs in each MSIV compartment HVAC subsystem and the valve/piping penetration room HVAC subsystem, then the design indoor temperatures may not be capable of being maintained. The operators will be notified of a rise in room temperature. Temporary ventilation or cooling may be required to control area temperature until heat loads in the areas can be reduced or chilled water is restored (Reference 23.40, Section 4.3).

- Structural failure of the coils resulting in a significant leak of chilled water. The use of suitable design standards and appropriate in service maintenance is deemed sufficient to reduce the risk of structural failure of the cooling coils.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of cooling coil to give confidence that if they are adequately maintained, they will have a good reliability in service.

23.12.4.3 Heating Coils

The highest classification of heating coils is Class 3. The coils are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Redundant heating coils are included with the provision of standby AHUs in the switchgear room, equipment room, and valve/piping penetration room HVAC subsystems. This redundancy provides further confidence that the heating coils will be able to deliver the reliability required to ensure the VXS meets its safety functions.

Possible failure mechanisms include:

- Failure of the heating coil dampers. Each AHU has a low temperature controller located in its discharge ductwork or in the area served. A fall in discharge temperature would be detected if the heating coil damper fails. The MCR would be notified and the standby AHU could be started.

- Failure of the complete hot water system. If hot water is lost to both AHUs of the switchgear room and equipment room HVAC subsystems and the room temperature was above the minimum room design temperature, the system may be operated in a normal manner; however, design area temperatures may not be maintained. In extreme ambient conditions, if the room temperature fell below the minimum room design temperature, the subsystems would have to be shut down and operations in the area served may need to be suspended (Reference 23.40, Section 4.3).

  If hot water is lost to the valve/piping penetration room HVAC subsystem and the temperature stays above the minimum room temperature, the subsystem can continue to operate normally. In extreme ambient conditions, if the room temperature falls below the minimum room temperature, the MCR will be notified and temporary heating may be required (Reference 23.40, Section 4.3).

- Structural failure of the coils resulting in a significant leak of hot water. The use of suitable design standards and appropriate in service maintenance is deemed sufficient to reduce the risk of structural failure of the heating coils.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of heating coil to give confidence that if they are adequately maintained, they will have good reliability in service.

23.12.4.4 Combination Fire/Smoke Dampers

The design of combination fire/smoke damper used in the AP1000 Design actuates in response to one of two signals: direct heat from a fire, or upon receipt of a smoke signal from one of the area smoke detectors. For the damper to close in response to heat from a fire, it does not require any external power source or actuation signals. This provides a high degree of inherent safety and high reliability. The fire load in the served areas will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire/smoke dampers is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

The combination fire/smoke dampers fail closed using a spring mechanism. Any failure that causes the fire/smoke damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will move to the closed position when required.

23.12.4.5 Fire Dampers

The design of fire damper used in the AP1000 design does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and the spring mechanism closing the damper. Additionally some VXS fire dampers are provided with position indication. This provides a high degree of inherent safety and high reliability. The fire load in the served areas will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire dampers is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

23.13 TURBINE BUILDING VENTILATION SYSTEM

23.13.1 Role

The VTS consists of the following subsystems:

- General area heating and ventilation
- Local area heating and ventilation
- Electrical equipment, south bay equipment, and personnel work area HVAC

The general area and local area heating and ventilation subsystems do not provide a primary nuclear safety function and, therefore, are not discussed in this section. The electrical equipment, south bay equipment, and personnel work area HVAC subsystem are subdivided into three independent HVAC systems. The south bay HVAC subsystem is the only VTS subsystem that supports Class 2 systems.

The south bay equipment HVAC system serves the component cooling water system (CCS) pumps, SG blowdown system (BDS) pumps, reactor coolant pumps' variable frequency drive power converter areas, the EDS battery room and the PLS through the provision of cooling and ventilation to equipment/components.

The VTS is supported by the ECS for electrical power, the PLS for control signals, the VWS and the VYS for chilled and hot water, respectively.

Further design details of this system and its constituent components are delineated in Reference 23.41 and Chapter 6.

23.13.1.1 South Bay Equipment Subsystem

The safety function of the south bay equipment HVAC subsystem is to support the CCS system through the provision of ventilation cooling and exhausting potential hydrogen build-ups in the battery room.

The subsystem consists of two 50-percent AHUs with integral supply fans, and cooling and heating coils. Fire dampers are installed at ductwork penetrations through fire barriers to the CCS rooms.

The south bay equipment HVAC subsystem is supported by the FPS that shuts the fire/smoke dampers on detection of fire in the served areas, the PLS that provides control functions, the ZOS to provide standby power to the VXS in the event of loss of offsite power, and the VWS and VYS for chilled and hot water, respectively.

23.13.2 System Components and Equipment Contributing to Safety Function

- **Supply and exhaust air fans** – The supply and exhaust fans are centrifugal type, single-width single-inlet, or double-width double-inlet, with high-efficiency wheels. Most of the fans have backward-inclined blades to produce nonoverloading characteristics. However, those fans installed in AHUs that have little or no ductwork may utilise forward curved blades. The fan operating conditions will be selected to ensure smooth stable operation over the specified operating range without fan surging or instability. The fans are isolated from the AHU casing with spring-type vibration isolators. The fans are designed and rated in accordance with SMACNA, ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11).

  In addition, the exhaust fans from the battery rooms in the equipment room HVAC subsystem have nonsparking wheels.

  The fans in the south bay equipment HVAC subsystem AHUs are required to operate to provide long-term cooling to the CCS equipment.

  The battery room exhaust air fan in the south bay equipment room HVAC subsystem is required to operate to prevent the build-up of hydrogen in the battery rooms in the long term.

  All the fans operate in response to signals from the PLS that include flow rate, temperature, and fire protection signals. Provision of the required supply and extract airflows do not contribute to maintaining nuclear safety as determined by the safety case and the supply and exhaust fans are class GNS equipment.

- **Cooling coils** – The chilled water cooling coils are counterflow, finned-tubular type. Each cooling coil is constructed with tubes and fins. Large cooling coil banks that are constructed from multiple cooling coils are provided with coil holding racks designed to allow each coil to be independently removed (side pull) from the housing. The cooling coils are designed and rated in accordance with ASHRAE 33 (Reference 23.23) and ANSI/ARI 410 (Reference 23.22).

  The cooling coils in the ventilation subsystems obtain a flow of cooling water through activation of the chilled water control valves in response to signals from the PLS. The flow of cooling water through the tubes and maintain an adequate surface for heat transfer between the air and cooling water do not contribute to maintaining nuclear safety as determined by the safety case and the cooling coils are class GNS equipment.

- **Fire dampers** – The fire dampers are constructed of galvanised carbon steel and actuated by fusible links designed to melt and release the damper blades when the air temperature reaches 74°C (165°F). The damper blades close via a spring mechanism. The fire dampers meet the design, testing, and installation requirements of UL 555 (Reference 23.18).

  The fire dampers are passive components operated by temperature and a spring mechanism. As such, no actuation signal is required. The fire dampers are essential to maintain the integrity of fire barriers discussed in the internal fire hazard section in Chapter 11. The functional requirement is that they are rated to be at least equal to the fire barrier that they penetrate, up to a maximum 3-hour rating.

23.13.3 Claims on Components and Equipment

23.13.3.1 Supply and Exhaust Air Fans

- The supply and exhaust air fans in the south bay equipment HVAC subsystem AHUs support operation of the CCS. The CCS supports a number of Category A safety functions and therefore provides a Category A safety function (see Chapter 17 and Appendix 15A). The CCS pumps and equipment have a defence in depth role and are classified as Class 2 equipment. The south bay equipment HVAC system does not contribute to maintaining nuclear safety as determined by the safety case and thus is classified as class GNS equipment.

  There are two 50-percent-capacity AHUs in the south bay equipment HVAC subsystem. The AHUs are sized so that one of the AHUs can cool both operating pumps. It is claimed that the fan in one of the AHUs will start on demand and continue to operate to provide cooling to the CCS equipment.

- The battery room exhaust fan in the south bay equipment HVAC subsystem prevents the build-up of hydrogen in the battery room. Significant build-up can only occur during charging, when ac electrical power is available. At that point in time, the batteries are not required to operate. As such, the battery room exhaust fans do not contribute to maintaining nuclear safety as determined by the safety case. Hydrogen detectors are used in battery rooms to protect against hydrogen build-up by alerting operators that hydrogen levels are building. Also, the volume of air in the battery rooms provides a delay between the failure of the exhaust fans and the hazard developing. The exhaust fans do not contribute to maintaining nuclear safety as determined by the safety case and are therefore GNS equipment. See Appendix 15A. The fans will operate to help prevent the build-up of hydrogen in the battery rooms when the batteries are being charged.

23.13.3.2 Cooling Coils

The cooling coils provide the same contribution to safety as the AHU fans discussed above (Section 23.12.3.1). For the same reasons, the cooling coils in the subsystems of the VTS under discussion do not contribute to maintaining nuclear safety as determined by the safety case. Thus, all the cooling coils are class GNS equipment. See Appendix 15A.

There are two 50-percent-capacity AHUs, with one cooling coil bank in each AHU. Only one AHU is required to operate to cool the CCS equipment. It is claimed that the chilled water control valves in one of the AHUs per subsystem will modulate to control the flow of chilled water and will, therefore, provide the cooling required to the served areas.

23.13.3.3 Fire Dampers

The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function. See Appendix 15A. As the fire dampers provide a contribution to achieving this safety function, they are deemed to be Category B Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit and maintain the integrity of the fire barrier.

23.13.4 Justification of Claims on Components and Equipment

23.13.4.1 Supply and Exhaust Air Fans

The fan design for subsystems with a significant amount of ductwork includes backward-inclined blades to produce nonoverloading characteristics. This will prevent overpressurisation of the ventilation distribution system if a damper in the system inadvertently closes. This is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

A hydrogen detector protects against hydrogen build-up by alerting operators that hydrogen concentrations are increasing. Also, the volume of air in the battery room effectively provides a delay between the failure of the exhaust fans and the hazard developing to permit operator intervention.

The highest classification of supply and return/exhaust air fans in the VTS AHUs is Class GNS equipment. The fans are to be designed and manufactured to normal industrial standards that are suitable for Class GNS equipment.

The battery room exhaust fan is also Class GNS equipment. It is designed and manufactured to normal industrial standards with enhancements to the design such as nonsparking wheels. This protects against the risk of ignition of any hydrogen in the room.

Multiple fans are included with the provision of pairs of AHUs in the south bay equipment area. This provides further confidence that the fans will be able to deliver the reliability required to ensure that the VTS meets its safety functions. No redundancy is provided for the electrical system battery room exhaust fan. This is appropriate because the fans do not contribute to maintaining nuclear safety as determined by the safety case, and the hydrogen levels are monitored.

The fan motors and their lubricants are designed to withstand the environmental effects over the design life of the plant. The battery room fan is provided with a direct-driven motor.

Conceivable failure modes for these types of fans include, for example, a failed bearing, excessive vibration. Such mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. MCR operators will be alerted to failure of any of the fans, which will enable them to take appropriate action.

Maintenance will be carried out in line with the manufacturer’s information. There is extensive experience in operating these fans, which gives confidence that if they are adequately maintained, they will have good reliability in service.

23.13.4.2 Cooling Coils

The highest classification of cooling coils is Class GNS equipment. The coils are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Multiple cooling coils are included with the provision of multiple AHUs in the south bay equipment HVAC subsystems. This redundancy provides further confidence that the cooling coils will be able to deliver the reliability required to ensure the VTS meets its safety functions.

Possible failure mechanisms include:

- Failure of the chilled water control valves. If the control valve on a cooling coil fails and the room temperature starts to rise, this would be detected by the room temperature sensor.

- Failure of the complete chilled water system. If chilled water is lost to both AHUs of the south bay HVAC subsystem, the subsystems may be operated to maintain air circulation. The VTS system specification document (Reference 23.41, Section 4.3) identifies that, in this mode of operation, design indoor temperatures may not be capable of being maintained, based on the outdoor temperature. CCS pump operation will be maintained because the pump motor will operate at temperatures well above the room design temperature.

- Structural failure of the coils resulting in a significant leak of chilled water. The use of suitable design standards and appropriate in-service maintenance is deemed sufficient to reduce the risk of structural failure of the cooling coils.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience in operating this type of cooling coil to give confidence that if they are adequately maintained, they will have a good reliability in service.

23.13.4.3 Fire Dampers

The design of the fire damper used in the AP1000 design does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and the spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. The fire load in the served areas will be kept to a minimum to reduce the risk and potential size of a fire. This also contributes to the inherent safety of the system.

The highest classification of fire dampers is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper were to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience in operating this type of damper to give confidence that if the dampers are adequately maintained, they will not seize or jam and will return to the closed position when the temperature rises above the specified point.

23.14 DIESEL GENERATOR BUILDING HEATING AND VENTILATION SYSTEM

23.14.1 Role

The primary safety function of the VZS is in support of the safety systems housed within the diesel generator building through maintaining appropriate temperature ranges and removing combustible vapours.

The system consists of the following four subsystems:

- Normal heating and ventilation
- Standby exhaust ventilation
- Fuel oil day tank vault exhaust
- Diesel oil transfer module enclosures ventilation and heating

Further design details of this system and its constituent components are delineated in Reference 23.42 and Chapter 6.

23.14.1.1 Normal Heating and Ventilation Subsystem

The safety function of the normal heating and ventilation subsystem is to maintain the ambient temperature of the diesel generator rooms within appropriate limits when the diesel generators are not operating. This is to ensure that the diesel generators will be able to start on demand. The subsystem also supports the equipment in the electrical equipment service module through maintenance of the ambient temperature during normal operation and when the diesel generators are operating.

There are two diesel generator rooms, and the system makes provision for one AHU per engine room. Cooling is provided by the supply of outside air (there are no cooling coils in the AHUs), while heating is provided by two electric unit heaters in each engine room. This allows the maintenance of the design minimum room temperature with a single heater operating except at extremely low design temperatures. The minimum design room temperature is based on personnel comfort for maintenance operations and higher than temperatures that will affect diesel generator operation.

One supply AHU is provided for each electrical equipment service module. Cooling is provided by the supply of outside air (there are no cooling coils in the AHUs), and heating is provided by an electric heating coil in the AHU.

The normal heating and ventilation subsystem is supported by the PLS.

The normal heating and ventilation subsystem supports the ZOS by maintaining the initial temperature of the diesel generators at start-up and maintaining the temperature of the ZOS electrical equipment.

23.14.1.2 Standby Exhaust Ventilation Subsystem

The safety function of the standby exhaust ventilation subsystem is to maintain the ambient temperature of the diesel generator rooms within appropriate limits when the diesel generators are operating.

The subsystem consists of two 50-percent-capacity roof mounted exhaust fans per engine room, and one or both fans are required to operate to maintain the room temperature

depending on outdoor ambient temperatures. The subsystem also includes motor-operated air intake dampers mounted in the exterior walls of the rooms.

The standby exhaust ventilation subsystem is supported by the PLS.

The standby exhaust ventilation subsystem supports the ZOS by maintaining the temperature of the diesel generators during operation.

23.14.1.3 Fuel Oil Day Tank Vault Exhaust Subsystem

The safety function of the fuel oil day tank vault exhaust subsystem is to prevent the build-up of a hazard by continuously exhausting combustible vapour from the fuel oil day tank vault.

The subsystem consists of one centrifugal exhaust fan for each vault, with the openings into and out of the vault protected by fire dampers.

The fuel oil day tank vault exhaust subsystem is supported by the PLS.

The fuel oil day tank vault exhaust subsystem supports the ZOS by preventing the build-up of combustible vapours that could affect operation of the ZOS.

23.14.1.4 Diesel Oil Transfer Module Enclosures Ventilation and Heating Subsystem

The safety function of the diesel oil transfer module enclosures ventilation and heating subsystem is to maintain the ambient temperature of the enclosures within appropriate limits.

The system consists of one roof fan and one electric unit heater per enclosure.

The diesel oil transfer module enclosures ventilation and heating subsystem is supported by the PLS.

The diesel oil transfer module enclosures ventilation and heating subsystem supports the standby diesel and auxiliary boiler fuel oil system (DOS) by maintaining the temperature of the diesel oil transfer module enclosures.

23.14.2 System Components and Equipment Contributing to Safety Function

Ductwork, duct supports, and accessories are constructed of galvanised steel. Ductwork subject to fan shutoff pressure is structurally designed for fan shutoff pressures. Ductwork, supports, and accessories meet the design and construction requirements of SMACNA Rectangular and Round Industrial Duct Construction Standards (References 23.13 and 23.14) and SMACNA HVAC Duct Construction Standards – Metal and Flexible (Reference 23.15).

Multi-blade, two-position shutoff remotely operated dampers are parallel-blade type. Multi-blade, control and balancing dampers are opposed-blade type. Backdraft dampers are provided to prevent backflow through shut down exhaust fans and to relieve pressure from the service module and diesel generator building. Dampers meet the performance requirements of ANSI/AMCA Standard 500 (Reference 23.12).

The following components make key contributions to the ability of the VZS to perform its safety function.

- **Supply and exhaust fans** – These are centrifugal type, single-width single-inlet, or double-width double-inlet, with high-efficiency wheels and backward-inclined blades to

produce nonoverloading characteristics. The fans are designed and rated in accordance with ANSI/AMCA Standards 210 (Reference 23.9), 211 (Reference 23.10), and 300 (Reference 23.11). In addition, the VZS system specification document identifies that the fuel oil day tank vault exhaust fans will have nonsparking wheels and motors (Reference 23.42, Section 5.1).

The electrical equipment service room AHU supply fans and fuel oil day tank vault exhaust fans operate in response to manual signals from the PLS and are required to operate to maintain the temperature in the electrical equipment service rooms and prevent the build-up of combustible vapours. These fans are Category C Class 3 equipment.

Failure of the fans in the engine room AHUs would only lead to an increase in temperature if there were very warm ambient conditions. If this happens, the standby exhaust fans would be initiated when the temperature reached a preset upper limit thus maintaining the temperature in the engine room. As such, no further analysis is required for the engine room AHU supply fans.

- **Electric heating coils** – These are finned tubular type with wire heating element embedded within a protective metal sheath. Coils will be wired for multiple stages, with each stage arranged across the full face of the coils (Reference 23.42, Section 5.1). The electric heating coils meet the requirements of UL 1995 for heating and cooling equipment (Reference 23.43).

  The heating coils operate in response to room temperature and fan operation status signals from the PLS. The heating coils are required to operate to maintain the temperature in the electrical equipment service modules within the preset limits. These electric heating coils are Category C Class 3.

- **Roof exhaust fans** – The roof exhaust fans in the standby exhaust ventilation subsystem are roof mounted, direct drive upblast ventilators. The diesel oil transfer module enclosure exhaust fans are direct driven fan roof ventilators. Both fan types are equipped with gravity dampers that open when the fan operates and close when the fan is shut down. The standby exhaust ventilation subsystem fans' dampers provide weather-tight closures when the fan is shut down to prevent the entry of rain or snow.

  The standby exhaust ventilation subsystem fans operate in response to temperature or diesel generator operation signals from the PLS. The diesel oil transfer module enclosure exhaust fans operate in response to temperature signals from the PLS. The roof exhaust fans in both subsystems are designed to Class 3 as they are the principal means to maintain the temperature in the engine rooms and diesel oil transfer module enclosures below the predetermined upper limit which is a Category C safety function.

- **Electric unit heaters** – these are horizontal single-stage or two-stage finned tubular type with adjustable louvers to direct discharge air down. Heating coils will consist of aluminium-finned copper-clad steel sheath elements. The electric unit heaters are UL-listed and meet the requirements of UL 1996 (Reference 23.36) and the National Electric Code (Reference 23.37). Unit heaters are of conventional, commercially available construction. (Reference 23.42, Section 5.1).

  Local space thermostats turn the unit heaters on and off as required for temperature control. The electric unit heaters therefore have a safety function to operate to maintain the temperature in the diesel oil transfer module enclosures above the predetermined

lower limit. The engine room unit heaters are non-safety since they are not required to support the diesel engine starting or operation.

- **Fire dampers** – these are provided at duct penetrations through fire barriers to maintain the fire resistance rating of the barriers. The fire dampers are constructed of galvanised carbon steel and are actuated by fusible links designed to melt and release the damper blade when the air temperature reaches 74°C (165°F). The damper blades close via a spring mechanism. The fire dampers meet the design, testing, and installation requirements of UL 555 (Reference 23.18).

  The fire dampers are essential to maintain the integrity of fire barriers discussed in the internal fire hazard section in Chapter 11. The fire dampers are passive components operated by temperature and a spring mechanism. As such, no actuation signal is required. The fire dampers are designed to Class 3 as they are the principal means of a fire damper rating will be at least equal to the fire barrier that they penetrate, up to a maximum 3-hour rating which is a Category B safety function.

23.14.3 Claims on Components and Equipment

23.14.3.1 Supply and Exhaust Fans

- The fuel oil day tank vault exhaust fans support the operation of the diesel generators. Failure of the fuel oil day tank vault exhaust fans does not directly affect operation of the diesel generators; they do reduce the chance of a fuel fire, so they provide a Category C safety function. Similarly, the fuel oil day tank vault exhaust fans are classified as Category C Class 3 equipment. See Appendix 15A.

  There is one exhaust fan provided for each fuel oil day tank vault. It is claimed that each exhaust fan will continue to operate to prevent the build-up of combustible vapours.

- The electrical equipment service module AHU supply fans support operation of the diesel generators. However, failure of the fans will not lead to the loss of function of the diesel generators. Temperature sensors in the service module would alert MCR personnel if the room temperature started to rise above pre-set limits. This would allow them to take appropriate action to ensure that the room temperatures did not compromise diesel generator operation. Failure of the electrical equipment service module AHU supply fans may reduce electrical cabinet safety margins but would not lead to a DBA and, therefore, the supply fans provide a Category C safety function. The electrical equipment service module AHU supply fans provide a minor contribution to nuclear safety and are Category C Class 3 equipment.

  There is one supply fan provided for each electrical equipment service module. It is claimed that each supply fan will continue to operate to maintain the electrical equipment within its design temperature limits.

23.14.3.2 Electric Heating Coils

The electric heating coil in the electrical equipment service module AHU supports the operation of the diesel generators. However, failure of the heating coil will not lead to the loss of function of the electrical equipment and diesel generators. Temperature sensors in the service module would alert MCR personnel if the room temperature started to fall below pre-set limits and allow them to take appropriate action to ensure the room temperature did not compromise electrical equipment and diesel generator operation. Failure of the electric

heating coil will not reduce safety margins and would not lead to a DBA. Therefore, the heating coil provides a Category C safety function. See Appendix 15A. The electric heating coil provides a contribution to nuclear safety and is Class 3 equipment. See Appendix 15A.

One electric heating coil is provided in the electrical equipment service module AHU. It is claimed that the electric heating coil will start on demand and continue to operate to maintain the electrical equipment within its design temperature limits.

23.14.3.3 Roof Exhaust Fans

- The standby exhaust ventilation subsystem fans support the operation of the diesel generators. Failure of the standby exhaust fans may affect operation of the diesel generators. Therefore, they support the diesel generator and provide a Category C safety function and are Category C Class 3 equipment. See Appendix 15A.

  There are two standby exhaust ventilation subsystem fans in each engine room. Both standby exhaust fans may be required to operate depending on the outside air temperature. It is claimed that each standby exhaust fan will start on demand and continue to operate to maintain the maximum temperature in the engine rooms within the design limits during diesel generator operation.

- The diesel oil transfer module enclosure exhaust fans support operation of the diesel generators. However, failure of the fans will not lead to the loss of function of the diesel generators. Temperature sensors in the diesel oil transfer module enclosures would alert MCR personnel if the room temperature started to rise above pre-set limits. This would allow them to take appropriate action to ensure that the room temperatures did not compromise diesel generator operation. Failure of the diesel oil transfer module enclosure exhaust fans will not reduce safety margins; therefore, the exhaust fans provide a Category C safety function. See Appendix 15A. The diesel oil transfer module enclosure exhaust fans provide a minor contribution to nuclear safety and are Category C Class 3 equipment. See Appendix 15A.

  There is one roof exhaust fan provided in the each diesel oil transfer module enclosure. It is claimed that each roof exhaust fan will start on demand and continue to operate to deliver its safety function.

23.14.3.4 Electric Unit Heaters

The electric unit heaters in the diesel oil transfer module enclosures support operation of the diesel generators. However, failure of the unit heaters will not inevitably lead to the loss of function of the diesel generators. Temperature sensors in the engine rooms and diesel oil transfer module enclosures would alert MCR personnel if the room temperature started to fall below pre-set limits. This would allow them to take appropriate action to ensure the room temperatures did not compromise diesel generator operation. Failure of the electric unit heaters will not reduce safety margins; therefore, the unit heaters provide a Category C safety function. See Appendix 15A. The electric unit heaters provide a minor contribution to nuclear safety and are Category C Class 3 equipment. See Appendix 15A.

One electric unit heater is provided in each diesel oil transfer module enclosure. It is claimed that each diesel oil transfer electric unit heater will start on demand and continue to operate to deliver its safety function.

23.14.3.5 Fire Dampers

The fire dampers protect against fire hazards that could, as part of a sequence of failures, result in loss of a safety function. This could compromise normally operating systems and safety systems delivering a specific function. Therefore, this is a Category B safety function (Reference 23.17). As the fire dampers provide contribute to achieving this safety function, they are deemed to be Category B Class 3 equipment. See Appendix 15A.

Single fire dampers are provided where the ducts pass through a fire barrier. It is claimed that the fire dampers will close when the air temperature in the duct reaches the design limit and maintain the integrity of the fire barrier.

23.14.4 Justification of Claims on Components and Equipment

23.14.4.1 Supply and Exhaust Fans

The fan design includes backward-inclined blades to produce non-overloading characteristics. This will prevent over pressurisation of the ventilation distribution system if a damper in the system closes. This is an inherently safe design feature and provides a high degree of confidence in maintaining the integrity of the ventilation system.

The highest classification of supply and exhaust air fans is Class 3. The fans are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment. In addition, the fuel oil day tank vault exhaust fans will have nonsparking wheels and motors to minimise the risk of ignition in the vaults.

Conceivable failure modes for this type of fan include, for example, a failed bearing, failed drive belt, etc. These types of mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. Also, the fan design will require grease fittings for rotating equipment to be located outside the equipment casing to avoid temporary shutdown of equipment to lubricate bearings or self-lubricating sealed bearings to be used. Operators will be notified of any fan failure by the system to allow them to take appropriate action.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of fan, providing confidence that if they are adequately maintained, they will have good reliability in service.

23.14.4.2 Electric Heating Coils

The electric heating coil is classified as Class 3 equipment. The heating coil is to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Failure of the electric heating coil will not lead to an immediate loss of diesel generator function. The operators would be alerted to heating coil failure and a reduction in temperature of the electrical equipment service module below pre-set limits. This would enable them to take appropriate action to ensure the electrical equipment and diesel generators can maintain their safety function.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of electric heating coil to give confidence that if they are adequately maintained they will have a good reliability in service.

23.14.4.3 Roof Exhaust Fans

The standby exhaust ventilation subsystem fans and the diesel oil transfer module enclosure exhaust fans are classified as Class 3. The fans are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

2- x 50-percent standby exhaust ventilation subsystem fans are included in each engine room such that a degree of cooling will still be provided if one fan fails. The requirement for operation of both fans is dependent on ambient air temperatures. This provides further confidence that the standby ventilation subsystem exhaust fans will be able to deliver the cooling required ensuring the VZS meets its safety functions. Redundancy is not included with the diesel oil transfer module enclosure exhaust fans. This is appropriate as they provide a Category C safety function.

Conceivable failure modes for this type of fan include, for example, a failed bearing or excessive vibration. These types of mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. Also, the standby exhaust ventilation subsystem fan design will require extended lube lines to be provided for bearing lubrication wherever applicable or self-lubricating sealed bearings to be used. Operators will be notified of any fan failure by the system to allow them to take appropriate action.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating these types of fans, designed and constructed to similar standards, to give confidence that if they are adequately maintained, they will have good reliability in service.

23.14.4.4 Electric Unit Heaters

The electric unit heaters in the engine rooms and the diesel oil transfer module enclosures are classified as Class 3 equipment. The heaters are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Failure of the diesel oil transfer unit heaters will not lead to an immediate loss of diesel generator function. The operators would be alerted to unit heater failure and a reduction in temperature of a diesel oil transfer module enclosure below pre-set limits. This would enable them to take appropriate action to ensure that the diesel generators can maintain their safety function.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of electric unit heaters to give confidence that if they are adequately maintained, they will have good reliability in service.

23.14.4.5 Fire Dampers

The design of fire damper used in the VZS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and the spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. The ignition sources in the fuel oil day tank vaults are minimised with the requirement for the exhaust fans to have nonsparking wheels and motors. This also contributes to the inherent safety of the system.

The highest classification of fire dampers is Class 3. The dampers are to be designed and manufactured to normal industrial standards that are suitable for Class 3 equipment.

Any failure that causes the fire damper to close is a failure to safety because the fire barrier will be maintained. The only conceivable failure to an unsafe position is if the damper was to seize or jam in the open position.

Maintenance will be carried out in line with the manufacturer's information. There is extensive experience of operating this type of damper to give confidence that if they are adequately maintained, they will not seize or jam and will move to the closed position when the temperature rises above the specified point.

APPENDIX 23A
AP1000 NUCLEAR VENTILATION – COMPARISON WITH UK PRACTICE AND BEST AVAILABLE TECHNOLOGY ASSESSMENT

23A.1 COMPARISON WITH UK PRACTICE

The AP1000 plant ventilation systems are designed to US codes and standards. The design satisfies the UK practice as described in References 23.1 and 23.2. This is discussed further in Appendix 23A. A justification for the acceptability of United States standards for use in the UK is provided in UKP-GW-GL-045 (Reference 23.44).

The extracts from areas with the potential for radioactive discharges are individually continuously monitored and alarmed. In addition, the plant vent combined discharge is monitored and alarmed.

Reference 23.1 defines a classification scheme for working areas according to the potential for radioactive contamination, whether surface or airborne:

- White means a clean area free from radioactive contamination, whether surface or airborne.
- Green means an area that is substantially clean. Only in exceptional circumstances is airborne contamination such that provisions must be made for its control.
- Amber means an area in which some surface contamination is expected. In some cases, there will be a potential for airborne contamination such that provision must be made for its control.
- Red means an area in which contamination levels are so high that there is normally no access without appropriate respiratory protection.

While the detailed access controls for each area are meant for individual operators, the classification provides recommendations for the design of the associated ventilation systems.

No HEPA filtration is required on the extract for all white areas. HEPA filtration is expected on the extract for all red areas. For green and amber areas, the need for HEPA filtration must be reviewed as part of the plant hazard assessment, taking into account the potential for airborne release.

Reference 23.1 recognises that in cases where the ventilation discharge has little accidental discharge risk, cleanup systems are not always justified. During normal running, to avoid passing large amounts of air through HEPA filters (which are expensive to install, maintain, and dispose of after use), standby systems serving a number of areas could be brought into use for fault conditions. This is particularly the case when the radioactive materials are contained in high-quality primary containment. In the AP1000 plant, all active liquids and resins are contained within pipework, pumps, and tanks designed to standards suitable for the temperature and pressure involved, and that activity is thus contained.

UK practice is also described in Reference 23.2. Reference 23.2 provides the following guidance: “Particulate material from both the management system for gaseous waste and the ventilation systems should be removed using filters. It is a good practice to ensure that all gas discharged from the plant that may be radioactive passes through high efficiency filters.” Therefore, compliance with Reference 23.2 is only discussed for potentially radioactive

exhausts, i.e., areas classified as green, amber, and red following the guidance provided in Reference 23.1.

The potential for routine and accidental activity in the areas served by each of the AP1000 plant ventilation systems is reviewed below.

23A.1.1 Nuclear Island Nonradioactive Ventilation System

The VBS serves the MCR, control support area, 1E electrical spaces, and the PCS valve room, as described in Section 23.11. These areas do not have sources of activity present during normal operation or fault conditions.

In line with Reference 23.1, the area served by the VBS is classified as white for both normal and fault conditions, and as such there are no provisions made for exhaust HEPA filtration.

23A.1.2 Annex/Auxiliary Building Nonradioactive Ventilation System

The VXS serves the office areas, switchgear rooms, locker rooms, battery rooms, computer rooms, toilets, and other similar spaces, as described in Section 23.12. These areas do not typically have sources of radioactive contamination present during normal operation.

A drain line from the BDS to the liquid radwaste system (WLS) passes through the areas served by the VXS. The drain line can be contaminated by the BDS if there are 1) fuel leaks, 2) steam generator leakage, and 3) a radiation monitor failure or an isolation valve failure. Since the drain system has no valves or connections within the area served by the VXS and it is gravity-drained, the chance of leakage into the VXS area is negligible as there would need to be a pre-existing leak co-incident with a fault.

It is not reasonably foreseeable for activity to be present in the areas served by the VXS and hence, in line with Reference 23.1, the area is classified as white for both normal and fault conditions, and as such no provisions are made for HEPA filtration.

23A.1.3 Diesel Generator Building Heating and Ventilation System

The VZS supplies air to and exhausts from the diesel generator building, as described in Section 23.14. The diesel generator building is a physically separate building.

There is no credible source or fault that would result in a radioactive release from the diesel generator building and thus there is no normal or fault condition where a HEPA filter would reduce radioactive releases; hence, HEPA filtration is not provided. In line with Reference 23.1, the area served by the VZS is classified as white for both normal and fault conditions, and as such there are no provisions made for HEPA filtration.

23A.1.4 Containment Recirculation System

The VCS recirculates and cools air within the containment during power operations and shutdown, as described in Section 23.4. The recirculation of the containment air results in an energy savings and a reduction in waste generated in the form of used filters when compared with what would arise from the level of once-through HVAC ventilation system. The air recirculated by this system is expected to contain some activity (mostly noble gases and some iodine), although it does not penetrate the containment boundary and thus does not give rise to any discharges to atmosphere.

During shutdown operations in the containment, local, filtered extract systems are available for particular operations where airborne activity may be generated. This reduces the potential for airborne activity to be released into the general containment atmosphere, which the recirculation system could spread to other parts of the containment building.

The extracted air is continuously monitored for airborne activity that would give early warning to workers in the containment of the presence of airborne activity.

There is no path to discharge the VCS to the environment and hence HEPA filtration is not provided.

23A.1.5 Containment Air Filtration System

The VFS purges the containment by providing fresh air from outside and exhausting air to plant vent. The VFS also exhausts from areas served by the VAS and the VHS after receipt of a High radiation signal in the VAS or the VHS exhaust respectively, or from one of the area radiation monitors.

Each VFS train is equipped with HEPA filtration and charcoal filters for removal of particulate and iodine vapour respectively. A high-efficiency filter (80 percent ASHRAE) is installed before the HEPA filter to increase operational life and reduce the quantity of low-level waste (LLW). A high-efficiency filter has a greater capacity and therefore will require less frequent changing and thus potentially reduce volumes of LLW produced. A high-efficiency filter is also installed after the charcoal filter to ensure that discharges are ALARP. Continuous monitoring of airborne discharges is provided to detect deterioration in the performance of either ventilation train. These provisions represent good industry practice for ensuring that discharges to the atmosphere and doses to members of the public are ALARP.

In line with Reference 23.1, the containment is an amber area with a potential for occasional releases. It is therefore provided with full-time filtration on the exhaust. The design of the VFS complies also with the guidance provided in Reference 23.2.

23A.1.6 Health Physics and Hot Machine Shop HVAC System

The VHS supply air system consists of two 100-percent-capacity air handling units, consisting of a low-efficiency and a high-efficiency filter bank, heating and cooling coils, and a supply fan with automatic inlet valves. The exhaust air system consists of two 100-percent-capacity exhaust fans sized to allow the system to maintain negative pressure, as described in Section 23.10.

The hot machine shop provides a location within the controlled area for repair and refurbishment of items of equipment from within the controlled area, i.e., they may not actually be contaminated or activated but it is easier to have a dedicated workshop rather than undertaking clearance monitoring, which may not be possible. Operations in the hot machine shop are conventional hands-on work, i.e., there is no provision for remote handling. The routine arisings of airborne contamination from machining operations are not expected to be significant because equipment that can be repaired will be decontaminated beforehand. Equipment that is too active to handle manually and cannot be decontaminated will be packaged and disposed of as radioactive waste.

Airborne contamination from the remaining space extract from the hot machine shop and other areas served by this system is not expected to be significant during either normal or fault conditions.

The facility has a dedicated decontamination facility that has HEPA filtration and a glovebox that also has HEPA filtration. The HEPA filters on the decontamination chamber and glovebox are typically ported so that a dispersed oil penetration (DOP) test can be performed. The portable decontamination units are also capable of DOP testing although equipment is not specified to date.

Individual machine tools have local exhaust ventilation arrangements that include HEPA filters. The HEPA filters on the individual machine tools are ported so that a DOP test can be performed.

HEPA filtration is not provided on the HVAC system; however, the VHS fans shut down on a High radiation signal and the exhaust is then directed through the VFS, thus reducing the airflow from the served spaces but allowing for the exhaust to be filtered.

The filtration system is in line with Reference 23.1 as follows:

- Gloveboxes are red areas, and therefore HEPA filtration is provided.
- Individual machine tools are amber areas with significant potential for low level of activity release, hence HEPA filtration is provided.
- Airborne contamination from the remaining space of the hot machine shop and other areas served by this system is not expected to be significant during either normal or fault conditions. Therefore, the remaining space is a green area with low risk; hence, no constant HEPA filtration is provided but the extract is directed to a VFS after receipt of a High radiation signal in the VHS exhaust.

The design of the VHS also complies with the guidance provided in Reference 23.2: HEPA filtration is provided on all exhausts that may be radioactive, whether as full-time filtration when there is a significant potential for activity release or using a stand-by filtered system if necessary when the release of activity is very unlikely.

It is further demonstrated in Section 23A.2 that the VHS design for the radiologically controlled part of the auxiliary and annex represent the best available technology (BAT).

23A.1.7 Radwaste Building Heating, Ventilation, and Air Conditioning System

The VRS supplies and exhausts air from the radwaste building, as described in Section 23.9.

The radwaste building has three potential sources of radioactive contamination, which are the following:

- Tanks for low-level liquid effluent for monitoring and sentencing. The monitor tanks contain water that has the potential of having radiological contamination. The water in the monitoring tanks is not expected to contain significant contamination and will typically be below environmental discharge limits.
- An area for loading packaged solid LLW into containers for dispatch to a LLW Repository (LLWR). Packaged solid radwaste is stored in the radwaste building. This

material is bagged or loaded into storage containers at the point where it is generated and processed, so the chance of a significant release is low. All LLW will have been prepackaged. Currently, primary circuit resins are classified as intermediate-level waste (ILW). Condensate polishing resins might be LLW in the event of SG tube failures and are encapsulated at the spent resin tank. Other LLW is not encapsulated. LLW processing equipment is currently expected to be permanently installed. ILW processing equipment is mobile if it is subjected to further treatment such as low or high force compaction in the radwaste building; then the equipment used will be self-contained with integral ventilation and HEPA filtration. The equipment may be permanently located at each site or may be transportable to undertake campaigns at more than one site. All of the AP1000 plant standard radwaste equipment located in the radwaste building is portable.

- Portable or permanently installed equipment for packaging ILW and/or compacting LLW and ILW. The current AP1000 design has provisions for portable radwaste processing equipment. This equipment will connect to the railcar bay auxiliary building HVAC systems; therefore, the risk of contamination from equipment and processing equipment is small. In addition, all potential sources are filtered at the component level.

The VRS general extract may contain significant airborne activity during either normal operation or fault conditions if the portable radwaste equipment is not properly operated.

In line with Reference 23.1, the radwaste building is classified as an amber area with the potential for significant airborne activity release. Because there is a possibility of a release in the unlikely event of a serious equipment failure, the VRS extract is passed through HEPA filters. The design of the VRS also complies with the guidance provided in Reference 23.2.

23A.1.8 Turbine Building HVAC System

The VTS serves all areas of the turbine building, as described in Section 23.13. The HVAC systems serving the switchgear rooms, rectifier room, security rooms, and plant control system cabinet rooms do not have a credible source of radioactive contamination. The general area of the turbine building is ventilated using about 850 m^3/s (1,800,000 cfm) exhausted through roof ventilators. This part of the AP1000 plant does not have a likely source of radioactive contamination. These areas do not have HEPA filtration because they do not offer a significant protection benefit.

The Bay 1 area of the turbine building contains the reactor coolant pump variable speed drives, CCS equipment (a nonradioactive system), and the BDS. The BDS may be contaminated in the very unlikely event of concurrent fuel defects, SG leak, radiation monitor or BDS isolation failure, and a BDS leak.

In line with Reference 23.1, the turbine building, except for the Bay 1 area, is a white area. The Bay 1 area is a green area with a very limited potential for airborne release, hence, no HEPA filtration is provided.

23A.1.9 Radiologically Controlled Area Ventilation System

The AP1000 plant VAS serves the RCA of the auxiliary and annex buildings, as described in Section 23.3. The VAS consists of two separate subsystems, the fuel handling area ventilation subsystem and the auxiliary/annex building ventilation subsystem combined to a single extract. Both of these subsystems are once-through-type ventilation systems.

The supply airflow rate is modulated to maintain the areas served at a slightly negative pressure differential with respect to the outside environment. The HEPA filtered exhaust air is directed to the plant vent for discharge and monitoring of offsite gaseous release.

23A.1.9.1 Fuel Handling Area

The fuel handling area ventilation subsystem supply and exhaust ductwork is arranged to exhaust the spent fuel pool area separately from the auxiliary building. It provides directional airflow from the rail car/bay filter storage area into the spent resin equipment rooms. The exhaust fans discharge the exhaust air through HEPA filters into the plant vent for monitoring of offsite airborne gaseous and other radiological releases.

All spent fuel handling operations are performed under borated water to provide radiation protection. Activity levels in the SFP are controlled by Technical Specification. The activity level in the SFP is reduced, if necessary, by transferring a portion of the SFP water to the WLS for discharge and replacing it with clean water. The SFP water is constantly filtered and purified by the SFS to remove radioactive corrosion products, fission product and other impurities to maintain low SFP radioactivity levels and water clarity.

Routine releases for the fuel handling area are low. The potential for accidental release is low; however, if the radiation monitors detect a high level of radiation, the fuel handling extract is diverted to the VFS, which contains both HEPA filters and charcoal filters. It can also be diverted manually if particular operations are being undertaken that could result in release of activity.

HEPA filtration is provided for the exhaust from the fuel handling areas as follows:

- The AP1000 plant fuel handling area is similar to other UK and European modern plant fuel handling areas, and it is common practice at those plants is to have HEPA filtration on the exhaust of the ventilation system serving the fuel handling area.

- The corrosion product crud that has accumulated on the spent fuel assemblies is highly radioactive. Crud slowly dissolves in the spent fuel water, which is cleaned up by the SFS twice every 24 hours using the purification loop. There is no accumulation of crud in the SFP thanks to good mixing achieved by the SFS. There is some uncertainty, however, about the potentiality of the crud to become airborne as the SFP water evaporates. In case of equipment failure, therefore, there is a potential for airborne crud to be released through the VAS exhaust.

HEPA filtration is provided for the spent fuel pool relief panel. In the unlikely case of spent fuel pool boiling, the HEPA filters ducted to the relief panel will remove particulates from the discharged air-steam mixture.

In line with Reference 23.1, the fuel handling area is classified amber with low risk for activity release, hence HEPA filtration is provided. This design is in line with the guidance provided in Reference 23.2.

23A.1.9.2 Auxiliary/Annex Building

The remainder of the radiologically controlled part of the auxiliary and annex building exhaust air ductwork is routed to minimise the spread of airborne contamination by directing the supply airflow from the low radiation access areas into the radioactive equipment and piping rooms with a greater potential for airborne radioactivity. In addition, the exhaust air ductwork is connected to the radwaste effluent holdup tanks to prevent the potential build-up of gaseous radioactivity or hydrogen gas within these tanks. The exhaust fans discharge the exhaust air into the plant vent for monitoring of offsite airborne radiological releases.

The supply and exhaust ducts are configured so that two building zones may be independently isolated. The annex building staging and storage area, containment air filtration exhaust rooms, containment access corridor, and adjacent auxiliary building staging, equipment areas, middle annulus, middle annulus access room, and security rooms are aligned with one zone. The other zone includes the remaining rooms and corridors, including but not limited to the radiation chemistry laboratory, primary sample room, SFP cooling water pump and heat exchanger rooms, normal residual heat removal pump and heat exchanger rooms, CVS makeup pump room, and lower annulus; and various radwaste equipment rooms, pipe chases, and access corridors. A radiation monitor is located in the exhaust air duct from each zone.

All active liquids and resins are contained within the system piping and equipment. Routine discharges are low; no single fault will result in higher discharge levels. If, however, the radiation monitors detect a high level of radiation, the fuel handling extract is diverted to the VFS, which contains HEPA filters. It can also be diverted manually if particular operations are being undertaken that could result in release of activity.

In line with Reference 23.1, the radiologically controlled part of the auxiliary and annex building served by the VAS is classified amber with low risk for activity release.

Reference 23.2 recommends providing HEPA filtration on all exhausts that may be radioactive. It is also the practice at UK and European plants to HEPA-filter the exhaust from the RCA of the annex and auxiliary buildings, however:

- The AP1000 design has greatly minimised, when compared with UK and European plants, the potential for release of activity in the general RCA, so that routine discharge is low and HEPA filters would have very little benefit.

- Some infrequent events (such as small break outside containment) will result in higher discharge level, but the use of the HEPA filters and charcoal filters in the VFS provide adequate filtration. Both the local area and ductwork exhaust monitors are used to actuate the extract through the VFS extract to ensure rapid detection and response time.

It is further demonstrated in Section 23A.2 that the VAS design for the radiologically controlled part of the auxiliary and annex represent the BAT.

23A.1.10 Duct Monitors

Beta scintillation monitors set up to detect the principal noble gases present (Kr-85 and Xe-133) are located in the VAS extract duct from the fuel handing area , the VRS radwaste building extract , the VHS health physics and hot machine shop extract , and the VFS containment purge extract ; and in each of the VAS main extract ducts from the annex building and the auxiliary building (Reference 23A.1). (Their approximate sensitivity is specified in the range 3.7e-3 Bq/m^3 (10^{-12}μCi/cc) to 3.7 kBq/m^3 (10^{-7}μCi/cc).

Releases from fuel or primary coolant will include releases of noble gas. The VAS and VHS monitors will stop the associated supply and exhaust systems and start the VFS extract to filter all extract from the impacted area. The VFS maintains the impacted area at a negative pressure with respect to atmosphere so that there is no unfiltered release to atmosphere during or after an abnormal release into the areas served by the VAS.

The VFS and VRS duct monitors alarm on a High signal.

23A.1.11 Area Monitors

Area gamma monitors are provided to measure the radiation intensities in specific areas of the AP1000 plant. The range of the area monitors is such that the normal and anticipated zone dose rate and any anticipated operational occurrences that would increase the zone dose rate are detected. Area monitors are located so as to provide warning of uncontrolled or inadvertent movement of radioactive material in the AP1000 plant.

Selected area monitors are used to actuate the VFS filtration. Using area monitors in addition to the duct radiation monitors to actuate the VFS has a high probability of reducing the filtration actuation time.

Area monitors that provide VFS actuation signals and the monitor locations are delineated in Reference 23A.1.

23A.2 BEST AVAILABLE TECHNOLOGY ASSESSMENT

23A.2.1 Radiologically Controlled Area Ventilation System – General Area of the Auxiliary Building/Annex Building

The AP1000 plant VAS consists of two separate subsystems, the fuel handling area ventilation subsystem and the auxiliary/annex building ventilation subsystem combined into a single extract. As detailed in Section 23A.1.9, the fuel handling area exhaust is HEPA-filtered, however, for the general area of the auxiliary building/annex building HVAC subsystem, the following different design options were considered:

- Option 1: the exhaust air goes to the plant vent without filtration but is directed to the VFS upon detection of a high level of radiation by the exhaust radiation monitor. The VFS system has both HEPA filters and charcoal filters on the exhaust.

- Option 2: the Regulators have asked Westinghouse to add HEPA filtration to the exhaust going to the plant vent. Westinghouse believes that the addition of HEPA filters to the plant vent exhaust is not the BAT for this part of the VAS area, which is considered to have a low risk of radiological contamination. As described below in option 3, Westinghouse proposes to improve the original system by linking more radiation detectors to the VFS switching signal to improve the system response time from

~30 seconds to less than 15 seconds. The linking of additional detectors both improves the reliability of the switching system and reduces the duration of potentially untreated atmospheric releases.

- Option 3 (AP1000 design): the exhaust air goes to the plant vent without filtration but is directed to the VFS upon detection of a high level of radiation by the exhaust radiation monitor or the local area monitors. The use of local and exhaust radiation monitors provides a system response of less than 15 seconds, and ensures good reliability as well. The VFS system has both HEPA filters and charcoal filters on the exhaust.

Options 1 and 3 present the same disadvantages, but Option 3 provides a more rapid containment of radiation and is thus a better option.

Table 23A-1 provides a BAT assessment to compare the benefits and costs of implementing Option 2 versus the Option 3 (AP1000 plant VAS design).

A number of assumptions have been made to generate quantitative data to facilitate comparison of the two options. These assumptions are as follows;

- 54 HEPA and 54 pre-filters required on VAS general area ventilation exhaust
- HEPA filters changed every 2 years
- Pre-filters changed every 4 months
- Cost of HEPA filters is £420 each
- Cost of pre-filters is £30 each
- Cost of electricity is 7.5p/kWh
- Waste filter compaction volume reduction factor is 3.6.
- Six compacted filters will fit into a 210-litre (55.47 gallons) drum.
- Cost of disposal of LLW to Drigg is £27,500 per half height International Organisation for Standardisation (ISO) container (includes cost of container, delivery of container, cost of transportation to Drigg, and cost of disposal at Drigg).
- LLW drums are 100-percent filled

As can be seen in Table 23A-1, the total cost of adding HEPA filtration to the general area of the auxiliary building/annex building ventilation is estimated to be ~£4,968,700 over the 60-year plant operating life + engineering costs + operating, maintenance, and decommissioning costs. The implementation of this option will also lead to the generation, handling, and disposal of 357 m^3 (9.4e4 gallons) of LLW.

It is thus concluded that the cost of adding continuous HEPA filtration is not justified given the implementation of improved reliability and speed of the VFS switching system.

It should be noted that adding filters to the VAS (Option 2) would not be possible without significant impact on building layout and significant cost. This additional cost has not been considered in the present BAT assessment.

23A.2.2 Health Physics and Hot Machine Shop HVAC System – Health Physics and Hot Machine Shop

The VHS includes localised HEPA filtration of potential radioactive sources (e.g., gloveboxes' exhausts and machine shop tools). However, different design options were considered for the area exhaust as follows:

- Option 1: the area ventilation could be discharged directly to the main plant vent at all times.
- Option 2: a first option to comply with the guidance provided in References 23.1 and 23.2 is to add HEPA filtration to the exhaust going to the plant vent.
- Option 3 (AP1000 design): the area ventilation could be discharged directly to the main plant vent but the exhaust is directed to the VFS carbon bed and HEPA filtration system in the event of detection of radiological contamination. The use of local and exhaust radiation monitors provides a system response of less than 15 seconds, and ensures a good reliability as well.

Option 1 is not acceptable based on the guidance provided in References 23.1 and 23.2. Table 23A-2 provides a BAT assessment to compare the benefits and costs of implementing Option 2 versus Option 3 (the AP1000 VHS design 3).

A number of assumptions have been made to generate quantitative data to facilitate comparison of the two options. These assumptions are as follows:

- 18 HEPA and 18 pre-filters required on VHS general area ventilation
- HEPA filters changed every 2 years
- Pre-filters changed every 4 months
- Cost of HEPA filters is £420 each
- Cost of pre-filters is £30 each
- Cost of electricity is 7.5p/kWh
- Waste filter compaction volume reduction factor is 3.6.
- Six compacted filters will fit into a 210-litre drum (55.47 gallons).
- Cost of disposal of LLW to Drigg is £27,500 per half height ISO container (includes cost of container, delivery of container, cost of transportation to Drigg, and cost of disposal at Drigg).
- LLW drums 100-percent filled

Table 23A-2 shows that over the 60-year plant operating life, the total cost of adding HEPA filtration to the health physics and hot machine shop ventilation is estimated at £1,656,200 + engineering costs + operating, maintenance and decommissioning costs. The implementation of this option will also lead to the generation, handling, and disposal of 119 m^3 (3.1435 gallons) of LLW.

In addition, the main source of radiological contamination is already treated by local HEPA filtration and the area is considered to have a low risk of radiological contamination.

It is thus concluded that the cost of adding continuous HEPA filtration to the health physics and hot machine shop is not justified given the local HEPA filtration and the connection of the VHS to the VFS switching system.

23A.2.3 Nuclear Ventilation Design Guidance

A number of clauses in the UK nuclear ventilation design guide (Reference 23.1), support the argument against adding HEPA filters to the plant vent exhaust in areas with a low risk of radiological contamination:

1. Clauses 2.4.1b) and 2.5.1b) outline measures that should be taken to minimise the creation of radioactive waste as far as practicable:

   2.4.1b) states that "for environmental protection (and also cost reasons) it is now accepted policy to minimise radioactive waste arisings as far as practicable; in particular, contaminated HEPA filters, being of low density are very expensive to store or dispose of as radioactive waste."

   2.5.1b) states that "total air flow through the system from inlet to discharge into the atmosphere should be minimised. This will result in the number of filters to be disposed of as radioactive waste also being minimized."

   It is estimated that adding HEPA filtration to the general area of the auxiliary building/annex building and to the health physics and hot machine shop ventilation will increase radioactive waste arisings by 476m^3 (1.25e4 gallons) with an associated LLW disposal cost of £1,776,900 (see Tables A-1 and A-2 for cost breakdown). The total cost of the filter addition over the plant life would be £6,624,000.

2. Clause 2.6.3 states that "the degree of containment, including the number of barriers required, for the particular plant must be determined by a risk assessment, taking account of the design safety principals for the project. This will take into consideration the severity and likely frequency of potential accidents."

   The infrequency of potential radioactive releases in the auxiliary/annex building is a major factor to be considered when assessing the benefits and costs of adding HEPA filters to the plant vent exhaust. The release of radiation above acceptable levels in the auxiliary/annex building is a highly unlikely occurrence and Westinghouse estimated a maximum of one or two discharges exceeding the VFS detector switching points during the 60-year lifespan of the plant. In this situation, the exhaust will be switched to the VFS system, which has HEPA filtration and carbon beds, in less than 15 seconds so that the potential release will be minimal.

3. Clauses 3.7.6 and 3.7.10 specifically refer to the option of using a standby cleanup plant for use with areas that are expected to be clean and that have low accident potential for loss of containment.

   Clause 3.7.6 states that "other extracted areas are cells usually incorporating shielding, which house active plant … Such items are in high quality primary containment. The extract from these cells will be clean if there has been no containment breach. The clean up requirements are usually dependent upon the accident potential of the system as assessed by hazard assessment, and single or double HEPA filtration may be required. An

option on these systems is to keep the clean-up plant on a standby basis, bringing it into use in the event of an accident. This option will have to be justified; it will be necessary to demonstrate that appropriate indication and control functions exist to bring the system into use in sufficient time to control the release to acceptable levels."

Clause 3.7.10 states that "In cases where the ventilation discharge has little accidental discharge risk, clean-up systems are not always justified. During normal running, to avoid passing large amounts of air through HEPA filters (which are expensive to install, maintain and dispose of after use), standby systems serving a number of areas, could be brought into use for fault conditions."

In the AP1000 plant, the operation of the VFS is effectively providing a standby system in the event that areas that are expected to be clean (i.e., the general area of the auxiliary building/annex building and to the health physics and hot machine shop) become contaminated.

23A.2.4 Conclusions of the Best Available Technology Discussion

In conclusion, the AP1000 design for the treatment of ventilation exhaust from the general area of the auxiliary building/annex building and the health physics and hot machine shop represent BAT for these ventilation systems.

Table 23A-1. BAT Comparison Table – VAS General Area Ventilation

Issue	Option 1	Option 2	AP1000 Design – Option 3	Advantage Option 2	Disadvantage Option 2	Advantage Option 3	Disadvantage Option 3
Filtration/ emissions	Connected added to the VFS to automatically switch to filtered exhaust if a high radiation signal is detected in exhaust duct.	Continuous HEPA filtration of area.	Connection added to the VFS to automatically switch to filtered exhaust if a high radiation signal is detected in exhaust duct or building. Contamination response time less than 15 seconds by linking area and exhaust detectors to initiating switching to VFS.	High level of particulate removal (Efficiency 99.97% on 0.3 micron particles) Reduced environmental emissions of radioactive particulates. Reduced reliance on detection systems. All air filtered, not just air contaminated above detection threshold.	Contaminated air not vented through VFS carbon bed – no radioiodine removal. Radioactive gases not removed by HEPA filters. No measurable reduction in normal emissions (reduction is over two orders of magnitude less than the instrument error range).	Upon detection of contamination, air is vented through VFS HEPA filter and carbon bed (particulate and gaseous contamination removed). Radiation detection response time reduced from ~30 to ~15 s. Reliability of switching improved with more detectors providing switching signal.	Switching to VFS relies on detection system. Contamination may pass out of building unfiltered for up to 15 seconds before system switches to VFS.
Energy use	VAS fans run continuously.	HEPA fans run continuously. Fan horsepower increased by 45-60 hp (33.6-44.7 kW).	VAS fans run continuously.	-	Up to an additional 23.51-GWh power consumption over 60-year operating life of plant.	No change to energy consumption of fans. Energy use of extra detectors negligible.	-
Waste	-	36 – 54 HEPA filters and same number of pre-filters (treated as LLW) HEPA filters will be replaced every 2-3 years. Pre-filters replaced every 4-6 months.	-	-	Total number of filters used = 189 per year and 11,340 over 60-year plant operating life. Volume of each filter is 4 ft^3. Volume of each compacted waste filter is 31.5 litres. Volume of compacted filter waste (LLW) = 5.95 m^3 per year and 357 m^3 over plant operating life. No. of LLW waste packages = 32 drums (210l) per year or 1,890 drums over plant operating life. This equates to 48.5 half-height ISO (HHISO) containers over plant operating life.	No additional HEPA filter waste (above filter usage for VFS system), therefore waste arisings are minimised.	-
Construction	Exhaust fans placed on roof with mounting foundations.	HEPA filtration units placed on roof with mounting foundations.	Exhaust fans placed on roof with mounting foundations. Extra ductwork.	-	HEPA and pre-filtration units placed on roof. Extra ductwork.	-	-
Maintenance	-	HEPA filters would be replaced every 2-3 years. Pre-filters replaced every 4 – 6 months.	-	-	Estimated number of HEPA filter change outs over operating life of plant is 1620. Estimated number of pre-filter change outs over operating life of plant is 9720.	-	-

24 RADIATION PROTECTION

24.1 Introduction

This chapter of the Pre-Construction Safety Report (PCSR) covers the protection of workers and members of the public against exposure to ionising radiation in normal operations and protection of essential workers following a major accident. Potential fault conditions are identified in Volume 3 of the PCSR. The frequency and consequences of accidents and the prevention and mitigation systems are also covered in Volume 3.

Radiation protection from external radiation under normal operating conditions, including routine maintenance, is achieved in the design by reducing, so far as is reasonably practicable (SFAIRP), the sources of radiation. Where sources cannot reasonably be reduced further, exposure to radiation is controlled by means of shielding and by controlling the duration of exposure. Protection from radioactive contamination is achieved by reducing the activity present in dispersible form, and providing suitable containment and ventilation, layout of areas, control of access, monitoring, and personal protective equipment (PPE).

Westinghouse has many years of experience in the design and maintenance of pressurised water reactors (PWRs). Maintenance has included such major operations as replacing steam generators (SGs) and reactor coolant pumps (RCPs) as well as standard refuelling operations. As a result, Westinghouse has developed a considerable understanding of the major sources of radiation exposure during operation and maintenance of its reactor design; it has been able to undertake continuous improvement programmes to reduce sources of external radiation in operating reactors and to reduce doses incurred during operation and refuelling.

The design of the AP1000 reactor has taken into account utility requirements for reliability; safe operation and maintenance; and reduction in operator dose. Experience from the continuing improvements in operating plants has been incorporated into the design (e.g., materials selection, and plant layout) and operating regime (e.g., reactivity control, water chemistry, and zinc addition) to reduce radiation levels from the plant. In areas where high external radiation levels are likely, suitable and sufficient shielding is provided to protect workers from high radiation levels during normal operations, maintenance, and fault conditions. As discussed in section 24.3, the AP1000 design has been simplified when compared to operating PWRs; the AP1000 PWR has fewer valves and less piping which is expected to provide reductions in personnel dose due to reduced maintenance times and activities.

Westinghouse has incorporated features into the design that reduce the outage time for refuelling and, as a result, reduce the duration of worker exposure to radiation. Where applicable in the design, remote inspection and maintenance systems have been allowed for to further reduce exposures during shutdown. This is an ongoing process and in the future, as new techniques become available, backfitting may be considered where reasonably practicable.

Segregation of areas and suitable extract ventilation systems prevent the spread of contamination (including tritiated water) within and outside of the containment and other buildings. Best available techniques (BATs) are used to restrict routine airborne and liquid discharges of radioactive material.

A single personnel entrance is provided for the radiologically controlled areas (RCAs) of the reactor containment, shield building, auxiliary building, annex building, and radwaste building. Non-radiation areas of the auxiliary/annex buildings are completely segregated from

the RCA. The AP1000 design is considered to restrict routine doses to operators and others SFAIRP.

External or internal faults, such as loss of external power or feedwater pump failure, will initiate plant responses that may include operator actions to bring the reactor to a safe state without any abnormal releases or further plant damage. In the unlikely event of coincident failures or operator errors resulting in a severe accident, the use of passive systems for mitigation of major accidents maintains the integrity of the reactor containment for 72 hours without standby systems. However, the main control room (MCR) will continue to be manned and some operations will be undertaken during this period to monitor and prepare to maintain the passive containment water inventory and spent fuel pool (SFP) cooling. The MCR is provided with an uncontaminated supply of air from pressurised cylinders; calculations demonstrate that the dose to workers in the MCR during this period will be limited. If the MCR needs to be evacuated during normal operations (e.g., in the event of a fire in the MCR), the reactor operators will transfer control to the remote shutdown station (Room 12303) but this is not intended for use during a major accident. Predefined routes are provided to locations that need to be accessed in a major emergency and the doses arising from essential actions following a major accident have been assessed.

24.2 Design Targets

An overriding aim in the design of the AP1000 reactor has been to ensure that doses to workers and members of the public are as low as reasonably achievable (ALARA). This is taken to be equivalent to the terms SFAIRP and as low as reasonably practicable (ALARP) as explained in the Health and Safety Executive (HSE) safety assessment principles (SAPs) (Reference 24.1). While regulatory limits provide an upper boundary for individual dose, the emphasis on ALARP ensures that individuals will not be expected to approach any dose limit.

It is therefore reasonable to compare the doses received in normal operations to the numerical targets specified in Reference 24.1 and as shown in Table 24-1.

The design and operating regime of the AP1000 reactor ensures that doses will be kept below the basic safety level (BSL), which, in some cases, is also the legal limit (LL) under the Ionising Radiations Regulations (IRR99) (Reference 24.2) and, in many cases, also show that doses will be at or below the basic safety objective (BSO). The design intent is that doses will be ALARA, which, as noted above, complies with the SFAIRP requirement of the IRR99.

The IRR99 (Reference 24.2) specify a dose limit for members of the public, which is included as the BSL (LL) in the HSE SAPs (Reference 24.1) and shown in Table 24-1. The IRR99 also recommend that a dose constraint of 300 μSv be applied to doses to members of the critical group from a single new source. In the SAPs, the HSE interprets a single source as being a site under a duty holder's control. The Environmental Permitting Regulations 2010 (EPR2010) (Reference 24.3) specify maximum doses to individuals that may result for a defined source of:

1. 0.3 mSv per year from any source from which radioactive discharges are first made on or after 13th May 2000; or

2. 0.5 mSv per year from the discharges from any single site.

It is therefore appropriate to assume a de facto annual dose limit of 300 μSv for members of the public from discharges of radioactive material as noted in Table 24-1, although an objective of 150 μSv has been established for new nuclear power plants.

The AP1000 design process commenced several years ago, and initially, a design target of 1 person-Sv per year was adopted for the annual collective dose to workers to ensure that individual doses are not controlled by dose-sharing among a large group. In addition to this target, the ALARP philosophy was also applied to the design process. At the time, the 1 person-Sv per year target was a challenging goal compared with the annual doses incurred in operating plants. However, as a result of improved practices, the numerical target has been met for annual doses in a number of existing plants. Further reductions have been achieved in existing plants by improvements such as use of low-cobalt materials in replacement SG tubing and zinc injection. While it is now apparent from the routine dose uptake assessment that a significantly lower design target could have been met, there is little point in doing so at this stage: the value selected would simply be chosen to be just above the estimated routine collective dose. What is clear from the large margin by which the design target has been met is that the process of continuous improvement in the design has not been limited, even though the design target has been achieved. In addition, the application of ALARP philosophies ensure that radiological conditions within the plant are constantly challenged, and have helped to drive continuous improvement as the AP1000 design has progressed.

The doses to workers and the means by which they are kept ALARP are assessed in this chapter. The means for ensuring that doses to members of the public are ALARP are discussed in detail in Chapter 26.

Numerical targets are also specified for the frequency and consequences of accidents and for the overall risks from all accidents on the site, both for workers and for members of the public (Reference 24.1). These are reproduced in Table 24-2. The consequences and risks from accidents are assessed in detail in Chapters 8 to 14 in Volume 3.

In the event of a major accident, the regulations on emergency preparedness (Reference 24.4) allow the statutory dose limits to be exceeded for the purpose of intervention during a "radiation emergency". Provisional guidance on acceptable maximum doses for personnel during intervention has been issued (Reference 24.5) as shown in Table 24-3 subject to the overriding requirement to apply ALARP.

The AP1000 plant MCR has been designed to restrict doses to personnel for the duration of a limiting design basis accident to 50 mSv in compliance with general design criterion 19 (Reference 24.6), which is below the provisional guidance level for intervention (Reference 24.5).

24.3 Radiological Protection of Workers – Normal Operation External Radiation

Normal operation comprises power generation and refuelling shutdowns. The main sources of radiation hazard during operation and during refuelling and maintenance are described in Table 24-4. The radionuclides generated in the fuel by the fission process have been calculated using the industry standard computer code (References 24.7 and 24.8) with parameters specific to the AP1000 reactor. The concentrations of fission products from the fuel in the primary coolant and elsewhere in the reactor systems and generation and transport of activated corrosion products (crud) have been determined using computer codes developed by Westinghouse (References 24.9, 24.10, 24.11, and 24.12). Other codes have been used for determining N-16 and other primary circuit activities (Reference 24.15) and activity in the secondary circuit (References 24.16 and 24.17). The computer codes used to determine the source terms are described in Table 24-5. The basic source term information is collated in the radiation analysis design manual (Reference 24.26). A high-level look at the codes and process used to evaluate radiation source terms is shown in Figure 24-14.

The effects of design changes on source terms, for example measures to reduce crud, are assessed as part of the design change process. The specific source terms used in calculations are referenced and justified in the relevant calculation notes. Independent verification of each calculation ensures the validity of the source term evaluation. A detailed matrix shows how each assessment has been used.

In the design process, engineering measures such as source term reduction and shielding design were used to reduce doses to levels that are ALARP, and these measures were given precedence over administrative measures, such as dose sharing and procedural control. All aspects of the design have been considered to ensure that doses are ALARP, starting with source term reduction. The plant has been designed to reduce and simplify maintenance and refuelling, which account for a significant proportion of the dose. Shielding is provided to keep dose rates in occupied areas ALARP during operation and shutdown; remote techniques have been facilitated to reduce doses from essential operations in high dose rate areas.

Doses incurred during planned shutdown and normal refuelling operations are considered in this section. Special operations that may need to be undertaken at some time in the life of the plant, such as SG or RCP replacement, have been considered in the design of the plant to ensure that they can be undertaken if necessary, and the design provisions to reduce doses will ensure that dose rates are ALARP. However, the doses from these operations are not included in the normal operation dose assessment because there is no certainty that they will be necessary in the life of the plant. It will be the responsibility of the plant operators to prepare the relevant safety cases at the time.

24.3.1 Source Term Reduction

The design of the AP1000 plant incorporates a range of features to minimise the production and transport of radioactive corrosion products (crud), within the primary circuit that experience has shown to be responsible for doses to operators, increased discharges, and associated problems in decommissioning. The means by which radiation source terms have been minimised in the design of the AP1000 reactor include the following:

- Material selection
- Material quality control
- Piping design
- Reactor coolant chemistry control
- Primary coolant and SFP cleanup (chemical and volume control system (CVS) and spent fuel pool cooling system (SFS))
- Surface treatment (SG channel head)

24.3.1.1 Materials Selection

Controlling the choice of materials that come in contact with the primary coolant leads to a reduction in the production of corrosion products, including Co-58, Co-60, Fe-55, and Ni-63. In the AP1000 design, the following points are of particular note:

- Ferritic low-alloy and carbon steels used in principal pressure-retaining applications have corrosion-resistant cladding on surfaces exposed to the reactor coolant (Type 304 for roll bonding and Type 308/308L for overlay). The corrosion resistance of the cladding material is at least equivalent to the corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy, martensitic stainless steel, and precipitation-hardened stainless steel.

- Equipment specifications for components exposed to high-temperature reactor coolant limit the cobalt content of the base metal as given in Table 24-17. The use of hard-facing material with cobalt content such as stellite is limited to applications where its use is necessary for reliability considerations. Nickel-based alloys in the reactor coolant system (RCS) (Co-58 is produced from activation of Ni-58) are similarly used only where component reliability may be compromised by the use of other materials.

- The specification of low-cobalt tubing material (Inconel™ 690) for the AP1000 reactor SG design is an important feature of the design, not only in terms of reduced exposure relative to the SG, but to the total plant radiation source term. The cobalt content has been substantially reduced to 0.015 weight percent for the AP1000 reactor SG tubing, as shown in Table 24-17.

- Lead, antimony, cadmium, indium, mercury, and tin metals and their alloys are not allowed to come in contact with engineered safety features' component parts made of stainless steel or high-alloy metals during fabrication or operation. Bearing alloys containing greater than 1 percent of lead, antimony, cadmium, or indium are not used in contact with reactor coolant.

24.3.1.2 Piping Design

The piping in pipe chases has a 60-year design objective in relation to corrosion and operating environment. Pipe bends are used instead of elbows where reasonably practicable to reduce potential crud traps. .

24.3.1.2.1 Reactor Coolant Pipe Connections

Piping connections to the reactor coolant loops are located on or above the horizontal centreline of the pipe wherever reasonably practicable, particularly where there is no flow from the branch pipe under normal operations. The purpose of this is to minimise crud build up in branch lines resulting from gravitational separation.

24.3.1.3 Materials Quality Control

To ensure low corrosion rates in the AP1000 plant, quality assurance and quality control systems will be implemented during manufacture and construction. Austenitic stainless steel materials used in the fabrication, installation, and testing of nuclear steam supply components and systems are handled, protected, stored, and cleaned according to recognised, accepted methods designed to minimise contamination that could lead to stress corrosion cracking (SCC). The procedures covering these controls are stipulated in process specifications. Tools used in abrasive work operations on austenitic stainless steel, such as grinding or wire brushing, do not contain and are not contaminated with ferritic carbon steel or other materials that could contribute to intergranular cracking or SCC.

24.3.1.4 Reactor Coolant System Chemical Control

Chemical control of the reactor coolant is critical in ensuring reduction of corrosion and subsequent crud formation and transportation, thereby reducing the amount of radioactivity carried by the coolant, and reducing plant dose rates. The AP1000 design includes several features and provides for multiple measures to control reactor coolant chemistry. Examples include:

- The use of a chemical and volume control system
- Provisions for the duty holder to employ good or best practices in plant chemistry
- The application of zinc addition to the AP1000 plant

Many of these features and their impacts on plant chemistry are discussed in detail in Chapter 21 of this report.

24.3.1.5 Scoring of Options for Minimising Production of Radioactivity, Including Particulate

The AP1000 PWR design includes several features that are intended to minimize the production of radioactivity, including particulates. This section and subsequent portions of this chapter discuss these features as they relate to particulate radioactivity; however, many of the features mentioned are also expected to effect a decrease in the production of other forms of radioactivity.

As part of the overall options studies for identifying the BAT for reducing discharges to the environment, the techniques identified for reducing the production of particulates within the primary circuit were subjected to the same scoring system against a number of criteria as shown in Table 24-5. Each option was given a score of between -2 and 2, with 2 indicating beneficial, -2 indicating detrimental, and 0 indicating neither beneficial nor detrimental. All the options described above had an almost identical high positive score, indicating that they should all be adopted. Scores were assigned based upon operating experience from existing plants using one of the identified methods for reduction of particulate production as shown in Table 24-6.

No techniques were adopted where the benefits were not so clear. This is largely due to the need for only proven technology to be incorporated in the primary circuit design to avoid inadvertent challenges to the integrity of the circuit is maintained over the life of the plant. However, it is reasonable to assume that research is ongoing into other suitable techniques and that if any reach the stage where they can be backfitted to an existing plant (like zinc injection), then they will be adopted in operational AP1000 plants and incorporated into future ones. In addition, should the research result in beneficial techniques requiring

significant changes to the design of the primary circuit components, incorporating these changes at major outages will be considered.

The same process of evaluating options and assigning scores was applied to techniques for removing radionuclides from the primary coolant and reducing their activities in liquid and aerial discharges. In this case, a wider range of techniques could be evaluated because low-pressure and -temperature systems do not have the same safety-critical performance requirements. The detailed BAT studies are discussed in Reference 24.20. Techniques with a negative or zero net benefit were rejected.

24.3.1.6 Primary Coolant and Spent Fuel Pool Cleanup

Spent Fuel Pool, Refuelling Cavity, and Refuelling Water Storage Tank

The SFS maintains a controlled temperature in the SFP, by cooling the water to compensate for decay heat from stored spent fuel, reducing the evaporation rate from the SFP. The SFS also cleans up the water from the SFP, the refuelling cavity, and the in-containment refuelling water storage tank (IRWST) by filtration and ion exchange. The radionuclides involved will depend on the time since the spent fuel was in the reactor and the number of fuel defects.

In the absence of significant levels of failed fuel, the γ emitting nuclides of concern are primarily Co-58 and Co-60 from radioactive crud. Crud is defined as minute, solid, corrosion products that arise from within or travel into the reactor core and become radioactive. These corrosion products can then be transported to other portions of the RCS where they may deposit on surfaces such as piping. The AP1000 design allows the addition of zinc acetate to reduce ongoing corrosion rates for RCS materials and to reduce the corrosion products released to the coolant, which results in a reduction in crud deposits. Crud is transported to the SFP when fuel assemblies are offloaded from the core into the SFP during outages. A small amount of crud is resuspended in the water during the course of fuel handling. The SFS provides two water volume changes of the SFP in 24 hours. The SFS achieves a much better decontamination factor than in previous generations of PWRs, which reduces crud levels in the SFP. .

The tritium concentration within the SFP is monitored and reduced by dilution. The levels of tritium in the SFP water (as well as in the primary coolant, the water in the refuelling cavity, and IRWST) can only be reduced by dilution (i.e., bleed to the liquid radwaste system and feed with untritiated makeup). Airborne concentrations of tritium arise from evaporation from the SFP, which depends on the water temperature and the relative humidity of the ambient air. The ventilation extract maintains a safe airborne concentration by ventilating air above the spent fuel pit, allowing fresh makeup air to enter the area. The operator will be responsible for determining an acceptable level of airborne activity during refuelling operations against liquid effluent discharges. The acceptable levels of activity in the SFP water will be determined by the operator based on the background dose rates and the acceptable airborne activity concentration.

The passive HEPA filters are normally isolated and will not be contaminated or contribute to the background dose rates unless actuated for an event.

The SFS is discussed in further detail in Section 17.9 of this PCSR.

Chemical and Volume Control System

The CVS passes a proportion of the primary coolant through filters and ion exchange systems to reduce the levels of crud and ionic fission products. If necessary, fission gases can also be

removed using the liquid radwaste system (WLS) degasifier. This reduces the dose rates to workers from the primary circuit components. The CVS also controls the reactor coolant chemistry reducing the production of corrosion products.

The purification rate is based on minimising occupational radiation exposure (ORE) and providing access to the RCS equipment. The CVS provides a RCS purification rate of 22.7 m^3/h (Reference 24.21): this represents at least one RCS mass per 16 hours and has sufficient purification and degasification capability (in conjunction with the WLS) to allow the reactor vessel closure head (RVCH) to be removed in a timely manner during a refuelling shutdown. In addition, purification during shutdowns has a positive impact on the ORE to workers during the outage. Further details on the CVS system are discussed elsewhere; specifically in Section 21.5.8 of this document.

Spent Ion Exchange Resin

Changing the CVS resins involves the following actions:

- Confirm that the designated spent resin tank has sufficient volume for receipt of spent resins.
- Confirm that all remotely operated solid radwaste system (WSS) valves are correctly aligned.
- Close CVS purification valves.
- Close valves in Room 11209 in containment.
- Depressurise the resin sluice line and demineraliser by opening containment isolation valves in Room 12444 in containment.
- Backwash or “fluff” the demineraliser resin bed to prepare for transfer.
- Carry out the transfer.
- Close valves and flush the transfer line.
- Drain the vessel.
- Fill the empty vessel with fresh ion exchange resin.

Collective doses to operators during shutdown are predicted to be 240 person-μSv to sluice a single resin bed and 240 to 480 person-μSv to refill the demineraliser with fresh resin. The CVS is equipped with two mixed-bed resin beds, either of which is sized for operation over and entire fuel cycle. Changing CVS resin with the plant operating at power, while possible, is not anticipated to be necessary. If it is necessary to undertake the operation at power, the doses are expected to be up to double the doses during shutdown.

The spent resins are likely to be intermediate-level waste (ILW). While the selection of a suitable strategy for the treatment and disposal of spent resins will be the responsibility of the operator, flexibility is provided in the design for the treatment and disposal of spent resins. The plant design includes a shielded cell that can be used for storage of a high-integrity container, which is filled with spent resin and lifted remotely into a shielded flask for transfer to a central processing facility where it will be immobilised in a form suitable for the future

ILW repository. Alternatively, the method of choice described in the Environment Report (Reference 24.45), is for spent resin to be transferred directly from the spent resin tanks via pipework to a mobile encapsulation unit in the railcar bay for treatment.

In addition, smaller quantities of granulated carbon may be generated from the guard bed on the gaseous radwaste system (WGS), although this material does not deplete and is anticipated to last for the life of the plant. If change-out is required, the media is also likely to be ILW and for which a suitable treatment and disposal option will need to be selected by the operator. The Environment Report (Reference 24.45) includes a discussion of one means of treatment for this waste (encapsulation) using a mobile encapsulation unit in the auxiliary building.

Filter Changes

A shielded filter transfer flask is used to change the higher-activity filters of the CVS, SFS, WLS, and WSS. The filter vessel is drained, and the concrete floor plug is opened remotely. The filter vessel head is removed and the transfer flask, without its bottom shield cover, is lifted and positioned on the port directly over the cartridge in the filter vessel.

A grapple inside the transfer flask is remotely lowered and connected to the filter. The filter is lifted into the transfer flask, and the flask is transferred to the bottom shield cover. The transfer flask is lowered onto and connected to the bottom shield cover. The transfer flask is then moved to the auxiliary building rail car bay where the filter may be placed in a shielded temporary storage space, loaded directly into a waste container, or otherwise processed for treatment. If necessary, a sample of the filter media is obtained through a port in the transfer flask.

The primary filters are also expected to be ILW. Treatment and disposal of spent filters will be the responsibility of the operator; the flexibility to allow for this has been incorporated into the design. The transfer flask could be used to load the filters into a shielded container, which could then be transferred to a central processing facility. Alternatively, as described in the Environment Report (Reference 24.45), the filters could be taken to a mobile encapsulation unit in the auxiliary building for treatment without leaving the RCA.

Estimated doses from filter changes are discussed in Section 24.3.3.1.

24.3.2 Design Features

The AP1000 design incorporates features to reduce doses to operators SFAIRP during normal operations at power and from routine refuelling, shutdown operations, and maintenance. This is achieved by a combination of plant design, plant layout, shielding, and remote operations. Provisions are also made in the design to limit doses received following a major accident.

Systems, structures, or components (SSCs) are designed for reliability to reduce the need for breakdown maintenance, and maintainability to reduce the duration of maintenance operations. The ability of Westinghouse plants to achieve a high level of availability is demonstrated by the average availability of Westinghouse design reactors of over 91 percent between 2000 and 2008 (based on data taken from Reference 24.22 excluding any plant permanently shut down before 2008). A number of plants achieve an availability of 100 percent for years where there is no refuelling outage.

Wherever reasonably practicable, multiple electric lights are provided for rooms containing highly radioactive components: thus the burnout of a single lamp does not require entry and immediate replacement of the defective lamp since sufficient light is still available.

Incandescent lights or long life lamps with appropriate barriers and protection, or not containing restricted materials, are provided inside containment and in the fuel-handling area. The fluorescent lights used outside containment do not require frequent service due to the increased life of the tubes. High pressure sodium underwater lighting with appropriate barriers and protection to prevent contact with the water, or long life lighting not containing restricted materials, are used for underwater lighting in the fuel handling areas as they provide longer lamp life, less service intervals, and less personnel exposure.

Shielding is provided to separate equipment such as demineralisers and filters from nonradioactive equipment. This provides unrestricted maintenance on the nonradioactive equipment and between radiation sources and access and service areas.

SSCs are designed to reduce access, repair, and removal times. Where appropriate, labyrinth entrances are provided for radioactive pump, equipment, and valve rooms. Adequate space is provided in labyrinth entrances for easy access, a benefit that reduces the time spent in radiation fields during operation, maintenance, and inspection. The reduced exposure duration is demonstrated in the input data used in the job exposure model (JEM) calculations in Appendices 24B, 24C, and 24D.

The WGS guard and delay beds, which are passive components with minimal maintenance requirements and the potential to be highly radioactive, are located in completely enclosed compartments and are provided with access via a shielded hatch or removable blocks.

SSCs are designed to accommodate remote and semi-remote operation, maintenance, and inspection. This has the benefit of reducing the time spent in radiation fields.

24.3.2.1 Plant Design

The AP1000 plant is designed to reduce radiation doses received during refuelling operations and the associated maintenance. This is based on designing out the maintenance requirement, simplifying operations to reduce the duration of exposure, and reducing dose rates to operators. The first two design factors have the added advantage of reducing the amount of work required, thus reducing the shutdown duration and cost and improving plant availability.

Reactor Coolant Pumps

In the UK, the AP1000 plant will use hermetically sealed wet winding RCPs (Reference 24.23) rather than the canned pumps called for in the standard specification.

The pump/motor unit consists of a pump section, where a semi-axial impeller/diffuser combination is mounted in a one-piece pump casing. A short and rigid shaft, supported by a radial bearing, connects the impeller to the high inertia flywheel. This flywheel consists of a one-piece forged stainless steel cylinder, with several smaller heavy metal cylinders inside. The flywheel is located inside the thermal barrier, which forms part of the pressure boundary. A specific arrangement of cooling water circuits guarantees a homogeneous temperature distribution in and around the flywheel which minimises the friction losses of the flywheel and protects the motor from hot coolant. The driving torque is transmitted by the motor shaft, which itself is supported by two radial bearings. A three-phase, high-voltage squirrel-cage induction motor generates the driving torque. The cooling water is forced through the stator windings and the gap between rotor and stator by an auxiliary impeller. The **AP1000** plant RCPs are designed to not require maintenance over the 60 year life of the plant.

Reactor Vessel Insulation

Insulation in the area of the reactor vessel (RV) head is fabricated in sections with quick-release clasps to facilitate removal of the insulation. Each section of insulation has permanent identification markings to enable rapid reinstallation.

Reactor Vessel

The RV welds are designed to accommodate remote inspection with ultrasonic sensors from the interior or exterior. Nozzles are tapered along the reinforced areas to provide a smooth transition, and pipe branch locations are selected to avoid interference from one branch to the next. Weld-to-pipe interfaces require a smooth, high-quality finish.

Integrated Reactor Head Package

The integrated head package (IHP) combines several separate components in one assembly to simplify refuelling of the reactor. The purpose of the IHP is to reduce the outage time and personnel radiation exposure by combining operations associated with movement of the RVCH during the refuelling outage. In addition, the IHP concept reduces the setdown space required in the containment. With the IHP, disconnections from and connections to the control rod drive mechanisms (CRDMs) and the digital rod position indication system (DRPI) and other components within the cooling shroud assembly are not made at the individual component.

The IHP (see Figure 24-1) consists of the following main elements:

- Shroud assembly
- Lifting system
- CRDM seismic support structure
- Cable support structure
- IHP cables
- Quickloc bullet couplings
- CRDM cooling system
- Radial arm hoist
- Operating deck-mounted connector panel

Shroud Assembly

The shroud assembly is a carbon steel structure above the reactor head that includes a shielding shroud and an air baffle. During normal operation, it directs the flow of cooling air to the CRDM coil stacks. The DRPI are also cooled by this air flow. The ductwork and air baffle are integral to, and supported by, the shroud assembly. The air-cooling fans are attached to the IHP. Structurally, the shroud is integrated with the CRDM “seismic support structure”. The shroud also provides shielding at the vessel flange region. The shroud structure is bolted to attachment lugs on the RVCH. Cabling, conduit, and their supports and attachment hardware for the CRDMs, CRDM coil, and in-core instrumentation are routed around the cable support attached to the shroud.

Lifting System

The lifting system enables the RVCH and IHP to be lifted as a unit. The lift legs transfer the head load during a head lift from the head attachment lugs to the lift rig. The lifting system

consists of lift legs, sling block, clevises, and sling rods to interface with the polar crane hook.

Control Rod Drive Mechanism Seismic Support Structure

The CRDM seismic support structure provides seismic restraint for the CRDMs. It is located near the top of the CRDM rod travel housings. The DRPI connector plate attached to the rod travel housing interfaces with spacer plates, where required, to form a system of bumpers that interface with the mechanism seismic support structure. This support interfaces with the shroud assembly to transfer seismic loads from the mechanisms to the RVCH.

Cable Support Structure

The cable support structure is located at an elevation above the top of the rod travel housings. It provides permanent support and routing for the CRDM power cables and DRPI cables, which remain with the IHP and are normally not disturbed. These cables terminate at the connector panels, which constitute the interface with the mating cables. Cable disconnects are made at the connector panels.

Integrated Head Package Cables

The IHP cables include those portions of the CRDM power cables, in-core instrumentation, and DRPI instrumentation cables extending from the connector plates to the user devices. These cables remain with the IHP and are normally not disturbed. The individual cable length is sized to provide an orderly arrangement. For a refuelling or other operation requiring movement of the IHP, the cables that span the space over the cavity from the operating deck to the IHP are disconnected at the connector panels. The cables are then moved away from the IHP.

Quickloc Assemblies

The Quickloc assemblies provide the means by which the in-core instrument thimble assemblies (IITA) penetrate the pressure boundary of the reactor. The IITAs are monitored by equipment outside the pressure boundary. The Quickloc assemblies have an upper flange that is an integral part of the RVCH instrument nozzle. Referred to as the Quickloc instrument nozzle, it has an open-centre geometry that allows the Quickloc stalk, which is attached to the upper internals, to pass through the RVCH during installation and removal of the RVCH from the RV. The Quickloc stalk provides the top of the guide path through which the IITAs are installed.

The Quickloc assemblies reduce the disconnection and connection times compared to the use of Conoseal clamps. The in-core thermocouple instruments are now included with the in-core instrument connections in the eight Quickloc assemblies and the Conoseal clamps have been eliminated. When the cables attached to the IITA are disconnected and the Quickloc pressure boundary is taken apart, the bullet nose is installed over the top of the IITAs and attached to the top of the Quickloc stalk. The bullet nose protects the IITA electrical connectors as the RVCH is installed and removed. It also provides a watertight seal for the electrical connectors.

Control Rod Drive Mechanism Cooling System

The CRDM cooling system is located at the top of the upper shroud assembly, on the outside of the exterior work platform of the operating deck. The CRDM forced-air cooling system comprises the fans, fan supports, dampers, ducts, duct fittings, duct supports, baffles, shroud, instrumentation, and electric service components required to meet the CRDM magnetic jack coil assembly cooling requirements. The system consists of the following: four fans, fan power cables, fan motor heater, fan vibration monitoring, fan damper control, and CRDM cooling system inlet and outlet temperature monitoring.

Radial Arm Hoists

The radial arm hoists are located on the middle shroud. The radial arm hoist system includes the beams, rails, trolleys, hoists, and structure required to support RVCH stud-tensioning equipment handling and related lifting.

Operating Deck-Mounted Connector Panel

The operating deck-mounted connector panel is located at the top of the upper shroud. The connector panel is supported on the operating deck near the end of the cable bridge to allow for quick disconnect of the head assembly cables prior to refuelling. The connector panel is not attached to the IHP.

Other Refuelling Design Features

A number of other design features reduce the duration of exposure during refuelling and are discussed below:

Refuelling Machine (RM)

The RM is mounted on a gantry at the 110.74 m (135'-3.00") level in the containment (Figure 24-3). The fuel removal procedure is as follows:

1. The RM is positioned over a fuel assembly in the core.

2. The RM mast is lowered over a fuel assembly and engages it.

3. The RM withdraws a fuel assembly from the core and raises it to a predetermined height sufficient to clear the vessel flange and still leave sufficient water covering the fuel assembly.

4. The fuel transfer system car is moved into the refuelling cavity from the fuel storage area, and the fuel basket is pivoted to the vertical position by the lifting arm.

5. The RM is moved to line up the fuel assembly with the empty fuel basket.

6. The RM loads the fuel assembly into the empty fuel basket of the transfer car.

7. The RM then moves back over the core area, and is aligned over the next fuel assembly to be removed in the core offload sequence.

8. In parallel with item 7, the fuel basket is pivoted to the horizontal position and the fuel transfer system container is moved through the fuel transfer tube to the fuel-handling area by the transfer car and pivoted to the vertical position.

9. The fuel-handling machine unloads the fuel assembly from the fuel basket.

10. The fuel assembly is placed in the spent fuel storage rack.

11. The fuel basket is pivoted to the horizontal position, moved back into containment and pivoted to the vertical position.

12. This procedure is repeated until the core is unloaded.

Core reload is essentially the reverse of the unloading sequence described above.

The engagement of the gripper with the fuel assembly top nozzle is shown in Figure 24-4.

Quick-Opening Fuel Transfer Tube Closure System

The fuel transfer tube connects the fuel transfer canal in the auxiliary building to the refuelling cavity in the containment. During reactor operation, the fuel transfer tube is sealed at the containment end and acts as part of the containment pressure boundary. The AP1000 plant includes a quick-opening fuel transfer tube closure system rather than the conventional bolted cover. The cover is also hinged so that it does not have to be lifted from the area. These features significantly reduce the time required to open or close the Fuel Transfer Tube, which is important to exposure reduction since crud tends to accumulate in this area.

Permanent Reactor Cavity Seal Ring

The permanent reactor cavity seal ring eliminates installation and removal operation associated with bolted or inflatable types of cavity seals.

Permanent Guide Studs

Using permanent guide studs eliminates the operations to install and remove guide studs.

Shielded Storage Stand

The storage stand for the IHP located on the operating floor 110.744 m (135’-3.00”) includes shielding for the RVCH. The shielded storage stand reduces background dose rate from the RVCH on the operating floor.

Steam Generators

The SG incorporates many design features to facilitate maintenance and inspection in reduced radiation fields. The tube ends are designed to be flush with the tube sheet in the SG channel head to eliminate a potential crud trap. The SG manways (entrance to channel head) are sized for easy entrance and exit of workers with protective clothing, and to facilitate the installation and removal of tooling.

The SG design includes a sludge control system/mud drum designed to reduce the need for sludge lancing, and reduces tube and tube support degradation. The design of SG tube support plates and the full-depth tube sheet expansion of tubes reduce corrosion and occupational exposure.

24.3.2.2 Plant Layout

The layout of the AP1000 plant has built on many years of experience to ensure that exposures are ALARP in the UK sense of the term.

Within the auxiliary building, the non-radiologically-controlled areas are physically separated from the radiologicaly-controlled areas with separate access routes from the annex building.

Facility design considerations directed toward minimising radiation levels in plant access areas and near equipment requiring personnel attention generally include the following:

- Radiation sources are separated from occupied areas, where practicable (for example, pipes or ducts containing potentially highly radioactive fluids do not pass through occupied areas).

- In those systems where process equipment is a major radiation source, the pumps, valves, and instruments are separated from the process component to allow servicing and maintenance of these items in reduced-radiation zones.

- Redundant components requiring periodic maintenance that are a source of radiation are located in separate compartments to allow maintenance of one component while the other component is in operation.

- Control panels are located in low-radiation zones.

- Shielding is provided to separate equipment such as demineralisers and filters from nonradioactive equipment to provide unrestricted maintenance of the nonradioactive equipment. Labyrinth shields or shielding doors are generally provided for compartments from which radiation could stream or scatter to access areas and exceed the radiation zone dose limits for those areas.

- For potentially high radiation components (such as ion exchangers, filters, and spent resin tanks), shielded compartments with hatch openings or removable shield walls are used. Equipment in nonradioactive systems that requires lubrication is located in low-radiation zones.

- For radioactive systems, adequate space and ease of movement in a properly shielded inspection area are emphasised. Where longer times for routine inspection are required and permanent shielding is not feasible, space is provided for portable shielding.

- Wherever reasonably practicable, lubrication of equipment in high-radiation areas is achieved with the use of tube-type extensions to reduce exposure during maintenance.

- Shielding is provided between radiation sources and access and service areas.

For the plant layout to ensure that exposures to workers are ALARP, areas of the plant are classified according to the Westinghouse radiation and access zone scheme shown in Table 24-7. These represent the maximum dose rates expected to be present in each area using conservative source terms in shielding calculations. For comparison, the area designations likely to be required under the IRR99 (Reference 24.2), and the maximum occupancy times which are likely to be applied by an operator in order to ensure that doses received by workers are ALARP, are also shown in Table 24-7.

The plant layout is such that access to a given radiation zone does not generally require passing through a higher radiation zone.

24.3.2.3 Shielding

Shielding plays an important role in protecting workers and members of the public from radiation generated during power operation, residual radiation during refuelling outages, and major accidents when fission products are released into the containment. Bulk shielding walls form the structure of the building and both provide and challenge the ability of the structure to withstand a seismic event. Conservatively, calculations for concrete shielding are based on a density of 2200 kg/m^{-3} (140 lb/ft^3) (Reference 24.24). No account is taken of any rebar.

The level of shielding is a balance between the protection provided, the requirements for accessibility, structural implications, and cost. The purpose of the shielding assessment is to demonstrate that the shielding design of the AP1000 plant provides an adequate level of protection based on the use of conservative source terms and the required occupancy of each area. The dose rates from best-estimate source terms will be lower than those from the shielding studies. In most cases, it is expected that this approach is sufficient to ensure that doses received in operation will be ALARP; any further dose reduction by means of additional or temporary shielding will be assessed on a case-by-case basis as necessary during operations. (Note that temporary shielding was not credited in the AP1000 design shielding analyses.)

The shielding can be broken down into the following:

- Primary shielding
- Secondary shielding
- Fuel transfer shielding
- Auxiliary component shielding
- MCR shielding

Primary Shielding

During operation, very high levels of neutron and gamma radiation are generated within the RV. When the reactor is shut down, the fission products in the fuel and activation products in the reactor internals present significant sources of radiation.

The primary shielding includes:

- Water annuli around the core
- Carbon steel pressure vessel
- Massive reinforced concrete structure surrounding the RV

The primary shielding (or its parts) performs the following functions:

- Reduces, in conjunction with the secondary shield, the radiation level from reactor sources to a level that makes limited access inside the containment during power operation possible.
- Limits the radiation level after shutdown from sources within the RV and permits limited access to RCS equipment in areas that require access for inspection or maintenance.
- Reduces the neutron fluxes incident to the RV to prevent material property changes that might unduly restrict plant operation.
- Limits the gamma ray fluxes in the primary shield concrete to avoid large temperature gradients and dehydration of the concrete.
- Limits the neutron activation of components and structural materials in accessible areas outside the primary shield throughout the life of the plant to prevent those components from becoming significant radiation sources after shutdown.

Air cooling is provided to prevent overheating, dehydration, and degradation of the shielding and structural properties of the primary shield.

The reactor cavity has been designed so that the dose rates on the operating deck due to neutron streaming are less than 1 mSv/h.

Secondary Shielding

The secondary shielding consists of the shield walls surrounding the reactor coolant loops, the concrete operating floor, and the shield building surrounding the containment.

During plant operations, the major radiation source in the RCS is N-16, which is created by neutron activation of oxygen during passage of coolant through the core. The secondary shielding surrounds the primary shielding and the reactor coolant loops and attenuates the radiation originating in the reactor coolant and the reactor to a safe level.

The secondary shield is designed to permit limited access to certain areas within the reactor containment during full-power operation by reducing dose rates to <1 mSv/h and to reduce the full-power radiation levels outside the shield building to allow normal, continuous occupancy by reducing dose rates in occupied areas to ≤2.5 μSv/h. In addition, the secondary shielding serves to reduce the radiation intensity outside the shield building in the unlikely event of an accidental release of fission products into the containment.

Fuel Transfer Shielding

During refuelling operations, irradiated fuel is removed from the reactor through a canal to the auxiliary building, then on to a water-filled spent fuel pit located adjacent to the shield building. After sufficient decay, the spent fuel is transferred under water to fuel transport flasks in the cask loading pit. The lift height of the RM is limited to prevent exceeding dose limits to personnel on the bridge.

The fuel transfer shielding consists of the water in the refuelling cavity, the water over the spent fuel storage area and the walls of the refuelling cavity, transfer canal, and spent fuel pit. In addition, shielding is provided on the spent fuel transfer tube.

The fuel transfer tube is surrounded by concrete and no part of it is unshielded during any portion of the refuelling operation. The only potential radiation streaming path associated with the tube shielding configuration is the 50.8 mm (2 inch) seismic gap between the fuel transfer tube shielding and the steel containment wall. Shielding of this gap is provided by a water-filled bladder. This "expansion gap" radiation shield effectively reduces the radiation fields during fuel transfer and accommodates relative movement between the containment and the concrete transfer tube shielding with no loss in shield integrity. A removable hatch in the shield configuration provides access for inspection of the fuel transfer tube welds. The opening of this hatch is administratively controlled and is treated as an entrance to a very high-radiation area. This hatch is in place during the spent fuel transfer operation.

Spent fuel in the SFP is handled using a bridge crane on a bridge deck spanning the SFP. To compensate for reduced shielding from the mast and reduced distance from the surface of the SFP, the bridge floor is supplemented with additional steel.

The fuel transfer shielding protects plant personnel from fission product gamma radiation emitted from the spent fuel elements during core refuelling operations using the source terms described in the "Shielding Source Terms" section. The following design objectives have been applied:

- Shielding shall be provided for protection of personnel during all phases of spent fuel transfer and storage.

- Shielding shall be based on the access requirements and radiation zone designations of the areas above and around the refuelling cavity, spent fuel pit, and fuel transfer path.

- Minimum water depths allowed above the top of the fuel assemblies will be established to limit radiation dose rates at the surface of the water to levels that do not restrict accessibility when the fuel assemblies are being transferred.

- The concrete walls of the fuel transfer canal and SFP shall supplement the water shielding and will limit the maximum radiation dose rates in adjacent working areas inside the auxiliary building to levels consistent with access requirements.

Auxiliary Component Shielding

Auxiliary shielding consists of walls, floors, ceilings, and removable blocks used for shielding of the various sources of radiation associated with plant systems. These systems include, among others, the CVS, the waste disposal systems, SFS, and the primary sampling system (PSS). The following design criteria have been applied for auxiliary shielding:

- It shall be designed on the basis of RCS activity levels corresponding to the presence of fuel defects in fuel rods producing 0.25-percent of the power within the core.

- The design shall be sufficient to account for long-term buildup of radioactive corrosion and fission products on piping, fittings, valves, pumps and other equipment normally carrying radioactive liquid or gas, such as filters and demineralisers.

- The design shall be consistent with the anticipated access requirements and radiation zone designation of the area for all modes of operation.

The shielding calculations for the AP1000 plant design are based on a conservative choice of radiological source terms to ensure that the design of the shielding is applicable throughout

the plant lifetime. In addition, appropriate radiation transport calculation techniques were selected for each source/geometry situation.

Control Room Shielding Design

Limiting post-accident conditions dictate the shielding requirements for the MCR. Taking into account shielding provided by the shield building structure, shielding combined with other engineered safety features – including dedicated shielding of the VES filtration unit – is provided to permit access to and occupancy of the MCR following a postulated accident, so that individual radiation doses are limited to 50 mSv whole body from contributing modes of exposure for the duration of the accident.

Wall Penetrations

To minimise radiation streaming through wall penetrations, where practicable, offsets are incorporated between the radioactive source and the normally accessible areas. If offsets are not practicable, penetrations are located as far as practicable above the floor elevation to reduce radiation exposure to personnel. If these two methods are not used, alternate means, such as baffle shield walls, or sealing or grouting the penetration annulus, are used.

Shielding Source Terms

Sources used in the design of plant shielding must limit the radiation levels within the plant and at a site boundary to within acceptable limits. The shielding allows a plant to operate safely with fuel cladding defects and ensures that, in the event of an accident, the integrated offsite exposure due to the contained activity does not result in any harmful offsite radiation exposures.

The major radiation sources considered in shield design within the containment are core neutron and gamma fluxes and N-16 activity while at power, RCS piping and corrosion product sources, and spent fuel sources during refuelling operations. The major radiation sources considered in the auxiliary building shield design are the fission products associated with small cladding defects and crud sources. For the design basis source term, it is assumed that there is a significant fuel defect level well above that anticipated during normal operation. It is assumed that small cladding defects are present in fuel rods producing 0.25 percent of the core power output (also stated as 0.25-percent fuel defects). The defects are assumed to be uniformly distributed throughout the core. Details of the assumptions for the calculation of the reactor coolant fission product concentrations, including pertinent information concerning the fission product escape rate coefficients, coolant cleanup rate, and demineraliser effectiveness, are listed in Table 24-18.

The assumption regarding fuel leakage is a conservative one. For the AP1000 reactor core, this would correspond to around 110 leaking fuel rods. This is more than is observed during typical operations at most plants.

Sources for normal operations and accident conditions are listed in the radiation analysis design manual (Reference 24.26). For normal operations and shutdown, these include the following:

- Fast neutron flux and gamma ray energy flux at the inside surface of the primary shield
- N-16 concentration in the RCS at various locations in the primary circuit

- Reactor coolant fission and corrosion product-specific activity, based on 0.25-percent fuel defect level (which is the upper limit)
- Pressuriser liquid and steam phase source strength and pressuriser N-16 source strengths
- Core average inventory at various times after shutdown
- Core average fission product and actinide inventory at shutdown
- Core average and spent fuel neutron source strengths at various times after shutdown
- Spent fuel gamma ray source strengths at various times after shutdown
- Spent fuel fission product and actinide inventory at shutdown
- Isotopic composition and specific activity of typical out-of-core crud deposits for various full-power years of plant operation
- Mixed bed and cation bed ion exchange resin specific and total activities
- Specific activities and source strengths in various vessels

The radiation sources used in the shielding analyses are based on operation at a core power of 3400 MWt. Post-accident calculations assume core melt sources increased by 2 percent to account for uncertainty in determining thermal power. (Note that this is considered conservative, as more realistic analyses show that fuel-cladding failures are limited.) To account for variations in fuel management, both first and equilibrium core fuel management schemes are evaluated. A high-level perspective on the various codes used to develop radiation source terms is shown in Figure 24-14.

The release scenario consists of an initial release of activity from the gaps of a number of failed fuel rods 10 minutes into the accident. It is assumed that 3 percent of the core inventory of the volatile species (defined as noble gases, halogens, and alkali metals) is instantaneously released.

During the next 30 minutes following the instantaneous gap activity release, that is, from 10 to 40 minutes into the accident, an additional 2 percent of the core inventory is added to the inventory that exists based on the previous gap activity releases. At this point, 5 percent of the total core inventory of volatile species has been considered to be released.

Over the next 1.3 hours, releases associated with an early in-vessel release period are assumed to occur, that is, from 40 minutes to 1.97 hours into the accident. This source term is a time-varying release in which the release rate is assumed to be constant in the duration time, consistent with the assumptions in Reference 24.27. Additional releases during the early in-vessel release period include 95 percent of the noble gases; 35 percent of the halogens; and 25 percent of the alkali metals; as well as fractions of the tellurium group, barium and strontium, noble metals, lanthanides, and cerium groups.

Reference 24.26 gives instantaneous and integrated gamma and beta source strengths at various times following an accident.

In addition, Reference 24.26 provides normal operational source terms based on Reference 24.28 adjusted for plant-specific parameters. The numerical values given in this

standard are based on data from operating plants that use Zircaloy-clad uranium-dioxide fuel. These data are intended for use in environmental analyses and evaluations where operating conditions over the life of the plant are considered.

Shielding Analysis Methodology

The shielding calculations completed for the AP1000 plant design make use of a full suite of computer codes based on Monte Carlo, discrete ordinates, and point-kernel radiation transport techniques. The choice of a particular technique for individual shielding analyses is based primarily on the type of radiation and the complexity of the geometry under consideration. In general, the Monte Carlo and/or discrete ordinates methodologies are employed for neutron transport as well as for situations involving complex geometry or where there is the potential for radiation streaming. Point-kernel methodologies are suitable for calculating dose rates through bulk shielding from gamma sources with relatively simple geometries such as pipes and cylindrical vessels.

An example of a Monte Carlo application is the analysis of the reactor cavity area surrounding the pressure vessel where concerns for radiation streaming and component activation at locations both above and below the pressure vessel are paramount. Here these techniques are used in the design and analysis of streaming shields intended to reduce not only operating dose levels, but also dose levels in locations requiring access for inspection and maintenance during shutdown conditions.

Other examples of the application of these techniques include the evaluation of streaming through various wall penetrations in the containment and shield building, analysis of penetration and labyrinth design in the auxiliary and radwaste buildings, and the calculation of post-accident doses at some locations within and outside the shield building.

Point-kernel methods are generally used in the calculation of photon dose rates in geometric situations that are characterised primarily by penetration through bulk shielding materials without complex transport paths due to radiation streaming or material variations. Examples of the use of these analysis approaches include determining the attenuation of shield walls or calculating doses external to piping carrying radioactive sources.

These analysis methods and their application in specific areas of the plant are described in the various shielding calculation notes associated with the design of the AP1000 plant. For example, Reference 24.29 covers the annex building, Reference 24.24 covers the auxiliary building, Reference 24.25 covers the spent fuel route, and References 24.58 and 24.59 cover the containment interior.

Shielding Analysis Codes

The specific radiation transport codes used in the shielding analysis for the AP1000 plant comprise the following:

- Monte Carlo: MCNP5 – MCNP5 is a radiation/particle transport code used to calculate radiation-related quantities within nuclear systems. The code is based on established Monte Carlo statistical methodology (References 24.30 and 24.31).

- Discrete Ordinates: DOORS 3.2 – The DOORS 3.2 package is a system of codes (and associated pre- and postprocessors) used to perform neutron and photon transport calculations in 1-D, 2-D, and 3-D geometry using the discrete ordinates method (References 24.32 and 24.33).

- Point Kernel: SCAP-II – The SCAP-II code is a generalised geometry shielding code for photons based on the use of the point-kernel methodology. SCAP-II can be run in the conventional point-kernel mode with buildup applied to the calculated uncollided flux or in a single scatter mode that allows the calculation of an explicit first scatter with buildup applied on the scattered leg (References 24.34, 24.35, and 24.36).

- MicroShield 6.20 – MicroShield is used to analyse shielding and to estimate exposure from photon sources (References 24.37 and 24.38).

Results of Shielding Assessments

The shielding provided ensures that areas requiring routine access are shielded from significant sources of activity. The dose rates within the containment, the auxiliary building, the annex building, the radwaste building, and the turbine building have been calculated for the following:

- Normal operation and shutdown (Reference 24.61)
- Post-accident (Reference 24.62)

Access routes and requirements during normal operations and shutdown are shown in Reference 24.63; post-accident access requirements are included in Reference 24.62.

The areas are classified according to the scheme shown in Table 24-7. These represent the maximum dose rates expected to be present in each area. Average dose rates are expected to be lower. They have been used to confirm that dose rates will be acceptable for the levels of access required during normal operation and refuelling shutdowns.

The rooms and areas are identified in References 24.61, 24.62, and 24.63 and the access requirements are shown in Appendix 24A, Tables 24A-1, 24A-2, 24A-3, 24A-4, and 24A-5.

Outside Areas

The shield building completely surrounds the RCS components and additional shielding is around specific sources such as the reactor, SGs, and pressuriser. The concrete shield building wall and the RV and SG compartment shield walls reduce radiation levels outside the shield building to less than the 2.5 μSv/h Zone I dose rate criterion from sources inside the containment (e.g., RV and primary loop components) during power operations and refuelling outages.

Dose rates outside the auxiliary building have been calculated based on conservative source terms and locations 300 mm (11.81 inches) from the outer walls. In most locations, where there is no specific source identified inside the walls, dose rates of 0.1 μSv/h have been calculated (Reference 24.24). The adopted convention has been that these areas are designated as Zone I (up to 2.5 μSv/h) areas with no restriction on access. However, dose rates in most areas and farther away from the cell containing the spent resin tanks will be significantly lower than the maximum for Zone I.

All areas outside the buildings, with one minor exception, have been shown by calculation to have dose rates of less than 2.5 μSv/h under all normal operating and shutdown conditions. The exception is an area outside of Room 12471 (the WSS valve/piping area) above 7 m (22.97 feet), where the dose rate from a 75 mm (2.65 inches) spent resin line at a distance of 300 mm (11.81 inches) from the 0.6 m (1.97 feet) outer wall is 90 μSv/h during infrequent spent resin movement operations (Reference 24.24). Operational controls prohibiting

working at height in this area during resin transfers will eliminate the potential for exposure of workers. The dose rate calculations are based on spent resin activities in Reference 24.26.

Nonradioactive Areas

All nonradioactive areas within the auxiliary/annex buildings and other buildings outside the nuclear island have been shown by calculation to have dose rates of less than 2.5 μSv/h under all normal operating and shutdown conditions. The adopted convention has been that these areas are designated as Zone I areas with no restriction on access, although dose rates may be below the Zone 0 upper bound.

Radiation Areas

The RCA covers all areas of the reactor containment, auxiliary building, annex building, and radwaste building that could have dose rates greater than 2.5 μSv/h and/or where contamination may occur, as well as the RCA entry/exit area.

All areas within the RCA where dose rates have been calculated to be below 25 μSv/h, based on conservative assumptions on inventory and location, have been designated as Zone II.

The classification represents the maximum dose rate in the area based on the worst allowable operating conditions (fuel-cladding defects in the rods generating 0.25 percent of the core power). Detailed results in Reference 24.24 show that, in a number of locations, high dose rates are transitory, occurring only when resin sluicing is in process. Operational dose rates will normally be significantly below the maximum.

Restricted Occupancy Areas

Restrictions on occupancy apply to all areas designated Zone III or above, with the access restrictions increasing as the zone designation increases, as shown in Table 24-7. The classification represents the maximum dose rate in the area based on the worst allowable operating conditions (0.25-percent fuel defects, as described above) or other worst-case situations (e.g., crud bursts 4 hours after shutdown, resulting in high dose rates from the normal residual heat removal system (RNS) pump/valve room before the CVS removes the activity). Operational dose rates in many areas will, therefore, normally be significantly below the Zone maxima.

Detailed arrangements for access control will be the responsibility of the operator but typically, physical access restrictions (locked doors) will be implemented on all Zone V and above areas and warning signs will be provided for Zone III and IV areas.

For normal maintenance operations, pumps and tanks will be drained and flushed where appropriate to reduce dose rates. The relevant procedures will be the responsibility of the operator. It is likely to be compulsory for Zone V and above areas. For Zone III and IV areas, an ALARP judgement will be made depending on the duration of the operation and the likely operator dose balanced against additional waste generation, time, and cost.

Post-Accident Conditions

The gamma ray source term following an accident increases to a maximum after 1.97 hours and then decreases as a result of radioactive decay and other physical processes. The containment sources for various times are shown in Reference 24.26.

The maximum dose rate in the MCR following an accident has been calculated to be Zone IV (Appendix 24A, Table 24A-1), i.e., <1 mSv/h. The dose rate falls rapidly from this maximum as the short-lived fission products decay. Calculations have been carried out on MCR occupancy and ingress/egress and four other specific operations that are expected to be needed following a major accident (Reference 24.39):

- SFP makeup valve alignment (64 and 168 hours)
- Temporary water hookup to passive containment cooling system (PCS) (64 hours)
- Ventilation control for temporary heating, ventilation, and air conditioning (HVAC) to MCR and control and instrumentation (C&I) equipment room (64 hours)
- Starting diesel generators and entering electrical equipment rooms to provide temporary power to transformers (64 hours)

The timing, duration, integrated dose from the operation, dose from ingress/egress at yard area, and total integrated doses are shown in Table 24-8. The total dose resulting from 30 ingress and egress operations at 12-hour intervals is 30.5 mSv. This number does not allow for relief shifts. The highest dose from a post-accident vital area access operation (SFP makeup valve alignment after 64 hours after the accident) is 43.6 mSv. However, this falls to 25.7 mSv if delayed to 168 hours (1 week) after the accident.

All doses are below the recommended maximum doses in References 24.5 and 24.60. However, any such entries will be planned in advance, taking into account the need to ensure that all such exposures were ALARP, noting that the calculated dose rates and integrated doses are based on a worst-case situation.

Remote Operations

Remote/robotic techniques have been developed for repetitive operations that would result in high operator doses where the additional dose incurred during setting up and removing the equipment still results in a worthwhile net dose savings. The following robotic/remote systems have been accounted for in the routine dose uptake assessment:

- Eddy current inspections of SGs and tube, eliminating the requirement for worker entry into the SG head.
- Examination of the RVCH and penetration welds, eliminating the need for workers' access beneath the head when on its storage stand.

Operators may develop further remote techniques or may adopt different methodologies as part of their ALARP measures.

Temporary Shielding

Where it can provide significant dose reduction, the use of temporary shielding is considered a "best practice" in reducing radiation exposure ALARP. In most cases, the use of temporary shielding is a plant specific decision based on the actual operating dose rates and required maintenance and repair operations experienced at individual plants. Dose data obtained from these operating plants is reflected in AP1000 dose uptake assessments and, to the extent temporary shielding was used, the dose reduction was reflected in the AP1000 evaluations. That is, the exposure from operating plant experience included in the AP1000 dose assessments reflects the reduction afforded by temporary shielding.

In general, the shielding philosophy of the AP1000 has been to employ permanent shielding if a dose rate reduction was necessary (as opposed to providing means for temporary shielding). As a consequence, there are many applications of permanent shielding in the AP1000 plant. However, to facilitate various activities that may benefit from temporary shielding, the AP1000 design includes the following specific examples that allow for temporary shielding:

- Components (such as pumps) in the WLS are designed to allow for sufficient space around these components to facilitate the installation of temporary shielding.

- Unit coolers in the VAS that support cooling of CVS and (RNS) components are placed to enable temporary shielding to be installed during maintenance activities.

- To support maintenance in several areas of the auxiliary building, embedment plates are installed to allow for lugs with a capability well above the weight of the heaviest component in that area. This provides sufficient margin to allow the duty-holder/licensee to apply temporary shielding during maintenance activities if needed.

- Many components were designed to allow for sufficient "pull space" around these pieces to support maintenance. In some cases, this pull space can also be used to facilitate temporary shielding.

- Within the containment vessel, sufficient laydown space is provided to allow for maintenance activities. This could be used for temporary shielding during maintenance activities in these areas.

To store removable shielding, a utility has several options, depending upon the size and nature of the shielding. The radwaste building includes space within the radiologically controlled area that may be used to store some temporary shielding. Other pieces of temporary shielding may be stored in areas of the auxiliary building.

24.3.3 Predicted Doses to Workers

Radiological safety can be assessed in terms of several quantities; of most biological importance to people is the quantity of radiation dose (either absorbed dose, or dose equivalent). To ascertain the safety of the workers in an AP1000 plant, the potential doses to workers (both as a whole and also as individuals) are discussed below and compared against established limits and standards.

24.3.3.1 Collective Dose

The AP1000 design includes a variety of ways to reduce worker dose compared with existing Westinghouse and other PWR designs. The improvements fall into three main categories:

- Reducing source term by reducing crud production and deposition:

– Low cobalt tubing
    - Zinc injection

- Reducing component numbers:

    - Valves
    - Pumps and heat exchangers (HXs)

  - Demineralisers
  - Filters

- Figure 26-7 compares the number of valves, pumps, cables, piping, and amount of seismically qualified building volume in the AP1000 plant with those in previous PWRs to illustrate the achievements made in simplification and standardisation with the AP1000 PWR. The reduction in valves, piping, and other components is expected to result in a reduction in plant collective doses – with fewer valves, there are fewer required in-service inspections, fewer in-service tests, and a decreased potential for leaks. Specific design features relate to:

  - Refuelling operations
  - SG EC inspection and tube plugging
  - RCPs

To assess the likely doses from operation of the AP1000 design, a baseline case for the total annual collective dose to workers was developed from the collective dose calculation for the AP600 reactor design (Reference 24.40), which was based on dose data from a standard Westinghouse 2-loop reactor. The doses were divided into the following categories (Reference 24.41):

- Reactor operations and surveillance
- Routine maintenance
- In-service inspection (ISI)
- Special maintenance
- Waste processing
- Refuelling

The contributions to the collective dose from specific tasks within each category were established in Reference 24.42. This gave a total collective dose of 1.68 person-Sv, broken down as shown in Table 24-9.

The calculated total annual collective dose agreed well with the doses from Westinghouse-designed 2-loop reactors at Prairie Island and Kewaunee. (Prairie Island reactors averaged 1.67 person-Sv from startup in 1973/74 to 1990 (using data from Reference 24.22.)) However, from 1996 until 2003 (when the SGs in unit 1 were replaced), the average annual collective dose at Prairie Island was 0.89 person-Sv and has shown a steady reduction over the years, indicating improvements in dose control techniques.

On the assumption that current best practice will be employed in future operating plants, the average collective dose of 0.89 person-Sv for years in which outages took place at Prairie Island units 1 and 2 from 1996 to 2003 has been used in an assessment of expected doses from the AP1000 plant (Reference 24.40).

The method used to account for the reduction in crud production in the AP1000 plant and the reduction in the number of components used in Reference 24.40 is described in more detail in Appendix 24B.

The AP1000 design presented for generic design assessment (GDA) includes significant improvements to reduce doses to workers from refuelling operations over and above the improvements to reduce the dose rate from crud, such as the IHP. The collective and maximum individual doses from refuelling are calculated in Reference 24.42 and summarised in Appendix 24C.

In addition, JEM calculations for the following specific tasks (References 24.42 and 24.44) are described in detail in Appendix 24D:

- RCP inspection
- SG sludge lancing
- SG secondary side visual examination
- SG EC tube inspection and tube plugging
- SG ISI
- RCP ISI
- RVCH inspections
- RV inspections

The predicted AP1000 plant outage doses are shown in Table 24-9. These are slightly different from those in Reference 24.40 to take into account the revised refuelling dose calculation (Reference 24.42) and a different treatment of doses from operations that are not undertaken at every outage.

Additionally, Westinghouse has estimated collective doses incurred from several expected operations, including changeout of reactor coolant filters and CVS makeup filters. Based on these assessments, a collective dose of 1.17 person-mSv for a reactor coolant filter change is expected, while replacing a CVS makeup filter causes an estimated 0.037 person-mSv (Reference 24.57).

The total dose in a year in which an outage takes place is predicted to be 239 person-mSv, including the whole of the dose from the highest ISI (the RV, head, and SG ISIs each incur significant collective dose but are not all carried out during the same outage, therefore, only the highest contribution has been included). The dose from removal and inspection of an RCP has not been included because it is not a normally anticipated event, but would add another 4.2 person-mSv.

Potential dose from operations such as SG replacement has not been considered because a specific case will be made by the operators for these operations should they be required during the life of the plant.

The collective dose in years when there are no outages will be significantly lower. For example, the Prairie island unit 1 and 2 dose in 2007, when neither unit had a refuelling outage, was 63 person-mSv (Reference 24.22).

24.3.3.2 Doses to Groups and Individual Workers from Specific Operations

The assessments in Appendixes 24B, 24C, and 24D provide estimates of the total annual collective dose for a year including an outage. The average individual dose depends on the number of workers involved. The number of workers and the total annual collective dose will vary significantly between a year when a refuelling outage takes place and a year when there is no outage.

The number of personnel with measurable doses at Prairie Island varies from 130 in a year with no outage to around 500 during an outage year on a single unit (Reference 24.22). No detailed manning levels have been established for an operating AP1000 plant and the number per unit will depend on whether there is more than one unit, as some resources will be shared. The number required should be less than on the Prairie Island units because the number of components requiring maintenance has been reduced. However, it would be unreasonable to assume that an AP1000 plant outage could be achieved with fewer than

300 workers, resulting in an average individual dose from the overall outage dose of 239 person-mSv of below 1 mSv.

The details in Appendixes 24B, 24C, and 24D indicate the average and maximum individual dose within each work category.

Reactor Operations and Surveillance

The annual collective dose from reactor operations and surveillance is estimated to be 39.3 person-mSv (Appendix 24A, Table 24A-5). This includes a contribution from chemistry sampling. The subtotal for Health Physics personnel is 16.7 person-mSv.

A significant proportion of the dose in this category is expected to arise during operations at power with more than 50 percent of the total arising from patrols and inspections. The dose will be shared evenly amongst a team of workers and is likely to be on the order of 0.5 mSv (i.e., shared amongst 80 workers).

Routine Maintenance

The majority of the routine maintenance dose is expected to be incurred during outages. The highest contribution is from SG sludge lancing (12.8 person-mSv). However, as shown in Appendix 24D, Table 24D-2, the sludge lancing operation has a total duration of 23.5 hours (three shifts). Therefore, the individual dose can be controlled by the operator.

In-Service Inspection

The ISI collective dose is the highest contributor to the total collective dose. Even with the large reduction in components and crud, the dose is dominated by inspection of valve bodies and bolting. A number of periodic examinations are not carried out at every outage. Remotely operated equipment is used where practicable.

The RVCH inspection and, in particular, the J-weld examinations, make the highest contribution of 10 person-mSv even though remotely operated equipment is used. The original assessment of the dose from this operation was carried out (2005) when it was a relatively new procedure and included a high individual dose from man access beneath the RVCH on its stand. However, the procedure has been revised so that the instruments are set up before the head is placed on the stand and removed only after the head has been lifted from it. The revised procedure ensures that no operation results in more than a 0.5-mSv individual dose.

The reduction in the number of components and the elimination of many items ensure that routine doses from ISI are ALARP. Future developments in remote techniques will be incorporated where reasonably practicable.

Special Maintenance

The issue of special maintenance arises either as a result of faults identified during ISI or because of significant replacements or upgrades. The latter cannot be predicted in advance. Specific cases will be made for both major repairs and upgrades by the operator at the time and includes making a sound ALARP justification.

The special maintenance of other components represents a typical value as some outages may find more faults than others. However, the reduction in the number of components and the elimination of many items ensure that routine doses from ISI are ALARP.

Waste Processing

The AP1000 plant radwaste system designs incorporate an uncomplicated approach to waste processing. The AP1000 design does not include waste or boron recycle evaporators and it does not include a catalytic hydrogen recombiner in the gaseous radwaste system. Elimination of high-maintenance components contributes significantly to lower anticipated doses due to waste processing activities.

Section 24.8 contains a detailed description of the proposed waste processing arrangements and an estimate of collective dose. Additional descriptions of wastes, waste types, and proposed treatment options are included in Chapter 26 of this document. As a summary, the routine waste arisings will consist of the following:

- Low-level waste (LLW)
    - HVAC filters
    - Protective clothing
    - Contaminated equipment
- Intermediate Level Waste (ILW)
    - Activated Carbon
    - Spent filter cartridges
    - Spent ion exchange resins
- High-level waste (HLW) – Spent fuel

Spent fuel is excluded from waste processing considerations because it will remain in the pond until a suitable dry storage facility is available.

The quantities of LLW and ILW arisings are given in the Environment Report (Reference 24.45) as the following totals:

- 19 x 3 m^3 (100 ft^3) drums or boxes for ILW
- 305 x 200 litre (55 gal) drums or eight half-height ISO (HHISO) containers for LLW

ILW processing equipment will need to be provided with suitable shielding (this would apply to the mobile encapsulation unit discussed elsewhere); there is no reason to expect exposures to significant dose rates.

It is concluded that the contribution to collective dose from waste processing included in Table 24-9 provides a suitable margin above that discussed in Section 24.8 and is therefore considered to be appropriate.

Refuelling

Refuelling is the most readily assessable category as it has clearly defined operations and start and end points.

The collective dose assessed in Appendix 24B (Table 24B-9) of 41.3 person-mSv is dominated by reactor disassembly and assembly, which in turn are dominated by disconnection and connection of the in-core instrumentation system (IIS), each of which results in an individual dose of 2.02 mSv. The refuelling team consists of a shift team of 32 plus a supervisor, and it is reasonable to expect that, apart from the maximum individual

doses, the dose will be evenly distributed, giving an average dose, excluding the supervisor, of 1.3 mSv.

The AP1000 design uses Quickloc couplings for the IIS connections, which are considered to be an improvement over, for example, the Conoseal connections used at existing PWRs.

It is clear that the IHP (and specifically the IIS) represents a significant improvement over previous designs where the flux thimbles were inserted through additional penetrations in the bottom of the RV (which the US Regulatory Guide on Control of Access to High and Very High Radiation Areas in Nuclear Power Plants (Reference 24.46) specifically identifies as creating a potentially hazardous situation because of the potential for workers to enter areas with very high radiation dose rates).

Therefore, although the maximum dose to a worker is estimated to be 2.02 mSv from disconnection and connection of the IIS, the design adopted represents the BAT.

Internal Doses

Westinghouse has performed an evaluation of the potential for internal dose uptakes in the AP1000 considering operating experience from existing plants of broadly similar design, and AP1000 design features. The evaluation concluded that internal exposures at existing nuclear power plants typically involve a small number of individuals and typically result in small committed effective dose equivalents (CEDEs) per individual. While the US and European Union use different International Commission on Radiological Protection (ICRP) standards for internal doses, the ICRP 30 standard used in the US is conservative for a majority of the nuclides that are typically ingested or inhaled at nuclear power facilities. For the radionuclides where the dose conversion factor (DCF) increases with the use of ICRP 68, only a relatively small increase in DCF (less than an order of magnitude) over those from ICRP 30 is seen.

Many of the recorded internal exposure events at existing plants are a result of human performance errors, and so it is important for the licensee to have an adequate radiological protection programme in place. Examples of actions within the responsibility of a licensee's radiation protection programme that could reduce or preclude internal doses are (note that these are the responsibility of the licensee/duty holder):

- Suitable procedures to control airborne activity and surface contamination to within acceptable levels

- Continuous review of airborne activity levels in areas such as the fuel handling area and containment and,

- Installation of additional 'frisking' probes at locations where contamination may arise, for example, the primary chemistry laboratory and the hot machine shop,

- Preplanning for any maintenance operations involving a breach of radiological containment such as pump or valve replacement

    - Setting up tenting or other ventilated enclosure,
    - Location of additional change barriers close to working area,
    - Specification of suitable PPE,
    - Use of portable activity in air monitors,
    - Mocking up the work in a non-radiological space before the task takes place

- Rigorous enforcement of access control and posting requirements during routine and maintenance operations,
- Rapidly responding to any incident with the potential for release of radioactive material (to identify contamination and minimise its spread), and
- A robust monitoring programme to identify trends and incidents in airborne radioactivity and surface contamination.

The AP1000 design has also further reduced the likelihood or magnitude of internal exposures through several design features including:

- Fewer valves and pumps requiring maintenance and potential replacement,
- Improved SFS decontamination flow (maximising cleanup of particulate in the Spent Fuel Pool) and cooling (minimising evaporative losses of the spent fuel pool),
- Physical boundaries between radiologically controlled areas and non-radiologically controlled areas,
- A comprehensive Radiation Monitoring System (RMS) design,
- The inclusion of an ALARA briefing room in the plant layout, and
- Comprehensive ventilation of plant areas.

Based on these considerations, internal doses should not be a major concern during the operation and maintenance of the AP1000 reactor when a rigorous radiation protection programme is employed.

24.3.4 Comparison of Doses against Numerical Targets

Target 1 – Normal Operation, Any Person on the Site

Employees working with ionising radiation:

- BSL(LL): 20 mSv
- BSO: 1 mSv

The highest individual dose from a single operation is estimated in Appendix 24B (Table 24B-9) to be 2.02 mSv from disconnection and connection operations on the IIS at the RVCH. This dose is above the BSO and is received in a short time (1.6 hours). It is possible for two workers to undertake this task so that the individual dose is 1 mSv (it is unlikely that more than two workers could be involved). However, as it is likely that some workers will receive exposures from other operations during refuelling, individual doses will exceed the BSO.

Some other operations involve either short exposures to relatively high dose rates (e.g., RVCH inspection has a 1-hour exposure up to 0.5 mSv/h) or longer exposures to moderate to high dose rates (e.g., SG sludge lancing has 12 hours exposure to 150 μSv/h). However, the maximum individual doses from these operations could, legitimately, be reduced by dose sharing among members of the team or between shifts. In addition, the number of such operations has been reduced SFAIRP.

As discussed above, BAT has been adopted to reduce the sources of radiation (especially crud) and the principle of keeping doses ALARP has been considered throughout the design of the AP1000 plant by minimising maintenance requirements, using remote techniques, and reducing exposure durations. For example:

- The number of pumps, valves, vessels, and other components and the length of primary circuit piping have been significantly reduced compared with previous generations of PWRs.

- The seal-less RCPs are designed to eliminate required maintenance and the potential for RCS seal leakage.

- The IHP design represents best current industry practice and the use of Quickloc couplings in place of Conoseal couplings has been part of the continuous improvement process by Westinghouse.

- The design facilitates remote SG inspection and tube plugging, and remote RVCH inspection.

In the operational phase, to ensure that individual doses are ALARP, administrative controls will be implemented. Operators will be expected to set dose constraints based on industry best practice. During outages and any other operations involving short duration exposure to high dose rates, entries will be carefully planned, taking account of previous experience, and, where appropriate, will be practiced on inactive mockups to minimise the duration of exposures. Worker doses will be monitored using personal alarming dosimeters (PADs) as well as statutory dosimeters and extremity dosimeters where necessary.

The overall collective dose is predicted to be significantly lower than any similar nuclear power plant. However, there remain some tasks that involve exposure to relatively high levels of external radiation, and no further viable improvements have been identified, at this time, that could reduce doses further. Therefore, it is concluded that individual doses in excess of the BSO, but still significantly below the BSL, are ALARP.

Target 1 – Normal Operation, Any Person on the Site

Other employees on the site:

- BSL: 2 mSv
- BSO: 0.1 mSv

The convention has been adopted that all non-radiation areas within buildings have been designated as Zone I areas (up to 2.5 μSv/h). Areas up to the limit of the Zone I designation could, in theory, result in radiation exposure up to 5 mSv for an annual occupancy of 2000 hours. However, the calculated dose rates represent an upper limit based on pessimistic assumptions. Non-radiation areas of the auxiliary building, particularly those adjacent to the shield building, could have detectable levels of radiation during full power operations, but these are low occupancy areas and no specific controls are considered necessary. There is no reason to expect the dose rates in normally occupied areas, such as the office areas of the annex building, to be detectable above ambient background conditions.

Dose rates outside the west of the spent resin storage tank room at an elevation of over 7 m have been calculated to be as high as Zone III (25 to 150 μSv/h) during spent resin transfers.

However, as permits will be required for working at height, the operator will be able to ensure that no additional exposures are caused.

There is no reason to believe that radiation from AP1000 plant operations will result in any employee in a non-radiation area receiving additional radiation exposure above background radiation levels above the BSO.

Target 2 – Normal Operation Any Group on Site

- BSL: 10 mSv
- BSO: 0.5 mSv

The average dose to all radiation workers on site depends on the total number of workers but is expected to be less than 1 mSv.

The doses to specific groups of workers also depend on the number in each group and the dose assigned to the group.

The only readily identifiable group, and probably the group with the highest average exposure, is the group of 32 workers undertaking the refuelling operation. The average dose to this group is estimated in Appendix 24B (Table 24B-9) to be 1.3 mSv.

As discussed in Appendix 24C, all aspects of the refuelling operation have been reviewed to identify best practices. Where improvements have been identified, these have been incorporated into the design. No further viable improvements have currently been identified that could reduce doses further. However, in line with continuing the improvement policy and learning from experience, any refinement of the procedures or new equipment that has been shown to reduce doses in other plants will be introduced in the AP1000 design where relevant.

Therefore, although the predicted maximum group doses are above the BSO, they are ALARP.

24.4 Radiological Protection, Members of the Public

24.4.1 Normal Operations

Doses to the public from normal operations are the sum of doses from external radiation, airborne discharges, and liquid discharges. Typically the contribution from direct external radiation from containment is insignificant, because dose rates are low and there is limited occupancy at the site boundary. External radiation is more likely to result from exposure to sediments containing radionuclides discharged as liquids.

24.4.1.1 External Radiation

The primary shielding provided by the reactor and the concrete primary shield; the secondary shielding around the SGs, pressuriser, and other primary circuit components; and the shield building around the containment ensure that dose rates outside during operation are less than 2.5 μSv/h based on conservative estimates of the source term. Calculations of dose rates between 30 m (98.43 ft) and 500 m (1640.42 ft) from the shield building (Reference 24.47) show the dose at 30 m (98.43 ft) is 0.0056 μSv/h, 0.0047 μSv/h at 70 m (229.66 ft) and 0.0015 μSv/h at 150 m (492.13). The dose rate profile has a maximum of 0.0061μSv/h at 50 m (164.04 ft) as a result of scattered radiation through the passive containment cooling

system air vents in the shield building. A comparison with existing UK PWR confirms that direct external radiation does not present a significant exposure pathway.

24.4.1.2 Routine Discharges

BAT is employed to reduce arisings and discharges SFAIRP so that doses to members of the public are ALARP. Techniques to minimise arisings and discharges include the following:

- C-14 minimisation
    - Oxygen scavenging
    - Control of nitrogen impurities in fuel
    - pH control by lithium hydroxide
- Cs-137
    - Minimisation of fuel defects in operation
    - Control of uranium contamination in fuel manufacture
    - Demineraliser
- I-131
    - Minimisation of fuel defects in operation
    - Control of uranium contamination in fuel manufacture
    - Mixed bed demineralisers
    - Deposition
    - Carbon delay beds
- N-16
    - Hydrazine addition
    - Oxygen elimination
    - Delay for Decay techniques
- Noble gases
    - Minimisation of fuel defects in operation
    - Carbon delay beds
- Activation products (see Section 24.3)
    - Minimisation of plant shutdowns
    - Carbon delay beds
    - HEPA filters
    - Liquid filtration and demineralisers

- Pu-241
    - Control of uranium contamination in fuel manufacture
    - Minimisation of plant shutdowns
    - Liquid filtration and demineralisers
    - HEPA filters
    - SFP clean-up system
- Sr-90
    - Minimisation of fuel defects in operation
    - Control of uranium contamination in fuel manufacture
    - Liquid filtration and demineralisers
    - HEPA filters
- Tritium
    - Li-7 tailored lithium hydroxide
    - Zirconium cladding
    - Grey rods
    - Minimisation of plant shutdowns
    - Minimisation of primary coolant leaks
    - Condenser

The plant design also facilitates the application of additional BATs by the duty holder to minimise radioactivity arising from routine discharges SFAIRP. Such additional BATs include the application of good chemistry and the potential use of ultrasonic fuel cleaning.

The predicted doses from routine airborne discharges are calculated in the Environment Report (Reference 24.45) to be 7.6 μSv from representative annual discharges and 12 μSv from the calculated annual discharge limits. The doses from liquid effluent discharges have been calculated to be 2.3 μSv for representative discharges and 3.8 μSv for calculated annual discharge limits.

The total annual predicted doses from discharges are therefore 9.9 μSv from representative discharges and 15.8 μSv for airborne and liquid discharges at the calculated limits.

24.4.1.3 Total Dose

The total annual predicted doses from all sources are therefore 14 μSv from representative discharges and estimated external radiation and 20 μSv for airborne and liquid discharges at the calculated limits. These are at or below the BSO for any person off the site (Reference 24.1).

Target 3 – Normal Operation, Any Person Off the Site

- BSL(LL): 1 mSv
- BSO: 0.02 mSv

The maximum dose requirements in EPR2010 (Reference 24.3) have also been met.

Maximum Doses to Individuals from a Defined Source (EPR2010)

- 0.3 mSv per year from any source from which radioactive discharges were first made on or after 13th May 2000, or

- 0.5 mSv per year from the discharges from any single site.

Westinghouse notes that an objective of 150 microSv per year has been established for future construction. The actual critical group dose will be dependent on habit survey data. However, it is reasonable to conclude that the systems employed to reduce activity in airborne and liquid discharges and to restrict direct radiation doses will ensure that doses are ALARP.

24.5 Control of Surface and Airborne Contamination

The RCA specified as Zone II or above in Appendix 24A also forms the boundary of the areas with potential for contamination. Within the RCA, some areas will have higher potential for surface and airborne contamination particularly during refuelling and maintenance. Access control and traffic patterns are considered in the plant layout to reduce the spread of contamination.

24.5.1 Personnel Access to the Radiologically Controlled Area

All personnel access to the RCA of the annex building, the auxiliary building, the shield building, the containment, and the radwaste building is via a single entry/exit area in the annex building, during normal operations and outages.

The facilities have been designed according to Reference 24.48, which has been developed in agreement with utility operators. Personnel will change from personal clothing into work clothing in the change rooms (Figure 24-5). It is normal for clothing to be worn in the RCA to be differentiated from work clothing that may be worn in nonactive areas to minimise the potential for spread of contamination but the plant operator will make such arrangements. The change rooms have been sized for 30 male and 12 female personnel at any time (male change room is 15.25 m (50 ft) x 16.15 m (53 ft), female change room is 6.7 m (22 ft) x 16.15 m (53 ft)). During outages there may be up to 200 personnel in the RCA at any one time but entry and exit will be staggered to avoid overloading the change rooms.

When in work clothing, personnel will go to the RCA entry area. Work permits, dosimetry including PADs, respirators, and keys for access to restricted areas will also be issued on entry to the RCA at the Health Physics Booth (Figure 24-6). The human factors aspects of this portion of the plant have been reviewed as part of several design reviews and iterations between Westinghouse, design partners, and Westinghouse AP1000 customers. The current layout is the result of several iterations and changes, which were enacted to address such concerns as ergonomics. Thus, although there is not a formal human factors assessment of this portion of the plant, these considerations have been included in the design. Additional PPE will be obtained from the PC Pickup and Suitup Room which includes provision for benches and shelving (Figure 24-7).

Although the radiation zoning for these areas is shown as Zone II in Table 24A-3, no sources of radiation are present or would need to be brought into the area and dose rates will be at or near indoor background levels.

Following a design basis accident, entry arrangements will be determined according to conditions at the time. Suitable forward control points are likely to be established at low dose rate locations.

Access into the RCA, the non-active areas of the auxiliary building, and the turbine building is limited to authorised personnel via turnstiles. Entries are recorded, enabling rapid roll calls in emergencies (Figure 24-8).

Additional PPE will be removed prior to exit from the RCA. Workers in work clothing will pass through installed personal monitors that will not allow egress on alarm except in emergencies. Washbasins and showers are located on the active side of the barrier for personal decontamination (Figure 24-10). First aid equipment is located within the area. Showers are also provided in the change rooms. As workers will have been monitored on exit, these showers do not need to be connected to the active liquid waste system although the waste water will be monitored as a precaution before discharge to the normal sewage system.

All personal equipment and portable tools taken into the RCA must be monitored at the Health Physics Booth before removal from the RCA and decontaminated, retained in the area, or disposed of as active waste. Decontamination of tools can be undertaken in the hot machine shop. Only essential items will be permitted to be taken into the active area to minimise the monitoring, decontamination, and waste generation.

Any equipment used in the active area could be stored in the RCA for reuse; for example, equipment that may be contaminated could be kept in the hot tool crib in the hot machine shop. Larger items which are not significantly contaminated could be kept in the staging and storage area on the first floor of the annex building. This could apply to dedicated equipment such as the remote control SG examination and tube plugging equipment and the RVCH remote inspection equipment; however, it may be cost effective to share such equipment among a number of reactors.

24.5.1.1 Hot Machine Shop

The hot machine shop (Figure 24-11) provides facilities for decontamination of tools and other items either to allow tools to be taken off site or to reduce the dose rates associated with the tools. If a tool cannot be decontaminated sufficiently for free release then a judgment would be made by the plant operator based on the residual contamination and the value of the item. The tool would either be scrapped as LLW or, if it was to be reused, it could be stored in the "hot tool crib". The plant operator would make the decision based on an ALARP assessment.

The hot machine shop also houses machine tools and an enclosure for undertaking work on pump seals. The amount of work which will be undertaken will be determined by the plant operator. It is likely that a lot of the work undertaken will be on components which are not significantly contaminated but which would be difficult to monitor sufficiently to clear them from the RCA. Dose rates in the hot machine shop will depend on the operations being undertaken. The shielding provided has been assessed for a 555 MBq Cs-137 source and a 148 MBq Co-60 source based on a dose rate of 150 μSv/h at 300 mm (11.81 ft) which is considered to be the limit for this area (Reference 24.29). However, this is purely used as a bounding case. In practice, the plant operator would make an ALARP justification for undertaking work on high dose rate components rather than disposing of them as waste. High dose rate components would remain in the hot machine shop for as short a period as possible and only essential workers would enter the workshop while such components were present.

Decontamination and local shielding would also be use as appropriate to ensure that doses were ALARP.

24.5.2 Equipment/Materials Access to the Radiologically Controlled Area

The number of access routes from the RCA to the environment is limited to the following:

- The containment access corridor in the annex building leading to the ground floor staging area in the auxiliary building
- The truck staging area in the radwaste building leading to the rail car bay in the auxiliary building
- The mobile systems facilities bays in the radwaste building

Drains, floors, and exterior concrete sloping are used at access points to prevent (potentially radioactive) fluids from the interior of the buildings escaping from the buildings, and also to prevent exterior surface water from entering the buildings.

The containment access corridor and the truck staging area provide for final contamination monitoring prior to dispatch.

24.5.3 Access Routes within the Auxiliary Building

Access requirements and the potential for the spread of contamination vary between power operation and refuelling outages.

During power operations, access requirements will be relatively low. Regular access will be required to the primary sampling room during both power operations and refuelling outages. Air and liquid filters may need to be replaced and some patrols, inspections, and calibrations will be carried out. In addition, fresh fuel will be brought into the plant in preparation for refuelling.

Air filters will be of the safe change type and therefore only precautionary contamination control arrangements will be required. Changing of CVS filters uses a bottom-opening transport flask, and only local contamination control arrangements will be required. Similarly, local contamination control arrangements will be set up for any breakdown maintenance where there is the potential for a spread of contamination.

During refuelling outages the RVCH IHP is removed and moved to a storage stand on the operating deck (110.744 m (135’-3”) level). The upper and lower refuelling cavities and fuel transfer canal are flooded, and the upper internals are lifted into their storage racks in the refuelling pool. Fuel is lifted out of the reactor, rotated to the horizontal position for transfer out of the containment, returned to the vertical by the up-ender, and placed in the spent fuel storage racks. New and reload fuel will be taken into the containment in a similar manner. In addition, the SGs will be opened and inspected during the refuelling outage and other maintenance operations on pumps will be undertaken. In addition to contamination controls at the RCA boundary, local contamination control areas are likely to be established within the containment and auxiliary buildings to limit the spread of contamination to the general operating areas.

Later in the life of the plant, after the refuelling shutdown is complete and the reactor is at power, decayed spent fuel will be loaded into fuel flasks to be taken out of the auxiliary building. The fuel transfer flask is loaded underwater in the loading pit connected to the SFP.

After loading, the flasks are transferred to the cask washdown pit for decontamination and initial monitoring before transfer to the transport vehicle in the rail car bay. Similarly, spent resin containers and filters from the CVS will be packaged in some suitable form for export to long-term storage or the ILW repository (Section 24.8). Fuel flasks and waste containers are transferred into and out of the rail car bay via the truck staging area of the radwaste building, which provides a buffer area where final clearance monitoring can be undertaken prior to leaving the RCA.

LLW arising in the containment or auxiliary building can be transferred to the radwaste building via the rail bay and truck staging area; LLW from the annex building, including the hot machine shop, can be transferred to the radwaste building via the access corridor and the truck staging area.

24.5.3.1 Access to the Containment

Access into the containment is via shielded personnel airlocks on the 100 m (100') and 110.744 m (135'-3") operating deck level and via equipment shield doors on the same levels.

Large items transferred into or out of the containment can be transferred through the auxiliary building and temporarily housed in a staging area in the annex building. Otherwise, large items from within containment can be removed from the nuclear island via the containment access corridor in the auxiliary building, which provides a buffer area where final clearance monitoring can be undertaken.

24.5.3.2 Local Access Controls

Local access controls will be implemented close to areas under maintenance with temporary barriers for additional PPE and monitoring as necessary. Different arrangements may be adopted to handle the larger numbers present during refuelling. However, the aim remains to isolate contamination to the area where it is generated and to decontaminate the area as soon as possible after the work has finished.

24.5.4 Surface Contamination Control

The AP1000 plant is designed to contain radioactive liquids and gases within vessels, pipes, and pumps. Potential sources of contamination, with the exception of the SFP, are isolated from normally occupied areas.

Liquid sampling systems are designed to maintain containment and, where necessary, shielding.

Surface contamination will be limited to areas where breach of containment is necessary for maintenance. Equipment is designed to minimise the generation and spread of contamination.

24.5.4.1 Drains from Vessels

Equipment vents and drains from highly radioactive systems are piped directly to the collection system to minimise airborne and floor contamination. Welded piping systems are employed on radioactive systems to the maximum extent practicable to reduce system leakage and crud buildup at joints.

24.5.4.2 Surface Treatment

Decontamination of potentially contaminated areas and equipment within the plant is facilitated by the application of epoxy paints and suitable smooth-surface coatings to the concrete floors and walls. Sloping floors with floor drains are provided in potentially contaminated areas of the plant, where practicable. In addition, radioactive and potentially radioactive drains are separated from nonradioactive drains.

24.5.5 Airborne Contamination

The containment and ventilation systems are described in detail in Chapter 23. There are a number of different systems serving active and inactive areas:

- Nuclear island nonradioactive ventilation system (VBS)
- Annex/auxiliary building nonradioactive ventilation system (VXS)
- Diesel generator building heating and ventilation system (VZS)
- Containment recirculation cooling system (VCS)
- Containment ventilation system (VFS)
- Health physics and hot machine shop HVAC system (VHS)
- Radwaste building HVAC system (VRS)
- Turbine building ventilation system (VTS)
- RCA ventilation system (VAS)
- MCR habitability system (VES)

The extracts from areas with the potential for radioactive discharges are individually continuously monitored and alarmed. Additionally, the plant vent combined discharge is monitored and alarmed. HEPA filtration is also provided for some of the areas with a higher potential for contamination, as discussed below.

The ventilation systems have been designed to maintain areas that have the potential for contamination at a negative pressure differential with respect to the outside atmosphere and to adjacent areas with lower potential for airborne activity.

The detailed classification of areas with respect to the potential for surface and airborne contamination will be the responsibility of the site operator. However, the classification used in Reference 24.49 and shown in Table 24-9 has been adopted here to justify the ventilation arrangements for the various areas.

24.5.6 Nuclear Island Nonradioactive Ventilation System

The VBS serves the MCR, control support area (CSA), Class 1 electrical spaces, and PCS valve room. These areas do not have sources of activity present during normal operation or during fault conditions. The VBS is described in more detail in Section 23.11.

HEPA filters and charcoal absorbers are provided in the MCR/CSA HVAC subsystem.

24.5.7 Annex/Auxiliary Building Nonradioactive Ventilation System

The VXS serves the office areas, switchgear rooms, locker rooms, battery rooms, computer rooms, toilets, and other similar spaces. These areas do not typically have sources of radioactive contamination present during normal operation. The VXS is described in more detail in Section 23.12.

A drain line from the steam generator blowdown system (BDS) to the WLS passes through some of the areas served by the VXS. The drain line can be contaminated by the BDS if there is a fuel leak and SG leakage, or an isolation valve failure. Since the drain system has no valves or connections within the area served by the VXS, and it is gravity drained, the chance of leakage into the VXS area is negligible.

It is not reasonably foreseeable for activity to be present in the areas served by the VXS. The area is classified as a white area for both normal and fault conditions. There is no requirement for HEPA filtration.

24.5.8 Diesel Generator Building Heating and Ventilation System

The VZS supplies air to and exhausts from the diesel generator building. The diesel generator building is a physically separate building. The VZS is described in more detail in Section 23.14

There is no credible source or fault that will result in a radioactive release from the diesel generator building, and thus there is no normal or fault condition. The area served by the VZS is classified as a white area for both normal and fault conditions. There is no requirement for HEPA filtration for radiological protection.

24.5.9 Containment Recirculation Cooling System

The VCS recirculates and cools air within the containment during power operations and shutdown. This results in an energy saving and a reduction in waste generated in the form of used filters when compared with that which will arise from the level of a once-through HVAC system. The air recirculated by the VCS is expected to contain some activity (mostly noble gases and some iodine), although it does not penetrate the containment boundary and therefore does not give rise to any discharges to atmosphere. The VCS is described in more detail in Section 23.4.

During shutdown operations in the containment, local, filtered extract systems will be used for particular operations where airborne activity may be generated. This reduces the potential for airborne activity to be released into the general containment atmosphere, which the recirculation system could spread to other parts of the containment.

The extracted air is continuously monitored for airborne activity that will give an early warning to workers in the containment.

There is no path to discharge the VCS to the environment, hence HEPA filtration is not provided.

24.5.10 Containment Ventilation System

The VFS purges the containment intermittently by providing fresh air from outside and exhausting air to the plant vent stack. The air exhausted by the VFS is filtered with high-efficiency filters, HEPA filters, charcoal filters, and high-efficiency post filters. The VFS also exhausts from areas served by the VAS and VHS after receipt of a high radiation signal in the VAS or VHS exhaust. The VFS is diesel backed to improve its reliability.

A radiation monitor located in the common ductwork downstream of the filtration units is provided to detect deterioration in performance of either ventilation train. These provisions represent good industry practice for ensuring that discharges to the atmosphere and doses to members of the public are ALARP. The VFS is described in more detail in Section 23.3.

The containment is an amber area with a potential for occasional releases. It is, therefore, provided with full-time HEPA filtration on the exhaust.

24.5.11 Health Physics and Hot Machine Shop Heating, Ventilation, Air-Conditioning System

The VHS consists of two 100 percent capacity exhaust fans (duty and standby) with supplies from duty and standby air-handling units sized to allow the system to maintain a negative air pressure differential with respect to adjacent areas.

The hot machine shop provides a location within the controlled area for repair and refurbishment of items of equipment from within the controlled area. This equipment may not actually be contaminated or activated, but it is easier to have a dedicated workshop rather than undertake clearance monitoring, which may not be possible. Operations in the hot machine shop are conventional hands-on work; i.e., there is no provision for remote handling. The routine arisings of airborne contamination from machining operations are not expected to be significant because equipment that can be repaired will be decontaminated beforehand. Equipment that is too active to handle manually and cannot be decontaminated will be packaged and disposed of as radioactive waste.

Airborne contamination from the remaining space extract from the hot machine shop and other areas served by this system is not expected to be significant during normal operations or fault conditions.

The facility has a dedicated decontamination facility with HEPA filtration and a glovebox with HEPA filtration.

Individual machine tools may have local exhaust ventilation arrangements that include HEPA filters. The VHS fans also shut down on a high radiation signal and the exhaust is then directed through the VFS, thus reducing the airflow from the served spaces but allowing for the exhaust to be filtered.

The VHS is described in more detail in Section 23.10.

24.5.12 Radwaste Building Heating, Ventilation, and Air-Conditioning System

The VRS supplies and exhausts air from the radwaste building.

The radwaste building has the following three potential sources of radioactive contamination:

- Tanks for low-level liquid effluent for monitoring and sentencing. The monitor tanks contain water that has the potential of having radiological contamination. The water in the monitoring tanks is not expected to contain significant contamination and will typically be below environmental discharge limits.

- An area for loading packaged solid LLW into containers for dispatch to the low-level waste repository (LLWR). Packaged solid radwaste is stored in the radwaste building. This material is bagged or loaded into storage containers at the point where it is generated/processed, so the chance of a significant release is low. LLW will be sorted, compacted, decontaminated, and size reduced in the radwaste building within ventilated

enclosures. Condensate polishing resins might be LLW in the event of SG tube failures and are encapsulated at the spent resin tank. Other LLW is not encapsulated. LLW processing equipment is currently expected to be permanently installed. ILW processing equipment is mobile. The equipment may be permanently located at each site or may be transportable to undertake campaigns at more than one site.

- The AP1000 design has provisions for portable ILW processing equipment. This equipment will connect to the railcar bay auxiliary building HVAC system (VAS). Therefore, risk of contamination from equipment and processing equipment is small. In addition all potential sources are filtered at the component level.

The VRS is described in more detail in Section 23.9.

The VRS general extract may contain significant airborne activity either during normal operation or fault conditions if the portable radwaste equipment is not properly operated.

The radwaste building is classified as an amber area with potential for significant airborne activity release. Therefore, the VRS extract is equipped with HEPA-filtration as discussed in Section 23.9 of this PCSR.

24.5.13 Turbine Building Heating, Ventilation, and Air-Conditioning System

The VTS serves all areas of the turbine building. The HVAC systems serving the switchgear rooms, rectifier room, security rooms, and plant control system cabinet rooms do not have a credible source of radioactive contamination. The general area of the turbine building is ventilated through roof ventilators. This part of the AP1000 plant does not have a likely source of radioactive contamination. These areas do not have HEPA filtration because it does not offer a significant protection benefit.

The Bay 1 area of the turbine building contains the RCP variable speed drives, component cooling water system (CCS) equipment (a nonradioactive system), and the BDS. The BDS may be contaminated in the unlikely event of concurrent fuel defects, SG leakage, radiation monitor or BDS isolation failure, or a BDS leak. The VTS includes dampers that can be closed if the BDS becomes radioactive (as detected by radiation monitors). This minimises the possible spread of contamination from the BDS room. An exhaust path from the BDS room to the turbine building vent can be actuated to reduce the airborne radioactivity in the BDS room to minimise the contamination level for personnel entry for inspection and maintenance. The VTS is described in further detail in Section 23.13.

The turbine building, except for the Bay 1 area, is a white area. The Bay 1 area is a green area with a very limited potential for airborne release. Therefore, HEPA filtration is not required.

24.5.14 Radiologically Controlled Area Ventilation System

The VAS serves the RCA of the auxiliary/annex buildings. The VAS consists of two separate air supply subsystems, the fuel-handling area ventilation subsystem, and the auxiliary/annex building ventilation subsystem. Both of these subsystems are once-through type ventilation systems.

During normal operation the supply air-handling units and the exhaust fans on each of the ventilation subsystems operate continuously to ventilate the areas served on a once-through basis. The supply airflow rate is modulated to maintain the areas served at a slightly negative pressure differential with respect to the outside environment. The unfiltered exhaust air is directed to the plant vent stack where the radioactive airborne discharges are monitored.

The exhaust air radioactivity is also monitored in the VAS ductwork prior to the monitoring at the plant vent stack. Detection of radiation in the exhaust ductwork will result in the supply and exhaust fans being shut down and initiation of the VFS.

24.5.14.1 Fuel-Handling Area

The fuel-handling area ventilation subsystem supply and exhaust ductwork is arranged to exhaust the SFP area separately from the auxiliary building. It provides directional airflow from the waste disposal container area into the spent resin equipment rooms.

All spent fuel-handling operations are performed under borated water to provide radiation protection. Activity levels in the SFP are controlled by technical specification (Tech Spec). The activity level in the SFP is reduced, if necessary, by transferring a portion of the SFP water to the WLS for discharge and replacing it with clean water. The SFP water is constantly filtered and purified by the SFS.

Routine releases for the fuel-handling area are expected to be low and the potential accidental release is low. However, the fuel-handling area is classified amber, and there is the potential for contamination to be present in the SFP water, which may become airborne if the spent fuel pool were to boil. In addition, the fuel-handling area extract on Sizewell B is filtered. Therefore, HEPA filtration of the fuel-handling area extract is provided as discussed in Section 23A.1.9.1 of this PCSR.

24.5.14.2 Auxiliary/Annex Buildings

The remainder of the radiologically controlled part of the auxiliary/annex buildings exhaust air ductwork is routed to minimise the spread of airborne contamination by directing the supply airflow from the low radiation access areas into the radioactive equipment and piping rooms with a greater potential for airborne radioactivity. Additionally, the exhaust air ductwork is connected to the radwaste effluent holdup tanks to prevent the potential buildup of gaseous radioactivity or hydrogen gas within these tanks. The exhaust fans discharge the exhaust air into the plant vent stack where the radioactive airborne discharges are monitored. The exhaust air radioactivity is also monitored in the VAS ductwork prior to the monitoring at the plant vent stack.

The supply and exhaust ducts are configured so that two building zones may be independently isolated. The annex building staging and storage area, containment air filtration exhaust rooms, containment access corridor, and adjacent auxiliary building staging, equipment areas, middle annulus, middle annulus access room, and security rooms are aligned to one zone. The other zone includes the remaining rooms and corridors, including but not limited to the radiation chemistry laboratory, primary sample room, SFP cooling water pump and HX rooms, RNS pump and HX rooms, CVS makeup pump room, lower annulus, and various radwaste equipment rooms, pipe chases, and access corridors. Radiation monitors are located in the exhaust air ducts of each zone.

All active liquids and resins are contained within system piping and equipment. Routine discharges are low; no single fault will result in higher discharge levels. However, if the radiation monitors detect a high level of radiation, the relevant extract is diverted to the VFS, which contains HEPA filters. The extract can also be diverted manually if particular operations are being undertaken that could result in the release of activity.

The radiologically controlled part of the auxiliary/annex buildings served by the VAS is classified amber with low risk for activity release. Therefore, the extract is not normally filtered, but the VFS is used when needed.

Section 23A.1.11 describes how area radiation monitors (in addition to duct monitors) can actuate the VFS extract filtration.

Where major breaches of containment that could result in airborne contamination are necessary for repairs, suitable local containment and filtered extract ventilation systems are used to control the spread of contamination and reduce discharges.

24.5.15 Main Control Room Emergency Habitability System

The AP1000 design includes an emergency habitability system for the MCR, which consists of a supply from banks of compressed air storage tanks that are available to maintain the MCR environment for up to 11 personnel over a period of up to 72 hours. The VES is initiated by "High-2" particulate or iodine radioactivity in the MCR supply air duct, or the loss of ac power for more than 10 minutes. More details can be found in Sections 6.9 and 23.7 of this PCSR.

24.6 Radiation Monitoring

The RMS provides plant effluent monitoring, process fluid monitoring, airborne monitoring, and continuous indication of the radiation environment in plant areas where such information is needed. Radiation monitors that have a safety-related function are qualified environmentally, seismically, or both. A description of the RMS is presented in Section 6.8.10.

The RMS provides radiation monitoring in operating areas, post-accident monitoring, duct monitoring, effluent monitoring, and process and fluid monitoring.

In addition, personal monitoring of exposure of all workers in the RCA will be undertaken by the plant operator in compliance with the IRR99. PADs will be used for short-term dose control in particular during refuelling and maintenance activities as part of the arrangements for ensuring that doses are ALARP. The operator may require the universal use of PADs for all work within the RCA and sufficient capacity has been provided in the conceptual design for their storage. Dose budgets will be prepared for specific operations (similar to the JEM calculations in Appendix 24B) and dose received will be compared against the initial estimates to provide assurance that best work practices are being followed and to determine where improvements can be made.

Data obtained during refuelling and maintenance operations will be used to identify tasks where dose reduction efforts should be concentrated.

24.6.1 Area Gamma Monitors

Area radiation monitors are installed in locations listed in Table 24-11. The CSA monitor is in the annex building outside the RCA and is provided for post-accident monitoring.

The permanent area monitors in the fuel-handling area are physically separated by a large distance and have overlapping fields of view to enable them to monitor for increasing radioactivity that could be an indication of fuel reaching criticality. Each monitor can detect radiation from a fuel criticality accident in the areas occupied by personnel where fuel is stored and handled. Indication and alarms are also provided in the MCR.

Additionally, area monitors provide signals to the C&I systems that are used for control of various ventilation systems, as described in Section 23A.1.11 of this PCSR. This allows for filtration of airflow upon detection of a high radiation signal.

24.6.2 Post-Accident Area Monitors

Post-accident area monitors include the following:

- **Containment high-range radiation monitors** – These four monitors measure the radiation from the radioactive gases in the containment atmosphere. The data are displayed in the MCR. Alarms are provided in the MCR and signals to the protection and safety monitoring system for containment air filtration isolation (High-1) and RNS valve closure (High-2) and containment isolation. The monitors have a nominal range of 10 mSv/h to 105 Sv/h.

- **Primary sampling room area monitor** – The primary sampling station is the location where samples are collected after a postulated accident. The monitor provides local readout, and audible and visual alarms are visible upon entry into the sampling room. Indication and alarm are also provided in the MCR.

- **CSA monitor** – The CSA is the location from which engineering support will be provided to the operators following a postulated accident. A local readout, and audible and visual alarms are visible upon entry into the CSA. Indication and alarm are also provided in the MCR.

- **Fuel-handling area criticality monitors** – Two radiation monitors perform general area monitoring of the fuel-handling and storage areas. Any increase in this could be an indication of fuel reaching criticality. The area radiation monitoring is augmented during fuel-handling operations by a portable radiation monitor on the fuel-handling machine. A criticality excursion will produce an audible local alarm and an alarm in the MCR.

24.6.3 Discharge Duct Monitors

Radiation monitors set up to detect the principal noble gases present (Kr-85 and Xe-133) are located in the extract ducts from the fuel-handling area, auxiliary/annex building (VAS), and containment purge extract (VFS). The ducts from the VRS and the VHS are monitored for Sr-90 and Cs-137.

Releases from fuel or primary coolant will include releases of noble gas. The VAS and VHS monitors will stop the associated supply and exhaust systems, and start the VFS extract to filter all extract from the impacted area. The VFS maintains the affected area at a negative pressure with respect to atmosphere, so that there is no unfiltered release to atmosphere during or after an abnormal release into the areas served by the VAS.

The VFS and VRS duct monitors alarm on a high signal, but do not stop the associated fans. The high signal alarms from VFS and VRS are displayed in the MCR to allow operators to determine the appropriate manual actions.

24.6.4 Main Control Room Supply Air Duct Monitors.

Radiation monitors (for I-131, Kr-85, Xe-133, Sr-90, and Cs-137) measure the concentration of radioactive materials in the air that is supplied to the MCR. The monitors initiate the supplemental air filtration system on High-1 gaseous, particulate, or iodine activity concentrations, isolate the air intake and exhaust ducts, and activate the VES on either High-2 particulate or High-2 iodine concentrations. Alarms are provided in the MCR.

24.6.5 Process Fluid Monitors

Fluid process, airborne, liquid, and gaseous radiation monitors include the following:

- **BDS radiation monitors** – The presence of radioactive material in the BDS indicates a leak between the primary and secondary side of the SG. The monitor initiates an alarm in the MCR, initiates closure of the SG blowdown containment isolation and flow control valves, and diverts flow to the WLS.

- **CCS radiation monitor** – Radioactive material in the CCS indicates leakage. The monitor initiates an alarm in the MCR for operator action.

- **Main steam line radiation monitors** – Radioactive material in the main steam line provides early indication of leakage in the form of an SG tube leak. The monitor initiates an alarm in the MCR for operator action.

- **Service water blowdown radiation monitor** – The monitor measures the concentration of radioactive materials in the blowdown flow from the service water system. The monitor initiates an alarm in the MCR for operator action.

- **PSS liquid sample radiation monitor** – The monitor's principal function is to indicate elevated reactor coolant sample radiation levels following a design basis event or severe accident. It may also be used to provide early indication of a possible fuel-cladding breach. The monitor isolates the sample flow and initiates an alarm in the MCR for operator action and locally.

- **PSS gaseous sample radiation monitor** – The monitor provides indication of significant radioactivity in a gaseous sample taken from the containment atmosphere. The monitor initiates an alarm locally and in the MCR for operator action.

- **Gaseous radwaste discharge radiation monitor** – The monitor provides an alarm in the MCR and terminates the release of radioactive gas to the plant vent by closing the discharge isolation valve when a predetermined setpoint is exceeded.

- **Containment atmosphere radiation monitor** – The containment atmosphere radiation monitor is part of the reactor coolant pressure boundary leak detection system described in Chapter 21.

- **Turbine island vent discharge radiation monitor** – This monitor measures the concentration of radioactive gases in the steam and non-condensable gases that are discharged by the condenser vacuum pumps and the gland steam condenser. This measurement provides early indication of leakage between the primary and secondary sides of the SGs. The monitor provides an alarm in the MCR for operator action.

- **Liquid radwaste discharge radiation monitor** – The liquid discharge monitor provides signals to isolate the discharge of liquid radwaste, stop the discharge pumps, and provide an alarm to the MCR if concentration exceeds a predetermined setpoint.

- **Waste water discharge radiation monitor** – Upon detection of radioactivity concentrations above a predetermined setpoint, an alarm in the MCR will be initiated. The C&I control system will isolate the discharge line, and the turbine drain tank pumps will be automatically tripped to stop further discharge. Following the alarm, the operator can manually realign the discharge to the Liquid Radwaste System for processing.

24.7 Operational Health Physics

The operational health physics organisation is the responsibility of the plant operator. Radiation Protection Advisers (RPAs) will be appointed to advise the operator on compliance with the IRR99. These RPAs may be separate from the executive control of health physics surveyors but will be required to advise on radiological protection requirements for permits to work, suitable PPE including respiratory protective equipment, and precautions on entry into areas with high radiation or contamination. The RPA will advise on the preparation of local rules for working in the RCA.

The plant operator will also be required to appoint Radiation Protection Supervisors (RPSs) according to the IRR99 to ensure compliance with local rules and permit-to-work conditions. The plant operator will also decide on the organisational structure of operational health physics (for example, consideration may be given to self monitoring at workplaces to reduce doses to health physics surveyors).

Provisions have been made for health physics operations in the AP1000 design although flexibility remains within the annex building for detailed arrangements, and there are no restrictions on additional facilities outside the power block.

24.7.1 Issue, Storage, and Maintenance of Dosimeters

Personal dosimetry will consist of the following:

- Statutory "whole body" dosimeters, e.g., thermoluminescent dosimeter (TLD) for monitoring of external dose as required under the IRR99
- Extremity monitoring (e.g., finger and head TLDs) for monitoring extremity dose for compliance with the IRR99
- PADs for monitoring external dose on a daily or task basis
- Personal air samplers where airborne activity is of concern

PADs can be issued from the Health Physics Booth (Figure 24-6), which is located in a suitable low-background area in the annex. The type of dosimetry and alarm settings will be dictated by the permit-to-work requirements, which can also be issued from the Health Physics Booth.

Statutory "whole body" monitors may be issued separately from an administrative area depending on the approved dosimetry service arrangements made by the operator for processing and recording doses. However, it is likely that the plant operator will need to operate as an approved dosimetry service at least for extremity dosimeters.

Urine samples may also be required for bioassay. Urine sampling to assess tritium exposure is likely to be required but faecal sampling will probably not be necessary. Because it is important to avoid cross contamination, part of the change rooms could be designated for urine samples or facilities could be provided outside the power block.

24.7.2 Portable Survey Equipment

Portable radiation survey instrumentation is stored at the Health Physics Booth and at in-plant control points. This instrumentation allows plant personnel to perform radiation, contamination, and neutron surveys, as needed, as well as collect samples of airborne activity for analysis. Transportable activity in air monitors may be used for operations where airborne contamination may be generated and where local control measures such as tenting are implemented.

The specification of the type and number of portable instruments will be the responsibility of the plant operator.

24.7.3 Calibration and Maintenance of Radiological Protection Instrumentation

There is no specific provision for calibration and maintenance of radiological protection instrumentation (RPI) within the existing AP1000 design. Functional testing will be carried out in situ. It will be the responsibility of the plant operator to make arrangements for annual examination and testing of all RPI (including PADs) in accordance with the IRR99. These arrangements may be outside the power block, at a central location offsite, or with a third party.

24.7.4 Collection of Liquid and Gaseous Samples for Radioactive Analysis

A summary of the samples likely to be taken on AP1000 design is given in Table 24-1. In addition, representative air samples will be taken from the main discharges stack and may be taken from workplaces using static air samplers.

The analysis of the samples will depend on their purpose and the level of activity present. Some samples will be prepared and analysed within the RCA. To avoid cross contamination, operational restrictions ensure that environmental samples may not be brought into the RCA for analysis. The plant operator may carry out analysis elsewhere onsite or at a central facility, or have the analysis undertaken by a third party.

24.7.4.1 Radiochemistry Laboratory

The radiochemistry laboratory (Room 12252) on the 94.666 m (82’-6”) level is equipped to prepare and analyse primary coolant samples.

24.7.4.2 Secondary Sampling Laboratory

The laboratory for analysing samples from the secondary circuit is located at the far end of the turbine building from the reactor (Figure 24-13). Dose rates from these samples, under normal operating conditions will be very low. The secondary sampling laboratory is not part of the RCA.

24.7.4.3 Counting Room

A room is provided in the health physics area of the annex building for analysis of swabs, filters, and other items using α, β, and γ counting equipment and γ spectrometry. Fly ash must not be used, or must be assayed and found to be below applicable limits before being used in the construction of these rooms to support a low background.

24.7.5 Job Planning Facilities

Areas, such as the ALARA briefing and operational support room in the annex building, are provided for familiarising personnel with plant procedures for both routine and nonroutine inspection and maintenance operations. Access will be provided to detailed plans, drawings, photographs, videotapes, previous inspection reports, previous radiation and contamination surveys, or previous work plans appropriate to the particular job prior to entry into radiation areas.

Procedures for routine inspection and maintenance operations will be reviewed before an outage to ensure that any lessons learned from previous outages have been incorporated.

24.8 Handling of Radioactive Waste

The following facilities form the AP1000 plant solid radioactive waste management system:

- Radwaste building
- Mobile encapsulation unit (MEU)
- ILW store
- Spent fuel store

These facilities were identified from the BAT assessment (Reference 24.20) as the preferred technique for dealing with the expected radioactive wastes. Throughout the design development (including the BAT assessment), efforts were made to gather information from other similar designs, processes, and facilities along with the experience of station operators. The Learning From Experience process (also called Lessons Learned) is an important feature of BAT. The information and data were ascertained in several ways:

- Literature research, e.g., Nirex documents, research papers
- Reference to previous designs, e.g., Sizewell B
- Liaison with equipment manufacturers, e.g., self-propelled transporters
- Liaison with utility companies and station operators to ascertain current waste-handling practices in the UK and abroad and some of the difficulties encountered, e.g., RWE, Engie (Tractebel), Iberdrola, Endessa, Vattenfall, British Energy (Sizewell B)

The radwaste building footprint and layout may change during site-specific detail design, when an exact radwaste-handling regime has been agreed. The owning utility may choose to increase the building size, build a separate radwaste treatment building, embrace a contractual radwaste management system, or use a combination of these options.

Cementitious encapsulation was derived from the BAT assessment as the current favoured technique for processing ILW. During site-specific detail design, utility companies can reassess this and may choose to adopt different systems. Overall, it is important to note that other techniques are available and these should be reconsidered at appropriate intervals to determine the suitability and maturity of new technologies and methods.

The LLW and ILW streams arising from the operation and maintenance of the AP1000 plant are shown in Table 24-13. The ion exchange resins, activated carbon, and filter cartridges have been identified as the only ILW arising from the AP1000 plant. These will be encapsulated in the auxiliary building rail car bay by the MEU. Therefore, all wastes entering the radwaste building will be classified as LLW or lower, negating the need for ILW-handling facilities within the LLW area.

24.8.1 Receipt of Solid Low-Level Waste

Solid LLW from the auxiliary building and containment can either be taken into the rail bay and then through the truck staging area into the radwaste building or via the annex building containment access corridor and radwaste building access corridor into the truck staging area. The solid LLW will be received at the radwaste building buffer/marshalling area (temporary container storage bay). The buffer/marshalling area (temporary container storage bay) is located in the northeast corner of the LLW processing area (Waste Accumulation Room 50351). LLW arising from the AP1000 plant will be collected and placed into specific bags/containers that are distinguished from nonactive waste bags/containers; for example, through colour. In general, wastes collected from radiation/contamination-controlled areas will be assumed to be LLW and treated as such until assessed and categorised.

As described in Reference 24.51, when collected, LLW will be transferred from the AP1000 plant areas to a temporary storage bay (buffer/marshalling area) located within the radwaste building until required for sorting. This is a tried and tested method currently implemented on existing nuclear sites across the UK.

24.8.2 Sorting and Packaging of Solid Low-Level Waste into Drums

Solid LLW will be sorted and packaged into drums in the LLW processing area of the radwaste building using a sealed and vented glovebox. When called for, an LLW container/bag will be transferred from the storage bay to the sorting glovebox, delidded/opened, and the LLW tipped onto a sorting table. The LLW will be sorted and graded by waste type and/or activity level and placed in drums ready for compaction/ISO loading, clearance monitoring, or offsite treatment (Reference 24.51, Section 3.4.5.4). This is a tried and tested method currently implemented on existing nuclear sites across the UK.

Solid wastes will, as far as practicable, be segregated and sorted at the source to minimise primary and secondary wastes (including labelling to identify the source, if required).

24.8.3 Characterisation of Solid Low-Level Waste

Solid LLW will be characterised and assayed in the radwaste building by a low-resolution gamma spectrometer (LRGS). The LRGS will be located in an area of low background activity, or will have additional shielding installed to ensure that measured count rates are attributable to emissions from the waste drum. The LRGS will be integrated with the package tracking system (Reference 24.51, Section 3.7.15.2).

The radwaste building layout shows the position of the LRGS in the Mobile Systems Facility Room 50350 directly adjacent to the door leading into the LLW processing area (Waste Accumulation Room 50351). During site-specific detail design this position could change, or local shielding may be added if the area's background radiation impedes the functionality of the LRGS.

24.8.4 Size Reduction and Decontamination of Solid Radioactive Waste

The only radioactive waste that will be subjected to size reduction and decontamination is LLW, and this will be performed using (enclosed and vented) workstations and in-drum compactor within the LLW processing area of the radwaste building.

During sorting, some of the waste may be removed from the sorting glovebox via temporary containers for reduction in size and/or decontamination at the enclosed workstations. The size reduction workstation will contain simple dismantling and cutting tools (i.e., spanners, cutting shears). The decontamination enclosure could include a small wet area for washing/wiping/scrubbing with decontamination solutions, as well as manual cleaning cloths/swabs. The selection of decontamination and size-reduction techniques will be part of the detail design stage (based on site preference and experience), but will emphasise avoiding increased generation of secondary wastes. On completion of the size reduction/decontamination, the waste is transferred back to the sorting glovebox via temporary containers for further sorting (Reference 24.51, Section 3.4.5.4).

As drums within the sorting glovebox are filled, a spring-back disc is placed on top of the compactable waste, the drum moved to the compactor unit, and the waste compacted. Following compaction, if the drum still has space for additional waste, it is returned to the filling position to allow additional waste to be added. This process of filling and compacting is repeated until the drum is full. Thereafter, the drum is lidded and sealed (Reference 24.51, Section 3.4.5.4).

24.8.5 Storage of Drummed, Solid Low-Level Waste

Drummed solid LLW will be placed into an HHISO container within the radwaste building prior to transit offsite to the LLW repository. Sealed, fully compacted drums are assayed using an LRGS. The information obtained during this assay is used as the basis for the final categorisation and sentencing arrangements for the drum (Reference 24.51, Section 3.4.5.4).

The HHISO loading area (and/or northern loading bay) of the radwaste building can be reconfigured if required to package waste in accordance with the conditions for acceptance of other offsite treatment facilities.

24.8.6 Storage of Large Low-Level Waste Items

Large items of LLW that cannot be size reduced and cannot be placed into drums are wrapped and placed directly into an HHISO container. This activity is conducted within the radwaste building.

Large LLW items will be transported to the radwaste building by suitable means (e.g., manual trolley, forklift truck, flatback lorry) and placed into the buffer/marshalling area. Where such items are too large to be moved within the building they would be wrapped and monitored for contamination in the containment access corridor and then be transported to the mobile systems facility area of the radwaste building outside the building.

Any waste that is too large to be packaged into a drum and cannot be reduced in size is wrapped before being passed through QA and placed directly into an HHISO container (Reference 24.51, Section 3.4.5.4).

Although not expected, the only large solid radwaste item that could be generated during the operation period of the AP1000 plant is the SGs. It is expected that the SGs will be radioactive but with an activity level that will fall into the LLW category. It is intended that these items are handled as they arise, are size reduced, and are decontaminated to the extent practicable. To facilitate this disposal route, a temporary facility could be erected; for example, a tent with mobile HVAC equipment and connections to AP1000 plant power, water, and air systems, as necessary (Reference 24.51, Section 3.5.7.1).

24.8.7 Loading Solid Low-Level Waste into Transport Packages

When LLW has been processed (decontaminated, size reduced, packaged, and assayed), it will be loaded by the radwaste building crane (using safe slinging/lifting methods for large loads) or a forklift truck into an HHISO container ready for dispatch offsite to the LLW repository.

After drums have completed QA, they are placed in an HHISO container positioned within the radwaste building (Reference 24.51, Section 3.4.5.4).

24.8.7.1 Storage of Filled Low-Level Waste Transport Packages Prior to Dispatch Offsite

Full HHISO containers (transport packages) can be stored in the LLW buffer store or remain in the loading bay of the radwaste building if the LLWR is not immediately available.

The LLW buffer store is a covered area comprising a concrete hard-standing area with a steel-framed overcanopy. The buffer store is designed for HHISO containers that have been filled in the radwaste building. Standard handling machinery (forklift truck) will be used to move the containers from the radwaste building to the buffer store. The combined capacity for HHISO containers within the buffer store and the radwaste building provides for up to 2 years waste arisings if the disposal route to the national LLW repository is temporarily unavailable (Reference 24.51, Section 3.2.1.3).

24.8.8 Conditioning of Intermediate-Level Waste

ILW will be encapsulated/conditioned using the MEU deployed within the auxiliary building rail car bay. The waste encapsulation will be carried out on a campaign basis. When not in use, the MEU will be stored in the radwaste building and moved to the AP1000 plant auxiliary building rail car bay for the campaign (Reference 24.51, Section 3.4.2.1). The MEU may be shared with other plants onsite or offsite.

24.8.9 Packaging of Intermediate-Level Waste

The MEU will be used to process ILW in the form of ion exchange resins, carbon guard bed media, and primary circuit filters. The MEU will encapsulate/immobilise the ILW in a cement matrix within a 3-m^3 (106 ft^3) Radioactive Waste Management Directorate (RWMD)-compliant container.

Dry ILW (primary circuit filters) is loaded into a 3-m^3 (106 ft^3) box that is positioned in the Waste Disposal Container Area, Room 12374. When the box is full or at a time to suit encapsulation campaigns, the boxes will be transferred to the MEU using the rail car bay crane.

During this transfer the rail car bay will be vacated and access prohibited to ensure that operator dose uptake is ALARP (Reference 24.51, Section 3.4.3.4).

Wet ILW (spent resin) will be pumped via shielded pipe work from a position local to the MEU directly into a 3-m^3 (106 ft^3) RWMD-compliant drum ready for encapsulation.

24.8.10 Characterisation of Intermediate-Level Waste

The packages will then be loaded into a shielded transport overpack for transfer to the ILW buffer store.

ILW packages will be assayed (characterised) in the ILW store import bay using a high-resolution gamma spectrometer (HRGS). The HRGS will be located in an area of low background activity or will have additional shielding installed to ensure that measured count rates are attributable to emissions from the waste drum. The HRGS will be integrated with the package tracking system (Reference 24.51, Section 3.7.16.1).

24.8.11 Buffer Storage of Intermediate-Level Waste Packages

The transporter bringing the packaged ILW from the rail car bay in a shielded overpack will enter via a shielded door and park in the package import bay of the ILW store. The waste packages will be transferred out of the overpack and into the shielded import bay. The import bay will be equipped with an HRGS and closed-circuit television cameras to assay and visually check the package. Other checks that may be necessary are dependent on visual inspection of the package (Reference 24.51, Section 3.4.7.1).

It is envisaged that, after immobilisation, the ILW packages will be immediately transferred to the ILW store. However, if the transport vehicle and overpack are not available, the encapsulated packages could be held temporarily within the MEU.

24.8.12 Personnel Access to Radwaste Building

Personnel involved in radioactive waste management will enter the RCA through the main entry area in the annex building, which limits access to authorised personnel. Additional PPE will be obtained at the subchange area within the annex building access corridor into the radwaste building work areas.

Egress from the radwaste building is via the subchange area, in which the protective clothing will be removed and placed in contaminated clothing containers (Reference 24.51, Section 3.4.6.1). Hand and foot contamination monitors and frisking probes will be provided at the subchange area for monitoring prior to return to the main RCA entry area.

The Monitor Tanks Room 50355 and Waste Accumulation Room 50351 within the radwaste building are classified as C2 areas and can only be accessed through a secondary subchange located in the northwest corner of the Waste Accumulation Room 50351.

24.8.13 Storage and Monitoring of Nonactive Wastes from the Radiologically Controlled Area

Very LLW/nonactive wastes can be generated through maintenance activities within the RCA and during decontamination/size reduction of LLW. These nonactive wastes will be monitored using the existing LLW monitoring equipment within the radwaste building, placed into bags/drums, and then transferred to the clearance and exemption area. The clearance and exemption area is located to the southeast of the Waste Accumulation Room 50351 within the Mobile Systems Facility Room 50350.

This area will be used for clearance monitoring of the waste to ensure it meets the required limits for disposal. Within the clearance and exemption area there is a working table and non-active waste clearance monitoring equipment. The exact equipment will be chosen at the detail design stage, depending on utility preference and experience.

Once the waste has been monitored and cleared it will be loaded into a dedicated HHISO container positioned to the west of the LLW HHISO loading area.

24.8.14 Radwaste Processing Dose Assessment

Radwaste processing involves the following facilities:

- Radwaste building
- Auxiliary building WLS, WGS, and WSS facilities
- Auxiliary building rail car bay (MEU)
- ILW store

24.8.14.1 Radwaste Building Occupancy

The total occupancy of the radwaste building is presumed to be 1280 man-hours per year: this is based on 4 workers, 8 hours per day, 5 days per campaign, 8 campaigns per year (i.e., 320 hours per year).

This figure is an estimate, taking into account the annual LLW arisings to be 8 HHISO containers (Reference 24.52) and each container taking 5 days to fill (8 campaigns of 5 days). During each campaign it is estimated that 4 workers will be required to operate the following radwaste equipment:

- Sorting glovebox
- Work stations (decontamination and size reduction)
- LRGS
- In-drum compactor
- Forklift
- Building crane
- Remote operation of the MEU (during ILW encapsulation campaigns)

24.8.14.2 Auxiliary Building Rail Car Bay (Mobile Encapsulation Unit) Occupancy

A conservative occupancy of 2000 hours per year (50 weeks per year, 5 days per week, 8 hours per day) has been used as the criterion for the surface dose rate limit on the MEU. This was taken as the worst-case scenario, in that other workers will be in the rail car bay performing unrelated tasks during the MEU operation. This is a very conservative value as the MEU is expected to be in operation for only 3 months of the year and the rail car bay will be used for other purposes, including import of new fuel and, in time, export of spent fuel; therefore reducing the maximum occupancy with the MEU present down to 480 hours (12 weeks per year, 5 days per week, 8 hours per day). The occupancy directly resulting from operation of the MEU is assumed to be 180 hours (3 hours per day, 5 days per week, 12 weeks per year), which is based on a 3-month ILW encapsulation campaign every 12 to 18 months, depending on the chosen refuelling cycle. Due to the remote operation design of the MEU, 3 hours per day is judged to be required for manual observation and recovery of the MEU. If it is assumed that 2 workers are involved, then the total time will be 360 man-hours. This is still a very conservative estimate, as under normal conditions manual intervention will only be required during setup and dismantling.

24.8.14.3 Intermediate-Level Waste Store Occupancy

A conservative occupancy of 2000 hours per year (50 weeks per year, 5 days per week, 8 hours per day) has been used as the criterion for the surface dose rate of the ILW store external wall. This was taken as the worst-case scenario on the grounds that other workers could be in the vicinity of the ILW store performing unrelated tasks.

It is envisaged that the ILW store will only require operators during the import and random inspection of packages. During the import of a package to the store it is assumed that the following workers will be required:

- One worker is required to operate the transporter within the import/export area.
- One or two workers are required in the ILW store control room.

The AP1000 plant will produce 19 ILW packages per year (Reference 24.51, Table 5) for storage within the onsite ILW store. Assuming the import of a package takes 1 day, the resulting occupancy will be 152 hours per year occupancy per worker.

During the inspection of a package it is assumed that one or two workers will be required in the control room for up to 40 hours per package.

Waste packages will be placed in vaults in the ILW store but these will remain open to allow packages to be retrieved for inspection. The packages could be retrieved using the existing emplacement equipment in reverse. The aim is to have the capacity to retrieve any targeted package within one week (Reference 24.53).

Currently, an ILW stored package monitoring strategy (Reference 24.49) does not exist. This will be developed during the site-specific design stage. Inspection and monitoring of ILW packages is discussed in PCSR Chapter 26, Radioactive Waste Management (Section 26.8.5.2). The total hours of occupancy related to monitoring is 1116 x 40/60 = 744 hours per worker, per year, giving a total occupancy of 1944 hours per year ((152 x 3) + (744 x 2)), with a maximum per worker of 896 hours per year (152 + 744).

24.8.14.4 Anticipated Dose Rate Profile of the Facility

The dose target for individual annual dose from radwaste operations is taken as the BSO (Table 24-1), i.e., 2 mSv.

The provisional radiological areas classifications for the radwaste building, the rail car bay during an encapsulation campaign, and the ILW store presented below will require further evaluation, by an agreed methodology, during the detailed design work associated with a specific site (Reference 24.51, Section 3.8.3).

Radwaste Building

A radiological classification of the radwaste building (Table 24-14) has been developed by the design team but will require review and endorsement by a RPA during detailed design. Radiation and contamination zone drawings have been developed supporting the classification assessment.

Ultimately, the area classification zoning is produced and implemented by the licensee during the specific site licensing stage (in line with site licence condition 18 (Reference 24.55)).

For the purpose of the GDA an existing Sellafield/British Nuclear Fuels Limited (BNFL) guidance (Tables 24-15 and 24-16) has been adopted (Reference 24.56, Pages 31 and 33).

The following radwaste building areas have been zoned R2:

- Mobile Systems Facility Room 50350
- HVAC Equipment Room 50353
- Truck Staging Area 50354
- Monitor Tanks Room 50355
- East-west radwaste corridor

This is very conservative, in that only during abnormal operations or when a HHISO is fully loaded could the dose enter this range. In these conditions the dose will be local to the source (i.e. HHISO) and could be managed and access limited through the erection of temporary barriers as required. During normal operation this dose would be much less, in line with an R1 classification (2.5 to 7.5μSv/h).

From the classification assessment the dose rate for the personnel access area of the radwaste building can be substantiated as 2.5 to 7.5μSv/h for the main area, and 7.5 to 25μSv/h for the LLW processing area. For this dose estimate it is assumed that the occupancy is evenly divided between these two areas.

Based on an individual occupancy of 320 hours per year and a collective occupancy of 1280 man-hours per year, the individual annual dose will be between 1.6 and 5.2 mSv, and the collective dose will be between 6.4 and 20.8 person-mSv. Realistically, most of the area will be at the lower limit and, therefore, a collective dose from an average dose rate of 6.5 μSv/h is reasonable, giving a collective dose of 8 person-mSv.

This results in an annual operator dose uptake at the target limit of 2 mSv. This is only an estimate, and the information supporting it is very conservative. If, during site-specific detail design, these values are substantiated, the site licensee could control the dose uptake through developed operating procedures.

Rail Car Bay (Mobile Encapsulation Unit)

The contact dose rate design specification for the MEU is designed to be 1μSv/h. The MEU will be deployed in the AP1000 plant auxiliary building rail car bay, and it has been assumed that there is an increased potential for operational staff to be in the area. Therefore, because of the increased occupancy, a lower dose limit is appropriate. The dose rate limit is determined by assuming a conservative occupancy of 2000 hours per year (50 weeks per year, 5 days per week, 8 hours per day) and a target annual dose of 2 mSv/y. This leads to a surface dose rate limit for the MEU of 1μSv /h (Reference 24.51, Section 3.9.2.3).

It was also assumed that the contact dose rates applicable to the overpack will be 50 μSv/hr. These dose rates can be reassessed during the detailed design phase associated with the specific site (Reference 24.51, Section 3.9.2.3).

The contact dose rate is used as a worst case; actual dose rates could be much less due to the distance from the source within the MEU. The contact dose rate specification of 1μSv/h is based on an occupancy value of 2000 hours per year (worst case, other personnel working in the area) and a dose target of 2 mSv per year.

As stated in Section 24.8.14.2, the actual occupancy directly resulting from operation of the MEU is estimated as 180 hours (substantially less than the assumed 2000 hours), giving a yearly dose uptake of 0.18 mSv using the current dose rate of 1μSv/h and a collective dose of 0.36 person-mSv per year.

The main operation of the MEU will be done remotely from within the radwaste building. The occupancy resulting from the operation of the MEU remotely is 480 hours per year (8 hours per day, 5 days per week, 12 weeks per year), which is based on a 3-month ILW encapsulation campaign.

There will be some additional dose from handling the shielded transport overpacks and transporting them to the ILW store. Assuming 2 workers are exposed for 1 hour per package at the contact dose rate of 50 μSv/h, the individual dose is 0.95 mSv and the collective dose is 1.9 person-mSv. The actual doses will be significantly lower, as the dose rate will fall with distance from the overpack and only a fraction of the operation will be close to the overpack. A reduction by 50 percent is reasonable to account for distance, giving a collective dose of 0.95 person-mSv.

Intermediate-Level Waste Store

The contact dose rate of the ILW store external wall is designed to be 0.5 μSv/h based on a target dose for others onsite of 1 mSv/y and a pessimistic occupancy of 2000 hours per year. In addition, the design will take account of the external dose rate at the site boundary and at the nearest habitation and workplace.

The actual occupancy directly resulting from operation of the ILW store is estimated as 896 hours (substantially less than the assumed 2000 hours), giving a yearly dose uptake of 0.448 mSv using the current dose rate of 0.5 μSv/h. Assuming 2 workers are present, the collective dose will be 0.896 person-mSv.

There will be some additional dose from handling the shielded transport containers at the ILW store. It can be assumed that the doses from unloading and emplacing packages will be the same as for loading the package onto the transport vehicle.

Total Dose from Radwaste Operations

The total collective dose from radwaste operations assessed above is 11.2 person-mSv. The overall collective dose in an outage year (based on 11 operators) includes a contribution of 22 person-mSv for waste processing. Therefore, the overall collective dose estimate includes a reasonable margin.

24.8.15 Design Features for Control of Surface and Airborne Contamination

Surfaces that may experience contamination will be finished with a decontaminable coating in preparation for decommissioning. In radioactive areas the materials for surface finishes must also be radiation tolerant (Reference 24.51, Section 3.5.14).

24.8.15.1 Radwaste Building

In addition to the overall radwaste building HVAC system, there is a requirement for a local dedicated air extraction system for the removal of any airborne waste particles within the following working enclosures:

- Sorting glovebox
- In-drum compactor enclosure
- Size reduction enclosure
- Decontamination enclosure

The air extraction system design will be based on established HVAC principles used within the nuclear industry and will incorporate flexible/adjustable overhead extraction hoods for large item size reduction. The LLW sorting, size reduction, and decontamination areas will be fully contained within a glovebox to mitigate the possible spread of contamination. Also the compaction of LLW is performed within the drum by an in-drum compactor to limit the spread of contamination. The spread of contamination is controlled through good housekeeping and dedicated HVAC hoods.

Waste will enter and exit the LLW processing area (Waste Accumulation Room 50351) via the west door. The threshold will act as a radiological control boundary. Package movements within the radwaste building but external to the Waste Accumulation Room 50351 will be achieved using the building crane or forklift. Package movements within the Waste Accumulation Room 50351 will be achieved using a dedicated pallet truck. Any waste packages leaving the LLW processing area will be fully swabbed and cleaned prior to crossing the threshold.

24.8.15.2 Rail Car Bay (Mobile Encapsulation Unit)

The MEU requires connections to the auxiliary building HVAC system to do the following (Reference 24.51, Section 3.4.4.3):

- Maintain containment by ensuring that air always flows towards areas with a relatively higher degree of contamination potential
- Provide a safe working environment for operating personnel
- Provide a satisfactory working environment for equipment
- Remove any airborne particulates from the discharge air to ensure that emissions are within the agreed limits for the module
- Provide sufficient ventilation to prevent any heat buildup and to maintain the temperature within the agreed limits for the module
- Maintain an air depression relative to ambient during operation of the encapsulation plant module to minimise the risk of an unmonitored release to the environment outside of the module

Additional details of the auxiliary building rail car bay HVAC systems are presented in Chapter 23.

The MEU is a fully shielded unit and sealed container used to mitigate the spread of contamination. The internals of the unit are capable of being washed down with demineralised water in the event of contamination through spillage. The washdown water is recycled through the process and used for further encapsulation. Packages leaving the MEU will be subject to QA testing and, where necessary, decontaminated through swabbing.

24.8.15.3 Intermediate-Level Waste Store

The ILW store will have its own independent ventilation plant (Reference 24.51, Section 3.6). Environmental conditions such as flow, temperature, moisture, and chloride content will be controlled by ventilation supplied at a low level via a plenum and by extract at a high level from the opposite end of the vault. The store will have inlet and outlet HEPA filters (Reference 24.51, Section 3.4.7.10). The condition of the stored packages will be routinely checked and where necessary remedial work will be conducted. ILW package import/export area of the ILW store. The ventilation system in this area will ensure a suitable cascade is provided to prevent migration of any contamination to the external environment (Reference 24.51, Section 3.4.7.1).

Table 24-1. Numerical Dose Targets and Legal Limits for Normal Operation (Reference 24.1)

Normal Operation – Any Person on the Site	**Target 1**
The targets and a legal limit for effective dose in a calendar year for any person on the site from sources of ionising radiation are:	
Employees working with ionising radiation:	
BSL(LL):	20 mSv
BSO:	1 mSv
Other employees on site:	
BSL:	2 mSv
BSO:	0.1 mSv
Note that there are other legal limits on doses for specific groups of people, tissues and parts of the body (IRR99).	
Normal Operation – Any Group on the Site	**Target 2**
The targets for average effective dose in a calendar year to defined groups of employees working with ionising radiation are:	
BSL:	10 mSv
BSO:	0.5 mSv
Normal Operation – Any Person off the Site	**Target 3**
The targets and a legal limit for effective dose in a calendar year for any person off the site from sources of ionising radiation originating on the site are:	
BSL(LL):	1 mSv
BSO:	0.02 mSv
Note that there are other legal limits to tissues and parts of the body (IRR99).	
Maximum Doses to Individuals from a Defined Source (EPR2010 (Reference 24.3))	
0.3 mSv(1) per year from any source from which radioactive discharges are first made on or after 13th May 2000 or	
0.5 mSv per year from the discharges from any single site.	

Note:

1. Recent guidance indicates that new power plants should target a dose below 150 microSv for this category.

Table 24-2. Numerical Accident Consequence Dose and Risk Targets (Reference 24.1)

Individual Risk of Death from Onsite Accidents – Any Person on the Site	**Target 5**
The targets for the individual risk of death to a person on the site, from on-site accidents that result in exposure to ionising radiation, are: BSL: 1×10^{-4} pa(1) BSO: 1×10^{-6} pa	

Frequency Dose Targets for Any Single Accident – Any Person on the Site	**Target 6**
The targets for the total predicted frequencies of accidents on an individual facility, which could give doses to a person on the site, are:	

Effective Dose, mSv	**Total Predicted Frequency per Annum**	
	BSL	BSO
2-20	1×10^{-1}	1×10^{-3}
20-200	1×10^{-2}	1×10^{-4}
200-2000	1×10^{-3}	1×10^{-5}
>2000	1×10^{-4}	1×10^{-6}

Individual Risk to People Off the Site from Accidents	**Target 7**
The targets for the individual risk of death to a person off the site, from on-site accidents that result in exposure to ionising radiation, are: BSL: 1×10^{-4} pa BSO: 1×10^{-6} pa	

Frequency Dose Targets for Any Single Accident – Any Person Off the Site	**Target 8**
The targets for the total predicted frequencies of accidents on an individual facility, which could give doses to a person off the site, are:	

Effective Dose, mSv	**Total Predicted Frequency per Annum**	
	BSL	BSO
0.1-1	1	1×10^{-2}
1-10	1×10^{-1}	1×10^{-3}
10-100	1×10^{-2}	1×10^{-4}
100-1000	1×10^{-3}	1×10^{-5}
>1000	1×10^{-4}	1×10^{-6}

Note:

1. "pa" stands for "per annum"

Table 24-3. Provisional HSE Internal Guidance on Dose Levels in Emergencies (References 24.5 and 24.60)

Emergency dose levels up to those listed below should normally be regarded as acceptable to HSE (subject to ALARP)	
Effective Dose	100 mSv
Equivalent Dose to Skin	1000 mSv
Equivalent Dose to Eye Lens	300 mSv
For life saving, it is desirable that for planning purposes the objective should normally be to apply the following levels:	
Whole Body Dose	500 mGy
Dose to Skin	5000 mGy

Table 24-4. Sources of Radiation

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Radiation Sources (Power Operation and Shutdown)				
Direct core radiation	Gamma and neutron flux	External radiation during operation	Workers	The reactor internals, RV, in-containment primary and secondary interior shield systems, and shield building attenuate the radiation, reducing the predicted dose exposure to workers in normal power operation to low levels. Strict control of access to the containment during operation is necessary to minimise dose uptake.
			Public	The plant geometry and shielding design ensure that exposure of members of the public to external radiation is negligible.
		External radiation during shutdown	Workers	The gamma and neutron flux is significantly reduced when the reactor is shut down and is shielded by the reactor internals, reactor pressure vessel, and in-containment primary and secondary interior shield systems. Water in the refuelling cavity reduces doses further during refuelling operations as described below.
			Public	The plant geometry and shielding design ensure that exposure of members of the public to external radiation is negligible.
Fission product	Fission products	Fission products in the reactor coolant and deposited on primary circuit surfaces present a direct and potential internal radiation hazard to maintenance workers	Workers	Fission products are normally retained within the fuel. Pinhole defects in the fuel rod cladding may lead to fission product release to the reactor primary coolant. The design basis for fission product leakage is operation with cladding defects in fuel rods producing 0.25% of the core thermal power. The secondary shield surrounding the RCS equipment (including piping, pumps, and SGs) protects personnel from the direct gamma radiation emanating from the fission products carried away from the core by the primary coolant in power operation.
			Public	The plant geometry and shielding design ensure that exposure of members of the public to external radiation is negligible.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Fission product (cont.)	Fission products	Fission products will be released in the unlikely event of a severe accident that damages the fuel clad. In this case, fission products present a risk to the workers and others.	Workers	Shielding is provided for the MCR and certain access routes based on the design basis loss-of-coolant accident (LOCA). Air is supplied to the MCR from pressurised cylinders to eliminate reliance on active ventilation systems in an emergency.
			Public	The containment and passive cooling systems mitigate the effect of such releases. The containment isolation can withstand an overpressure of 0.6 MPa (87.023 psi) gauge.
Coolant activation processes	N-16	The activation of oxygen in the primary coolant results in the formation of N-16, which is a strong gamma emitter. Due to its short half-life of 7.1 seconds, N-16 is not a concern outside containment. N-16 is the predominant contributor to the activity in the RCPs, SGs, and reactor piping during operation. The activity in each component depends on the transit time to the component and the residence time.	Workers	The secondary shield surrounding the RCS equipment (including piping, pumps, and SGs) protects personnel in power operation. The source is terminated when the reactor is shut down.
			Public	Due to its short half-life of 7.1 seconds, N-16 is not a concern outside containment. The source is terminated when the reactor is shut down.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Coolant activation processes	Ar-41	The activation of residual argon in the primary coolant results in the formation of Ar-41, a short-lived isotope source (half-life 1.827 hr).	Workers	The secondary shield surrounding the RCS equipment (including piping, pumps, and SGs) protects personnel in power operation. The source is terminated when the reactor is shut down.
			Public	The shielding ensures that exposure of members of the public to external radiation is negligible. The source is terminated when the reactor is shut down and decays quickly away.
Coolant activation processes (cont.)	Tritium	A number of processes add tritium to the reactor coolant. Tritium is created as a result of ternary fission, where the uranium nucleus splits into three, and can then diffuse through the fuel clad or leak through fuel clad defects. Tritium is also produced as a result of neutron reactions with soluble boron, soluble lithium, and deuterium in the reactor coolant. Tritium emits beta radiation and presents limited public health implications. Tritium exists in the reactor coolant primarily combined with hydrogen (that is, a tritium atom replaces a hydrogen atom in a water molecule) and thus cannot be readily separated from the coolant by normal processing methods.	Workers	Presents no significant hazard during power operations.
			Public	Tritium discharges are assessed in the Environment Report (Reference 24.45) and will be monitored to ensure that doses to the public are low.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Coolant activation processes (cont.)	C-14	C-14 may be produced by neutron activation of O-17 (n,α reaction) and N-14 (n,p reaction). It is also present in activated corrosion products (see below). C-14 emits low-energy beta radiation and presents no hazard during power operation. C-14 is present in all coolant liquor released during maintenance activities and is an important isotope in radioactive waste management but presents only a limited hazard to workers.	Workers	Presents no significant hazard during power operations.
			Public	C-14 discharges are assessed in the Environment Report (Reference 24.45) and will be monitored to confirm that doses to the public are low.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Activation of corrosion products (crud)	Co-58, Co-60, Fe-55, Fe-59, Mn-56, Mn-54, Cr-51	The activation of primary circuit component corrosion and wear products results in dissolved activation products within the primary coolant. These may be deposited as a contamination film on primary circuit components (termed crud). The dominant gamma-emitting isotope in crud is Co-60 (half-life 5.27 yr). Activated corrosion products in reactor coolant and deposited on primary circuit surfaces (crud) present a direct and potential internal radiation hazard to maintenance workers.	Workers	BAT has been incorporated in the design and operating regime (including material selection and zinc injection) for the AP1000 design to keep the formation and deposition of crud ALARP. Shielding is provided for reactor components where crud is likely to be present, and for vessels and pipes used to remove crud and fission products from the primary coolant. The secondary shield surrounding the RCS equipment protects personnel in power operation. Access to high dose rate areas is physically restricted, and any entries into such areas will be strictly controlled. Although BAT is used to reduce crud SFAIRP, it is not possible to eliminate it completely; therefore, design features have been incorporated to reduce the maintenance operations required and the preparation time for inspection and maintenance. In addition, remote inspection systems have been developed to reduce the need for workers to remain in high dose rate areas such as the SGs and RVCH.
			Public	In addition to techniques to limit the production of these nuclides, BAT is incorporated in the plant to reduce the concentration of these nuclides from liquid waste before discharge, and HEPA filtration will reduce routine atmospheric discharges SFAIRP.
Containment atmosphere	Ar-41	The main source of airborne activity in containment is activation of naturally occurring argon in the atmosphere.	Workers	Ar-41 has a short half-life (1.827 hr) and does not present a hazard to workers so long as it does not build up in the containment. Periodic purging prevents excessive activity buildup.
			Public	Ar-41 is discharged from the ventilation stack so that the dose to the public is ALARP.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Radiation Sources (Refuelling)				
Spent reactor fuel	Gamma and neutron (fission products and actinides)	Spent fuel is the primary source of radiation during refuelling.	Workers	Extensive shielding is provided for areas surrounding the refuelling cavity and fuel transfer canal to limit radiation levels to refuelling personnel. Water provides shielding over the spent fuel assemblies during fuel handling.
			Public	Protection of workers ensures protection of the public from high radiation levels. Additionally, physical security and the use of dry storage casks when the spent fuel is removed from the SFP protect the public from radiation exposure due to spent fuel.
Irradiated control and grey rods	Gamma	Irradiated control rods and grey rods present a hazard from external gamma radiation. The gamma ray source strengths of the irradiated control rods and grey rods are used in establishing radiation shielding requirement during refuelling operations and during shipping of irradiated rods.	Workers	Extensive shielding is provided for areas surrounding the refuelling cavity and fuel transfer canal to limit radiation levels to refuelling personnel. Water provides shielding over the spent fuel assemblies during fuel handling.
			Public	Protection of workers ensures protection of the public from high radiation levels. Protection measures mentioned above for spent fuel are also applicable.
Secondary source rods	Gamma and neutron	The photoneutron source material used in the secondary source rods is an equal volume mixture of antimony and beryllium (Sb-Be).	Workers	Extensive shielding is provided for areas surrounding the refuelling cavity and fuel transfer canal to limit radiation levels to refuelling personnel. Water provides shielding over the spent fuel assemblies during fuel handling.
			Public	Protection of workers ensures protection of the public from high radiation levels. Protection measures mentioned above for spent fuel are also applicable.

Table 24-4. Sources of Radiation (cont.)

Source	Source Term/ Radionuclide	Hazard	Exposed Group	Protection Measures
Radiation Sources (Refuelling) (cont.)				
In-core Thimbles	Gamma	High dose rates to workers during refuelling. (Early designs had thimbles inserted from beneath the RV, resulting in high doses during RV inspection).	Workers	Thimbles remain in the upper internals and are stored under water during refuelling.
			Public	Localised high dose rates only. Shield building eliminates hazard to public.
Activated RV, primary shield concrete	Gamma: Na-24, Co-60	High dose rates to workers during RV inspections and who maintain the digital metal impact monitoring system.	Workers	Neutron shield collar to minimise activation of the lower vessel cavity. Robotic inspection of undervessel components under development.
			Public	Primary shielding and shield building eliminates hazard to public.
Coolant Activation Processes	Tritium	Tritium is present in all coolant liquor released during maintenance activities and can, therefore, present a potential internal radiation hazard to maintenance workers.	Workers	Ventilation extract systems limit the airborne concentration of tritium. Normal protective clothing, particularly the use of gloves, and controlled area procedures prevent uptake via skin absorption and ingestion. During refuelling the level of tritium in the primary coolant will be diluted by the water from the IRWST.
			Public	Tritium discharges are assessed in the Environment Report (Reference 24.45) and will be monitored to demonstrate that doses to the public are low.

Table 24-5. Source Term Derivation

Computer Code	Output	Purpose
ORIGEN (Oak Ridge National Laboratory) (References 24.7 and 24.8)	Determination of core activities at various irradiation and decay times: • Fuel nuclides and their heavy metal reaction and decay products • Fission products and decay products • Light elements and other activation products in reactor coolant, cladding and fuel assembly materials and reactor components	Core inventories for: • Primary circuit activity concentration assessment • Accident analyses • Spent fuel handling/storage shielding • SFP decay heat • Waste handling and decommissioning
FIPCO (Westinghouse) (References 24.9 and 24.10)	Design basis fission product activity levels in: • Primary coolant • Pressuriser • CVS demineraliser	• Accident analyses • Shielding assessments • ILW arisings
CORA (Westinghouse) (References 24.11 and 24.12)	Generation and transport of corrosion products in the RCS of a PWR giving activity concentrations in: • Primary coolant • Pressuriser • CVS demineraliser • crud	• Shielding assessments • Routine dose assessment • ALARP assessments
SSP (Westinghouse) (Reference 24.15)	N-16 sources, auxiliary system sources and expected source terms in primary and secondary systems	• Shielding assessments • Environmental discharges
SECONS (Westinghouse) (References 24.16 and 24.17)	Activity concentrations and source strengths in: • Secondary water • Secondary steam • BDS • AP1000 electrodeionisation units	• Shielding assessments • Ion exchange resin arisings • Environmental discharges

Table 24-7. Plant Radiation Zones

Designation	Maximum Design Dose Rate	Westinghouse Radiation Zone Designation		Typical UK Area Designation Arrangements Details to be Specified by Operator[1]
		Description	Access	
0	≤0.5 μSv/h	No radiation sources	Unlimited general occupancy	Undesignated area
I	≤2.5 μSv/h	Very low or no radiation sources	No restriction on access	Supervised area
Restricted Area Zones				**Controlled Area**
II	≤25 μSv/h	Low radiation sources	Occupational access	Further subdivision for normal operations Areas >2.5 μSv/h subject to limits on occupancy
III	≤150 μSv/h	Low to moderate radiation sources	Periodic access	Access restricted to 1 to 10 hours per week
IV	≤1 mSv/h	Moderate radiation sources	Limited access	Access restricted to <1 hour per week
V	≤10 mSv/h	High radiation sources	Controlled access	Access restricted to a few hours per year at most
VI	≤100 mSv/h	High radiation sources	Normally restricted Post-accident: limited	No access during normal operations[2] Limited post-accident access
VII	≤1 Sv/h	High radiation sources	Normally severely restricted Post-accident: restricted	No access during normal operations Very limited post-accident access
VIII	≤5 Gy/h	High radiation sources	Normally inaccessible Post-accident: severely restricted	No access during normal operations Extremely limited post-accident access

Designation	Maximum Design Dose Rate	Westinghouse Radiation Zone Designation		Typical UK Area Designation Arrangements Details to be Specified by Operator[1]
		Description	Access	
Restricted Area Zones				**Controlled Area**
IX	> 5 Gy/h	Very high radiation sources		No access

Notes:

1. These are typical arrangements based on an existing UK operator. It is the responsibility of an operator to make appropriate arrangements to ensure that doses are ALARP.
2. There is a potential conflict in some areas identified in Appendix 24A where rooms are identified as Zone VI during shutdown and requiring access during shutdown (e.g., the RV cavity), which, with the example UK designation, will prohibit entry. However, the zones are based on conservative source terms including 0.25 percent fuel defects. In operation, dose rates in such areas are expected to be lower than calculated. In other areas, dose rates are nonuniform and entries will be possible with care.

Table 24-8. Summary of Integrated Doses and Durations of Defined Post-Accident Operations

Post-Accident Action	Timing (After Accident) (hr)	Duration (min)	Inhalation Dose (mSv)	Direct Dose (mSv)	Total Integrated Dose (mSv)
MCR Occupancy	Various	30 days	37.1	6.2	43.3
MCR Ingress and egress(1)	Various	55.25	0.45	29.5(2)	30.5
SFP Makeup Valve Alignment	64	44.5	1.1	42.5	43.6
	168	44.5	0.06	25.6	25.7
Temporary Water Hookup to PCS	64	75.6	0.07	12.8	12.9
Ventilation Control for Temporary HVAC to MCR and C&I Equipment Room	64	103.1	9.97	0.06	10.0
Electrical Equipment Rooms – Start Diesel Generators and Provide Temporary Power to Transformers	64	82.7	10.0	1.1	11.1

Notes:

1. It is assumed that a 12-hour shift begins at the time of the accident. A shift change occurs every 12 hours afterwards for 30 days.
2. The dose considers ingress/egress for one crew on 12-hour shifts for 30 days only. MCR occupancy doses are evaluated in a separate calculation.

Table 24-9. Breakdown of Collective Dose

Overall Categories	Original Dose in Outage Year from (Reference 24.42) (person-mSv)	Average % of Dose per Category	Prairie Island Average Outage Year Dose 1996-2003 (person-mSv)	Adjusted AP1000 Outage Year Dose (person-mSv)	% of Dose per Category
Reactor Operations and Surveillance	263.0	9.27	82.9	39.3	16.49
Routine Maintenance	245.7	16.14	144.3	44.9	18.82
ISI	297.0	27.26	243.7	60.2	25.26
Special Maintenance	629.2	25.28	226.0	30.1	12.64
Waste Processing	72.0	2.60	23.2	23.2	9.46
Refuelling	170.0	19.46	174.0	41.3	17.32
Total	**1676.9**	**100.00**	**894.1**	**239.0**	**100.00**

Table 24-10. Containment Area Classification (Reference 24.49)

Area Classification	Description
White	Clean area free from radioactive contamination, whether surface or airborne.
Green	An area which is substantially clean. Only in exceptional circumstances is airborne contamination such that provisions must be made for its control.
Amber	An area in which some surface contamination is expected. In some cases there will be a potential for airborne contamination such that provision must be made for its control.
Red	An area in which contamination levels are so high that there is normally no access without appropriate respiratory protection.

Area Classification	Surface Contamination $Bq.cm^{-2}$ $\beta\gamma$	Airborne Activity DAC	Typical Area
White	<4	<0.01	Nonactive areas
Green	Usually <4	<0.03	Most of the RCA during normal operations
Amber	Possibly >4	<0.1	Some parts of containment during shutdown e.g., around SGs and RVCH stand
Red	>4 expected	>0.1	Flask pit before and during decontamination Vessel and pump rooms during breach of containment

Note:
Detailed surface contamination limits and maximum airborne activity concentration allowed in each area will be specified by the operator. A possible area classification scheme and limits are shown below. Only $\beta\gamma$ contamination is likely to be present; if present, levels for α surface contamination would be 10 percent of the $\beta\gamma$ limits.

Table 24-11. Area Radiation Monitor Locations

Area
Primary Sampling Room
Containment Area Personnel Hatch – Operating Deck – 135'-3" (110.74 m) Elevation(1)
MCR
Chemistry Laboratory Area
Rail Car Bay/Filter Storage Area(2)
Liquid and Gaseous Radwaste Area
CSA
Radwaste Building, Mobile Systems Facility(2)
Hot Machine Shop
Annex Staging and Storage
Fuel-Handling Area(3)
Containment Area Personnel Hatch – Maintenance Level – 100'-0" (100 m) Elevation

Notes:

1. Radiation levels are monitored by the permanent containment area radiation monitor and by a portable bridge monitor during refuelling operations. The containment area radiation monitor is located to best measure the increase in exposure rates for this area and to provide an alarm locally and in the MCR.
2. Monitors areas used for storage of wet wastes (including processed and packaged spent resins) and dry wastes.
3. Radiation levels are monitored by the permanent fuel-handling area radiation monitors and by a portable bridge monitor during fuel-handling operations. The fuel-handling area radiation monitors are located to best measure the increase in exposure rates for this area and to provide an alarm locally and in the MCR.

Table 24-12. Summary of Liquid and Gaseous Samples for Radioactive Analysis

General Radiological Sample Purpose	Example Sample Collection Point(s)	Description
Primary system samples	Primary sampling room in the auxiliary building, on or near elevation 89.789 m (66’-5”)	Samples of the RCS and other primary fluids to satisfy requirements, monitor plant conditions, or support operations
SFP samples	SFP in the auxiliary building, on or near elevation 110.744 m (135’-3”)	Samples taken to monitor plant conditions or satisfy Tech Specs
Secondary and blowdown samples	Secondary sampling system in the turbine building, on or near elevation 106.248 m (100’-6”)	Satisfy Tech Specs, and monitor plant conditions (primary to secondary leakage)
Waste samples	Samples from WSS, WLS, WGS, radwaste building, or other locations as needed	Samples taken to characterise or quantify waste parameters
Environmental samples	Waste monitor tanks, building sumps (turbine building or annex building, for example), retention basin, waste water system WWS, groundwater monitoring wells, and other exterior locations	Samples taken to satisfy environmental requirements or to document/quantify the activity released to the environment
Operational samples	Various	Taken as needed to support outages/local procedures

Table 24-13. Radioactive Low and Intermediate Waste Streams

Item	Type	Category	Description
1	Wet Solid	ILW	Ion exchange resins (polymeric types, WLS)
2	Wet Solid	ILW	Ion exchange resins (mineralic types, WLS), could contain charcoal from filter guard bed
3	Dry Solid	ILW	Filter cartridges (from WLS)
4	Dry Solid	LLW	HVAC HEPA filters, disposable PPE, general LLW
5	Liquid	VLLW	WLS dischargeable liquid effluent
6	Gaseous	VLLW	WGS dischargeable gaseous effluent

Table 24-14. Radwaste Building Area Classification

Area	Location	Notes	Radiological Classification	Contamination Classification
50353	HVAC Equipment Room	Safechange HEPA Filters	R2	C1
50355	Monitor Tanks Room	Tank internals will be C3	R2	C2
50351	Waste Accumulation Room	General personnel areas	R2	C2
50351	Sorting Enclosure	Local C3 (internal) with appropriate contamination controls	R2	C3
50351	In-Drum Compactor	Local C3 (internal) with appropriate contamination controls	R2	C3
50351	Size Reduction Enclosure	Local C3 (internal) with appropriate contamination controls	R2	C3
50351	Decontamination Enclosure	Local C3 (internal) with appropriate contamination controls	R2	C3
50350	Mobile Systems Facility	General personnel areas	R2	C1
50354	Truck Staging Area	General personnel areas	R2	C1

Table 24-15. BNFL Classification of Areas – Radiation

Area Classification	Action Level (µSv/h Gamma)	Target Level
R0	<2.5	ALARP
R1	2.5 – 7.5	ALARP
R2	7.5 – 25	ALARP
R3	25 – 100	ALARP
R4	100 – 500	ALARP
R5	>500	ALARP

Note:
1. Intermittent local areas of elevated dose rate may be present.

Table 24-16. BNFL Classification of Areas – Contamination

Area Classification	Surface Contamination		Airborne Contamination Level
	Bq/cm² α	Bq/cm² β	DAC
C0	<0.4	<4	<0.01
C1	RPA advice on Local Practice		
C2	>0.4	>4	<0.05
C3	>4	>40	<1
C4	>40	>400	<10
C5	>400	>4000	>10

Note:
1. Actual contamination levels will generally be much lower in practice.

Table 24-17. Equipment Specification Limits[1] for Cobalt Impurity Levels

Region, Component or Application (Specific Inclusions and Examples are noted parenthetically)			Maximum Weight Percent of Cobalt
Primary Components	Steam Generator Tubing	(Inconel tubing)	0.015
	Primary Component Other than the Steam Generators	(Primary weld cladding surfaces, core shroud, lower and upper core plates, lower core barrel, and neutron panels or thermal shields)	0.05
Fuel Assembly Components		(Inconel and stainless steel components in the Fuel Assembly)	
Auxiliary Heat Exchangers			
Other Components in Regions of High Neutron Flux[4]			
Steam Generator Surfaces other than tubing			0.10
Small Components	In regions of high neutron flux[4]		0.20
Bolting Materials or Fasteners			
	Outside of regions of high neutron flux[4]	(Bolting materials in primary and auxiliary components)	Not limited
Weld Material, other than cladding[2]			
Bearing and Hardfacing Materials[3]			
Other Auxiliary Components[2]		(Valves, piping, instrumentation, and tanks)	

Table 24-17. Equipment Specification Limits[(1)] for Cobalt Impurity Levels (cont.)

Notes:

1. Should a part be fabricated with cobalt above these limits, the responsible engineer must evaluate that cobalt input, considering the wetted surface of a particular component and determine whether using the part as-is or refabricating the part better controls cobalt SFAIRP. This demonstration shall be in accordance with ALARP design principles.
2. Stainless steels manufactured without cobalt limitations generally contain 0.15-0.20 weight percent cobalt. This is based upon historical evaluations of the cobalt content of stainless steels documented in Reference 300.
3. Low- or no-cobalt materials will be used, as available.
4. The following components are to be considered to be in a "high flux" region:
   - in the radial direction – all reactor internals components to a height of at least 0.607 m (2 feet) above and 0.607 m (2 feet) below the active core region. In addition, the weld layer on the inside of the reactor vessel opposite the core and 0.607 m (2 feet) above and 0.607 m (2 feet) below the active core elevations should be considered to be in the "high flux" region.
   - above the core – all components up to and including the upper core plate
   - below the core – all components down to the lower support plate
5. The cobalt content of vent and drain lines is not restricted as these lines are not expected to produce significant cobalt input as a result of corrosion and wear.
6. Temporary equipment that is installed and removed prior to fuel load is not subject to the limitations provided in this table. The limitations in this table apply to surface exposed to reactor coolant that may produce corrosion, activation, or wear products. Equipment that is removed from the primary circuit prior to fuel load is exempt from these limitations as any wear or corrosion products from this temporary equipment is expected to be minimal, can be cleaned up by the CVS filtration train, and has no mechanism to directly deposit or dwell in regions of high neutron flux.
7. Parts that are not exposed to reactor coolant are not subjected to the limitations on cobalt shown in the table above.
8. These limits apply only to components subjected to normal operating fluid temperatures of 93.33°C (200°F) or more.

Table 24-18. Parameters Used in the Calculation of Design Basis Fission Product Activities

Core thermal power (MWt)	3,400
Reactor coolant liquid volume (ft^3)[(a)]	9,575 (271.134 m^3)
Reactor coolant full-power average temperature (°F)	578.1 (303.39°C)
Purification flow rate (gal/min)	
Maximum	100 (22.71 m^3/hr)
Normal	91.3 (20.74 m^3/hr)
Effective cation demineralizer flow, annual average (gal/min)[(b)]	9.1 (2.07 m^3/hr)
Nuclide release coefficients (the product of the failed fuel fraction and the fission product escape rate coefficient)	
Equivalent fraction of core power produced by fuel rods containing small cladding defects (failed fuel fraction)	0.0025
Fission product escape rate coefficients during full-power operation (s^{-1}):	
Kr and Xe isotopes Br, Rb, I, and Cs isotopes Mo, Tc, and Ag isotopes Te isotopes Sr and Ba isotopes Y, Zr, Nb, Ru, Rh, La, Ce, and Pr isotopes	6 x 5 10^{-9} 1.3 x 10^{-8} 2.0 x 10^{-9} 1.0 x 10^{-9} 1.0 x 10^{-11} 1.6 x 10^{-12}
Chemical and volume control system mixed bed demineralizers	
Resin volume (ft^3)	50 (1.416 m^3)
Demineralizer isotopic decontamination factors:	
Kr and Xe isotopes Br and I isotopes Sr and Ba isotopes Other isotopes	1 10 10 1

Table 24-18. Parameters Used in the Calculation of Design Basis Fission Product Activities (cont.)

Chemical and volume control system cation bed demineralizer	
Resin volume (ft^3)	50 (1.416 m^3)
Demineralizer isotopic decontamination factors:	
Kr and Xe isotopes Sr and Ba isotopes Rb-86, Cs-134, and Cs-137 Rb-88, Rb-89, Cs-136, and Cs-138 Other isotopes	1 1 10 1 1
Other isotopic removal mechanisms	See Note c.
Initial boron concentration (ppm)	1,400
Operation time (effective full-power hours)	12,492

Notes:

a. Reactor coolant mass used in defining fission product activities is based on above stated conditions before thermal expansion (conservative).

b. Flow calculated at 15.513 MPa abs (2250 psia) and 121.11°C (250°F).

c. For all isotopes, except the isotopes of Kr, Xe, Br, I, Rb, Cs, Sr, and Ba, a removal decontamination factor of 10 is assumed to account for removal mechanisms other than ion exchange, such as plateout or filtration. This decontamination factor is applied to the normal purification letdown flow.

12702	PCS air cooling diffuser	118.440 m & 124.384 m (160’-6” & 180’)	V	II	IX	**Occasional access required**
12702	Shield building roof east (and west)	118.440 m & 124.384 m (160’-6” & 180’)	V	II	IX	**Occasional access required**

Notes:

1. Room 12152: Radiation may exceed the Zone II level locally during sampling.
2. Room 12161: Zone III dose rates may occur with the degasifier out of service.
3. Rooms 12171 and 12172: May be as high as Zone VII dose rates in the event of degasifier failure.
4. Room 12251: Radiation may exceed the Zone III level during filter replacement operations.
5. Room 12252: Radiation may exceed the Zone II level with the presence of radioactive sources.
6. Room 12255: Zone V during reactor coolant degasification operations using makeup pumps in the CVS semi-closed loop configuration.
7. Room 12261 (alcove): Zone IV dose rates may occur in the immediate vicinity of the opening to Room 12262 during shutdown conditions.
8. Room 12268: Zone IV contribution from spent fuel in the vertical position in the up-ender.
9. Room 12306: Blowdown piping may reach Zone II levels with concurrent fuel cladding defects of 0.25 percent and SG tube leakage of 1935 litres per day (500 gpd).
10. Room 12351: Zone III dose rates will occur within ~1.2 m (4.0 feet) of the opening to Room 12363, unless a shielded door is employed.
11. Room 12371: During spent resin disposal container transfer or loading, Zone VII dose rates may occur within this room.
12. Room 12371: During spent fuel transfer and/or transportation cask handling or loading operations, Zone V dose rates may occur within the room.
13. Room 12371: Due to radiation from the SFP, Zone IV dose rates may occur in the northwest corner of this room. If freshly discharged assemblies are loaded near the south edge of the SFP, Zone V dose rates may be possible.
14. Room 12371: Over the WDC hatch, Zone VII dose rates may occur in this location when the hatch to Room 12374 is open.
15. Room 12462: The cask washdown pit can be as high as Zone 5 during cask handling/washdown operations.
16. Room 12463: The underwater spent fuel assembly is at least 1.52 m (5.0 feet) from the south, east, and north walls.
17. Room 12463: During underwater spent fuel assembly transfer operations, this area can be as high as Zone IX. When a loaded cask (with lid in place) is present, dose rates may be as high as Zone V.
18. Room 12562: This area may have dose rates as high as Zone V during spent fuel transfer cask-handling operations. Dose rates as high as Zone III may occur during spent resin handling operations.
19. Room 12564: Zone II dose rates occur at all accessible locations that lie above the SFP water surface.
20. Room 12472: Zone III dose rates may occur during resin transfer.
21. Room 12168: Zone VI dose rates may occur with the degasifier out of service.
22. Room 12341: Zone IV dose rates may occur near the fuel transfer tube hatch during fuel transfer.
23. Room 12362: During cask movement Zone V Levels May exist in this area

Note:

1. This dose rate, which occurs off the building west wall, near the southwest corner, at elevations between 7.3 and 9.75 m (23 and 32 ft), only occurs during spent resin sluicing operations. At other times, the dose rate is Zone I.

APPENDIX 24B
AP1000 ANNUAL OCCUPATIONAL DOSE ASSESSMENT

24B.1 Methodology

Baseline collective doses were determined for individual tasks within the following overall categories:

- Reactor operations and surveillance
- Routine maintenance
- ISI
- Special maintenance
- Waste processing
- Refuelling

These gave the total doses in each category with none of the dose reduction methodologies incorporated in the AP1000 design as shown in Table 24B-1. The total collective dose of 1.68 person-Sv is high and represents historical data before improvements were made in operational practices to reduce worker doses. The information on doses from the individual tasks in Reference 24.40 was, therefore, used only for the relative contributions to the total.

The baseline case for the total collective dose to workers from outages was taken from the recent history of two Westinghouse reactors (Prairie Island 1 and 2), each generating 522 MWe. The first reactor commenced commercial operation in 1973 and the second in 1974. They represent a standard two-loop Westinghouse nuclear power plant.

The rolling average annual collective doses recorded during outages at the Prairie Island reactors have shown a steady improvement over the years from 1670 person-mSv between startup and 1990, to 894 person-mSv between 1996 to 2003 (Reference 24.22). The average collective dose from Prairie Island units 1 and 2 from 1996 to 2003 has been used in Reference 24.40 as being representative of doses received when modern practice radiation dose control procedures are applied during outages. The latest information on collective dose from the Prairie Island units (Reference 24.22) shows that the rolling average collective dose is continuing to fall. In addition, the collective dose for 2007 (62.8 person-Sv) gives a clear indication of the operational dose when there is no refuelling outage.

To estimate the distribution of the total collective dose among the work categories, the fraction of the total collective dose in each category from 1995 to 1997 was averaged as, shown in Table 24B-2. The fractions were applied to the mean collective dose of 894 person-mSv, as shown in Table 24B-1.

The dose from each subtask within each work category was then determined and adjustment factors were applied to take account of the differences between the AP1000 design and existing Westinghouse PWRs.

24B.2 Component Reduction Adjustment

The amount of work to be carried out, and therefore the dose incurred, will be affected by the number of components, which has been significantly reduced in the AP1000 design compared with previous Westinghouse reactors. A component adjustment factor has, therefore, been determined based on the number of components of each type in the AP1000 design, as shown in Table 24B-3.

The number of components in the AP1000 design is slightly higher than in the AP600 design but this has been taken into account in the adjustment factor.

24B.3 Crud Reduction Adjustment

A number of techniques have been used in Reference 24.40 to assess the benefits of the reduction of cobalt concentration and zinc injection on the dose rate from crud by comparing plant dose rates and corrosion calculations. Some changes, such as the use of zinc additions following SG replacement, were accompanied by other changes, such as electropolishing SG channel heads and use of low-cobalt tubing. Therefore, an exercise was undertaken in Reference 24.40 to normalise the dose reductions achieved to take account of additional changes so that a reduction factor could be estimated for zinc addition. The dose reduction factors identified from the normalisation study can be summarised as follows:

- Use of low-cobalt tubing in the SGs:
    - Comparison of plants with replacement SGs with low-cobalt tubing with plants with normal cobalt content SG tubing: average reduction factor 0.70
    - Results of corrosion studies and analysis: reduction factor calculated as 0.82
    - A reduction value of 0.76 was adopted as the average of the two values
- Use of no-cobalt valves:

– Results of corrosion studies and analysis: reduction factor calculated as 0.87

- Zinc addition to RCS:
    - Addition of zinc to plants after eight or nine cycles reduced dose rates by about 50 percent
    - Comparison of dose rates from piping in similar plants, one of which added zinc following SG replacement, gave a reduction factor of 0.26
    - As the data are only for one or two cycles of zinc addition from startup of a new plant or a plant with replacement SGs, a reduction factor of 0.40 was assumed

The effect of zinc addition alone makes a significant difference to the dose rates from crud deposition. Therefore, it is considered that a more detailed description of the determination of this value in Reference 24.40 is required.

The addition of zinc to the RCS reduces the corrosion rate and subsequent transport of the major materials of construction in the RCS. Until recently, the effect of zinc on plant dose rates was available only from plants that added zinc while in their ninth or later cycle. By this time, the component corrosion films have been somewhat stabilised and the effect of coolant additives is diminished. Nonetheless, plant data indicated that dose rates would be reduced by about 50 percent after about four cycles of zinc addition (Reference 24B.1).

The Angra 2 plant was designed by Siemens before various stellite reduction methods were incorporated in the Konvoi plants (Reference 24B.2). At the time of preparation of Reference 24.40, zinc addition had continued for two cycles. Comparison of piping dose rates with those on similar plants such as the KWG Ghronde plant that did not undergo stellite reduction (Reference 24B.3) enabled the effects of zinc injection to be assessed. Dose rates were determined from interpolation of data presented in a figure in Reference 24B.4.

Cycle of Operation	Ghronde	Angra 2	Ratio, Angra/Ghronde
1	49.2	8.7	0.18
2	68.1	11.6	0.17

The next comparison involved identifying a number of plants where a range of dose reduction techniques had been incorporated and comparing doses after and before SG replacement where the replacement SGs had electropolished channel heads (Reference 24B.5). A total of 14 plants were included; 4 did not have electropolished channel heads and, of the remaining 10, 8 used normal coolant chemistry while Farley 1 and 2 were operated with zinc injection before and after SG replacement. The dose reduction ratios achieved in each plant were normalised to take account of the other dose reduction techniques applied, which gave the following dose reduction ratios.

Source Reduction Technique	Dose Rate Reduction Factor	Code
High vs. low-cobalt impurity fuel grid nickel braze	0.80	FGNB
High vs. low-cobalt fuel grids (Inconel vs. Zircaloy)	0.72	FGIZ
High vs. low-cobalt impurity SG tubing	0.70	ISGT
Varying vs. constant coolant pH	0.86	CCpH
Overall reduction	0.35	All

By dividing the ratio of doses before and after SG replacement by the relevant ratio, based on one or more of the dose reduction factors above, the dose reduction ratio resulting from electropolishing the channel heads can be determined. The comparison of the dose reduction factor achieved by using electropolished channel heads on plants with zinc injection to the factor on plants with normal coolant chemistry gives the reduction factor achieved by means of zinc injection.

The dose reduction factors on plants with normal coolant chemistry in Reference 24.40 are as follows:

SG Replacement Plants with Electropolished Channel Heads – Normal Coolant Chemistry				
Plant	**Elements of Normalisation**	**Normalisation Factor**	**Ratio Before Normalisation**	**Ratio After Normalisation**
Braidwood 1	ISGT (0.70)	0.70	0.47	0.67
Byron 1	ISGT (0.70)	0.70	0.52	0.74
Catawba 1	ISGT (0.70)	0.70	0.21	0.30
McGuire 1	FGNB (0.80) ISGT (0.70)	0.56	0.14	0.24
McGuire 2	FGNB (0.80) ISGT (0.70)	0.56	0.26	0.46
Harris	ISGT (0.70)	0.70	0.33	0.47
Summer	FGNB (0.80) ISGT (0.70)	0.56	0.34	0.61
South Texas 1	ISGT (0.70)	0.70	0.58	0.82
Mean:				**0.54**

The dose reduction factors on plants with zinc injection before and after SG replacement in Reference 24.40 are as follows:

SG Replacement Plants with Electropolished Channel Heads – Zinc Addition Coolant Chemistry				
Plant	**Elements of Normalisation**	**Normalisation Factor**	**Ratio Before Normalisation**	**Ratio After Normalisation**
Farley 1	All	0.35	0.05	0.13
Farley 2	FGIZ (0.72) ISGT (0.70)	0.50	0.04	0.08
Mean:				**0.11**

For comparison, the dose reduction ratios before and after normalisation on plants where the channel heads in the replacement SGs were not electropolished in Reference 24.40 are as follows:

SG Replacement Plants with Nonelectropolished Channel Heads – Normal Coolant Chemistry				
No. Anna 1	All	0.35	0.41	1.18
No. Anna 2	All	0.35	0.49	1.40
Ringhals 2	All	0.35	0.36	1.03
Ringhals 3	FGNB (0.80) ISGT (0.70)	0.56	0.55	0.99
Mean:				**1.15**

The average normalised ratio in the plants with electropolished channel heads and normal coolant chemistry is 0.54. These results indicate a beneficial effect of electropolishing, which on the average results in a dose rate about one-half of that for plants without electropolishing. The long-term dose rate trends in the plants indicate a levelling. This suggests a continuing benefit of electropolishing.

The range of the normalised ratios in plants with electropolishing (0.24 to 0.82) indicates that all factors affecting the dose rates have not been taken into account. One reason for the higher values noted in Braidwood 1 and Byron 1 could be due to the longer cycle length after SG replacement compared with that before. A reason for the South Texas 1 higher value could be due to limited data after SG replacement.

The low normalised ratios in plants that use zinc addition illustrate a significant effect on the channel head dose rates. The absolute channel head dose rates in the two plants were 6.2 and 3.4 Sv/h, the lowest observed in any Westinghouse plant after one cycle of operation. The average normalised value of 1.15 for plants without electropolishing also indicates that not all the factors have been taken into account in the normalisation factors, but that the dose rate trend is similar to that before replacement; thus, confirming the dose rate reduction effect of electropolishing. The effect of zinc addition can be estimated by comparison of the average effect in the Farley plants to that in the other plants with electropolished channel heads. On an overall basis, the average effect is 0.11/0.54 = 0.20, or essentially the same as that obtained from the Angra 2 evaluation. Another estimate of the effect can be obtained by excluding the values from the three high plants (see above) and using the average of the remaining five (0.42). This will yield a zinc addition effect of 0.11/0.42 = 0.26.

Since there are only data from one or two cycles of zinc addition in a “new” plant, on a conservative basis, a zinc reduction factor of 0.40 will be assumed in this calculation note. If more data becomes available, the factor can be updated.

As the Prairie Island reactors have an energy density of 93.5 kW/litre compared with 109.7 kW/litre for the AP1000 design, a correction was applied for the increase in core flux that increases the activation of corrosion products.

The overall effects on the source term relative to the Prairie Island plant were determined to be the following:

- Low-cobalt tubing 0.76
- No-cobalt valves 0.87
- Power density 1.17
- Zinc addition 0.4
- Product of above 0.31

In addition, electropolishing of the SG channel head was determined to provide a further reduction factor of 0.5 for work specifically related to this area of the SG.

The factor applied to each task contribution to the total dose in each work category was determined according to whether the dose was from general background, in which case the factor of 0.31 was appropriate, or from specific components. In the latter case, a conservative reduction factor of 0.62 (2 x 0.31 to allow for crud traps) was applied in combination with the component reduction factor, as shown in Appendix 24A, Table 24A-4.

24B.4 Dose Estimates

The doses from each of the following work categories, excluding refuelling, were calculated:

- Reactor operations and surveillance
- Routine maintenance
- ISI
- Special maintenance
- Waste processing

Other assumptions are shown in the comments in the relevant tables.

Because of the major differences in design between pumps and the reactor head and upper internals on the AP1000 design compared with previous reactors and the use of robotics for many operations, it was not appropriate to scale doses from the following:

- RCP inspection
- Refuelling
- SG sludge lancing
- SG secondary-side inspection
- SG EC tube inspection
- SG ISI

Specific JEM calculations were carried out in Reference 24.42 for refuelling, as shown in Appendix 24C, and in Reference 24.44 for other operations, as shown in Appendix 24D.

24B.5 Results

The contributions from each task within each category are shown in the following:

- Table 24B-4, Dose Estimate for Reactor Operations and Surveillance
- Table 24B-5, Outage Dose from Routine Maintenance
- Table 24B-6, Outage Dose from In-Service Inspection

- Table 24B-7 Outage Dose from Special Maintenance
- Table 24B-8, Annual Dose from Waste Processing
- Appendix 24C

The ISIs include periodic examinations that are not carried out at each outage. While it would not be appropriate, for comparison against the numerical targets, to average such exposures out over the inspection interval, it would also give a falsely high collective dose to include all periodic examinations in 1 year. Therefore, the highest collective dose contribution from a periodic ISI has been included.

The total annual dose in the year with the highest contribution from ISI is shown in Table 24B-9 as 239.0 person-mSv. Collective dose in years where no refuelling outage takes place and in years where the periodic ISI dose is small will be lower.

Total (Highest year)					**60.2**	Note 2

Notes:

1. It is assumed that the RV and RVCH will be inspected at intervals of 5 years or every third outage (Reference 24.40). The dose from each inspection is estimated to be 10 mSv.
2. The ISIs on the RV, head, and SGs will not be expected to be undertaken in the same year. Therefore, the highest year dose is the year in which there is an outage with the RVCH ISI.

APPENDIX 24C
REFUELLING DOSE ESTIMATE

24C.1 Introduction

The collective dose to the group of workers undertaking the refuelling operations has been estimated using the JEM system, which uses a Microsoft Excel spreadsheet to estimate worker doses (Reference 24.42). The dose calculation is based on dose rates at existing plants, modified as appropriate for the reduction in crud as a result of the design and operating regime of the AP1000 plant and other design changes and durations of tasks based on the preliminary AP1000 plant refuelling outage schedule.

24C.2 Overview of Refuelling Operations

Prior to the plant shutdown, new fuel assemblies must be inspected and placed into the new fuel storage area or staged in the spent fuel pool. Generally, the new fuel arrives at the plant anywhere from a few months to a few days prior to the start of a refuelling. At this time, the fuel handling tools and equipment in the SFP are checked and repaired as necessary.

When the plant has been shut down, radiation surveys and equipment checks are performed inside containment. These checks include a survey of the fuel transfer system, RM, and surrounding structures.

When the equipment checks have been completed, preparation of the RVCH begins with the disconnection of the seismic supports and removal of RVCH insulation. The CRDM and DRPI electrical cables are then disconnected and the cable bridges are swung clear. The in-core instrument bullet-nose assemblies that include the in-core thermocouple connections are then disconnected at eight locations near the top of the vessel head. The RVCH vent and reactor vessel level instrumentation system (RVLIS) are also disconnected at this time.

When the RVCH has been prepared for removal, the RV studs are de-tensioned and removed. Next, stud hole plugs are inserted into the vacant stud holes, and by this point in the refuelling, the quick opening transfer tube closure has been opened. After all equipment has been removed from the cavity, the head lift begins. The RVCH is transferred from the RV to the head storage stand located on the operating deck. During the movement of the head, the refuelling cavity is flooded. Next, the CRDM drive shafts are unlatched and the upper internals lift rig is attached to the upper internals. The lift rig is equipped with features that move the thimble support plate such that the in-core instrumentation can be moved with the upper internals package. The upper internals are then removed and placed on their storage stand.

At this point, fuel unloading operations commence. At some point during the fuel unloading, the old RVCH O-rings are removed and inspected, and new O-rings are installed if necessary.

The fuel movement procedure can be summarised as follows:

- The RM is positioned over a fuel assembly. The hoist is then lowered until the grippers engage in the upper nozzle of the fuel assembly. The used fuel assembly is then lifted and placed in the up-ender for transfer to the SFP.

- The carriage containing the used fuel assembly is then lowered from the vertical position to a horizontal position by the up-ender. The carriage is then transferred through the transfer tube to the SFP via the conveyor system.

- On the SFP side of the transfer tube, the carriage is rotated by the SFP up-ender device to the vertical position. The assembly is then removed from the carriage by the fuel-handling machine and placed in a spent fuel storage rack. This process continues until all of the fuel is moved to the SFP.

- New fuel is lifted from its storage area and placed into the SFP elevator. The elevator is lowered to the bottom of the pit. Then the fuel-handling machine is used to carry the assembly to the transfer carriage. The fuel-handling machine releases the new fuel assembly and the carriage is lowered to the horizontal position by the SFP up-ender. The carriage is then transferred to the refuelling cavity via the conveyor system where it is raised to a vertical position by the cavity up-ender. The new fuel assembly is now ready to be moved by the RM.

- The new assemblies and reload assemblies to be replaced are moved to the RV and placed in their proper core location.

Fuel transfer continues until all of the fuel assemblies in the reactor core have been replaced with new fuel or reload assemblies. When the operation is complete, the core is mapped with an underwater camera to ensure that the assemblies are in their proper locations.

Following this inspection, the RV upper internals are reinstalled and the thimble support plate is lowered into position. The CRDM drive shafts are latched and a drag test is performed on each roc cluster control assembly (RCCA).

The cavity water level is then drained to the RV flange elevation. The RV flange is remotely cleaned and inspected.

The reactor head is placed on the vessel and the in-core instrument bullet-nose fittings are reconnected.

After cavity cleaning, the stud hole plugs are removed and the stud holes are cleaned and lubricated. The RV studs are threaded into the vessel and the tensioning sequence completed. The tensioning equipment is then removed from the cavity. The RVCH vent is re-attached and the head insulation reinstalled. Finally, the cable bridge is swung back into position and the cable connections are re-established.

24C.3 Nominal Dose Rates and Radiation Zones

The dose rates used in the calculation of the refuelling doses (Reference 24.42) are shown in Table 24C-1. The order of the zone numbering in the original calculation has been reversed to avoid confusion with the radiation zoning system in Table 24-7. The approximate relationship between dose rates used in this calculation and the radiation zones in Table 24-7 are shown in Table 24C-1 for comparison.

The dose rates are based on the location of the operations and the dose rates used in the original refuelling JEM (Reference 24.44):

- Zone VI was increased from 5 to 7.5 mSv/h based on the change in location from the maximum outside the IHP to that outside the flange during raising and lowering of the head and/or during flange cleaning.

- Zone V was increased from 0.5 to 1 mSv/h based on a change in location from a typical location near the flange with the head raised to the estimated dose rate in the work area where the in-core instrument stack "quick-disconnects" are made.

- The typical Zone IV location was changed to a location near the RV flange since the in-core thimbles are no longer retracted into the area above the top of the head. The dose rate is increased slightly from 0.02 to 0.025 mSv/h.

- The dose rate for Zone III of 0.01 mSv/h does not change from the previous value. However, since the in-core thimbles are no longer retracted into the area above the top of the head, the location is defined as that in the area where the cable tray CRDM connectors and CRDM fan connectors are located.

- Zone II was previously defined as the area where thimble work was done above the top of the head. In addition, it was the value used as the maximum value during fuel movement. Since the in-core thimbles are no longer retracted into the area above the top of the head, the primary work location is considered to be that on the manipulator crane and/or SFP bridge deck during fuel movement. From Reference 24.25 this area is such that a conservative exposure rate is 0.025 mSv/h.

- Zone 1 is on the operating deck where the dose rate is considered to be 0.01 mSv/h. This value does not change from the value used in the previous analysis. It is considered to be an effective dose rate and variations are to be expected, e.g., at edge of the refuelling cavity/SFP, with a high level of activity in the water, or near the reactor head on the storage stand. However, the operating deck radiation fields during refuelling at current operating plants are typically 0.01 mSv/h or less.

24C.4 Other Assumptions in the Job Evaluation Model

The estimate of the collective and individual doses from refuelling is based on a group of 8 workers on a rolling 4-shift basis (32 workers) and one supervisor.

The individual dose calculation assumes that one member of the group of workers undertakes tasks within each dose rate zone. Where the overall duration of the task is more than a single shift, this is overpessimistic.

24C.5 Results

The results of the JEM calculation in Reference 24.42 are shown in Table 24C-2 rearranged and converted to SI units. The mean and maximum individual doses are shown in Table 24C-3.

The total collective dose is 41.29 person-mSv incurred during 722 working hours. The split in man-hours, collective dose, and maximum individual dose among the tasks is as follows:

Task Category	Total Man-Hours	Collective Dose (person-mSv)	Maximum Individual Dose (mSv)
Job preparation	106	1.105	0.600
Reactor disassembly	148	14.155	2.016
Fuel movement	196	2.329	0.540
Reactor assembly	256	23.525	2.016
Job cleanup	16	0.175	0.040
Totals	**722**	**41.29**

Totals		**32**	**41.288**	**1.290**	
Maximum individual dose					**2.016**

Notes:

1. The task duration precludes exposure of a single worker at both low and high dose rates. With no worker rotation the maximum dose is 800 μSv.
2. The task duration precludes exposure of a single worker to high and low dose rates for the entire task (three shifts). The maximum individual dose is estimated to be 200 μSv.
3. The task duration precludes exposure of a single worker for the entire task (four shifts). The maximum individual dose is estimated to be 160 μSv.
4. The task manning level precludes a single worker being exposed to low and high dose rates. The maximum individual dose is estimated to be 1.25 mSv.

APPENDIX 24D
DOSE ESTIMATES FOR SPECIFIC TASKS

24D.1 Specific Tasks

There are a number of tasks for which it is not appropriate to scale doses received on other Westinghouse plants. For these operations specific JEM assessments have been undertaken in Reference 24.40. The following tasks are covered:

- RCP inspection
- SG sludge lancing
- SG secondary-side visual examination
- SG EC tube inspection and tube plugging
- SG ISI
- RCP ISI

Two other specific tasks were identified in the occupational dose assessment (Reference 24.40), which is carried out within a specific time or number of outages:

- RVCH inspections – Bare metal examination every third outage or 5 years; nondestructive testing examination of penetrations every fourth outage or 7 years.

- RV Inspections – Every 10 years (around every 6 outages).

A JEM calculation was undertaken for the RVCH inspection, which was carried out in Reference 24.44 (this reference also contains the JEM calculation for the refuelling dose, which has been superseded by Reference 24.42). However, on review, the method adopted involved man-access beneath the RVCH to remove instruments, which resulted in an individual dose of 5 mSv. Further discussion with specialists provided the following information:

On a typical job immediately following the close out of the inspection we tear down and remove the control equipment outside of the headstand (with the head on the stand) and then later when the head is moved back onto the vessel we remove the inspection equipment from inside the stand. For the AP1000 head inspections there will be no planned manual inspections underneath the head and no other planned personnel entries underneath the head while it is on the stand.

Although the inspections can last up to 4 or 5 days, they are performed remotely with the operators stationed outside the containment. During the actual span of the inspection we have very little time spent in containment. As you can see the majority of out of containment time is spent setting up and tearing down equipment.

24D.2 Job Exposure Models

The JEM calculations for inspections are shown in the following tables:

- Table 24D-1, Outage Dose Estimate from RCP Inspection

- Table 24D-2, Outage Dose Estimate from SG Sludge Lancing

- Table 24D-3, Outage Dose from Visual Inspection of SG Secondary Side

- Table 24D-4, Dose Estimate for SG EC Tube Inspection and Tube Plugging
- Table 24D-5, Dose Estimate for SG ISI (10-yr Interval)
- Table 24D-6, Dose Estimate for Canned Motor RCP (The European AP1000 design will use wet-winding pumps; however, the dose from maintenance of canned pumps has been included because it is expected that the maintenance dose from wet-winding pumps will not be significantly higher.)
- Table 24D-8, Reactor Vessel Head Inspection Dose

The same technique was adopted for the RV head inspection dose calculation as for the refuelling dose calculation. Dose rates were determined for various locations, as shown in Table 24D-7 (Reference 24.44); the dose calculation was based on numbers of workers, task durations, and dose rate zones determined by specialists within Westinghouse. The total collective dose of 10.0 person-mSv shows good agreement with doses from actual similar operations on existing plants (Reference 24.44). The highest individual exposure is 5 mSv from removal of the inspection equipment following the J-weld examinations, taking 0.5 hr at 10 mSv/h. However, it is noted in Reference 24.44 that, when it was written in 2005, the J-weld examinations were the first of their kind to be undertaken in the industry and it was expected that, with experience and improvements to equipment and techniques, the doses incurred would be significantly reduced.

There is no JEM calculation for the RV ISI but the total collective dose of 10 person-mSv is based on experience from a number of plants.

Table 24D-1. Outage Dose Estimate from RCP Inspection

Activity	Average Dose Rate (μSv/h)	No. of Workers	Time (hr)	Collective Dose (person-mSv)
Electrical[1]				
Measure insulation resistance to ground	0	1	0.2	0
Measure winding resistance	0	1	0.2	0
Mechanical	**N/A**	**N/A**	**N/A**	**N/A**
Total per pump				**0**
Total four pumps				**0**

Note:

1. Electrical measurements may be made from the RCP switchgear located outside the containment.

Table 24D-2. Outage Dose Estimate from SG Sludge Lancing

Activity	Average Dose Rate (μSv/h)	No. of Workers	Time (hr)	Collective Dose (person-mSv)
Move equipment into containment	40	6	4	0.96
Remove insulation and handhole cover	150	1	0.5	0.075
Complete pre-lance water balance	150	2	1	0.3
Install lance on handhole	150	2	0.5	0.15
Operate water lance	150	2	12	3.6
Complete post-lance water balance	150	2	1	0.3
Remove equipment	40	6	4	0.96
Install handhole cover and insulation	150	1	0.5	0.075
Total per SG				**6.42**
Total two SGs				**12.84**

Table 24D-3. Outage Dose from Visual Inspection of SG Secondary Side

Activity	Average Dose Rate (μSv/h)	No. of Workers	Time (hr)	Collective Dose (person-mSv)
Remove insulation and two manway covers(1)	4	2	2.5	0.02
Inspect separators orifices and feedwater ring(1)	40	1	0.5	0.02
Install two manway covers and insulation and lower water level below handholes(1)	4	2	2.5	0.02
Remove insulation and secondary handhole cover	150	2	0.5	0.15
Photograph support plates	150	2	2	0.6
Install handhole covers and insulation	150	2	0.5	0.15
Total per SG				**0.96**
Total two SGs				**1.92**

Note:

1. Secondary-side water level at the lower deck plate

Table 24D-4. Dose Estimate for SG EC Tube Inspection and Tube Plugging

Activity	Average Dose Rate (μSv/h)	No. of Workers	Time (hr)	Collective Dose (person-mSv)
Move equipment into containment	8	4	4	0.128
Install ventilation equipment	200	1	1	0.2
Remove insulation on both manway covers	150	2	0.2	0.06
Remove both manway covers with handling fixture	200	2	1	0.4
Remove both manway inserts(1)	1200	2	0.1	0.24
Install fixture on manway(1)	1200	2	0.1	0.24
Install universal/robotic arm on manway	200	2	0.25	0.1
Insert nozzle hot and cold leg dams with robotic arm	200	2	0.5	0.2
Replace dam fixture tool with EC end effector on robotic arm (hot leg channel)	200	1	0.25	0.05
Perform EC exam of 3340 tubes (33 1/3%)	4	1	111	0.444
Remove EC end effector and replace with mechanical plugging tool	200	1	0.2	0.04
Insert plugs in three tubes	200	1	0.75	0.15
Transfer robotic arm to cold leg channel	200	2	0.25	0.1
Insert plugs in three tubes	200	1	0.75	0.15
Remove robotic arm	200	2	0.25	0.1
Remove hinged fixture(1)	1200	2	0.1	0.24
Install manway inserts(1)	1200	2	0.1	0.24
Install both manway covers with handling fixture	200	2	1	0.4
Replace insulation both manway covers	200	2	0.2	0.08
Remove ventilation equipment	200	1	0.5	0.1
Move equipment out of containment	8	4	2	0.064
Total per SG				**3.726**
Total two SGs				**7.452**

Note:

1. The dose rates for these operations would be reduced by electropolishing the SG bowl, but no credit was taken. The minimum effect would be a reduction of 0.48 person-mSv per SG or 0.96 person-mSv total. There may be a reduction of some of the other dose rates where the SG bowls make a contribution.

1. Only 1 SG inspected at every 10 year or 6 outages.
2. Both SGs inspected at each outage.

Table 24D-6. Dose Estimate for Canned Motor RCP ISI

Activity	Average Dose Rate (μSv/h)	No. of Workers	Time (hr)	Collective Dose (person-mSv)
Pump Removal				
Position maintenance cart under pump	20	2	2	0.08
Install walkways and tensioner platform	20	2	2	0.08
Disconnect wiring and piping, attach actuator to pump	20	2	0.5	0.02
Install stud tensioners, remove and store nuts and eight studs	80	2	4	0.64
Lower motor on the cart	900	2	0.5	0.9
Move cart to crane access area, install shields over impeller and on pump casing	150	2	3	0.9
Inspection				
Visual inspection of twenty-four 3 1/2" studs, nuts, and washers	20	2	2	0.08
Ultrasonic Testing (UT) scan and dye penetrant testing of studs	20	2	2	0.08
Remotely conduct visual inspection of casing internal surface	20	2	4	0.16
Pump Installation				
Lower pump and maintenance cart to pump compartment, and position under pump casing	20	2	4	0.16
Remove pump casing shield	150	2	0.5	0.15
Raise motor until seated	80	2	1	0.16
Install walkway and tensioner platforms	20	2	2	0.08
Install eight studs and all nuts in two passes	80	2	4	0.64
Reconnect wiring and piping, detach actuator	20	2	0.5	0.02
Store the maintenance cart	20	2	1	0.04
Total 1 pump				**4.19**

Notes:

1. In the European version of the AP1000 design, it is currently proposed that the canned pumps will be replaced by wet-winding pumps (Reference 24.44). The implications of this change on maintenance doses is not yet known. However, as the motor windings and rotor have a cooling water supply, it is expected that the doses will be no greater than those for the canned pumps. In lieu of specific information, the dose estimate for canned pump maintenance has been used. The times provided for activities are estimates; actual maintenance times may vary.
2. The inspection of one pump is only scheduled for the first cycle of operation. If the RCPs are not removed for maintenance, ISI is limited to external visual inspection and UT scan.

Table 24D-7. Nominal Dose Rates Associated with Reactor Vessel Head Inspection

Zone ID for Calculation (Reference 24.44) (Reversed)	Description	Dose Rate (mSv/h)	Zone ID Based on Dose Rate

25 ACCIDENT MANAGEMENT

25.1 INTRODUCTION

It is expected that the design of a nuclear facility built in the United Kingdom (UK) will be robust and meet modern international good practices and thus provide adequate protection against low probability potential accidents (Reference 25.1). The AP1000 plant is designed to be operated so that defence in depth against significant faults or failures is achieved by the provision of several layers of protection, as discussed and demonstrated in Chapters 8 through 14.

Accident management provides the final level of defence to ensure that all reasonably practicable steps have been taken to minimise the radiological consequences of any potential accident. Accident management encompasses emergency and abnormal procedures, severe accident management guidelines, and offsite emergency plans. Emergency and abnormal procedures will dictate steps for the operator to take in order to manage and mitigate an unplanned event in preventing any release of radioactivity to the environment. Severe accident management guidelines will detail steps for the plant staff to follow in diagnosing and mitigating challenges to containment fission boundaries, which may otherwise result in a release of radioactivity to the environment. Offsite emergency plans, recognising a high improbability of radioactive releases, provide guidance to the plant staff and offsite civil authorities in order to protect the general public in the event of a release of radioactivity to the environment.

This chapter describes general arrangements and facilities to facilitate the management of accidents currently considered in the AP1000 UK plant design. Any site-specific arrangements will be described in site-specific Pre-Construction Safety Reports (PCSRs).

25.2 FRAMEWORK FOR EMERGENCY MANAGEMENT

Systematic plant and site-specific arrangements must be made for emergency preparedness and response in case of nuclear and radiological incidents (Reference 25.1).

Principle AM.1 of the Office for Nuclear Regulation (ONR) safety assessment principles (SAPs) (Reference 25.1) states:

> Strategies and plans should be in place to prepare for and manage accidents at the facility and/or site.

The siting, design, construction, and operation of the AP1000 plant is subject to the granting of a nuclear site licence by the ONR and compliance with the conditions attached to the licence.

ONR will only permit the operation of a nuclear facility when it has fully satisfied itself that the licensee has made an adequate safety case and developed appropriate safety standards. The safety case identifies instrumentation needed to monitor the state of the plant and the level of severity of an accident, and any equipment to be used to control the accident or mitigate its consequences. Where additional hardware would facilitate accident management, this is also documented within the safety case. The implementation of these standards significantly reduces the chances of an accidental event occurring and resulting in the uncontrolled release of radioactivity.

The responsibilities of the operator when responding to a nuclear emergency, both in relation to protecting the public and to protecting their own workforce, is governed by a number of acts, principally the Health and Safety at Work Act (HSWA) (Reference 25.2), the Nuclear Installations Act (NIA) (Reference 25.3), and the Radiation (Emergency Preparedness and Public Information) Regulations (REPPIR) (Reference 25.4). Other legislation, such as the Fire and Rescue Services Act (Reference 25.5) and the Food and Environment Protection Act (Reference 25.6), governs the response of specific organisations.

The HSWA places a general duty on all responders to do all that is reasonably practicable to reduce risk, while the Ionising Radiations Regulations (Reference 25.7) contain specific requirements for the protection of employees and the public from radiation.

Site licence condition (SLC) 11 (Reference 25.8) under the NIA (Reference 25.3) requires that there shall be “adequate arrangements”, which must be approved by the ONR, for dealing with any accident or emergency arising on site. These “adequate arrangements” are expected to be detailed in the operator’s site-specific emergency plans and associated documentation. The “adequate arrangements” would likely incorporate procedures for dealing with an accident or emergency to ensure that appropriate measures are available for protecting the public and the workforce. Additionally, these arrangements are expected to be capable of covering a wide range of events, from minor incidents restricted to onsite locations to large incidents or emergencies that could result in a significant release of radioactive material to the environment. It is anticipated that the licensee keeps a record of all such incidents, notifies ONR when appropriate, investigates the cause of each incident, and produces a report of the investigation to ensure that lessons are learned.

The licensee of each AP1000 site in the UK will be required to establish arrangements through emergency plans for managing emergencies arising from activities on the site; these plans are to be submitted to and approved by the ONR in accordance with SLC 11. The ability of the operator to implement such plans must be demonstrated to the ONR and rehearsed regularly to satisfy the requirements of the license. The

REPPIR (Reference 25.4) establishes a framework for the protection of workers and the public through emergency preparedness for a radiation emergency and concentrates on requirements of the emergency phase of any accident at a nuclear site. These regulations place a requirement on the licensee (duty holder) and local authorities to ensure that offsite emergency arrangements are in place and rehearsed regularly, setting out the response to be taken in the event of a release of radioactivity that presents a hazardous condition. These duties include, among other things, the need for hazard identification and risk evaluation and the development and testing of offsite emergency plans. The purpose of the offsite plan is to bring together the emergency arrangements of all offsite agencies involved in the response to a radiation emergency occurring at the premises. A radiation emergency is defined as an event likely to result in a member of the public receiving an effective dose of 5 mSv during the year immediately following the emergency.

The Nuclear Emergency Planning Liaison Group (NEPLG) is a forum that brings together, under the Department for Business, Energy & Industrial Strategy (BEIS) chairmanship, a wide range of organisations with interests in offsite planning for an emergency at civil and defence nuclear sites. NEPLG identifies, discusses, and finds solutions to common problems, and facilitates improvements in planning, procedure, and organisation that would form a framework of advice to the emergency planners. It has produced consolidated guidance documentation detailing the response to an emergency at a nuclear site; i.e., the consequence management of the emergency affecting people and the environment. The response arrangements are designed to be put into effect regardless of the nature of the initiating event, whether it is an accident or a terrorist incident. The NEPLG consolidated guidance also identifies the requirements for onsite and offsite emergency response centres (References 25.9, 25.10, 25.11, 25.12, and 25.13).

The NEPLG consolidated guidance will be taken into account by any prospective site licensee to ensure that members of local emergency planning consultative committees and councils are made aware of the guidance.

The International Nuclear and Radiological Event Scale (INES) is a recognised tool for promptly communicating to the public in consistent terms the safety significance of reported nuclear and radiological incidents and accidents, excluding naturally occurring phenomena such as radon. The INES tool is presented in Reference 25.14.

It is not the intention of this section of the PCSR to detail the incidents and/or failure combinations of systems that would require declaration as a site incident or nuclear emergency. The probabilistic safety assessment (PSA) (see PCSR Chapter 10) identifies incidents and failure combinations that would lead to significant offsite releases; however, the specific definitions of site incident and nuclear emergency declarations will be determined within site-specific operating plans and procedures.

The licensee's emergency arrangements require the declaration of either a "site incident" or a "nuclear emergency", depending on the nature of the event, by a duly authorised person.

The definitions of these two declaration states follow:

- **Site incident** – A hazardous condition that is confined in its effect to within the boundary of the site security fence.

- **Nuclear emergency** – A hazardous condition that results, or is likely to result, in the need to consider urgent countermeasures to protect the public outside the site security fence from a radiological hazard.

A site incident may not call for the full implementation of the operator's emergency plan or the alerting of the offsite emergency services. The possibility of a site incident developing into a nuclear emergency is continuously assessed by staff in the main control room (MCR).

A nuclear emergency is likely to call for the full implementation of the site operator's emergency plan. Active countermeasures may include additional offsite radiation and contamination surveys, the restriction of foodstuffs produced close to the site, sheltering, issuing of potassium iodate tablets to people who work or live close to the incident location, and evacuation of areas immediately adjacent to the site. Such countermeasures will depend upon the severity of the accident.

The ability to implement offsite countermeasures should be based on UK and relevant international advice and will be demonstrated in the safety case. Similarly, assumptions that

the onsite effects will be limited by the implementation of accident management and emergency preparedness arrangements would be demonstrated within the site-specific safety case.

25.3 AP1000 PLANT EMERGENCY MANAGEMENT ARRANGEMENTS

This section identifies the generic emergency arrangements and accident management programmes currently included in the AP1000 UK plant design. Any site-specific arrangements will be described in site-specific PCSRs.

The licensee will develop and maintain an accident management programme specific to the site location and environs, AP1000 design, and safety case. Such a programme is intended to take the form of an emergency plan and shall be informed of the aforementioned regulations and guidance in addition to AP1000-specific attributes and defined emergency actions.

In addition, and as integral to these programmes, the licensee will develop and maintain external emergency arrangements and communications with appropriate governmental and regulatory entities for the purpose of facilitating emergency response to site assistance and informing offsite actions.

It is expected that any emergency plan will be informed from many sources both internal and external to the site. The UK AP1000 PSA (see further Chapter 10) provides one source of information from which an accident management programme can be informed. The fault and accident analysis provides another source of information. These studies highlight the importance of actions as significant responses to a set of design basis accidents (DBAs).

Additionally, the licensee will develop and implement severe accident management guidance using the suggested framework provided in the Framework for AP1000 Severe Accident Management Guidance, (Reference 25.15) and the Executive Volume For AP1000 Severe Accident Management Guidelines (Reference 25.16). The site-specific licence application will consider any differences between the as-built plant and the AP1000 certified design. Any significant impact on the safety case will be determined and evaluated.

If a severe accident occurs, actions to terminate fission product release have been predefined in Reference 25.15 and Reference 25.16. These actions will be incorporated into the accident management programme as it is developed. Table 25-1 provides a link between a desired plant outcome – e.g., a controlled stable core – and the high-level actions required to achieve this. This is supported by Table 25-2, which identifies the strategies for severe accident management and the equipment required.

To further development of the emergency arrangements for the AP1000 plant, such planning will likely include actions for increased environmental monitoring following a major accident and release of radionuclides. Such actions are intended to address surveys of soils and agricultural products as may be required or prudent. Contingency plans will also be developed and integrated with the environmental monitoring programme (Reference 25.17).

25.4 ONSITE EMERGENCY RESPONSE FACILITIES

The operator of any UK AP1000 facility, as a result of the SLCs and/or REPPIR regulations, will address the site response to emergency conditions through both operations emergency procedures (abnormal operating procedures (AOPs), emergency operating procedures (EOPs), and Severe Accident Management Guidelines (SAMGs); see Chapter 13) and coordinated onsite response arrangements and actions. These onsite emergency management actions will be integrated with offsite support organisations, including representation at the

strategic coordination centre and the communications interfaces among plants, public, and external agencies.

In support of the onsite emergency management response arrangements, the UK AP1000 operator will plan for and have available emergency response facilities to coordinate and manage site actions. These facilities are broadly classified as having the following functions:

- Direct accident management and plant recovery control through resources located in the MCR, remote shutdown room (RSR), or at the south auxiliary building diverse actuation system (DAS) panel.

- Incident or emergency technical support through the technical support centre (TSC), including accident management, engineering, and external communications roles.

- Operational support through the operations support centre (OSC), including plant logistical support and offsite radiological monitoring coordination roles.

The MCR provides an engineered protected environment from which operators can safely monitor and control plant processes. The major tasks performed in the control room include monitoring, supervising, managing, and controlling those aspects of the plant processes related to thermodynamic and energy conversion processes under normal, abnormal, and emergency conditions. The principal emergency response function of the MCR is to provide human interface resources that determine the plant state and implement the desired changes to the plant state during normal and emergency operations.

The MCR provides alarms and other information to alert the operator to the need for further investigation. Plant process data displays permit the operator to observe abnormal conditions and define the plant state with suitable controls, enabling the operator to execute plant control and recovery actions. The process data displays and the alarms also provide feedback to enable the operator to observe the effects of the control actions.

Operators in the MCR are also provided with information via the equipment monitoring functions (see Table 25-3) to monitor radiation levels and radioactivity in the environment surrounding the plant and to monitor the habitability of the MCR. From the MCR, staff can monitor plant areas where access may be required to service equipment (necessary to monitor or mitigate the consequences of an accident and estimate the magnitude of the release of radioactive material through identified pathways) and continually assess radioactive releases. Table 25-3 summarises the functions monitored in the MCR that allow the operator to mitigate the consequences of an accident.

The MCR is a controlled environment with habitability systems capable of keeping the environment suitable for prolonged occupancy of up to 11 persons throughout the duration of the postulated accidents. The habitability systems provide the capability to detect and protect MCR personnel from external fire, smoke, and airborne radioactivity. Automatic actuation of the individual systems that perform a habitability systems function is provided. Smoke detectors, radiation detectors, and associated control equipment are installed at various plant locations as necessary to provide the appropriate operation of the systems. In the unlikely event that the normal power source or the heating, ventilation, and air conditioning system becomes unavailable, there are passive systems (batteries, compressed air) to support the MCR for up to 3 days.

Additional information about the MCR and its supporting habitability systems are provided in Chapters 6, 9, and 23.

An additional remote operations emergency response facility is also provided within the adjoining RSR. The RSR is physically and electrically separated from the MCR. In the unlikely event of MCR evacuation, safe shutdown conditions may be established and maintained by the plant operators using the remote shutdown workstation in the RSR. This remote shutdown workstation contains indications and controls that allow an operator to achieve and maintain safe shutdown of the plant following an event when the MCR is unavailable.

As a final level of direct accident management and plant recovery control emergency response facilities, a remote DAS workstation is located in the south side of the auxiliary building. This panel can be used to shut down the reactor, and provides capability for manual actuation of key safety features. The DAS panel is located in the south side of the auxiliary building while both the MCR and RSR are on different levels of the north side of the auxiliary building.

The DAS is described further in Chapter 19.

The MCR, RSR, and the remote DAS workstation are designed in accordance with human factors engineering principles and practices.

Two additional onsite support facilities are designated as part of the emergency response function. Operation of both these facilities is designed to provide additional resources in support of the MCR accident management and recovery responses.

The TSC provides an area and resource for use by personnel providing plant management and technical support to operating staff during an emergency. Activation of this facility relieves the reactor operators of peripheral duties and communications not directly related to accident management operations and prevents congestion in the MCR. The TSC is located in the control support area (CSA) of the annex building. The TSC is shielded and operated at a slight positive pressure with atmospheric filtration. Should habitability be challenged within the TSC due to a lack of cooling or a high radiation level following an accident, the plant management function of the TSC is transferred to the MCR or OSC.

The TSC can accommodate a minimum of 25 people with a floor space of at least 6.97 m^2 (75 ft^2) per person and has voice communication equipment for communication with the MCR, the OSC, and external agencies.

An additional facility, the OSC, is an onsite emergency response facility available to provide a centralised habitable area for operations support personnel and resources. Like the TSC, the OSC is designed to relieve operators of peripheral duties and eliminate personnel congestion in the MCR. OSC managers are responsible for coordinating the assignment of duties and tasks to personnel outside the MCR and TSC in support of plant emergency management operations. These duties may typically involve tasks such as offsite radiation monitoring or sampling, onsite repairs to faulted equipment, or performance of manual valve line-ups. The OSC also provides resources for communicating with the MCR and TSC. This permits the personnel reporting to the OSC to be assigned emergency operations support responsibilities.

It is possible that the TSC and OSC resources could be shared between more than one AP1000 unit on the same site, however, this will be a site-specific issue and will be determined as part of the application for a site-specific licence. The appropriate location, design, and specification of the OSC will be determined as part of the application for the site-specific licence and therefore is not discussed any further within this chapter.

The operator of any UK AP1000 facility, as a result of the SLCs, will be responsible for designing the emergency operations facility, including the specification of the location and communication with the facility in accordance with the AP1000 human factors engineering programme.

25.5 CONCLUSION

This chapter identifies the UK requirements for emergency response to a nuclear incident and emergency. It also identifies the provisions available in the current AP1000 UK plant design to respond to a nuclear incident or an emergency as well as identifying the requirements for contingency plans that will be fully integrated with the environmental monitoring programme. This chapter also confirms that the AP1000 UK plant design facilitates the management of an incident or emergency by the provision of the MCR, TSC, and OSC.

Table 25-1. AP1000 High-Level Action Relative to Severe Accident Goals (Reference 25.15, Table 5-1)

Goal	Element	High-Level Action
Controlled, stable core	Water inventory in reactor coolant system (RCS)	Inject into RCS Depressurise RCS
	Water inventory in containment	Inject into containment
	Heat transfer to steam generators (SGs)	Inject into RCS Inject into SGs Depressurise SGs
	Heat transfer to containment	Inject into RCS Inject into containment Depressurise RCS
Controlled, stable containment	Heat transfer from containment	Depressurise containment Vent containment
	Isolation of containment	Inject into SGs Depressurise RCS
	Hydrogen prevention/control	Vent containment Pressurise containment Burn hydrogen Depressurise RCS Inject into containment
	Core/concrete interaction (CCI) prevention	Inject into containment Depressurise RCS
	High-pressure melt ejection (HPME) prevention	Inject into containment Depressurise RCS
	Creep rupture prevention	Depressurise RCS Inject into SGs Inject into containment
	Containment vacuum prevention	Do not vent containment Pressurise containment
Terminate fission product releases	Isolation of containment	Inject into SGs Depressurise RCS
	Reduce fission product inventory	Inject into containment Depressurise RCS Depressurise containment
	Reduce fission product driving force	Depressurise containment

Table 25-2. Summary of High-Level Severe Accident Management Strategies for AP1000 UK Plant (Reference 25.15, Table 5-2)

Action	Purpose (Positive Impact)	Other Considerations (Negative Impacts)	Equipment
Depressurise containment	Remove decay heat from containment Prevent overpressurisation Mitigate containment fission product leakage Alleviate equipment and instrumentation challenges due to harsh conditions Increase containment water inventory	Hydrogen flammability Containment vacuum of venting Fission product release if venting	Passive containment cooling system (PCS) with water from passive containment cooling water storage tank (PCCWST) or other source Fan coolers Containment vent through normal residual heat removal system (RNS) to spent fuel pit
Pressurise containment	Create inert atmosphere so that hydrogen cannot burn Prevent containment vacuum from failing containment structure	Removal of hydrogen will eventually be needed More oxygen for hydrogen to burn Possible failure to isolate pathway used for pressurisation	Containment heat sinks Fan coolers Automatic depressurisation system (ADS) valves Instrument air
Intentionally burn hydrogen	Let hydrogen burn while containment failure is not a risk to prevent future containment challenge	Pressure and temperature spike	Hydrogen igniters including alternate power source
Vent containment	Avoid containment failure due to overpressurisation Hydrogen burn	Radiological releases Potential future concerns with containment failing from subatmospheric loads No guarantee that vent pathway will be able to reclose	RNS suction line from RCS to spent fuel pool (with ADS valves or other openings between RCS and containment)

Table 25-2. Summary of High-Level Severe Accident Management Strategies for AP1000 UK Plant (Reference 25.15, Table 5-2) (cont.)

Action	Purpose (Positive Impact)	Other Considerations (Negative Impacts)	Equipment
Mitigate fission product release	Reduce release for fission products to atmosphere	Hydrogen burn Containment flooding Hydrogen build-up in lower compartments	Containment fan coolers Containment spray SG water inventory RCS ADS valves Containment isolation Flood containment
Inject into RCS	Restore core cooling (immediate and long term) Scrub fission products Prevent or delay vessel failure	Creation of hydrogen Creep rupture of SG tubes	Core makeup tank Accumulators In-containment refuelling water storage tank (IRWST) RNS Chemical and volume control system (CVS)
Inject into containment	Create inventory in sump for recirculation Submerge lower head of RPV to prevent failure Cool core debris Prevent limit CCI Prevent basemat melt through Reduce flammable gas production Prevent HPME Reduce fission product inventory	Ex-vessel steam explosions Hydrogen generation	Gravity drain of IRWST RNS injection of cask loading pit Spent fuel system injection into refuelling cavity
Inject into SGs	Heat sink Cover SG tubes to prevent creep rupture Scrub fission products Make SGs available to depressurise	Thermal shock of SG tubes Fission product release from leaking tubes Creep rupture of SG tubes (if SG is first depressurised, creating large pressure differential)	High pressure: Main feedwater Startup feedwater Low pressure: Condensate Firewater Service water

26 RADIOACTIVE WASTE MANAGEMENT

26.1 INTRODUCTION

The management of radioactive waste, which may be gaseous, liquid, or solid, from operational and decommissioning phases, spans all the stages in the life cycle of the AP1000 design.

A safety case for radioactive waste management should consider not only generation and immediate management or treatment, but also longer-term storage and ultimate disposal. It must also address longer-term safety and environmental issues associated with a particular waste stream (e.g., safety during onsite storage pending final offsite disposal). The aim is to demonstrate that treatment of the AP1000 plant radwaste can be undertaken safely and does not pose a significant risk either to workers or to members of the general public. Please note that for completeness, non-radioactive waste is also addressed in a number of sections below.

This chapter of the Pre-Construction Safety Report (PCSR) is part of the generic design assessment (GDA) for the AP1000 design. This GDA precedes the assessment that will be put forward by potential operators for an installation at a specific site. In some parts of the chapter, especially those related to the management of solid radwaste, the design described is specific to the GDA; the operator may propose a different radwaste strategy.

This chapter considers in turn the gaseous, liquid and solid waste streams. It describes how the proposed reactor design and operation minimise the generation of radioactive waste. It also describes how each type of waste is handled at the reactor site, using the best available techniques (BAT) to minimise current and future impacts, and considers the disposability of the solid radioactive waste. The waste systems are described in further detail in Chapter 6. The chapter builds upon and references many underlying documents. In particular it draws on the Environment Report (Ref. 26.1), the integrated waste strategy (IWS) (Ref. 26.2), the radioactive waste management case (RWMC) evidence reports for intermediate-level waste (ILW) (Ref. 26.3) and high-level waste (HLW) (Ref. 26.4), and the AP1000 Nuclear Power Plant BAT Assessment (Ref. 26.5).

Issues related specifically to decommissioning are handled in Chapter 27. Many of the issues related to operation are described in detail in the Environment Report (Ref. 26.1). Normal discharges to air and water and proposed discharge limits are summarised in Section 26.5 below and detailed in the Environment Report.

Achieving the optimum balance between corrosion, mechanical performance under irradiation, and the generation of activation products such as Co-60 and Ni-63 in radioactive waste is a complex issue that spans several technical areas. For example, the behaviour of activated corrosion products in the primary circuit (and hence the activity in the ion exchange resins and also in the oxide films of out-of-neutron-flux primary circuit components) depends on the primary circuit chemistry, which is covered in Chapter 21. It also depends on the corrosion properties of materials used in the circuit and in the fuel assemblies (Chapters 15 to 23), while the elemental and isotopic composition of the materials used affect the rates at which activation products are generated under neutron irradiation.

This chapter demonstrates that the wastes arising from the proposed generic design and management of the AP1000 design pose no unacceptable risks.

This chapter starts with a summary of the AP1000 design waste management facilities, and then outlines the radioactive waste management strategy. Some general information on discharges to air and water is followed by detailed descriptions (Sections 26.6, 26.7, and 26.8) of the systems for processing gaseous, liquid and solid wastes, including their discharge or disposability. Having described the systems, their responses to external and internal hazards are collated in Section 26.9. A brief description of record-keeping is followed by some overall conclusions.

26.2 SUMMARY OF AP1000 DESIGN WASTE MANAGEMENT FACILITIES

The generic AP1000 design site contains the following groups of buildings (Ref. 26.2, Section 2.1).

26.2.1 Nuclear Island

The nuclear island comprises the reactor containment vessel, the concrete shield building that surrounds the containment vessel, and the auxiliary building. The auxiliary building contains mechanical and electrical equipment plus the main control room, handling areas for fresh fuel, spent fuel, liquid and gaseous radwaste, and main steam and feedwater isolation valve compartments, and the rail car bay where the mobile encapsulation unit (MEU) will be placed during treatment of ILW.

26.2.2 Non-Nuclear Island

The non-nuclear island comprises the following:

- The annex building, including the main personnel entrance, the health physics area, ancillary diesel generators and fuel supply, technical support centre, and various heating, ventilation, and air conditioning (HVAC) systems

- The turbine building, housing the main steam turbine, the generator, and the makeup water purification system

- The diesel generator building, housing two diesel generators and their associated HVAC equipment

- The radwaste building incorporates the GDA facilities necessary to handle the solid low-level waste (LLW) arisings from AP1000 plant operations and maintenance. This includes equipment for treating, packaging, and assaying LLW and for clearing very low-level waste (VLLW). The radwaste building also includes the holdup and monitoring tanks that are part of the liquid waste system, devices for waste monitoring and radiological characterisation, and three truck bays wherein mobile waste-handling equipment may be parked and connected.

Figure 26-1 shows the buildings of the nuclear and non-nuclear islands.

26.2.3 Waste Storage Facilities

The waste storage facilities are not shown in Figure 26-1. They are not part of the standard plant and will be selected by the operator. For the GDA cast, they include the following:

- A dry-storage system for spent fuel (which is the only HLW produced by the AP1000 design). This could be used to retain spent fuel after the AP1000 plant is decommissioned. The United Kingdom (UK) Nuclear Decommissioning Authority (NDA) is currently investigating the credible options for dealing with spent fuel (Ref. 26.6).

- An ILW store. The first phase of the store would accommodate the arisings expected from the first 20 years of operation; subsequent extensions would accommodate further 20-year increments. The ILW store could be used to retain ILW after the AP1000 plant is decommissioned. The NDA is currently exploring options for managing ILW (Ref. 26.7).

- The LLW buffer store, designed for half-height International Organisation for Standardisation [1] (HHISO) containers that have been filled in the radwaste building. In the event that the national LLW repository (LLWR) is temporarily unable to accept disposals, the combined capacity for HHISO containers in the buffer store and the radwaste building can accommodate up to 2 years' arisings of LLW, including arisings from possible abnormal events. Note that the HHISO containers stored within the radwaste building are those being filled. No full HHISO containers will be stored in the radwaste building.

26.3 STATEMENT OF THE SAFETY CASE

Before considering the detailed strategy and operations, it is helpful to consider the preliminary safety statement. The summary in this section has been taken from the UK AP1000 Radwaste Preliminary Safety Statement[2] (Ref. 26.8, Sections 8 and 9). Although the full set of risks to be considered include both the longer-term risks posed by the radioactive wastes and discharges as well as the immediate risks that arise from operating the radioactive waste management facilities, this section concentrates on the immediate risks. The longer-term risks are covered in more detail by the sections dealing with disposability, particularly Section 26.8.6.

The following sections present a summary of the acceptability of the treatment of AP1000 plant radwaste by comparison with appropriate safety criteria.

---

1. Formally International Organisation for Standardisation (ISO); these containers are universally known as ISO containers.
2. The hazard and operability study (HAZOP) 1 study report (Ref 26.46) and the Preliminary Safety Statement (Ref 26.8) were performed on a preliminary design of the waste processing equipment in the radwaste building. Since these reviews took place, a number of design improvements have been made to the radwaste building. These design improvements have had the effect of improving the safety within the radwaste buildings and therefore the conclusions from these reviews are still valid for conservative purposes of GDA. However, they will need to be readdressed at the site-specific stage.

26.3.1 Normal Operations

26.3.1.1 Compliance with Criteria (Normal Operations)

It is expected that the operations for the treatment of AP1000 plant radwaste will not result in a significant dose uptake to operators. The radiation levels within the auxiliary building where radwaste processing will take place and the ILW store are expected to be low, on the order of 0.5 μSv/hr (0.05 mrem/hr) or less.

The estimated dose rate for the radwaste building is 2.5 to 7.5 μSv/hr (0.25 to 0.75 mrem/hr). The estimated contact dose rate for the MEU is 1 μSv/hr (0.1 mrem/hr) (Ref. 26.9, Section 3.9.2.3). The contact dose rate of the ILW store external wall is designed to be 0.5 μSv/hr (0.05mrem/hr).

The expected dose uptake during normal operations will be confirmed upon completion of the dose budget assessment. Compliance with normal operations criteria cannot be confirmed until these are available. The detailed plan for showing compliance with normal operation criteria will be part of site licensing.

26.3.1.2 As Low As Reasonably Practicable Demonstration (Normal Operations)

The following measures will be implemented to ensure that the predicted dose uptake to operators and members of the public is as low as reasonably practicable (ALARP):

- The MEU will provide shielding and will be operated remotely to minimise the potential operator dose uptake during encapsulation operations.
- The MEU, overpack, and ILW store will all be provided with interlocks to ensure that appropriate shielding is in place during package import/export operations.
- HVAC systems will be provided for the auxiliary building, radwaste treatment facility, the mobile encapsulation plant, and the ILW store to minimise the potential for inhalation of airborne contamination.
- Operations within the facilities will be undertaken in accordance with approved procedures, which will identify any specific precautions required during the operations to minimise the dose uptake.
- Awareness of potential hazards by administrative, operational and supervisory staff will be a first line of defence against unnecessary radiation exposure and will be ensured through appropriate training of staff.
- Analysis of abnormal behaviour and incidents on the plant will be undertaken to anticipate and prevent hazards and to confirm that the reliability of plant items is acceptable.
- If any equipment, component or system failure is revealed, the risk of undertaking a repair compared with its remaining in the failed state will be assessed and a decision will then be made on whether or not the failure requires immediate repair.
- Detection systems will be employed within the auxiliary building, radwaste building and ILW store to alert operators to high dose rates so that the operators can undertake immediate evacuation before any significant dose uptake occurs.

26.3.2 Accident Conditions

26.3.2.1 Compliance with Criteria (Accident Conditions)

A detailed hazard identification process was undertaken in support of the treatment of AP1000 plant radwaste and is presented in Chapter 9. The hazard identification process identified numerous fault sequences associated with the treatment of AP1000 plant radwaste. Owing to the preliminary nature of the design of the solid radwaste treatment, a deterministic assessment rather than a probabilistic safety assessment was used to assess the hazards.

All of the identified fault sequences had adequate safeguards.

26.3.2.2 As Low As Reasonably Practicable (Accident Conditions)

The hazard assessment and the fault schedule presented in Chapter 9 give an assessment of the safeguard provision against all credible design basis hazards for the treatment of AP1000 plant radwaste. However, one area that the hazard assessment and fault schedule do not address is the space in which the radwaste operations are to take place.

Part of the reason that this has not been assessed to date is that systems related to solid radwaste management, for example, for treatment, storage, and transportation, could be shared at the utilities option. This is already the case for several existing pressurised water reactors (PWRs). Better utilisation of space could be implemented by dedicating each of the multiple radwaste buildings to treating specific types of waste generated across the site. For example, one radwaste building could include equipment to treat site compactable waste, another to package site metallic waste, and so forth. Alternatively, a separate building could be constructed for treating site solid radwaste. Also, sharing of facilities would allow for operating experience (for example, the same workers) to be shared across the AP1000 plants on a site.

As a result, it has been determined that it would be most appropriate to address the hazard of space available for the radwaste treatment and processing operations, ensuring that ALARP criteria are implemented during detailed design, once the utility has decided upon its preferred method. The UK regulators have agreed with this approach.

It is therefore considered that the risks associated with the treatment of AP1000 plant radwaste have been reduced to ALARP criteria so far as is reasonable to date and will be considered further during detailed design.

26.3.2.3 Methodology Review

The methods to be employed in the treatment of radwaste arising from the AP1000 plant need to be in accordance with current standards, and the methodology needs to be in accordance with best practices in the nuclear industry.

The preliminary safety statement for solid radwaste treatment was developed using up-to-date standard techniques, including a comprehensive hazard identification study in the form of a hazard and operability studies (HAZOP). This was subsequently developed into a thorough hazard listing, and the accident scenarios of significance were carried forward into a fault schedule, where they were quantified.

Each fault in the fault schedule was compared with nuclear industry approved benchmark criteria, which were derived from the accident dose criteria appropriate to the preliminary safety statement. Any shortfalls were considered by the ALARP assessment.

Applying ALARP to reduce normal operation doses and accident risks to as low as reasonably practicable is in line with the most recent current standard industry guidance.

The safety statement in the Radwaste Preliminary Safety Report (Ref. 26.8) demonstrated, in line with current standards, the following:

- There would be sufficient control at all times of hazards.
- All reasonable steps would be taken to eliminate or mitigate hazards, irrespective of time-at-risk arguments.
- Contingency plans had been developed to deal with fault conditions should they deteriorate further.

These methods, used to produce the safety statement, are considered to be in accordance with current standards (Ref. 26.8, Section 8).

26.4 RADIOACTIVE WASTE MANAGEMENT STRATEGY

This section provides a brief overview of the purpose and content of the IWS. To save later repetition, the section includes comments on generation, minimisation and accumulation that relate to all three types of waste (gas, liquid, and solid).

26.4.1 Purpose and Future Development of the Integrated Waste Strategy

The IWS described in Reference 26.2 is compatible with both government policy and with the other strategies for the site. The strategic aim is to reduce the risks and environmental impact arising from AP1000 plant operations by minimising the amount of waste produced and accumulated, and ensuring that radioactive waste is put into a passively safe state. The IWS considers both radioactive and nonradioactive waste.

The IWS is based on the expected waste and spent fuel generation and management practices throughout the operation and decommissioning of an AP1000 plant. It builds on the Environment Report (Ref. 26.1), which lists all the radioactive and nonradioactive wastes that are expected to arise during operation and decommissioning, as well as the datasheets for radioactive waste (Ref. 26.10), calculations of the quantities of waste arisings (Ref. 26.11) and the outline of radioactive waste management and disposal (Ref. 26.9). The IWS applies to the generic site and is to be used in the GDA; it identifies the strategic issues relating to waste management and guides the development of waste management plans. During further site-specific analysis, the utility operator of an AP1000 power plant may develop its own strategy, which would change or replace the submitted IWS. This would for example include construction wastes, which are not included in the current IWS.

The IWS feeds into the integrated management system (IMS) for the facility. The IMS, which covers all activities on the site and not just waste management, will include environmental and safety management features and will be accredited to the UK implementation of international standards such as ISO 9001 and ISO 14001. Further details of the requirement for integration of the IWS into an IMS are provided in the AP1000 Integrated Waste Strategy (Ref. 26.2, Section 3.4).

26.4.2 Overview of the Integrated Waste Strategy

The purpose of this section is to demonstrate that the IWS contains all the appropriate information. The various waste management systems are described more fully in the later sections of this chapter.

- The IWS (Ref. 26.2, Section 2.1) includes a description of the generic AP1000 design site.

- The key waste facilities for operation, namely the liquid radwaste system (WLS), gaseous radwaste system (WGS), and solid radwaste system (WSS) are described in the IWS (Ref. 26.2, Section 2.2). The same section of the IWS also includes a description of the management and facilities for spent fuel and a description of the system to control the chemistry and volume of the reactor coolant.

- The high-level objectives for a specific AP1000 design site will be developed by the utility operators. Typically they will address the minimisation of operational hazards from all site operations, the safe and cost effective storage, handling, and treatment of wastes from all aspects of plant operation, and the eventual delicensing of the site following decommissioning and remediation (Ref. 26.2, Section 2.2.11).

- The assumed final end point for a nuclear site (Ref. 26.2, Section 2.2.10) is that the reactor and associated facilities will be decommissioned and dismantled, and the site at least restored to a standard that is suitable for final end use. The spent fuel and ILW storage facilities could be retained until the national HLW and ILW repositories become available, but once the spent fuel and ILW had been transferred to the national repository the onsite storage facilities would be decommissioned and dismantled. The final site end point demonstrated achievable in Chapter 27.4.2 is a fully cleared site suitable for delicensing.

- Waste management policy, including references to UK government waste management policies for England, Scotland, and Wales and Legislative Requirements and Regulatory Expectations, is covered in the IWS (Ref. 26.2, Section 3). Section 3.1.1 presents the proposed waste management hierarchy. The principles (avoidance, minimisation, reducing/recycling, and abatement) that underpin the IWS for the AP1000 design are consistent with UK waste management policy. Figure 3-3 from this section is reproduced as Figure 26-2; it shows the nuclear BAT management factors for optimisation of waste releases.

- An IMS builds on the IWS and can be fully developed only for a specific site (Ref. 26.2, Section 3.3). The IMS will be developed according to the features of the waste management organisation. It will incorporate environmental and safety management features and will identify any research and technology requirements relating to waste management.

- The IWS (Ref. 26.2, Section 4) describes how the strategy was formulated. The section includes the methodology for the strategic options study (Ref. 26.2, Section 4.2): i.e., how options were selected (via dialogue with prospective site licencees, in order to capture the benefits of their experience in operating similar plants). Joint environmental and safety assessments were used to achieve an overall balance between environmental and safety matters. Table 26-1 lists various assumptions and exclusions. The site end point will be site-specific and may be subject to future consultation and the requirements of future UK government policy, but Section 4.5 presents a set of generic working

assumptions. Section 4.7 covers the stakeholder engagement process that is based on independence, transparency, openness, clarity, and accessibility.

- The overview of site waste strategy, which includes a timeline showing what will happen and when, is provided in the IWS (Ref. 26.2, Section 5). The Environment Report (Ref. 26.1, Figures 3.5-1 and 3.5-2) (reproduced in this chapter as Figure 26-3 and Figure 26-4) provides an overview of the AP1000 design solid waste management strategy. The approach is flexible: for example, interim storage facilities for LLW (Refs. 26.12 and 26.13) have been designed to accommodate two years of LLW arisings, in case the route to the LLWR is temporarily unavailable. The gaseous and liquid radwaste systems are shown in Figure 26-5 and Figure 26-6.

- The IWS itself constitutes Section 6 (Ref. 26.2). This includes information that can be used by the utilities to construct RWMCs: details of strategies for managing nonradioactive solid, liquid and gaseous wastes; descriptions of strategies for managing radioactive liquid and gaseous wastes, solid LLW, ILW, and spent fuel; and a description of the strategy for decommissioning waste. In addition, Evidence Reports for RWMCs have been prepared to cover ILW (Ref. 26.3) and HLW (Ref. 26.4). These reports will develop as the design moves into the site-specific phase and will continue to be enhanced throughout the operational lifetime of the new build plant and beyond.

26.4.3 Waste Generation

The Westinghouse waste management plan comprises the systematic identification of the solid waste and gaseous and liquid discharges generated over the operational and decommissioning period of the AP1000 plant (Ref. 26.1, Chapter 3). So far, solid waste inventory estimates have been developed based on operational experience with existing plants. This ensures that the strategy is realistic and is able to cope with the activities and volumes of waste that are expected to be generated (Ref. 26.1, Chapter 3). The annual releases of radioactive air emissions and effluents are based on proprietary calculations determined from the revised gaseous and liquid effluents computer programme (GALE) code (Ref. 26.1, Chapter 3).

Specific information on the generation of gaseous, liquid and solid wastes is included below, in Sections 26.6, 26.7, and 26.8, respectively.

26.4.4 Minimisation of Wastes at Source

During its operating life and decommissioning, an AP1000 reactor will generate solid waste, liquid discharges, and gaseous emissions. Minimising the amount of waste produced at source has two significant safety benefits:

- The final quantity of waste will be reduced, hence reducing the consequences of operating the AP1000 reactor.

- The reduced quantity of waste implies less waste-processing, which reduces operator dose and hence improves safety.

To assist in understanding the waste minimisation procedures used in the AP1000 facility, Westinghouse has produced the UK AP1000 Environment Report (Ref. 26.1) and the AP1000 Nuclear Power Plant BAT Assessment (Ref. 26.5). These documents explain how the quantity and activity of radioactive waste, and its accumulation on the site, are minimised.

Since the start of the AP1000 design process Westinghouse has considered safety, environmental protection and waste minimisation, through concepts comparable to the UK regulatory principles of ALARP, BAT, and the waste management hierarchy, including waste minimisation at source. Efforts were made to gather information from other similar designs, processes and facilities, along with the experience of station operators (Ref. 26.9, Section 2.2.3). This learning from experience (LFE) concept can be found in the Radwaste Treatment Options Study Report (Ref. 26.14, Appendix 3). The Environment Report (Ref. 26.1, Sections 2.3 and 3.5.4) consolidates and summarises the development, layout, and design features of the AP1000 plant, incorporating minimisation and abatement techniques employed for radioactive and nonradioactive wastes. Some examples of ALARP, BAT, and waste management hierarchy principles are given below.

- Figure 26-7 illustrates that the AP1000 design reduces the amount of valves, pipes, and other components compared to previous generations of PWRs. Hence less waste will be generated during maintenance activities (repair and replacement) and decommissioning.

- The AP1000 reactor coolant pump shaft seals, which are a potential source of excessive leakage of reactor coolant, are eliminated altogether through the use of sealless pumps.

- During the removal of core decay heat following an accident, the reactor coolant remains within containment; only decay heat energy is transferred out of containment.

- The Environment Report (Ref. 26.1, Section 3.2) describes waste-minimisation at source measures such as limiting the level of cobalt in reactor internal structures, which reduces the amount of Co-60 produced by activation reactions.

Sections 26.6, 26.7, and 26.8, which describe the gas, liquid, and solid waste systems, contain further information on waste minimisation.

26.4.5 Use of Best Available Techniques

Application of BAT to waste management requires that all reasonable opportunities should be taken for waste minimisation, reuse, and recycling. Where possible, wastes should be declassified by segregation and cleaning to free-release standards.

The descriptions below of the various waste management systems explain the segregation processes and refer to particular instances of BAT in the proposed AP1000 design. One clear use of BAT is the AP1000 design philosophy to minimise waste, as described in Section 26.4.4.

One of the criteria in the engineering process undertaken for the proposed AP1000 generic design solid waste management facilities was that the plant design should be ergonomically arranged for ease of transfer to ensure that the solid waste management system collects and stores radioactive wastes within shielding to maintain radiation exposure to plant operation and maintenance personnel ALARP (Ref. 26.9, Section 2.2.1).

The AP1000 design IWS is consistent with the waste hierarchy shown below, as well as the key BAT management factors for optimisation of releases from nuclear facilities shown in Figure 26-2. These factors correlate closely as follows:

Waste Hierarchy	BAT Waste Management Factor
Avoid	Use low-waste technology
Minimise	Use low-waste technology Efficient use of resources Reduce emissions
Reduce/Recycle	Use low-waste technology Use fewer hazardous substances
Abatement	Reduce emissions

26.4.5.1 Best Available Techniques Assessment for Key Radionuclides

The formation and abatement of key radionuclides has been assessed by Westinghouse for the AP1000 design using forms prepared for this analysis. The BAT forms include the source of the radioactivity, the pathway to the environment from the source, normal and maximum emissions as predicted by Westinghouse, and comparison with emissions from other nuclear power stations (Ref. 26.5, Appendix A).

Specific instances of BAT in the systems for processing gaseous, liquid, and solid wastes are included in the appropriate sections below.

26.4.6 Minimisation of Accumulation of Radioactive Waste

The final element of the AP1000 design waste strategy is to minimise the accumulation of radioactive waste at the reactor site. This means that radioactive waste should either be discharged, as permitted by the discharge limits, or shipped to suitable LLW, ILW, or HLW repositories as soon as possible. Minimising the inventory of waste on the site has similar safety benefits to minimising the amount arising: the reduced quantity of radwaste on the site reduces the radiological risks that arise from the site.

Westinghouse's waste management strategy requires LLW to be shipped for disposal routinely according to schedules agreed to by the plant operator and the NDA (Ref. 26.1, Section 3.5.1.4, and Ref. 26.15). A preliminary application has been made to the LLWR to confirm their acceptance of LLW from an AP1000 reactor. The Acceptance in Principle (D1) forms obtained from the LLWR are presented in UK AP1000 D1 Form Submission (Ref. 26.16) and contain activity estimates based on solid waste activity calculations (Ref. 26.17).

In the cases of ILW and spent fuel, it is expected that AP1000 plant operators will transport the waste offsite as soon as national repositories are available to accept these wastes (Ref. 26.2, Section 3.1.3). The NDA disposability assessment (Ref. 26.15) concluded that, when compared with legacy wastes, there are no new issues that challenge the fundamental disposability of the wastes expected to arise from operation of the AP1000 plant.

26.5 GENERAL INFORMATION ON DISCHARGES OF RADIOACTIVITY TO AIR AND WATER

Before considering the gaseous and liquid radwaste systems separately, it is helpful to present some general information on the proposed discharges of radioactivity to air and water.

The existing methodology used in the GALE code for calculating gaseous radwaste discharges was benchmarked against operating plant data. When significant differences were noted, the algorithms or input parameters for the GALE code were adjusted to obtain reasonable agreement. The representative data for the AP1000 plant were calculated by normalising 2001 to 2004 US plant data to plant power level. The base plant data generally reflect waste management techniques and philosophies that have been incorporated in the AP1000 design. However, using the 2001 to 2004 data is expected to result in conservative values for the AP1000 design because a number of recent AP1000 design improvements are expected to give reduced activity releases. For example:

- Fewer valves and components will result in fewer leakage pathways.
- Reactor coolant pumps without seals result in less leakage into containment.

From the representative annual emissions given here in Table 26-2 and Table 26-3 worst-case annual discharges and indicative discharge limits have been calculated. The calculation method follows Environment Agency (EA) guidelines; the GDA limits have been proposed on the basis of the expected highest “rolling 12-month” discharges within the reactor cycle.

The expected release rates of airborne radioiodine, noble gases, H-3, C-14, Ar-41, I-131, and beta particulates, liquid discharges of H-3, C-14 and “all isotopes without other limits” vary month by month through the reactor cycle. The maximum release rates (in TBq/y) are approximately two-thirds of the proposed limits for radioactive discharges (Ref. 26.18, Table 7-1). The margin provides some contingency to cope with operational occurrences. The proposed limits are reproduced here in Table 26-4; the actual discharge authorisations will be set by the EA and will be site-specific. The report Generic Design Measurement and Assessment of Discharges (Ref. 26.19) provides background detail on how discharges will be measured and assessed.

The proposed monitoring systems for gaseous and liquid discharges are broadly equivalent to monitoring systems currently used in operating UK nuclear power plants. This provides confidence that the AP1000 design monitoring techniques are in line with current best practices in the UK. During the detailed AP1000 design, consideration will be given to any future EA certification requirements for the monitoring of radioactive discharges. This may include sampling and monitoring equipment, qualifications of personnel involved in monitoring, and laboratory accreditation. None of the monitoring requirements require new technology or measurement techniques. This provides confidence that the AP1000 design monitoring techniques can be designed and engineered to demonstrate BAT and meet applicable UK requirements (Ref. 26.1, Section 6.2.1).

26.6 TREATMENT OF RADIOACTIVE AND POTENTIALLY RADIOACTIVE GASES

The strategy for dealing with radioactive gases is the following:

- To contain them as they arise

- To reduce the activity to ALARP and certainly to below the agreed discharge limits, either by decay or by removing the longer-lived radionuclides

- To hold the gases for sufficient time to measure the activity level and demonstrate that they comply with the limits

- Once they have been demonstrated to comply with the limits, to release them to the atmosphere

Avoiding uncontrolled releases and reducing the activity levels in the controlled discharges will reduce the risks to the public.

Starting with how radioactive gases arise in the AP1000 system, this section describes WGS for handling the gases and the ventilation systems for the various buildings. It also specifies the release points and the tables in the Environment Report (Ref. 26.1) that provide exhaustive lists of the gaseous emissions to air, by source, by radionuclide, and by month in the reactor cycle.

Each of the potentially radioactive gaseous discharges is radiologically monitored before being released (Ref. 26.1, Section 3.3).

26.6.1 Sources of Radioactive Gases

During reactor operation, radioactive isotopes of iodine and the noble gases xenon and krypton are created as fission products. All reasonable steps are taken to minimise the failure of the fuel rod cladding and thus minimise the release of radioactive fission products into the coolant (Section 22.1). A defect in the fuel cladding would allow a portion of these radionuclides to be released to the reactor coolant . Hence leakage of reactor coolant may result in noble gases being released to the containment atmosphere.

The principal point at which radioactive species are released from the coolant to the gas phase is the chemical and volume control system (CVS), which controls the chemistry of the reactor coolant. As well as dissolved fission products, tritium produced by activation reactions can accumulate in the coolant. The WLS degasifier removes gases from the coolant and feeds them to the WGS.

Within the containment building, naturally occurring Ar-40 in the atmosphere may be activated to form radioactive Ar-41.

26.6.2 Gaseous Radwaste Treatment System

The WGS is designed to perform the following major functions on an intermittent basis (approximately 70 hours per year):

- Collecting radioactive or hydrogen-bearing gaseous wastes

- Processing and discharging the waste gas while keeping offsite releases of radioactivity within acceptable limits

The AP1000 design WGS is a once-through, ambient temperature, activated-carbon delay system. The radioactive gases entering the system are carried by hydrogen and/or nitrogen gas. This gas stream passes through:

- The gas cooler, where it is cooled to about 4ºC (39ºF) by the chilled water system

- The moisture separator, which collects condensed water vapour (including condensed tritiated water vapour) from the cooled gas and discharges it to the WLS

- An activated-carbon-filled guard bed, which protects the delay beds from abnormal moisture carryover or chemical contaminants

- Two activated-carbon-filled delay beds in series where xenon and krypton are delayed by a dynamic adsorption process; radioactive decay of the fission gases during the delay period significantly reduces the radioactivity of the gas flow leaving the system

- A radiation monitor

The gases are then discharged to the ventilation exhaust duct.

The minimum calculated holdup times are 38.6 days for xenon and 2.2 days for krypton (Ref. 26.1, Section 3.3).

Each of the two delay beds is designed to provide the full required system capacity under design basis conditions. During normal operation, a single bed provides adequate performance. This provides operational flexibility to permit continued operation of the WGS in the event of operational upset in the system that requires isolation of one bed.

The use of a gas cooler, a moisture separator, a guard bed, and delay beds is a common gas treatment system throughout the nuclear power industry.

In the course of demonstrating that this system uses BAT, the BAT assessment (Ref. 26.5, Section 4.3.2.1) provides some further details of equipment and processes.

26.6.3 Ventilation and Filtration Systems

This section gives brief details of the ventilation and air-filtration systems in the AP1000 design that can handle radioactivity. It excludes nonradioactive ventilation systems that exhaust to the atmosphere such as the diesel generator building heating and ventilation system (Ref. 26.5, Table 4.1). This section is based on the Environment Report (Ref. 26.1, Sections 3.3.2 to 3.3.7).

26.6.3.1 Containment Air Filtration System

The containment air filtration system (VFS) is described in Chapter 23 Containment and Nuclear Ventilation Systems, Section 23.3.

The VFS serves the containment, the fuel-handling area, and the other radiologically controlled areas of the auxiliary and annex buildings, except for the hot machine shop and health physics areas, which are served by the Health Physics and Hot Machine Shop Heating, Ventilation, and Air Conditioning System (VHS) described in Section 23.10.

26.6.3.2 Radiologically Controlled Area Ventilation System

The Radiologically Controlled Area Ventilation System (VAS) serves the fuel-handling area of the auxiliary building, and the radiologically controlled portions of the auxiliary and annex buildings, except for the health physics and hot machine shop areas which are provided with a separate ventilation system. The VAS is described in Section 23.8.

26.6.3.3 Condenser Air Removal System

The condenser collects any inward leaks of air and any noncondensable gases contained in the turbine exhaust steam. The condenser air removal system (CMS) removes these gases from the steam side of the three main condenser shells and exhausts them into the atmosphere via the condenser air removal stack.

During normal operation and shutdown, the main condenser has no significant inventory of radioactive contaminants. The noncondensable gases and vapour mixture are not normally radioactive and are discharged to the atmosphere. However, it is possible for the mixture to become contaminated following a steam generator (SG) tube leak. Radiation monitors associated with the steam generator blowdown system (BDS), SG system (SGS) (main steam), and the condenser air removal system determine whether the secondary side is radioactively contaminated. Unacceptable levels of radiation trigger corrective action.

26.6.3.4 Turbine Building Ventilation System

The turbine building ventilation system (VTS) is described in Section 23.13. The system maintains acceptable air temperatures in the turbine building for equipment operation and for personnel working in the building.

26.6.3.5 Radwaste Building Ventilation and Filtration System

The Radwaste Building HVAC System (VRS) system is described in detail in Section 23.9. Air will be extracted from the radwaste building equipment via low-level grilles, conveyed through high-integrity ductwork to high-efficiency particulate air (HEPA) filters and discharged to the main plant exhaust stack. Dedicated HEPA-filtered branches will extract air from the waste-sorting cabinets.

26.6.3.6 Intermediate-Level Waste Store Ventilation and Filtration

The ILW store will be equipped with two HEPA filters in series to remove radioactive particulates present in the ILW building atmosphere.

The stack monitoring system for the ILW store will provide continuous monitoring of stack discharges to atmosphere. Stack monitoring system outputs and signals will be displayed in the central control room (Ref. 26.9, Section 3.7.17.1). The stack monitoring system shall be in accordance with British Standard (BS) 5243 (Ref. 26.21).

26.6.4 Emissions to Air

26.6.4.1 Release Points

Under normal operating conditions, the main plant vent and ILW ventilation stack are the only potential sources of gaseous radioactive emissions. The other emission points act as sources of radioactive air emissions only in abnormal conditions such as a loss of coolant accident or primary-secondary tube leak failure. This system is described in detail in Chapter 23.

The main plant vent is located on the side of the containment building. The Environment Report (Ref. 26.1, Table 3.3-3) shows its dimensions, flow rates, temperature, and stack height.

26.6.4.2 Expected Emissions

Table 26-5 shows expected monthly discharges through the fuel cycle. Table 26-2 gives representative 12-month discharges to air based on months 7 to 18 of the fuel cycle, worst-case annual discharges (taking into account plant ageing and other factors), and calculated annual discharge limits for radioiodines, noble gases and a number of other radionuclides.

The following tables from the Environment Report (Ref. 26.1) provides further comprehensive details of emissions to air, by source, by radionuclide and by month in the reactor cycle.

Table 3.3-6	Expected annual release per building or area of radioiodines to the atmosphere, averaged over the 18-month fuel cycle
Table 3.3-7	Expected annual release per building or area of radioactive noble gases, tritium, and C-14 to the atmosphere, averaged over the 18-month fuel cycle
Table 3.3-8	Expected annual release per building or area of radioactive particulates to the atmosphere, averaged over the 18-month fuel cycle
Table 3.3-11 to 3.3-22	Detailed monthly discharges in gas per building or area of radioiodines, noble gases, H-3, C-14, Ar-41, Co-60, Kr-85, Sr-90, I-131, Xe-133, Cs-137, and other particulates

Table 26-6 compares the annual gaseous discharges from the AP1000 design with the UK PWR Sizewell B and with four Westinghouse PWRs in the US. The table also includes liquid discharges (see Section 26.7.5). Although the balance between gaseous and liquid discharges varies from plant to plant, the total discharge per gigawatt of electrical output from the generic AP1000 design is significantly less than that from Sizewell B and less than or approximately equal to those from the other Westinghouse PWRs.

26.6.5 Best Available Techniques for Gaseous Radwaste Treatment

The BAT for gaseous treatment (Ref. 26.5, Section 4.3.2) is summarised here for four systems: the WGS, VRS, VFS, and VAS.

26.6.5.1 Best Available Techniques for Gaseous Radwaste System

The carbon delay beds in the WGS have been designed as a folded serpentine configuration. Although this configuration may have larger total void volumes than a straight configuration, long void channels are less likely to form in the carbon and hence contact between the gas and solid is increased. The serpentine configuration also minimises the space requirements. The number of legs in the beds has been chosen to optimise the balance between reducing discharges, which is favoured by increasing the number of legs, and minimising solid radioactive waste arisings, which is favoured by reducing the number of legs (Ref. 26.1, Section 3.3.5.1).

26.6.5.2 Best Available Techniques for Systems

BAT analyses for ventilation and filtration systems are discussed in Chapter 23, Appendix 1.

26.7 LIQUID RADWASTE SYSTEM

The strategy for dealing with radioactive liquids at a coastal site is to do the following:

- Contain the liquids as they arise
- Reduce the activity to ALARP and certainly to below the agreed discharge limits, e.g., by filtration or ion exchange
- Monitor the activity level and demonstrate that it complies with the agreed limits
- Release the effluents to sea

The WLS is designed to control, collect, process, handle, store, and dispose of liquid radwaste generated as the result of normal operation, including anticipated operational occurrences.

This section describes the WLS, how it operates and how it represents the application of BAT. It is based on the Environment Report (Ref. 26.1, Section 3.4).

26.7.1 Sources of Liquid Radwaste

There are several possible sources of liquid radwaste, as shown below (Ref. 26.1, Section 3.4.1). Table 26-7 shows the volumes that are expected to arise, per day (normal and maximum) and over the life of the plant.

Reactor Coolant System Effluents

The effluent subsystem receives borated and hydrogen-bearing liquid from two sources: the reactor coolant drain tank (RCDT) and the CVS. The RCDT collects leakage and drainage from various primary systems and components inside containment. Effluent from the CVS is produced mainly as a result of reactor coolant system (RCS) heatup, boron concentration changes, and RCS level reduction for refuelling. The RCS effluents contain dilute boric acid at concentrations up to 2700 ppm. This borated water is the principal input in terms of volume and activity.

Floor Drains and Other Wastes with High Suspended Solids

Floor drains and other wastes are collected by various building floor drains and sumps and routed to one of two waste holdup tanks each with a volume of 57 m^3 (2013 ft^3). They potentially have high suspended solid contents.

Detergent Wastes

Detergent wastes coming from the plant hot sinks and showers as well as some cleanup and decontamination processes are routed to the chemical waste tank, which has a volume of 29 m^3 (1024 ft^3).. Detergent wastes are typically high in dissolved solids but very low in radioactivity.

Chemical Wastes	Chemical wastes collected from the laboratory and other relatively small-volume sources are collected in the chemical waste tank where they may, if appropriate, be combined with detergent wastes. They may comprise mixed nonhazardous, hazardous, and radwastes or other radwastes with high dissolved-solids content. These wastes are generated at a low rate.
SG Blowdown	SG blowdown is normally nonradioactive and is accommodated within the BDS. However, if SG tube leakage results in significant levels of radioactivity in the SG blowdown stream, this stream is redirected to the WLS for treatment before release. In this event, one of the waste holdup tanks is drained to prepare it for blowdown processing.

26.7.2 Liquid Radwaste Treatment System

Figure 26-6 shows the WLS. The liquid radwaste is collected in the following five tank systems:

- Reactor Coolant Drain Tank
- Effluent holdup tanks
- Waste holdup tanks
- Chemical waste tanks
- Monitor tanks (treated liquid radwaste)

Effluent is radiologically monitored before being discharged (Ref. 26.1, Section 6.2.1).

26.7.2.1 Degasification of Reactor Coolant System Effluent

The RCS effluents, cooled if necessary, pass to the vacuum degasifier to remove hydrogen and dissolved radioactive gases before storage in the three effluent holdup tanks. The stripped gases are vented to the WGS.

The contents of the effluent holdup tanks may be:

- Recirculated and sampled
- Recycled through the degasifier for further gas stripping
- Returned to the RCS via the CVS makeup pumps
- Directed to the monitor tanks for discharge
- Passed through the filtration and ion exchange treatment system

26.7.2.2 Pre-Filtration

The contents of the effluent holdup tanks and waste holdup tanks are normally passed through a treatment system comprising an upstream filter followed by four ion exchange resin vessels in series and a downstream filter.

A pre-filter is provided to collect particulate matter in the effluent stream before ion exchange. The pre-filter is particularly important for removal of solids present in effluent collected from the floor drains, which are directed to the waste holdup tanks.

26.7.2.3 Deep Bed Filtration

The deep bed filter is a stainless steel vessel containing a layered bed of activated charcoal above a zeolite resin. The activated charcoal provides an adsorption media for removal of trace organics and provides protection for the ion exchange resins from contamination with oil from the floor drain wastes. Moderate amounts of other chemical wastes can also be routed through this vessel.

The top layer of activated charcoal collects particulates and, being less dense than the zeolite, can be removed without disturbing the underlying zeolite bed. This minimises the production of solid waste. The lower layer of the deep bed filter is clinoptilolite zeolite, which possesses an affinity for caesium.

The decontamination factors for deep bed filtration (100 for both caesium and rubidium) are included in Table 26-8 which collects together the factors for filtration and ion exchange.

26.7.2.4 Ion Exchange

Four ion exchange beds are provided following the deep bed filter. The ion exchange vessels are stainless steel, vertical, cylindrical pressure vessels with inlet and outlet process nozzles plus connections for resin addition, sluicing, and draining. The process outlet and flush water outlet connections are equipped with resin retention screens designed to minimise pressure drop. The design flow provides an adequate margin for processing a surge in the generation rate of this waste.

The ion exchange media will be selected by the plant operator to optimise system performance according to prevailing plant conditions. Typically, the first bed will contain a cation exchange resin, and the second two beds will contain mixed bed resins. Any of these vessels can be manually bypassed and the order of the last two can be interchanged, so as to provide complete usage of the ion exchange resin.

The ion exchange beds operate in the borated saturated mode. This means that the boric acid present in the reactor coolant effluent passes through the ion exchange beds without reduction in concentration.

The cation filter removes caesium, rubidium and other cations (with assumed decontamination factors of 10) but not iodine; the mixed waste ion exchangers have decontamination factors of 10 to 100 for iodine and 2 to 100 for other ions. These factors are compiled in Table 26-8.

26.7.2.5 After Filter

This filter is provided downstream of the ion exchangers to collect particulate matter such as resin fines. The unit is constructed of stainless steel and has disposable filter cartridges.

26.7.2.6 Monitor Tanks

Treated effluent is discharged to the six monitor tanks located in the radwaste building. Information on the design of the monitor tanks and their secondary containment can be found in Tables 3.4-2 and 3.4-3 of the Environment Report (26.1).

The total tank volume allows up to approximately 42 days' storage during normal power operations. The storage period is reduced during the short periods associated with higher discharge rates resulting from boron dilution near the end of core life and during RCS heat-up following refuelling. The worst case for the storage period is a few days. This would result from the unusual case of a shut-down shortly after an outage with little time between the first outage and restart. As the time between the first outage and the second restart increases, the storage time increases.

The release of treated liquid waste from any monitor tank to the environment is permitted only when sampling of the subject tank's contents indicates that such a release is permissible. If the effluent does not meet the permissible limits, it can be returned to a waste holdup tank or recirculated directly through the filters and ion exchangers.

A radiation monitor is located on the common discharge line downstream of the WLS monitor tanks. These radiation monitors will provide a signal to terminate liquid radwaste releases if the discharge concentration in the line exceeds a predetermined set point.

Effluent meeting discharge limits for radioactivity is pumped from the monitor tanks in a controlled fashion to the cooling water return from the circulating water system (CWS). The cooling water stream provides a substantial dilution of the discharged effluent before release to the environment.

26.7.2.7 Potential to Bypass Ion Exchange

Routine bypass of the WLS ion exchangers is not expected. However, the WLS is designed to be flexible and capable of handling a relatively wide range of inputs, including both high-grade water (from reactor effluents) and low-grade water (floor drains).

Each collection tank (effluent holdup tank, waste holdup tank) typically will be stirred and sampled prior to processing. Analysis of the sample from a specific batch of liquid will allow the operator to determine the optimum processing technique.

When processing a batch of reactor effluents, all WLS ion exchangers and filters are expected to be in service. However, when processing effluent from floor drains from the waste holdup tanks it is possible that some batches may be very low in radioactivity. For example, actuation of the fire water system in the radiologically controlled area of the plant could lead to a significant volume of uncontaminated fire water being collected by the WLS. In this case it may be acceptable and preferable to bypass one or more of the WLS ion exchangers in order to maximise the life of the media, thereby minimising solid radwaste arisings and associated occupational radiation exposure.

In all cases, processed water downstream of the WLS ion exchanger or filter train is collected in a monitor tank and is sampled prior to discharge to the environment.

26.7.2.8 Use of Mobile and Temporary Equipment

The WLS is designed to handle most liquid effluents and other expected events using installed equipment. However, for events occurring at a very low frequency, or producing effluents not compatible with the installed equipment, temporary equipment may be brought into the truck bays of the mobile treatment facility in the radwaste building.

Connections are provided to and from various locations in the WLS to these mobile equipment connections. This allows the mobile equipment to be used in series with installed equipment, as an alternative to it with the treated liquids returned to the WLS, or as an ultimate disposal point for liquids that are to be removed from the plant site for disposal elsewhere.

The radwaste building truck bays and lay-down space for mobile equipment, along with the flexibility of the numerous piping connections to the WLS, allow the plant operator to incorporate mobile equipment in an integrated fashion.

The connection of temporary lines between permanent plant radwaste storage tanks and mobile radwaste receptors (e.g., radwaste containers or mobile radwaste treatment systems) is a very common and well-understood process in operating nuclear power plants.

A dewatering return line, identical to the resin supply line, allows for dewatering equipment also to be tested prior to resin-handling operations, to ensure that process equipment has been properly aligned and all connections are firm. The automatic line flushing controller includes provisions for flushing the temporary lines connected to mobile waste receptors once resin-handling operations are complete.

Plant procedures are expected to incorporate best practices for the assembly of temporary piping systems connected to mobile waste receptors, including:

- Integration of standard plant procedures and procedures generated by the owner/vendor of mobile waste receptor through a step-by-step walkthrough
- Colour-coding of temporary lines and unique identifier tags indicating to which components each hose will be attached
- Including step-by-step signoffs and independent verification at each appropriate step of equipment set-up and operation
- Visual verification and hydraulic testing of waste flow paths with primary water to confirm piping arrangement and end connections prior to radwaste transfers
- Verification of procedure(s) for abnormal events during operations

Temporary equipment may also be used to clean up the condensate storage tank if it becomes contaminated following SG tube leakage. This use of temporary equipment is similar to that just described, except that the equipment is used in the yard rather than in the radwaste building truck bays.

These provisions to use mobile and flexible technology properly interconnected with permanent systems allow for evolving state-of-the-art methods to be applied to waste processing throughout the life of the plant. Using such methods has the potential to reduce risks from operating equipment, operator doses, and doses to the public.

Mobile systems are currently available in the US and have been proposed for use in Europe and the UK. In 2005, the Electric Power Research Institute (EPRI) undertook a review of LLW mobile processing and treatment systems for advanced nuclear plant (ANP) designs. In this review, they identified a number of known mobile technologies that are or could be applicable to a LLW management programme for an ANP. Skid or transporter container-mounted units that currently exist include:

- Tubular ultrafiltration
- Reverse osmosis units
- Ion exchange vessels
- Drum/paddle dryers
- High-velocity vacuum dewatering
- Activated carbon beds
- Solidification systems This list is not exhaustive. In Europe, the use of mobile treatment facilities for liquid radioactive waste generated from the dismantling of submarines in Russia has been proposed and preliminary designs drawn up (Ref. 26.25). In the UK, mobile plants have been targeted at solidification of wastes including sludges (Ref. 26.26). A transportable intermediate-level waste solidification plant was commissioned in 2003 at Trawsfynydd, which is currently being used to treat approximately 80 percent of the wet ILW at the site.

The mobile units typically are transported and operated in shielded containers with controls located outside of the container. Shielded containers are used to provide protection to operators and to enable the containers to meet transport regulations as they are moved between sites.

26.7.2.9 Detergent Waste

Detergent wastes are collected in the chemical waste tank. They have low concentrations of radioactivity and contain soaps and detergents not compatible with the ion exchange resins. If their activity is low enough, then they can be discharged without processing. When detergent waste activity is above acceptable limits and processing is necessary, the waste water may be transferred to a waste holdup tank and processed in the same manner as other radioactively contaminated waste water, if the installed equipment is suitable to do so. If onsite processing capabilities are not suitable for the composition of the detergent waste, then processing can be performed using mobile equipment.

The mobile equipment would comprise a concentration step (e.g., evaporation or reverse osmosis) to reduce the volume of waste to the extent necessary to allow an encapsulation plant to immobilise the concentrate in a cementitious grout. The encapsulated waste would be shipped to the LLWR. The condensed evaporator distillate or reverse osmosis permeate would be transferred to a waste holdup tank for further processing in the WLS or transferred to a monitor tank for sampling and discharge.

26.7.2.10 Chemical Waste

Chemical wastes are normally generated at a low rate (0.03 m^3/day (1.06 ft^3/day) [Ref. 26.1, Table 3.4-1]) and collected in the chemical waste tank. These wastes are only collected: no processing is provided. Provisions have been made to allow for chemical addition to the tank for pH or other adjustment. When combined with the radioactive sink and shower drains, the chemical wastes may be sufficiently dilute to be discharged without processing.

If the mixed liquid is not dischargeable or if the constitution of the chemical waste means that mixing is inadvisable, special processing will be required. Piping is provided to permit processing by mobile equipment brought into the radwaste building truck bays. Following such processing, the fluid may be returned to the WLS holdup tank for further processing and discharge, discharged directly, or transferred for further processing elsewhere.

Drainage of chemicals to the chemical waste tank will be controlled by procedure, ensuring that no incompatible waste streams are mixed. The chemicals to be used in the laboratory will be decided on by the utility operator.

26.7.2.11 Sludge

Sludge is not expected to accumulate significantly on the bottoms of liquid waste treatment tanks. These tanks are designed to minimise sludge formation by including provisions to slope the effluent holdup tank from one end to the other into a dirt pan section where particulate material can collect. The vertical tanks are sloped to the low point where particulates will be collected. The discharge pump suction is taken from the dirt pan or low point for drawing waste water out of the tank, thus performing a self-cleaning action. The tanks are also fitted with oversized manways that allow for access should any additional cleaning be necessary for tank maintenance or during decommissioning.

26.7.3 Disposability of Liquid Wastes

The waste from the chemical waste tank will be immobilised in cementitious grout using a mobile plant. In order to reduce the volume of waste requiring encapsulation, the waste will be dewatered e.g., by use of an evaporator, to the extent necessary to form a suitable grout mix. The resulting evaporate is encapsulated, typically in a 200-litre (7.06 ft^3) drum.

The completed waste packages are loaded into HHISO containers for shipment to the LLWR. Evaporator distillate is condensed and returned to the WLS.

Encapsulation is a simple and proven means of dealing with mobile LLWs. It is acceptable to the LLWR, and it meets the LLWR's current conditions on the physical nature of the waste form and the expected activity level (Ref. 26.27).

26.7.4 Best Available Techniques for Liquid Radwaste Treatment

The BAT optioneering considered for WLS (Ref. 26.1, Section 3.4.4, and Ref. 26.5, Section 4.3.3.1) is summarised below. Other options may be possible.

26.7.4.1 Ion Exchange Versus Evaporation

Liquid radwastes may be treated by ion exchange (to remove contamination, enabling the remaining liquid to be discharged) or by evaporation (to reduce the volume of contaminated liquid).

In Europe, many nuclear reactors are located on major rivers and not on coastal sites. It is common for these reactors to be equipped with evaporators to minimise the radioactive liquid discharges. However, the standard AP1000 design does not have evaporators based on considerations shown in the Environment Report (Ref. 26.1, Section 3.4.4.1).

Including evaporators would contradict the AP1000 design overriding principles of safety and simplicity. Compared to a traditional evaporator-based liquid radwaste system, the ion-exchange AP1000 system provides effectiveness and simplicity, and will tend to minimise operator doses and solid radwaste arisings. The complexity of the traditional evaporator design leads to significant maintenance with associated occupational radiation exposure and also allows more opportunity for operator errors. The relatively passive nature of the ion-exchange-based AP1000 system provides effective operation with lower

maintenance, lower operator doses, simpler operation, and at lower capital and operating costs.

The fact that the generic site for the AP1000 design is a coastal site and not a river site also lessens the value of using evaporators for minimising the discharge of boric acid. Unlike river water, seawater already contains significant boron concentrations.

The ion exchange treatment process has been shown to effectively control offsite discharges. This is the reason that the proposed WLS treatment system using ion exchange beds and filtration rather than evaporation is a BAT (Ref. 26.5, Section 4.3.3.1.1).

26.7.4.2 Enriched Boric Acid Versus Natural Boric Acid

Boron-10 in the form of boric acid is used for reactivity control in the AP1000 design.

The boron in natural boric acid contains approximately 20 percent boron-10, whereas the boron in enriched boric acid contains 60 percent boron-10. Because the same amount of the boron-10 isotope is required regardless of whether it is provided in the enriched or natural form, using enriched boric acid means that the total concentration of boron required in the RCS could be reduced by a factor of three. This would permit the quantity of lithium hydroxide (an alkali used to control the pH of the coolant, balancing the weak boric acid) to be similarly reduced, resulting also in a reduction on the amount of tritium produced from neutron activation of lithium-6 and so providing a safety benefit.

However, it is also possible to reduce the production of tritium from the lithium hydroxide by enriching the lithium hydroxide in lithium-7 (and reducing correspondingly the amount of lithium-6), while retaining the larger lithium hydroxide inventory required to balance the natural boric acid. Because the generation of tritium from boron-10 is the same for both options, adjusting the isotopic composition of the lithium to reduce the tritium generation from lithium hydroxide by a factor of three or more will ensure that the total tritium generation is at least as low as for the system with enriched boric acid. Moreover, enriched boric acid is approximately 200 times more expensive than natural boric acid (Ref. 26.1, Section 3.4.4.2). Therefore, using natural boric acid and lithium hydroxide that is enriched in lithium-7 provides a more cost-effective method of reducing the tritium generated in the RCS than using enriched boric acid.

Using “gray rods” for mechanical shim control, rather than relying on chemical shim control via boric acid, also helps to reduce tritium production and thereby increase safety.

26.7.4.3 Cartridge Filtration Versus Cross Flow Filtration

The WLS incorporates an after-filter downstream of the ion exchangers to collect particulate matter such as resin fines. The radioactive particulate load in the WLS influent is already reduced by passage through the pre-filter, deep-bed filter, and three ion-exchange beds before the after-filter. Using cartridge filters offers a low-pressure system that is suitable for the low flow rates (~8 m^3/day (282.5 ft^3)) associated with the WLS. The filters are readily replaceable and treated as LLW.

Cross-flow filtration techniques of microfiltration, ultrafiltration, nanofiltration, and reverse osmosis potentially offer more effective particulate removal efficiency than cartridge filtration. All of these techniques use membrane processes that segregate a liquid that permeates through a membrane from a concentrate that is retained. The driving force of the process is the pressure difference across the membrane. However, these processes have a number of disadvantages, including a more complicated system with probable higher

maintenance and operator doses, the requirement for higher pressures, and increased radwaste from decommissioning.

On balance, the proposed use of cartridge filters is BAT for filtration after the ion-exchange beds (Ref. 26.5, Section 4.3.3.1.3).

26.7.5 Liquid Discharges

Process liquids are normally discharged to one of the six monitor tanks shown in Figure 26-6. The release of treated liquid waste from any monitor tank to the environment is permitted only when sampling of the subject tank's contents indicates that such a release is permissible (Ref. 26.5, Section 4.3.3, and Ref. 26.1, Section 3.4.3.6).

Table 26-9 shows expected monthly discharges through the fuel cycle. Table 26-3 gives representative 12-month liquid discharges based on months 7 to 18 of the fuel cycle, worst-case annual discharges (taking into account plant ageing and other factors), and calculated annual discharge limits for tritium, carbon-14, and a number of other radionuclides.

Table 26-6 shows that the normalised total annual liquid radioactive discharges from the AP1000 reactor are significantly less than those from Sizewell B and from comparable recently-built Westinghouse PWRs in the US.

The following tables in the Environment Report (Ref. 26.1) provide comprehensive details of liquid emissions by source, by radionuclide, and by month within the reactor cycle:

Table 3.4-6	Expected annual release per building or area of radioactive liquid effluent discharges, averaged over the 18-month fuel cycle, all radionuclides.
Table 3.4-7 to Table 3.4-18	Detailed monthly liquid discharges per building or area of H-3, total non-H-3, C-14, Fe-55, Co-58, Co-60, Ni-63, Sr-90, Cs-137, Pu-241, and other particulates.

26.8 SOLID RADWASTE SYSTEM

Gaseous and liquid radioactive wastes need containment and decontamination until they can be proven to meet authorised discharge limits. Solid wastes, on the other hand, are easier to control physically but are more diverse. They will contain the radioactive contamination that has been removed from the gas and liquid wastes, and will include highly radioactive material such as spent fuel. Division into LLW, ILW, and HLW recognises that the different types of solid radwastes need different handling.

Storing waste in a passively safe configuration minimises the need for active safety systems and thus reduces risk. The desire to process waste into a passively safe form must be balanced against the likelihood that delaying processing would reduce operator dose, and it does not foreclose any future management options.

An option to store solid LLW, ILW, and HLW arising from the AP1000 reactor has been developed to ensure that these wastes are managed in compliance with UK regulatory and legislative requirements. The Environment Report (Ref. 26.1) will serve as the basis for the following sections, and the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9) is used as a supporting reference to provide information and to demonstrate how

the solid waste management strategy defined by the IWS (Ref. 26.2) is to be implemented. The following sections provide detail on how the principle of passive safety will be addressed.

After outlining the overall strategy for dealing with solid radwastes, this section considers the sources of solid radwaste, and then describes how each category of waste is handled at the AP1000 plant and comments on the ultimate disposability of the waste. The section concludes with a consideration of BAT for solid radwaste. Where appropriate, the descriptions consider in turn LLW, ILW, and HLW. The hazard analysis builds on the information here; but, because it is also relevant to gaseous and liquid wastes, it is presented in Section 26.9.

26.8.1 Strategy for Solid Radwastes

The strategy for solid radwastes utilises the waste hierarchy through storage and decontamination techniques designed to reduce the activity of the waste as far as reasonably practicable. The description below is based on that given in the Environment Report (Ref. 26.1, Section 3.5.1).

Westinghouse expects that the LLW, ILW, and spent fuel waste streams will be capable of being disposed in NDA facilities and has selected waste forms, treatment processes and containers accordingly.

Uncertainties and risks relating to the achievement of this strategy will be identified as the strategy is implemented and managed by documenting and discussing them with the utility customers and the EA. The main uncertainties, risks and assumptions in this strategy are associated with radioactive waste and spent fuel disposal at NDA facilities. The NDA is not presently able to provide information on the spent fuel packages that it will accept; therefore, Westinghouse will assume that current practices for spent fuel packaging, as well as LLW and ILW packages, remain acceptable once the AP1000 plant is built and operating. This includes container designs and sizes, and acceptable waste forms.

Nearby facilities, where and when available, will be used to the extent practical to minimise the environmental impact of transport. During site operations, communications will be maintained to assess onsite and offsite interdependencies, such as those between the AP1000 plant and offsite disposal facilities.

Figure 26-3 shows the AP1000 design solid radwaste management strategy. This strategy will include:

- Waste minimisation
- Avoidance of the unnecessary introduction of waste into the environment
- Waste characterisation and segregation
- Collection and retention of data on the waste and waste packages
- Consideration of options in a BAT assessment
- Communications with interfacing facilities and stakeholders
- Assurance that steps in the management of waste are compatible
- Characterisation of risks and uncertainties

26.8.2 Sources of Solid Wastes

26.8.2.1 Operational Solid Wastes

Solid LLW includes dry active wastes, general trash, and mixed wastes as a result of normal plant operation, including anticipated operational occurrences (AOOs) i.e., events that are anticipated to occur at least once in the plant lifetime. Section 26.8.2.2 discusses the inclusion of condensate polishing system (CPS) resins as LLW.

ILW arises from the periodic replacement and maintenance procedures, e.g., replacement of filters. The bounding design case is that the filter and resin wastes are in contact with high coolant activity associated with 0.25 percent fuel failure. Modern PWR fuel is considerably more reliable than this, and it is possible that the filter and resin activity levels will be low enough for them to be disposed as LLW.

The only source of HLW is spent fuel, i.e., fuel that is no longer efficient in creating electricity because its fission process has slowed. However, it is still thermally hot, highly radioactive, and potentially harmful. The reference 18-month equilibrium cycle feeds (and discharges) 64 fuel assemblies every 18 months. On average, this means that approximately 43 assemblies per year are discharged and stored in the spent fuel pool storage area. Each fuel assembly consists of 264 fuel rods. The fuel rods consist of uranium dioxide ceramic pellets contained in cold-worked and stress-relieved zirconium alloy (ZIRLO™) tubing, which is plugged and seal-welded at the ends to encapsulate the fuel.

The solid radwastes comprise the following:

LLW
compactable paper, tape, clothing, plastic, elastomers
noncompactable metallic items, glass, wood
condensate polisher spent resin
dry granular carbon
HVAC filter – granulated charcoal
compressible rigid plastic – gaskets, valve packing, insulation
HVAC filter – uncompacted fibreglass or metal
electro-deionisation unit – resin/membrane module
heat exchanger insulation
filter – pleated polyester
wet granular particles – sludge
waste oil
mechanical pump seal – silicon carbide
pump diaphragms – Buna n
degasifier separator – canned pump
resin transfer screw pump

ILW
ion exchange resin
gray rod cluster
wet granular carbon
filter cartridge – metallic cylinder
control rods
neutron Source Rods

HLW
spent fuel

In addition, the possible replacement of SGs or the reactor pressure vessel head (RPVH) would generate large one-off items (see Section 26.8.11).

The Environment Report (Ref. 26.1, Table 3.5-1 and Appendix A) gives detailed breakdowns of the volumes of these wastes. The volumes are comparable with those from existing plants. Table 26-10 shows that solid discharges from the AP1000 plant are much lower than those from existing nuclear power plants and other UK reactors.

26.8.2.2 Justification of Spent Ion Exchange Resins as Intermediate-Level Waste

This short section explains why the AP1000 reactor spent ion exchange resins are identified as ILW.

The expected activity of primary spent ion exchange resin is 78.1 TBq/y (2111 Ci/y) . The expected volume is 7.79 m^3/y (275.1 ft^3/y) (Ref 26.11, Section 6.1). As the density of resin is of the order of 1 t/m^3 (62.43 lb/ft^3), the implied specific activity of 10.0 TBq/m^3 (7.7 Ci/ft^3) clearly exceeds the LLW threshold of 12 GBq/te beta/gamma (0.15 mCi/lb beta/gamma). Thus, the primary resins are classified as ILW.

A secondary ion exchange resin waste stream comprising condensate polishing resins also arises within the AP1000 design. Under normal operating conditions, the condensate polishing resin will be nonradioactive and will be discharged as nonradioactive waste. Under abnormal conditions (e.g., SG tube failure), there may be a transfer of primary circuit activity into the secondary circuit. The amount of activity transferred will be very small, and the activity of the CPS resin will not exceed the limits for LLW. To be conservative, the waste disposability assessment and the waste arisings tables in the Environment Report (Ref. 26.1, Appendix A1) list the condensate polishing resin as LLW.

26.8.2.3 Decommissioning Wastes

The basic AP1000 design principles minimise the creation of radwaste during operations and decommissioning. The AP1000 reactor was designed to have fewer valves, pipes, and other components so less waste will be generated during maintenance activities such as repair and replacement (see Figure 26-7). This reduction in components also leads to lower quantities of waste being generated during decommissioning. The level of cobalt in reactor internal structures is limited to below 0.05 weight percent, and in primary and auxiliary materials to less than 0.2 wt. percent (Ref. 26.1, Section 3.5). This reduces the production of Co-60, which is typically the radionuclide with highest activity in activated metal components. Surfaces, including steel wall and floor surfaces, will be sealed to prevent penetration and to facilitate decontamination.

The wastes generated during decommissioning comprise the following materials (Ref. 26.1, Section 3.5.10), which are described more in detail in Chapter 27.

Small-Volume Components

The small-volume components at decommissioning include various electrical equipment, filters, electro-deionisation units, and skids. These wastes are classified as LLW.

Large-Volume Components

The large-volume components include the reactor head, which is not expected to require replacement during the operational period of the AP1000 plant. The quantities of ILW and

LLW large-volume component wastes generated during decommissioning are shown in Table 26-11.

It is assumed that the reactor vessel is disposed intact and is not decontaminated. No benefit would be gained from decontaminating the reactor vessel, as most of the dose would come from activation of vessel materials. Techniques may be developed in the future that would allow the decontamination of the reactor vessel without significant dose uptake to the operators. This would subsequently allow the reactor vessel to be cut up in a way similar to the method outlined for the reactor pressure vessel head (Ref 26.1, Section 3.5.7.1). This will be assessed as part of the individual site's decommissioning plan.

Decontamination of the reactor systems could be accomplished with some piping modifications to bypass the reactor vessel, as well as with the use of existing filter and demineraliser vessels.

Waste from Decontamination Operations

The following systems may become contaminated during normal and shutdown operations for maintenance and disposal purposes:

- BDS
- CVS
- Startup feedwater system (FWS)
- Primary sampling system (PSS)
- Passive core cooling system (PXS)
- RCS
- Normal residual heat removal system (RNS)
- Reactor system (RXS)
- Spent fuel pool cooling system (SFS)
- SGS
- Containment hydrogen control system (VLS)
- WGS
- Liquid radwaste system
- Radioactive waste drain system (WRS)
- Solid radwaste system

The plant areas that house these systems have the potential to become contaminated in the event of an accidental release of radioactive material. Decontaminated materials are expected to be handled in the hot machine shop, the cask washdown pit, or the area where the decontaminated equipment is located. Drains are located throughout the plant at various locations, including the rooms where decontaminated materials are handled, in case an unexpected spill occurs in an area where contaminated materials are handled. The spill can thus be flushed with water and drained for waste processing. Ultimately, the correct method of handling the spill will depend on the situation, and the utility will be responsible for making the appropriate decision about how to clean it up.

For the decontamination procedure for specific equipment or areas, see the decontamination considerations report (Ref. 26.55).

The only plant area with the potential to become activated is structural module CA-04, which surrounds the reactor.

The AP1000 decontamination equipment facilities provide decontamination capabilities for decontamination of the above systems.

The plant is designed to have a decontamination glovebox, a high-pressure demineralised water sprayer, and a dry ice pellet blaster located in the hot machine shop (Room 40358) for the decontamination of components and equipment that have become contaminated (Ref. 26.29).

The high-pressure demineralised water sprayer and dry ice pellet blaster are portable units that can be used to decontaminate equipment in situ if required. If the component can be transported to the hot machine shop, a decontamination basin is available for decontamination if the component is too large for the decontamination glovebox. If a component is too large for the decontamination basin, other areas such as the cask washdown pit can be used in conjunction with the portable decontamination units.

Waste produced during decontamination operations will be minimised utilising the waste hierarchy. The decontamination of the AP1000 plant has been simplified through a number of design features, e.g., controlling the spread of contamination, minimising the potential for cracks and crevices in large pools and pits, sloped tank bottoms, and coated surfaces.

The routine operation of systems designed to capture radioactivity throughout the operational life of the plant (e.g., WLS, WGS, WSS, CVS, and SFS) has the benefit of reducing the accumulation of activity in the pipes, vessels, and components to be decommissioned (Ref. 26.55).

Discharge and disposability assessments will be carried out as part of the BAT/ALARP assessments required when selecting the optimum chemical decontamination agents. Until these assessments have been made, it is not possible to assess the expected reduction in contamination levels that will be achieved during post-operational cleanout and decommissioning.

Achievable decontamination factors vary widely between techniques and between different applications of the same technique. Operator experience, treatability studies, and monitoring are all important in determining the achievable decontamination factors. Some examples of decontamination factors achieved on decommissioning projects have been published (Ref. 26.30).

Typical secondary wastes that may arise from utilising decontamination techniques include effluent, ion exchange resins, filters, abrasives, dross, used tools, and personal protective equipment. The decontamination waste streams will be treated, recycled, or disposed of in ways that are consistent with the techniques described in the Integrated Waste Strategy (Ref. 26.2) and the Environment Report (Ref. 26.1). The volume of decontamination waste is expected to be insignificant when compared with other operational or decommissioning wastes.

Dry Active Waste

The compactable dry active waste created during decommissioning operations (e.g., rags, overalls, gloves, and packaging) is LLW and is estimated to be generated at a rate of 135 m^3 (4767 ft^3) per year. This volume can be reduced fivefold to 27 m^3 (953.5 ft^3) per year using a low-force compactor. Assuming an accumulated decontamination operation of 3 years, the dry active LLW generated during decommissioning would be 81 m^3 (2860 ft^3) (see Table 26-11). The use of supercompaction could reduce this number further.

Demolition Waste

Only a very small fraction of demolition waste (rubble) is likely to be considered LLW, with the majority being nonradioactive or made nonradioactive during the decontamination process. The estimate of LLW demolition waste includes 2165 m^3 (76460 ft^3) of concrete and 158 m^3 (5580 ft^3) of steel (Ref. 26.1, Appendix A6).

The LLW demolition waste includes waste from the demolition of modules within containment. These modules are steel structures, some with concrete-filled wall sections, which would be cut into transportable pieces with little volume increase.

The demolition waste also includes 199 m^3 (7028 ft^3) of concrete in the vicinity of the core. This represents a 1.5-m (4.92 ft) thickness of concrete around the reactor vessel cavity, which may contain enough activation products to be treated as LLW. This is originally a concrete monolith, but when broken up and packaged, it will contain significant voidage. The Environment Report (Ref. 26.1, Section 3.5.10) estimates that the actual packaged LLW volume will be 400 to 600 m^3 (14130 to 21190 ft^3), implying 50 to 67 percent voidage.[3]

The total ILW decommissioning waste associated with large-volume components and waste from decontamination operations is estimated to be about 800 m^3 (28250 ft^3). The total LLW associated with decommissioning large- and small-volume components, compactable dry active waste and demolition waste is estimated to be about 5500 to 6000 m^3 (194200 to 211900 ft^3).

The management of decommissioning waste is being planned with the expectation that the LLW, ILW, and spent fuel waste streams will be capable of being disposed in NDA facilities. This is consistent with the conclusions of the Disposability Assessment (Refs. 26.15 and 26.31) carried out by the Radioactive Waste Management (RWM) of the NDA.

26.8.3 Minimisation of Solid Wastes

Philosophy and General Techniques for Minimisation

Over the past 15 years, Westinghouse has made several design decisions to reinforce the concepts of safety through simplicity, ALARP, and BAT (Ref. 26.5). Examples of the decisions related to waste minimisation, waste generation, and waste disposal are described in more detail in the Environment Report (Ref. 26.1, Section 2.6) and the BAT assessment (Ref. 26.5, Section 4.1.3). These techniques aim to minimise waste generation and to meet the design requirements with the lowest radioactive effluent, lowest risk for accidental loss or leakage, high reliance on proven technology, lowest risk for public or operator radiation exposure, and lowest overall plant cost. Some examples follow:

- Reduction of containment penetrations, which reduces the risk for containment leakage
- AP1000 design improvements that have eliminated the requirement to pump borated makeup water continuously into the RCS or to include complicated water processing systems in the design
- Use of demineralisers for the treatment of the borated radioactive letdown water

3. For comparison, close-packed spheres in an infinite space have 26 percent voidage.

- A zinc addition subsystem to reduce water stress corrosion cracking and crud-induced power shift, as well as the potential release of active corrosion products into the WLS

The design of the AP1000 plant also takes into account prevention of contamination by using secondary containment systems for the AP1000 plant chemical storage tanks (Ref. 26.1, Section 2.9.4, Table 2.9-6). Some of the plans need to be reviewed during site-specific analysis and designed as necessary to ensure that they will comply with UK guidance (Ref. 26.32). Prevention of radioactive contamination is also minimised by using system, structure, and component (SSC) designs and operational procedures that limit leakage and/or control the spread of contamination. In this regard, the spent fuel pool and connected pools are examples of structures designed to eliminate unidentified leakage to the groundwater. These are documented more fully in the Environment Report (Ref. 26.1, Section 2.9.5). Westinghouse prepared a document (Ref. 26.33) to demonstrate that these practices are consistent with the United States (US) Nuclear Regulatory Commission (NRC) Regulatory Guide 4.21 (Ref. 26.34), which is considered good practice for this area.

Further principles that minimise the production of LLW, ILW, and HLW follow.

Low-Level Waste

LLW is minimised by the following activities (Ref. 26.1, Section 3.5.4.1):

- Good housekeeping
- Appropriate operating procedures
- Segregation
- Volume reduction
- Sealed surfaces (including steel wall and floor surfaces) to prevent penetration and to facilitate decontamination
- Limiting the amount of material brought into containment
- Training all staff allowed to enter radiologically controlled areas (RCAs)
- Provision of waste facilities immediately outside of the RCAs, for the disposal of unnecessary packaging materials
- Provision of tool stores within the RCAs to prevent contamination of clean tools brought in from outside
- Testing filter performance to ensure filters are only replaced when necessary
- Provision of radwaste advice on radiation work permits

Intermediate-Level Waste

ILW is minimised by the following activities (Ref. 26.1, Section 3.5.4.2):

- Optimum operation of the reactor in terms of power generation per tonne of fuel

- Selecting fuel with minimal potential for fuel defects, thereby minimising the radioactive isotope contamination of the primary cooling water circuit, reducing the load being treated by the ion exchange resin beds and hence the volume of ILW
- Received fuel being carefully inspected for any imperfections
- Minimisation of plant shutdowns
- Use of gray rods (low-density neutron absorbers) for mechanical shim control rather than relying on coolant chemistry
- Use of sealless coolant pumps eliminates seal leaks and creation of radioactive waste water
- Selection of materials of construction with a composition low in cobalt
- Use of zinc addition for corrosion control
- Selections of ion exchange media to give an optimum decontamination factor, which will minimise the number of ion exchange media changes required and reduce the waste volume
- Flexibility in routing effluent through the different ion exchange beds to optimise resin uptake
- Testing filter performance to ensure filters are only replaced when necessary
- Segregation procedures to prevent dilution of ILW streams by mixing them with LLW streams
- Formulation trials to determine an optimum blend ratio for the conditioning matrix producing the optimum number of waste packages
- Suitable operating procedures

High-Level Waste

The fuel economics and the amount of spent fuel are closely correlated. Both are optimised when the fuel cycle is designed with fuel being discharged from the reactor as close as is reasonable to the licensed discharge burnup limit. Westinghouse fuel is designed and verified for 62 GWd/MTU maximum burnup for the lead rod (Ref. 26.35), which translates to a batch average burnup of approximately 50 GWd/MTU.

The proposed 18-month fuel cycle will help to support the design intention of minimising spent fuel. This is based on an assumed 97 percent capacity factor and a 21-day refuelling outage, giving a cycle length of approximately 510 effective full power days. Although an annual cycle would give slightly fewer spent fuel assemblies over the life of the plant (2517 versus 2653), the number of shutdowns would increase from 40 to 60. The vast majority of Westinghouse customers (i.e., the utility operators) choose the longer fuel cycle (Ref. 26.1, Section 3.5.4.3).

26.8.4 Handling of Solid Radwaste

In contrast to handling the gaseous and liquid systems, handling the solid radwastes focuses on appropriate segregation and then on packaging the wastes in a way that is suitable for long-term storage, transport and disposal. Figure 26-4 is a plan of how solid radioactive waste is handled on the generic AP1000 design site: LLW goes to the radwaste building, whereas ILW and HLW go to the auxiliary building.

The engineering aspects of the AP1000 design were developed to ensure the design of the solid waste management facilities fulfilled the functional requirements and criteria defined in the Radioactive Waste Arising, Management and Disposal report (Ref. 26.9, Sections 2.2.1 and 3). These activities were managed by a quality management system operated in accordance with the applicable international standards:

- A final waste form conforming to current regulatory requirements that can be produced, handled, and managed on site and stored safely
- A workable design based on currently available technology of appropriate maturity
- A design that can be accommodated within the confines of the generic site
- A design that demonstrates ALARP principles
- A design that demonstrates BAT principles
- A design that is safe, for which potential hazards have been identified and for which the appropriate mitigation measures have been incorporated
- The plant design is ergonomically arranged for ease of transfer and ensures that the solid waste management system collects and stores radioactive wastes within shielding to maintain radiation exposure to plant operation and maintenance personnel ALARP
- A design compliant with UK regulations, codes, and standards
- 60-year operational capacity
- 100-year design life of spent fuel store and ILW store

The design of AP1000 and the process used to select radwaste treatment equipment provide flexibility to the operator in case the utility decides to reassess solid waste treatment to consider the latest developments in technology and different packaging arrangements (Ref. 26.1, Section 3.5.1.3). For example, one of the benefits of using a mobile encapsulation plant for ILW is that the technology can be updated as required in line with developing best practices (Ref. 26.9, Section 3.3.2.3) in order to reduce doses to operators and/or the general public.

The Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3.8) covers the radiological areas classification in terms of radiation and contamination zoning.

The following sections describe how waste is classified and segregated, and the onsite treatment of LLW, ILW, and HLW.

26.8.4.1 Segregation of Waste

In order to facilitate safe and effective management of radioactive waste, the waste should be characterised and segregated according to their activity and other physical and chemical properties.

Segregation ensures that lightly-contaminated waste (e.g., LLW) remains separate from higher-activity waste that may require more packaging and more costly deep geological disposal. Characterisation ensures that the physical, chemical, radiological and biological properties of particular waste packages are assessed and recorded, enabling the packages to be managed appropriately.

The radwaste building contains facilities (buffer/marshalling area) for segregated storage of various categories of solid LLW prior to processing (Ref. 26.2, Section 2.1.1.3). Also within the buffer/marshalling area will be a dedicated space for the decay storage of waste if and when required.

The WSS is designed to be able to segregate solid wastes by activity level and by physical and chemical characteristics, and also to segregate clean wastes originating in the RCA (Ref. 26.2, Section 2.2.3). Figure 26-3 and Figure 26-4 outline the segregation steps.

26.8.4.2 Waste Characterisation

The Letter of Compliance (LoC) process used by NDA RWM advises that waste streams are assessed before disposal. The issued LoC may be conceptual, interim or final, with the later stages requiring more information. A final-stage LoC advises that details of the physical, chemical, radiological, and biological properties of the waste, whereas a conceptual assessment would require only a general description of the waste (e.g., including assessed radionuclide inventory and whether or not it will contain organic material) along with a description of the methods proposed to characterise the waste fully.

The design of the waste management system will ensure that the required information is captured as described in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3.3.7).

Waste will be categorised for treatment as conventional or radioactive. Radioactive wastes will be categorised as VLLW, LLW, ILW, and HLW. They will be further characterised and (kept) segregated according to their required treatment, as determined by chemical composition, compactability, and radionuclide inventory.

26.8.5 Solid Waste Storage

In addition to the nuclear and non-nuclear islands buildings, there are facilities for the onsite storage of solid LLW, ILW, and HLW generated during AP1000 plant operation. These are described below.

26.8.5.1 Low-Level Waste Handling and Storage

The LLW store is located within the boundary of the licensed site to the rear of the radwaste building (Ref. 26.1, Section 2.3.6.1). This store comprises the LLW buffer and the radwaste building, which includes the waste accumulation room. The radwaste building also holds monitoring tanks containing processed effluent that are ready for release to the environment (Ref. 26.1, Section 3.4.3.6). The mechanical aspects and facilities of the radwaste building

and associated design requirements are detailed in Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Sections 3.4.5 and 3.2.1.3).

LLW is bagged, collected manually, and transported to the buffer/marshalling area of the waste accumulation room. The waste is packaged in HHISO containers. A forklift truck specifically designed for container handling will be used to move the HHISO containers from the radwaste building to the buffer store. HHISO containers will be handled within the radwaste building by the overhead crane. The HHISO container will be transported by road to the LLWR at Drigg for final disposal (Ref. 26.1, Section 3.5.9.1).

The AP1000 plant design includes provisions for the decontamination of any contaminated material that may arise from equipment replacement parts, tools and other metallic, plastics, or cloth parts and materials that may arise from outage activities. Any of these materials that can initially be classified as ILW are intended to be decontaminated to an LLW category.

The waste management strategy requires LLW to be shipped for disposal routinely according to schedules agreed to by the plant operator and the UK NDA. A facility will be available to store LLW during periods (up to 2 years) when waste cannot be received by the LLWR (Ref. 26.11).

Facility Design

The radwaste building is a non-seismic building with portable-shielding and lockable doors to minimise unauthorised entry and inadvertent exposure. This structure contains no systems essential for maintaining nuclear safety, but is designed for wind and seismic loads in accordance with the Uniform Building Code. The foundation of each building is a reinforced concrete mat (Ref. 26.9, Section 3.2.1.2).

Access to the radwaste building work areas by authorised personnel is assumed to be via the annex building change and health physics rooms, in which personnel will change into “clean conditions” protective clothing. Departure from the radwaste building will be via the change rooms, in which the protective clothing will be removed and placed in contaminated clothing containers (Ref. 26.9, Section 3.4.6).

The Waste Accumulation Room 50351 in the radwaste building is used to buffer, store, sort, and process incoming packaged LLW. Personnel ingress to and egress from this room will be via the subchange in the northwest corner.

The LLW buffer store is a covered area comprising a concrete hard-standing area with a steel-framed canopy (Ref. 26.9, Section 3.2.1.3).

Reserve Storage Capacity

Separate areas are reserved for the storage of several items, such as empty waste disposal containers (Ref. 26.9, Section 3.2.1.3).

Plant Availability

It is anticipated that LLW processing will be required all year round. Plant availability within the radwaste building will be 52 weeks per year at 5 days per week with a 7.5 hour working day. Multishift working will be possible, if required, depending on chosen campaign requirements (Ref. 26.9, Section 3.3.8).

Control System

The requirements for security systems for the radwaste building will be determined during the detailed design associated with the specific site (Ref. 26.9, Section 3.7.11). The facilities within the radwaste building will generally be manually operated, with an appropriate level of interlocks incorporated to prohibit mal-operation (Ref. 26.9, Section 3.3.6.2). Closed-circuit television (CCTV) cameras will be positioned to allow operations in the radwaste building to be monitored (Ref. 26.9, Section 3.7.10).

Transfer, Inspection, Maintenance and Monitoring of Waste Packages

Waste packages are handled in the LLW processing area, giving consideration to the radiation protection, environment and safety aspects (Ref. 26.1, Section 3.5.9.1). One example of the safety procedures is that LLW will be sorted under controlled conditions through the use of glove boxes (Ref. 26.1, Section 3.5.7.1).

HHISO containers will be handled within the radwaste building by the overhead crane and moved to the buffer store using a forklift truck specifically designed for container handling (Ref. 26.9, Section 3.2.1.3). The HHISO container will be transported by road to the LLWR at Drigg for final disposal (Ref. 26.1, Section 3.5.9.1).

Instruments monitor and control the process variables associated with LLW processing. This includes radiometric measurements within LLW handling equipment. Assaying of LLW drums to ensure that compliance with the site discharge criteria can be demonstrated uses a low-resolution gamma spectrometer (LRGS) located within the radwaste building. The LRGS will be located in an area of low background activity, or additional shielding will be installed to ensure that measured count rates are attributable to emissions from the waste drum. The LRGS will be integrated with the package tracking system (Ref. 26.9, Sections 3.7.15.2 and 3.7.17). Once drums have demonstrated that they meet quality assurance (QA) requirements, they are placed in a HHISO container positioned within the radwaste building (Ref. 26.9, Section 3.4.5.4).

Package Type

The waste package used for LLW is one that is currently accepted by the LLWR. As such, it has been designed to comply with the current requirements for handling, retrieval, transport, storage, and disposal (Ref. 26.9, Section 3.3.2.2).

26.8.5.2 Intermediate-Level Waste Handling and Storage

ILW is stored within suitable contamination-zoned and shielded areas of the auxiliary building prior to treatment in the MEU. Maintenance, control console, shielding, ventilation, safety, and seismic qualification of the MEU are discussed in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Sections 3.4.3 and 3.9.2), together with the waste tracking system.

Once the ILW is encapsulated in waste packages acceptable to RWM (e.g., 500-litre (17.66 ft^3) drum, 3 m^3 (105.9 ft^3) drum and box), the boxes and drums will be transported to an onsite ILW store. During transport to the ILW store, the waste package (drum or box) will be placed in an overpack, which will provide shielding in order to limit exposure to operators and the public. A self-propelled trailer will be used to move the waste packages to the ILW store along designated routes. During transfer, the package is to be suitably shielded to ensure dose uptake to personnel is ALARP. Based on the expected resin load and the assumed dose levels, the overpack shielding required for a single processed ILW package is steel of 0.19-m

(0.62 ft) thickness or concrete of 0.63-m (2.1 ft) thickness (Ref. 26.9, Sections 3.4.7.3 and 3.9.2).

Inside the ILW store, the packages will be placed and recovered using an overhead crane. The packages will be stored until a national ILW repository becomes available.

The first phase of construction will provide an ILW store suitable for 20 years of ILW production. The ILW store will be designed for a total inventory of 60 years of operational waste arisings from one AP1000 unit. The ILW store has a 100-year design life and could be used to retain ILW after the AP1000 plant is decommissioned and until the national ILW repository becomes available (Ref. 26.9, Section 3.4.7, and Ref. 26.1, Section 3.5.8.2).

Facility Design

The auxiliary building is designed to withstand the effects of natural phenomena. The ILW store is a reinforced concrete structure (Ref. 26.1, Sections 2.3.1 and 2.3.6.2), consisting of a waste package reception area and a shielded vault serviced by a certified nuclear crane. Figure 26-8 shows plan and section views of the ILW store. Further details are found in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3). A seismic assessment has determined that the AP1000 plant ILW store does not need to be seismically qualified from a radiological consequence perspective (Ref. 26.8, Section 6.8.3.1 and Ref. 26.9, Section 3.4.7.11). For response to external hazards, see Section 26.9.2..

The ILW storage facilities are designed to minimise unauthorised intrusion and to provide radiation shielding. The requirements for store shielding are listed below.

The assessment of shielding thickness addresses both onsite doses to workers and offsite doses to members of the public, in accordance with the assessment criteria discussed in the Radioactive Waste Arisings, Management and Disposal report (Reference 26.9, Section 3.9.3.1). The assessment considers two source terms:

- Store populated only by 3 m^3 (105.9 ft^3) RWM-compliant drums
- Store populated only by 500 litre (17.66 ft^3) RWM-compliant drums, placed in standard stillages

For the dose rates to the public, there are two site boundary distances considered for the generic site:

- The assumed distance to the site boundary is 200 m (656.2 ft).

- The distance from the site boundary to the nearest dwelling is a further 80 m (262.5 ft) (a total of 280 m (918.6 ft)).

The shielding and dose requirements imply that the walls of the ILW store should be constructed of 1 m (3.3 ft) thick concrete and the roof of 0.74 m (2.42 ft) thick concrete, both with minimum density 2.35 te/m^3 (146.7 lb/ft^3) (Ref. 26.9, Section 3.9.3).

In-store and encapsulation equipment will be modular, and components will be regularly or routinely replaced rather than being designed for the full 100-year storage period. All components that are subject to wear are located in such a manner that will allow easy access, removal and replacement with the minimum of disturbance to adjacent components (Ref. 26.9, Section 3.4.7.7).

Reserve Storage Capacity

The basic module for ILW storage accommodates 20 years of arisings. It may be expanded or duplicated as required to meet the necessary 60-year capacity (Ref. 26.9, Section 3.4.7.2). The vault sizing is also discussed in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3.4.7.5). In this section, it is stated that the store will initially be sized to contain the waste arising from nominally 20 years of operation of the AP1000 plant, minimising the initial capital expenditure. The actual rate and quantity of waste arising from operation will inform the planning and sizing of future store extensions. The onsite ILW store could be used as interim storage for the AP1000 plant decommissioning waste. If the national ILW repository is available before the end of AP1000 plant operations, ILW decommissioning waste could be shipped direct to the repository without interim storage onsite. Having the national ILW repository available before the end of AP1000 plant operations will also allow for the decommissioning and dismantling of the onsite ILW store using the decommissioning facilities created for the AP1000 plant. In this case, the onsite ILW store will be emptied and all stored waste packages shipped to the repository. Waste arisings from the dismantling of the ILW store will be similar in nature to the ILW, LLW, and conventional waste arising from AP1000 plant decommissioning. ILW packages will be shipped directly to the national ILW repository (Ref. 26.2, Section 6.9.3.1).

Control System

The requirements for security systems for the ILW store (e.g., building access turnstiles, swipe card systems, intruder alarm, and/or audio listening systems) will be determined during the detailed design associated with the specific site (Ref. 26.9, Section 3.7.11).

The ILW store will have a dedicated control console. More detail on the operating modes (normal and manual modes and recovery mode, intended to be used following equipment failure) can be found in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Sections 3.3.6.2 and 3.4.7.4). The primary control positions for controlling process operations will typically be local to the process and will be provided (where possible) with direct viewing of the main operations, supported by CCTV where appropriate. The CCTV cameras are described in the Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3.7.10).

The operators within the control room will be suitably shielded from both packages in the vault and the import/export area (Ref. 26.9, Section 3.4.7.4).

Transfer, Inspection, Maintenance and Monitoring of Waste Packages

The ILW storage requirements and procedures to ensure safety, radiation protection, transportability, stock control, and ability to retrieve waste packages are provided in the Environment Report (Ref. 26.1, Section 3.5.8.2):

- The ILW store incorporates a receipt area with waste package assay equipment and a shielded vault serviced by a certified nuclear crane. The packages will be transferred into the receipt area via a shielded door and then transported by the crane to a position in the store vault determined using the tag information.

- The package position will be recorded in the control log for ease of future retrieval. The packages will be placed in the store layer by layer to limit the potential topple height of stored packages. The layers will be constructed from the furthest point of the store working back to the receipt area.

- The chosen transfer path for placing/retrieving a package will be such to minimise the effective drop height.

- The store design and operation will be such to enable retrieval and visual examination of individual packages. CCTV within the import/inspection area will be used to facilitate this.

- The same facilities used during placement of the ILW packages into the store will be used to ship the ILW packages.

Some of these topics are also covered in Radioactive Waste Arisings, Management and Disposal (Ref. 26.9, Sections 3.4.2.3 and 3.4.7).

Instruments monitor and control the process variables associated with ILW processing. These include radiometric measurements within the ILW import/export equipment and general area monitoring. ILW packages will be assayed using a high-resolution gamma spectrometer (HRGS) located within the ILW store building before they are transferred to the ILW store vault and before they are sent to the repository. The HRGS will be located in an area of low background activity or will have additional shielding applied to ensure that measured count rates are attributable to emissions from the waste drum. The HRGS will be integrated with the package tracking system (Ref. 26.9, Section 3.7.16.1). The LRGS (in the radwaste building) and HRGS ensure that compliance with the site discharge criteria can be demonstrated (Ref. 26.9, Section 3.3.7).

Remedial action strategy for ILW packages is considered when external damage or defects are found (Ref. 26.9, Sections 3.4.3.3 and 3.4.7.1). All ILW packages will be visually inspected during handling and, if defects or external damage are found, the package will be flagged as “rogue”. A rogue package may arise from:

- Overfill of a package during encapsulation, causing spillage and contamination to the outer surface

- Malfunction during lidding, causing an unsealed package

- Corrosion or damage to the package, resulting in a containment failure

Any rogue package will be transferred to a secondary containment vessel (SCV). The SCV is a container of similar design to the RWM packages that is sized to fit over the RWM 3 m^3 (105.9 ft^3) box or drum. If an ILW package is found to be rogue as a result of QA inspections, it will be inserted into an SCV, lidded, and positioned in the store as normal. A small batch of empty SCVs will be stored within the radwaste building until required.

Overpacking of failed ILW packages was chosen for the purpose of GDA, ensuring that operator dose uptake is ALARP. Currently, no area or equipment exists to conduct structural repair/remedial work on a nonconforming or failed waste package. This option may be developed by the licencee during site-specific detail design.

A suitably shielded crane maintenance area is to be provided containing facilities to radiologically monitor and manually decontaminate equipment by means of swabbing. Maintenance access to this area will be assessed, as will the identification of routes for import and export of any maintenance items and materials. The maintenance requirements will be in line with the Lifting Operations and Lifting Equipment Regulations 1998, as well as other applicable regulations (Ref. 26.9, Section 3.4.7.7).

Package Type

The BAT optioneering study (Ref. 26.14) has determined that the waste packages should be RWM-compliant types in order to meet the expected conditions for acceptance for the national ILW repository. As such, they will comply with the requirements for handling, retrieval, transport, storage, and disposal. The in-store and encapsulation equipment, such as the MEU, four-drum stillages, and the nuclear crane will be suitable to engage and handle these RWM waste packages (Ref. 26.9, Sections 3.4.3.3, 3.4.7.2, and 3.4.7.12).

Continued Safe Storage of ILW

The ILW store is to be fully independent and capable of functioning beyond decommissioning of the AP1000 plant (Ref. 26.9, Section 3.4.7.15). In making the GDA, RWM assumed that interim storage was required for a period of 100 years (Ref. 26.31, Section 5.1.1). This is consistent with the 100-year lifetime assumed in the NDA's UK Radioactive Higher Activity Waste Storage Review (Ref. 26.36, Section 1.5.3).

It is envisaged that when an ILW repository becomes available, the ILW packages will be removed from the store and monitored again with the HRGS before being sent to the repository. If the HRGS result of a package indicates the radionuclides in the package have decayed such that the package could be LLW, the package will be temporarily placed in an LLW storage area. The LLW disposal facility will be contacted to ensure the appropriate records are prepared for LLW disposal at that time.

Figure 26-9 (reproduced from report on long-term storage of AP1000 ILW and spent fuel in the UK (Ref 26.56)) outlines the management plan for the ILW facilities. Because the precise timescales depend on decisions still to be taken (e.g., on approval to build new power stations or an opening date for a final disposal facility), the diagram shows the sequence and parallelism of events rather than explicit dates.

26.8.5.3 High-Level Waste Storage

After spent fuel is removed from the reactor, it will be stored in the fuel storage pool. Details of the fuel storage pool can be found in Section 6.10.3.

Because spent fuel is not expected to be reprocessed, Westinghouse has proposed using the Holtec International dry storage cask system for spent fuels (HI-STORM) 100U to dry-store the spent fuel once it has been removed from the storage pond for the operational period of the plant and beyond. The HI-STORM 100U system consists of three primary components:

- HI-STORM 100U underground vertical ventilated module (VVM)
- Multipurpose canister (MPC), each of which contains 32 spent fuel assemblies
- Holtec International transfer cask for HI-STORM (HI-TRAC), which holds the MPC during loading operations

Figure 26-10 shows the HI-STORM 100U system and its components. Once the spent fuel assemblies have reached the acceptable limits for heat generation (currently assumed to be about 100 years), and assuming that the national geological disposal facility (GDF) is available, they will be transported from their dry cask storage to the GDF.

The RWMC evidence report for HLW (Ref. 26.4, Section 10) outlines the currently best understood and proposed conditioning and disposability options for spent fuel. The packaging

plant for handling the AP1000 plant spent fuel will be designed with features to ensure that the risks and detrimental effects to the public and the environment as well as plant operators are ALARP. More detailed information can be found in Section 26.8.6.3 of this PCSR and in the Environment Report (Ref. 26.1, Section 3.5.9.3).

In order to demonstrate within the GDA that the packaging of spent fuel from AP1000 plant operations is achievable and safe, further information is presented below relating to:

- An outline of the current option for packaging of AP1000 plant spent fuel for dry storage
- A description of spent fuel repackaging system as a way of demonstrating that the necessary technology exists for packaging fuel for the GDF. Information relating to the GDF proposed for Sweden (this incorporates many features expected in the UK GDF) and from other countries

The availability of the necessary technologies for packaging spent fuel, the research undertaken by Svensk Kärnbränslehantering AB (SKB) in Sweden and other organisations worldwide such as Holtec International in the US, Gesellschaft für Nuklear-Service mbH (GNS) in Germany and the conclusions of the NDA spent fuel disposability report give confidence that the packaging of spent fuel from an AP1000 reactor is achievable and safe within GDA.

Facility Design

The dry spent fuel storage is a seismically qualified below-ground dry-storage facility that provides radiation shielding for the spent fuel (Ref. 26.1, Sections 2.3.6.3 and 3.5.8.3). For example, the HI-STORM 100U underground VVM provides for storage of a Holtec MPC in a vertical configuration inside a subterranean cylindrical cavity entirely below the top-of-grade. The principal function of the VVM structure is to provide the biological shield and cooling facility.

Transfer, Inspection, Maintenance and Monitoring of Waste Packages

HLW packages will be transported from the spent fuel cooling pond in their dry cask storage Holtec MPC to the HLW store using an appropriate transport vehicle. The Holtec MPC is one option that can be used for the interim storage, transport and final disposal of the AP1000 plant spent nuclear fuel. There are various other systems under development that could also be used for the interim storage, transport, and/or disposal. It may also be possible to place the AP1000 plant spent fuel directly into an RWMC disposal canister, once removed from the cooling pond, if the canister is designed for such a purpose.

Once the spent fuel assemblies have reached the acceptable limits for heat generation, they will be transported from their dry cask storage to the national GDF once it is available. During transport, each waste package will be placed in an overpack to provide radiation shielding and also to ensure the integrity of the waste during a road accident. The total weight of the waste package will be within appropriate limits for transport on UK roads when necessary. It is envisaged that transport of packaged spent fuel would be undertaken using a disposal canister transport container. This is an RWM transport container concept that provides two layers of shielding (Ref. 26.1, Section 3.5.9.3).

The assessment undertaken by NDA assumed that spent fuel packages would be overpacked for disposal (Ref. 26.1, Section 3.5.9.3).

Package Type

The decision on how to package spent fuel for storage is one that will be taken up by a future licencee. Two options, the MPC and a Castor cask, are discussed in more detail below. Once the package has been selected, compliance with requirements for handling, retrieval, transport, storage, and disposal can be assessed. However, sufficient information is available already on the various options to indicate that spent fuel may be stored safely.

The MPC was proposed for use at Yucca Mountain and is a single package equally suitable for onsite storage, transport, and permanent disposal in a future repository. It can hold up to 32 PWR assemblies. The MPC lid provides sufficient structural capability to permit the loaded MPC to be lifted by threaded holes in the MPC lid (Ref. 26.1, Section 3.5.8.3). The Environment Report (Ref. 26.1, Section 3.5.8.3) presents more information regarding the three main components of the dry storage system. As indicated above, the MPC can be accommodated in the HI-STORM 100U system.

A Castor V/21 cask containing 21 spent PWR assemblies (with burnups in the range 30 to 35 GWd/MTU) has been in storage at the Idaho National Environmental and Engineering Laboratory since 1985. A series of examinations was undertaken in 1999 and early 2000 to investigate the integrity of the Castor V/21 cask. The findings of those inspections (Ref. 26.37) concluded that there is no evidence of significant degradation of the Castor V/21 cask systems important to safety from the time of initial loading of the cask in 1985 up to the time of testing in 1999. Although the burnup of this fuel is lower than that expected for the AP1000 plant fuel, these findings provide some confidence that the Castor cask would also be a suitable container for long-term fuel storage. A 2008 NRC fact sheet (Ref. 26.38) also commented that dry spent fuel storage in casks is considered to be safe and environmentally sound. More information regarding the long-term storage of spent fuel can be found in the report on long-term storage of AP1000 ILW and spent fuel in the UK (Ref. 26.56)

The licencee is responsible for selecting a spent-fuel storage system and should undertake further work to ensure that it meets the requirements for handling, retrieval, transport, storage, and disposal. The evidence above indicates that it will be possible to meet the requirements for safe long-term interim storage of spent fuel.

26.8.6 Disposal of Solid Radwaste

26.8.6.1 Waste Acceptance Criteria for Disposal

Acceptance criteria will be established by the operator for admitting waste to the storage facility, as well as the final repository, and arrangements implemented to ensure radioactive wastes will meet the acceptance criteria. Relevant factors were described previously, and are summarised below.

Sections 26.8.5.1 and 26.8.5.2 of this chapter describe the compatibility of LLW and ILW packages with handling, transport, and storage requirements, including their suitability for retrieval and transport following the expected storage periods. These sections also address briefly the arrangements for examination, testing and auditing of LLW and ILW packages.

Waste packages will be monitored to demonstrate the absence of surface contamination before being placed in storage. In the case of LLW, the waste package will be decontaminated using manual cleaning cloths or swabs. The decontamination waste will be handled and disposed of with other LLW (Ref. 26.9, Section 3.4.5.4). The ILW package

decontamination processes within the store will be undertaken if required. Dry methods such as swabbing are preferable, as they eliminate liquid effluents (Ref. 26.9, Section 3.4.7.14).

26.8.6.2 Disposability of Low-Level Waste

Westinghouse has sought assurance from the LLWR that the expected LLW streams will be disposable. Table 26-12 compares the total activity in the LLW packages that will be transported to the LLWR with the activity triggers for acceptance (Ref. 26.39). For each of the listed activity groups, the waste packages meet the LLWR conditions for acceptance. Moreover, the LLWR has agreed in principle to accept the relevant waste (Ref. 26.16).

The acceptance in principle from the LLWR (Ref. 26.16) includes the immobilisation of approximately 0.5 m^3 (17.7 ft^3) of waste oil per year. The preferred option for the disposal of this waste stream is incineration at the Tradebe (formerly Pyros) incinerator at Fawley (Refs. 26.40 and 26.41).

The acceptance in principle from the LLWR was obtained in the event that this was deemed impractical, and the waste could be immobilised and shipped to the LLWR. The same treatment would be applied to the condensate polishing resins that had been in place during the 30-day leak from the primary to secondary circuits, even if this is considered highly unlikely to occur.

Incineration has also been identified as a potential disposal route for 3.85 m^3 (136 ft^3) per year of condensate polishing resins. Normally these will be nonradioactive. However, calculations have shown that both 7-day and 30-day tube leaks would lead to activity levels that exceed the criteria for acceptance at the incinerator (Ref. 26.17). For the 7-day leak, a storage and decay period of 3 years would enable the waste to meet the acceptance criteria. If this were deemed impractical, the waste could be immobilised in cementitious grout and shipped to the LLWR. The same treatment would be applied to the resins that had been in place during the 30-day leak, although such a leak is considered highly unlikely to occur.

26.8.6.3 Nuclear Decommissioning Authority Disposability Assessment of Intermediate-Level Waste and Spent Fuel

The RWM of the NDA has investigated the disposability of ILW and spent fuel. RWM produced a disposability assessment report (Refs. 26.15 and 26.31), which raised a number of issues. The RWMC evidence reports for ILW (Ref. 26.3) and spent fuel (Ref. 26.4) (which were not available when the RWM work started) address a number of the issues.

26.8.6.4 Further Evidence on Spent Fuel Disposal

The geological disposal facility proposed for Sweden incorporates many features expected in its UK counterpart. The Swedish radwaste management organisation SKB has undertaken a significant research programme and has proposed a design of canisters for spent fuel disposal (Ref. 26.42, Section 4).

SKB's proposed disposal method is to package the spent fuel in copper canisters and embed the filled canisters within Bentonite clay at a depth of 500 m (1640 ft) in the crystalline bedrock of the GDF. This provides three separate environmental isolation barriers (canister, Bentonite clay, and bedrock) for the spent fuel and prevents contamination from getting into groundwater. The copper canister is nearly 5 m (16.4 ft) long and has a diameter of over 1 m (3.3 ft). The copper shell is 5 cm (0.164 ft) thick. Inside the shell there is an insert of cast iron

for greater strength. The copper shell is highly resistant to corrosion in the environment expected to prevail in the final repository.

SKB has developed a canister laboratory research facility to develop technology for welding the lid and bottom onto the canister, and also to ensure the equipment used in the encapsulation process will achieve the necessary quality and output. SKB is using ultrasound technology and radiography to test welds and canister components and has developed a programme to determine the reliability of different inspection methods (see e.g., Reference 26.43).

SKB has documented current scientific knowledge of the climate-related conditions and processes relevant to the long-term safety of a repository to a level required for an adequate safety assessment (Ref. 26.44).

The encapsulation canister proposed by the NDA in the disposability assessment is similar to the canister used in the facilities being developed by SKB. The entire fuel element is deposited in the encapsulation canister and therefore no additional waste streams (e.g., ILW fuel assembly structural elements) are generated. The SR-Can assessment carried out by SKB (Ref. 26.45 and its many supporting reports) determined that this encapsulation process and associated repository have environmental impacts that are minimised. The packaging plant for handling AP1000 plant spent fuel will be designed with features to ensure that the risks and detrimental effects to the public, environment, and plant operators are ALARP.

The availability of the necessary technologies for packaging spent fuel, the positive comments from the Swedish regulator, the research undertaken by SKB in Sweden and other organisations worldwide such as Holtec International in the US, GNS in Germany and the conclusions of the NDA spent fuel disposability report all give confidence that the encapsulation of spent fuel from an AP1000 reactor is achievable and safe within the terms of GDA.

26.8.7 Best Available Techniques for Solid Radwaste

Following the development of the engineering aspects, the BAT assessment of the solid waste management unit was developed to identify suitable processes for managing the ILW and LLW streams. This is described in the BAT assessment document (Ref. 26.5) and summarised in the Environment Report. The BAT assessment focused on the available and currently proven technologies that have been used in the UK and elsewhere for the treatment of LLW and ILW. Initially, an optioneering process was carried out to identify a set of radwaste treatment options. This, along with the assessment criteria, is described in the Solid Waste BAT assessment report (Ref. 26.14).

The treatment options considered include cement encapsulation of solid ILW and compaction of compactable LLW (Ref. 26.1, Section 3.5.5). Each step in the management of radwaste will be compatible with all other steps, including pre-treatment, treatment, storage, disposal, handling, and onsite and offsite transport. Figure 26-11 summarises the ILW and LLW radwaste treatment options that have been selected following the BAT exercise carried out by Westinghouse. Figure 26-12 and Figure 26-13 give more detail on the initial option screening exercise for LLW and ILW.

Westinghouse proposes that the dry spent fuel storage system be used on the generic AP1000 design site (Ref. 26.1, Section 3.5.6). The selection of the spent fuel storage system can be deferred for a period to allow new techniques to be incorporated, if appropriate (Ref. 26.9, Section 3.2.1.3).

The AP1000 design and the process used for selection of radwaste treatment equipment provide flexibility to the operator to allow for the planning of the use of the most appropriate and efficient systems as they become available (Ref. 26.1, Sections 3.5.7 and 3.5.5.6). For example, the cement encapsulation system is mobile and designed to be easily removed, providing the utility with the option to replace the equipment after operations have started if newer technology has been developed.

The proposed locations of the ILW and spent fuel storage facilities (Ref. 26.1, Sections 2.3.6.2 and 2.3.6.3, respectively) have been selected to minimise the transportation distances between the auxiliary building and the stores and to facilitate safe transfer of waste. Similar constraints were considered in the optioneering exercise for the location of the encapsulation plant (Ref. 26.9, Section 3.4.3.4).

26.8.8 Best Available Techniques Assessment for Nonradioactive Waste Treatment

The nonradioactive waste produced by the AP1000 plant is less significant than the radioactive waste. However, BAT should still be applied to this waste. This section considers briefly the sources of gaseous discharges, liquid discharges and solid waste. It provides the references to the detailed descriptions of how BAT is used to manage the significant (liquid and solid) waste, and some examples of those techniques.

26.8.8.1 Nonradioactive Emissions to Atmosphere

There are only two gaseous nonradioactive emission sources, the mobile encapsulation plant and the standby generators (Ref. 26.1, Section 4.1.1). If powdered grout materials are handled on the mobile encapsulation plant for ILW encapsulation, then local auxiliary building extraction systems and bag filters will be provided to reduce airborne emissions to acceptable levels (Ref. 26.1, Section 4.1.1.1). The contribution of standby diesel generators to the overall thermal rated input and air pollution from the combustion of the gases is minimal, as is air pollution arising from gaseous products of combustion.

26.8.8.2 Nonradioactive Liquid Discharges

Regarding the liquid nonradioactive waste treatment, the IWS (Ref. 26.2, Section 6.5) demonstrates that the treatment systems used to prevent the uncontrolled release of contaminants to the environment make use of current BAT, and ensure that all discharges are ALARP. The nonradioactive waste water systems comprise the waste water system, the sanitary drainage system, the seawater cooling systems, storm water, fire water, and various closed-loop cooling systems such as that for the turbine building (Ref. 26.1, Section 4.2). There may be circumstances that require the development of an impact evaluation and management in the site-specific design.

26.8.8.3 Nonradioactive Solid Wastes

The sources of solid nonradioactive waste are summarised in Table 26-13. The conventional waste management strategy will ensure, to the extent practicable, that techniques will be used to prevent or minimise the production of wastes. Examples are:

- Reusing receptacles, hoses, and other plant consumables, where it is safe to do so
- Using appropriate signage to remind staff of the need to reduce waste
- Reusing HEPA filter boxes

- Providing waste collection facilities in the RCA outside of contamination-controlled areas from which waste can be monitored and, if it is not contaminated, removed from the RCA for disposal as nonradioactive waste

- Learning from operator experience shared between the sites and externally from other organisations in the UK and overseas

Figure 26-14 shows the proposed treatment and disposal of nonradioactive waste.

26.8.9 Management of Orphan Waste

The AP1000 design and processes seek to minimise "orphan"[4] waste, so-called because of their incompatibility with current or developing disposal techniques. A detailed review of AP1000 plant systems and rooms was performed to ensure that creation of orphan waste will be as low as reasonably practicable. This review identified no orphan waste streams (Ref. 26.2, Section 3.1.2).

26.8.10 Processing of Radioactive Waste into a Passively Safe State as Soon as Is Reasonably Practicable

The AP1000 design is aimed to maximise operational flexibility and minimise waiting times. The design and layout of equipment also consider access for installation, operation, recovery, inspection, maintenance, and decommissioning. Any package shall be capable of being retrieved from any position within the store, and at any time, during the 100-year storage period (Ref. 26.9, Section 3.4.7.8).

Incoming LLW will be brought into the facility and temporarily stored in a buffer or marshalling area within the radwaste building until required for sorting (Ref. 26.1, Section 3.5.7.1).

Solid ILW will be encapsulated on a campaign basis when sufficient volume of waste is available to complete an encapsulation run, typically coinciding with refuelling outages after 18 months of operation (Ref. 26.9, Section 3.3.2.3).

The spent fuel assemblies are initially stored in the spent fuel cooling pond to allow radioactive decay to occur and decay heat to be removed before being transferred to dry cask storage (Ref. 26.1, Section 3.5.7.3).

26.8.11 Treatment of Large Solid Items of Radioactive Waste: Steam Generators and Reactor Pressure Vessel Head

Large solid radioactive waste items are not expected to be generated during normal operation of the AP1000 plant. However, as a contingency, the SGs and the RPVH may require replacement. This section describes the arrangements for handling these large items.

The layout of the containment is designed to permit the removal of either steam generator through a temporary opening cut through the top of containment, then through the centre of the passive containment cooling air diffuser. During a steam generator removal operation, the steam generator is lifted from the steam generator compartment by a temporary construction trolley and then through containment by a large mobile crane. It is expected that the SGs will

4. Materials for which no final treatment or disposal route has yet been identified (Ref. 26.2, Table 9-1).

fall into the LLW category. It is intended that these items are handled as they arise and are size reduced, the pieces being decontaminated to the fullest practicable extent. Decontaminated pieces that are no longer radioactive will be released to conventional waste-handling facilities for recycling or disposal. Decontaminated pieces that remain radioactive will be wrapped before placement into HHISO containers and sent for disposal at the LLWR (Ref. 26.9, Section 5.2.3.4).

Decontamination materials are expected to be similar in nature to those already used for operational AP1000 plant LLW arisings as dealt with in the AP1000 plant radwaste building and will be packaged and disposed of in the same manner.

To facilitate this disposal route for large items, a temporary facility would be erected, for example a tent with mobile HVAC equipment and connections to the AP1000 plant power, water, and air systems as necessary. Following processing of the SG, the temporary waste-handling facility would be decontaminated as necessary and dismantled.

The materials used in the construction of the SGs are nickel-chromium-iron alloys and austenitic stainless steel (Section 6.2.2). These materials and their associated activities will meet the current conditions for acceptance at the LLWR, classified as metallic wastes.

If replacement of the reactor pressure vessel head is necessary, treatment of the replaced RPVH will be similar to that for replaced SGs. The replaced RPVH is expected to be LLW and will be handled as it arises. It will be size-reduced and the pieces decontaminated to the maximum extent practicable. Decontaminated pieces that are no longer radioactive will be released to conventional waste-handling facilities for recycling or disposal. Decontaminated pieces that remain radioactive will be wrapped before placement into HHISO containers and sent for disposal at the LLWR.

26.9 RESPONSE TO PROCESS, EXTERNAL AND INTERNAL HAZARDS

This section is relevant to gaseous, liquid and solid radwaste, and builds on the detailed descriptions of the facilities presented in Sections 26.6, 26.7, and 26.8.

26.9.1 Process, External and Internal Hazards for Low-Level Waste

26.9.1.1 Response to Process Hazards

A number of hazards that have been identified associated with the AP1000 plant LLW radwaste treatment operations are described in the UK AP1000 Radwaste Preliminary Safety Statement (Ref. 26.8, Section 6.8.1). These include:

- Spread of contamination
- Loss of containment of packages
- Contaminated wounds

The unmitigated consequences of each of these faults are considered below.

Spread of Contamination

During AP1000 plant radwaste treatment operations, spread of contamination and dose inhalation can occur due to:

- Contaminated packages

- Failure of pipework in the mobile encapsulation plant
- Release of contamination during operations to size-reduce LLW

The spread of contamination will be minimised by the application of well-designed procedures. In addition, the mobile encapsulation plant will be operated remotely. It is therefore considered that the potential dose uptake from inhalation of small quantities of airborne contamination will be negligible, and is therefore not subjected to detailed quantification.

Loss of Containment of Low-Level Waste Package

The inventory of a LLW package is significantly lower than that of the ILW package and the consequences of a loss of containment are consequently smaller. The consequence for a LLW package is calculated as <0.1 mSv (10 mrem) (worker), <0.1 mSv (10 mrem) (public) (Ref 26.8, Table 5.1).

Contaminated Wounds

A contaminated wound can be caused by an operator error during LLW size reduction operations. It is possible that a sharp edge is created during LLW cutting operations and the operator receives a wound from a section that is contaminated. The dose to an operator due to a contaminated wound is estimated in the UK AP1000 Radwaste Preliminary Safety Statement (Ref. 26.8, Appendix B) to be 38 μSv (3.8 mrem), which would be regarded as an event of relatively low significance.

26.9.1.2 Response to External Hazards

A number of preliminary safety reviews have been carried out on the design and operation of the radwaste building (Ref. 26.9, Section 4.1). HAZOP studies were performed to underpin the design of the radwaste building. Some of the issues identified during the HAZOP studies are related to the selection of a specific site and these will be carried forward for full resolution during the detailed design associated with a specific site. The output of the HAZOP 1 study is incorporated into the UK AP1000 Radwaste Process Hazard Study 1 Report (Ref. 26.46) and considers the extreme weather conditions as external hazards.

26.9.1.3 Response to Internal Hazards

The radwaste building will include environmental controls that are part of the main AP1000 plant control systems. These comprise (Ref. 26.9, Section 3.3.5.6):

- Control of the HVAC system (Ref. 26.19 , Section 9.4)
- Fire detection system
- Environmental surveillance and general radiometric display systems

The radwaste building HVAC system is designed to permit periodic inspection of the system (Section 23):

- Each component is inspected prior to installation.

- Components of each system are accessible for periodic inspection during normal plant operation.

- A system air balance test and adjustment to design conditions is conducted in the course of the plant pre-operational test programme.

- Air flow rates are measured and balanced in accordance with the guidelines of the Sheet Metal and Air Conditioning Contractors National Association HVAC systems – testing, adjusting, and balancing.

- Instruments are calibrated during testing.

- Automatic controls are tested for actuation at the proper setpoints.

- Alarm functions are checked for operability.

In addition to the overall radwaste building HVAC system, there is a requirement for a local dedicated air extraction system for the removal of any airborne waste particles above the following working areas:

- Sorting glovebox enclosure
- Size reduction glovebox enclosure
- Decontamination glovebox enclosure
- Large item laydown area

The air extraction system design will be based on established HVAC principles used within the nuclear industry and will incorporate flexible/adjustable overhead extraction hoods at each work area.

There is the potential for fires to occur within the radwaste building. An addressable multizone fire detection and alarm system will be installed throughout the radwaste building. Monitoring devices will include, but not be limited to, smoke and heat detectors, manual call points, and visual or audible alarms. The fire detection system will be designed to meet the requirements of BS 5839 Fire Detection and Alarm Systems (Ref. 26.47). Requirements for a permanently installed fire suppression system will be reviewed during the detailed design phase. These systems are described more fully in Radioactive Waste Arisings, Management and Disposal report (Ref. 26.9, Section 3.7.9).

The consequences of a fire in the radwaste building are considered to be significantly lower than for an ILW fire, due to the lower inventory. The worst-case consequences associated with an LLW fire are therefore considered to be <0.1 Sv (10 rem) (operator) and <0.1 mSv (10 mrem) (public) (Ref. 26.8, Section 6.8.2).

The radwaste building will also be provided with environmental surveillance (e.g., temperature (Section 23.9.1) and general radiometric display systems). The general display system will use gamma monitors and combined airborne alpha/beta monitors, which will provide radiological area monitoring. These monitors will be connected to annunciators located adjacent to the main personnel access door into the radwaste buildings. Alarms will be provided for both high gamma and instrument fault conditions. Alarms will be repeated in the AP1000 plant central control room (Ref. 26.9, Section 3.7.17).

The monitor tanks located in the radwaste building contain a radiation monitor on the common discharge line downstream. These radiation monitors will provide a signal to terminate liquid radwaste releases if the discharge concentration in the line exceeds a predetermined set point (Ref. 26.1, Section 3.4.3.6). The radwaste building is also designed to contain any liquid spills from the liquid waste monitor tanks. These provisions include a

raised perimeter and floor drains that lead to the WLS waste holdup tanks (Ref. 26.1, Section 2.3.5, and Ref. 26.9, Section 3.4.5.2). All floor drains are grouted into the surrounding concrete to ensure that any leakage will be collected in the floor drain rather than bypassing the drain (Ref. 26.1, Section 2.9.5.4).

26.9.2 Process, External and Internal Hazards for Intermediate-Level Waste

26.9.2.1 Response to Process Hazards

A number of hazards have been identified associated with the AP1000 plant radwaste treatment operations. These include (Ref. 26.8, Section 6.8.1):

- Spread of contamination
- Loss of containment of packages
- Loss of containment of overpacks
- Increased external dose

The unmitigated consequences of each of these faults are considered in the subsequent sections.

Spread of Contamination

During AP1000 plant radwaste treatment operations, spread of contamination and dose inhalation can occur due to:

- Contaminated packages
- Failure of pipework in the mobile encapsulation plant

The spread of contamination will be minimised by the application of well-designed procedures. In addition, the mobile encapsulation plant will be operated remotely. It is therefore considered that the potential dose uptake from inhalation of small quantities of airborne contamination will be negligible, and is therefore not subjected to detailed quantification.

Loss of Containment of Packages

A number of faults have been identified that have the potential to damage the ILW package in the auxiliary building. These include:

- Dropping an empty package during crane movement
- Control failure of the lid grapple resulting in damage to package lid
- Control system, mechanical or power failure, or operator error resulting in the mobile encapsulation plant shield door impacting a package
- Control system, mechanical failure, or operator error resulting in a package impacting the mobile encapsulation plant shield door
- A package, driven in incorrect direction due to control failure or operator error, falls off the mobile encapsulation plant rails

- Control system failure or mechanical failure of the grout fill head results in impact to a package

- Control system failure or operator error results in the overpack door impacting a package

The bounding consequences of a loss of containment of an ILW package in the auxiliary building can be calculated using a release fraction (RF) of 1E-5, which is appropriate for a single RWM 3 m^3 (105.9 ft^3) box/drum dropped from 25 m (82 ft) (Ref. 26.48). This is judged to be a pessimistic value as no package will be dropped by as much as 25 m (82 ft) but it allows an upper bound of the consequences of an impact to be determined. In addition, the building will provide a decontamination factor (DF) of 10 for releases to the public. The consequences of a loss of containment of an ILW package in the auxiliary building are therefore calculated as (Ref. 26.8, Section 6.8.1.2 and Appendix B):

- Public = Dose × RF/DF = 7.57E1 * 1E-5/10 = 7.57E-5 mSv (7.57E-6 rem)
- Worker = Dose × RF/DF = 3.72E5 * 1E-5/1 = 3.7 mSv (0.37 rem)

It should be noted that this worker dose is considered to be pessimistic, as there will be no operator present in the auxiliary building during encapsulation operations.

A number of faults have been identified that have the potential to damage the ILW package in the ILW store, which include:

- Control failure or operator error resulting in a package being impacted by overpack or by the ILW store inner shield door

- Control failure or operator error resulting in package toppling from receipt conveyor

- Control failure or operator error resulting in impact between crane and package

- Control failure or operator error resulting in crane/package impact with ILW internal structures

- Control failure or operator error resulting in crane impacting stored packages

- Crane failure/lifting beam failure resulting in a dropped load

- Crane failure resulting in crane collapse

- Remote operation of crane resulting in increased potential for operator error

- Toppling of packages due to seismic activity

The unmitigated consequences of the loss of containment of a single ILW package in the import/export bay of the ILW store are considered to be identical to those calculated above for a loss of containment within the auxiliary building (i.e., 7.57E-5 mSv (7.57E-6 rem) [public], 3.7 mSv (0.37 rem) [worker]).

There is the potential for multiple packages in the ILW store to be toppled by a seismic event that does not result in collapse of the ILW store. However, the public consequences of this event will be bounded by the consequences of total collapse of the ILW store, which is considered separately (see Section 26.9.2.2). The operator consequences will be minimal as there is no operator access to the ILW store vault (Ref. 26.8, Section 6.8.3.1).

Collapse of the crane resulting in loss of containment of multiple packages can only occur in the ILW store vault, i.e., remote from the operator. It is therefore considered that loss of a single package in the import/export bay of the ILW store provides a suitably bounding consequence for an operator. For a member of the public to receive a dose of >0.1 mSv (0.01 rem) would require 1300 packages to fall, and this is not credible given that the total number of packages in the ILW store from 60 years of AP1000 plant operations is approximately 1100 (Ref. 26.8, Section 2.1.3.3). It is therefore considered that the dose to a member of the public from crane collapse will be <0.1 mSv (0.01 rem).

Loss of Containment of Overpacks

During the transfer of the package from the auxiliary building to the ILW store, it will be contained in an overpack. There is the potential for this overpack to be damaged in the following facilities:

- Loss of containment of overpack in the auxiliary building
- Loss of containment of the overpack external to the buildings
- Loss of containment of the overpack within the ILW store

There is the potential for a loss of containment of the overpack in the auxiliary building due to the following faults:

- Control system failure or operator error results in package impacting overpack door
- Control system failure or operator error results in external shield door impacting overpack
- Control failure, drive mechanism failure or operator failure results in jacking failure/uneven jacking

The overpack provides an additional DF of 10 over that provided by the package and therefore the potential consequences will be a factor of 10 lower than those identified in the Radwaste Preliminary Safety Statement (Ref. 26.8, Section 6.8.1.2) for the loss of containment of a package. Including the factor of 10 gives estimated doses of 7.57E-6 mSv (7.57E-7 rem) (public) and 0.37 mSv (0.037 rem) (worker).

The following hazards were identified in the HAZOP report (Ref. 26.46) that have the potential to result in a loss of containment of the overpack external to the buildings.

- Vehicle impact into shielded transporter
- Control failure or operator error results in impact between ILW store external shield door and overpack/transporter

The overpack provides an additional DF of 10 over the package, however, the public DF of 10 for a building is no longer applicable; therefore, the potential public consequences will be the same as those identified in the Radwaste Preliminary Safety Statement (Ref. 26.8, Section 6.8.1.2), and the operator consequences a factor of 10 lower than those identified in the same section (Ref. 26.8, Section 6.8.1.2) for the loss of containment of a package, i.e., 7.57E-5 mSv (7.57E-6 rem) (public) and 0.37 mSv (0.037 rem) (worker).

There is the potential for a control failure, drive mechanism failure, or operator error to result in uneven jacking and toppling of an overpack and subsequent loss of containment within the ILW store. The unmitigated consequences of a loss of containment of an overpack in the ILW store are considered to be identical to those calculated above for a loss of containment within the auxiliary building, i.e., 7.57E-6 mSv (public) and 0.37 mSv (worker).

Increased External Dose

There is the potential for an operator to receive an increased external dose uptake from the mobile encapsulation plant and the ILW store.

Faults that have the potential to result in an increased dose rate from the mobile encapsulation plant include:

- Blockage resulting in shine from open mobile encapsulation plant shield door
- Control failure resulting in mobile encapsulation plant shield door being ajar resulting in shine path to operator
- Control system, mechanical or power failure or operator error resulting in the mobile encapsulation plant shield door impacting a package and damaging the shield door
- Control system, mechanical failure or operator error resulting in a package impacting the mobile encapsulation plant shield door
- Control failure, blockage or loss of services resulting in overpack door being open
- Failure to decontaminate pipe after a campaign
- Pipe not sufficiently shielded

The first five faults have the potential to result in an operator receiving an increased external dose uptake from an unshielded package and are considered to bound the dose rate from a pipe.

The unmitigated dose from an unshielded package has been calculated as 23.6 mSv (2.36 rem) to an operator standing 2 m (6.6 ft) from a 3 m^3 (105.9 ft^3) box for 30 minutes (Ref. 26.8, Appendix B). A member of the public 280 m (918.6 ft) from the box would receive 0.1 mSv (0.01 rem) box only if exposed for 140 hours. This is judged to be an incredibly long time, giving the maximum credible dose as <0.1 mSv (0.01 rem).

A number of faults have been identified that have the potential to result in an increased external dose uptake from the ILW Store, which include:

- Control failure or operator error results in both ILW Store shield doors being open.
- ILW store external shield door closes when operator is in the import/export area.
- Control failure or operator error results in impact between ILW store external shield door and overpack/transporter
- Control failure or operator error results in transporter impacting with ILW store
- Control failure or operator error results in ILW shield door error

- Control failure or operator error results in package impacted by overpack or ILW store inner shield door

The unmitigated dose uptake from the unshielded contents of the ILW store has been calculated as 274 mSv (27.4 rem) to the operator and 1.6 mSv (0.16 rem) to a member of the public (Ref. 26.8, Appendix B).

26.9.2.2 Response to External Hazards

A number of preliminary safety reviews, such as HAZOP studies and modern standards reviews, have been carried out to establish the safety issues applicable to the ILW store. These safety reviews have considered the hazards related to and the operability of the store and the seismic aspects of the building (Ref. 26.9, Section 4.1). HAZOP studies were performed to underpin the design undertaken to establish the requirements for the ILW store. Some of the features identified during the HAZOP studies are site-specific, and these will be carried forward for full resolution during the detailed design associated with a specific site.

The external hazards identified during the HAZOP 1 study (Ref. 26.46) included:

- Seismic events
- Extreme weather
- Aircraft crash

Assessments have been carried out of the consequences associated with the design basis earthquake for the ILW store. These assessments concluded that the ILW store does not need to be seismically qualified from a radiological consequence perspective as the unmitigated public offsite doses are less than 1 mSv (0.1 rem). Notwithstanding the above, ALARP arrangements must be implemented. Therefore, if it is reasonably practicable to introduce seismic withstand attributes to the design and construction of the ILW store, then it would be prudent to do so (Ref. 26.8, Section 6.8.3).

Chapter 16 considers whether the design-basis hazards such as wind and snow loading of the ILW store would lead to acceptable behaviour of the generic design in a general UK location. However, owing to the generic nature of the design and the unknown location at which the AP1000 reactor will be constructed, it is not possible to design the ILW store to take account of site-specific extreme weather requirements (Ref. 26.8, Section 6.8.3).

The hazards and risks represented by potential aircraft crashes will be site-specific and dependent on the frequencies of aircraft crashes for different categories of aircraft (light aircraft, helicopters, small transport, large transport, and military combat aircraft). However, given that the public consequences of collapse of the ILW store are below 1 mSv (0.1 rem) (as assessed for the seismic event), it is anticipated that the consequences of an aircraft crash will also be below 1 mSv (0.1 rem) and will not require aircraft impact withstand attributes to be incorporated into the design (Ref. 26.8, Section 6.8.3).

26.9.2.3 Response to Internal Hazards

The auxiliary building will be served by two forced ventilation systems, the containment air filtration system and the radiologically controlled area ventilation system. These systems will control environmental parameters, such as temperature, pressure, and airborne contamination within the building. These systems will be provided with systems to monitor airborne radioactivity and alarms (Ref. 26.1, Sections 3.3.2.2 and 3.3.3).

In addition to this, the auxiliary building will contain radioactive liquid tanks from the WLS (Ref. 26.1, Section 2.9.5.2). Adequate provisions have been made to provide warning of potential overflows through high-level alarms. The consequences of any overflow or leakage are mitigated by the provision of floor drains grouted into the surrounding concrete to ensure that any overflow or leakage will be collected into the building sump, and by sealing surfaces to prevent the uptake of contamination (Ref. 26.1, Sections 2.9.5.2 and 2.9.5.4).

The ILW store will have its own independent ventilation plant. This plant will provide HVAC. The ventilation system design will be based on well-established principles, such as air cascade systems where appropriate, to minimise the possibility of back diffusion of contamination. A list of key assumptions relating to the in-vault environmental conditions will be derived for validation with RWM. This will include identification of the need (or otherwise) for dehumidification and removal of chlorides (given potential coastal locations). The design of the ventilation system will need to include provision for the management of heat generated from stored waste packages (although this is expected to be small, if not negligible) in addition to other heat loads, such as those from plant and equipment. Ventilation will be supplied at low level via a plenum and extracted at high level from the opposite end of the vault. The store will have inlet and outlet HEPA filters in series to remove radioactive particulates present in the ILW building atmosphere. The ventilation system will be consistent with the radiological classification of areas required for the building (Ref. 26.9, Section 3.8).

The generation of effluents arising from ILW store operations will be assessed throughout the design period and reduced or eliminated as far as possible. At a minimum, ventilation stack monitoring systems and associated upstream monitoring systems for ventilation systems will be required. Liquid effluent requirements will be similarly assessed. Should it be determined that decontamination processes are required within the store then “dry” methods (such as swabbing) will be used, thus eliminating liquid effluents (Ref. 26.9, Section 3.4.7.14).

There is the potential for fires to occur within the auxiliary building or the ILW store. In addition there is a fire hazard during transfer of the ILW packages from the auxiliary building to the ILW store. A fire within the auxiliary building has the potential to arise from the following faults:

- Mobile encapsulation plant engine failure
- Electrical fault in the mobile encapsulation plant

In the worst case, it is considered that there is the potential for a single ungrouted package within the mobile encapsulation plant to be consumed within a fire. The release fractions applicable to the release from a drum are specific to the properties of the element being released. The dose due to the release of the activity from a package during a fire that breaches the package is 46.3 mSv (4.6 rem) (public) and 6.83 Sv (683 rem) (worker exposed for 1 minute) (Ref. 26.8, Appendix B).

Assuming that the mobile encapsulation plant and the building both provide a decontamination factor of 10, then the calculated consequences of a fire in the auxiliary building are:

- Public = 46.3/100 = 0.46 mSv (0.046 rem)
- Worker = 6.83 /10 = 0.68 Sv (68 rem)

It should be noted that these consequences are pessimistic, as they assume that the package will fail, resulting in a significant release of activity (Ref. 26.8, Section 6.8.2).

A fire may occur in the ILW store due to a transport engine failure or an electrical failure. The potential for a fire that consumes the entire ILW store inventory was considered and dismissed as not being credible based on the lack of potential ignition sources and any significant flammable inventory and the provision of fire resistant electrical systems. The worst credible consequences therefore arise from a fire involving a single ILW package, which are the same as those calculated above for the auxiliary building, i.e., 0.46 mSv (0.046 rem) (public) and 0.68 Sv (68 rem) (worker) (Ref. 26.8, Section 6.8.2).

An addressable multi-zone fire detection and alarm will be installed throughout the occupied part of the ILW store building. Monitoring devices shall consist of, but not be limited to, smoke and heat detectors, manual call points and connected to visual/audible alarms (Ref. 26.9, Section 3.7.9). The fire detection system will be designed to meet the requirements of BS 5839 Fire Detection and Alarm Systems (Ref. 26.47). Requirements for a permanently installed fire suppression system will be reviewed during the detailed design phase. Radiometric alarms will be provided for both high gamma and instrument fault conditions (Ref. 26.9, Section 3.7.19). Area gamma monitors and combined alpha/beta monitors will be connected to annunciators located adjacent to the main personnel access door into the radwaste or ILW store buildings. Alarms will be provided for both high gamma and instrument fault conditions. Alarms will be repeated in the main control room (MCR) (Ref. 26.9, Section 3.7.17.2).

26.9.3 External and Internal Hazards for High-Level Waste

26.9.3.1 Response to External Hazards

The spent fuel store for the generic site is a seismically qualified facility and comprises spent fuel flasks, flask loading equipment within the AP1000 plant, a suitable transport vehicle, and below-ground storage cells (Ref. 26.1, Section 2.3.6.3).

26.9.3.2 Response to Internal Hazards

As previously mentioned in Section 26.8.5.3 of this chapter, the HI-STORM 100U system consists of three primary components.

HI-STORM 100U Underground Vertical Ventilated Module

The VVM provides for storage of an MPC in a vertical configuration inside a subterranean cylindrical cavity entirely below the top-of-grade (Ref. 26.1, Figure 3.5-18a). The principal function of the VVM structure is to provide the biological shield and cooling facility (Ref. 26.1, Section 3.5.8.3).

The MPC storage cavity is defined by the cavity enclosure container (CEC), consisting of the container shell integrally welded to a bottom plate. The CEC is a closed bottom, open top, thick-walled cylindrical vessel, which has no penetrations or openings. Thus, groundwater has no path for intrusion into the interior space of the MPC storage cavity.

Corrosion mitigation measures commensurate with site-specific conditions are implemented on below-grade external surfaces of the CEC. All external and internal surfaces of the VVM are coated with an appropriate surface preservative. An optional concrete encasement around the coated external surface of the CEC may be added to control the pH at the CEC-to-subgrade interface. A corrosion allowance equal to 3 mm (0.12 inch) on the external surfaces of the VVM in contact with the subgrade is nevertheless assumed in the structural evaluations.

The closure lid is a steel structure filled with shielding concrete and incorporates a specially designed air ventilation system (Ref. 26.1, Section 3.5.8.3).

Multipurpose Canister

The MPC and HI-TRAC in the HI-STORM 100U system are identical to those in the Holtec aboveground system that has been in use for several years.

The MPC is a single package equally suitable for onsite storage, transport, and permanent disposal in a future repository. The MPC is constructed entirely of stainless steel alloy materials with the exception of the Metamic, a fixed neutron absorber, which is contained within the canister for criticality control. The fuel assembly basket contained within the MPC is a honeycomb multi-flanged plate weldment that forms the square fuel cells in the basket. There is complete edge-to-edge continuity between the continuous cells that provides an uninterrupted heat transmission path, making the MPC an effective heat-rejection device.

The top end of the Holtec MPC uses a closure system that includes a lid equipped with vent and drain ports used to remove air and water and to backfill the canister with helium (Figure 26-15a). A closure ring provides a redundant confinement boundary for the MPC lid. The vent and drain ports are covered, helium leak checked, and seal-welded before installing the closure ring. The closure ring is a circular ring that is edge welded to the canister outer shell and lid (Figure 26-15b). The MPC lid provides sufficient structural capability to permit the loaded MPC to be lifted by threaded holes in the MPC lid.

The heat from the fuel stored in the core region of the basket is removed by the thermosiphon (circulatory) action (Figure 26-10). As a result, high-heat-rate fuel[5] can be placed in the core region, surrounded by the cooler (and older) fuel in the periphery. This approach, known as "regionalised" storage, is extremely effective in mitigating the dose emitted from a basket in the lateral direction. The effectiveness of regionalised storage in reducing dose derives from the fact that almost 95 percent of the dose from the basket comes from the peripheral fuel; the inner region fuel contributes very little to the dose (Ref. 26.1, Section 3.5.8.3).

HI-TRAC Transfer Cask, which Holds the MPC during Loading Operations

HI-TRAC is the acronym for Holtec International transfer cask or "shuttle cask" for HI-STORM 100U. HI-TRAC is a slim cylindrical cask with removable bottom and top lids. HI-TRAC can be mounted on top of a HI-STORM 100U overpack to deliver or retrieve an MPC (Figure 26-15c and Figure 26-15d). HI-TRAC is a heavy-walled steel and lead cylinder with a water jacket attached to the exterior of the vessel. The main structural function of HI-TRAC is provided by carbon steel. Water and lead provide the main neutron and gamma shielding functions, respectively (Ref. 26.1, Section 3.5.8.3).

26.10 RECORDS

Good records of the waste characteristics, preserved for whatever timescale is necessary for a particular waste stream or package, will ensure that the waste can be managed safely in the future. The office for nuclear regulation (ONR) requires licencees to make arrangements for recording and preserving all the necessary information (Ref. 26.49).

5. The gamma radiation emitted is approximately proportional to the heat emission rate from the fuel.

The RWM of the NDA has issued a Work Instruction (Ref. 26.50) on generating assessments of the nature and quantity of waste streams. This document includes a description of how to assess the radiochemical and chemical data that should be recorded for each waste stream. It is supported by a report (Ref. 26.51) presenting sets of radionuclide concentrations, known as guidance quantities, that waste producers may use to assess the requirements for recording radionuclide data associated with their wastes. An additional document (Ref. 26.52) gives guidance on assessing which assay methods may be capable of delivering suitable inventory data for radionuclides of interest.

Compliance with the assessments and recommendations made during the NDA RWM LoC process will ensure that the information required now and in the future for the safe management of radioactive waste is recorded.

Waste package inventory records will be completed to maintain an inventory record of each waste package and its location within the ILW store vault (Ref. 26.1, Section 3.5.8.2). These waste package reports will be sent with the ILW packages to the ILW repository (GDF), when it becomes available within the UK. The need for a waste tracking system will be assessed during the detailed design associated with a specific site (Ref. 26.9, Section 3.4.7.13). This system, if needed, will ensure that the location of individual waste packages can be established. This tracking system shall also record data relating to the package, such as reference number, radiological inventory, and production date, in compliance with RWM requirements. The system shall be technology proof, in that any changes in technology shall be easily adopted without losses in data.

An example of the system that is presently used is the British Radwaste Information Management System (BRIMS) (Ref. 26.53). BRIMS is based on an Oracle database and is used by UK radwaste producers to record information about their wastes. In addition to recording the numerical information used to produce the UK Radioactive Waste Inventory (e.g., Ref. 26.54), BRIMS also records contextual information about waste streams.

LLW is planned to be recorded after being sorted, processed, and packaged (Ref. 26.9, Section 3.2.1.3).

26.11 CONCLUSIONS

This chapter of the PCSR provides evidence that:

- Westinghouse has produced an IWS to address the radioactive wastes and spent fuel produced by the AP1000 plant, which is appropriate for the assessment of a generic design.
- The wastes may be contained and cooled where necessary.
- Gaseous and liquid radwaste may be handled safely, with discharges that are ALARP.
- Solid radwastes may be handled safely.
- As far as can be ascertained during the GDA, all wastes are or will be disposable.
- BAT is used throughout.

Table 26-1. Assumptions and Exclusions for the Integrated Waste Strategy (Ref. 26.2, Table 4-1)

Item	Description
Assumption 1	National LLWR is available within 2 years of site operations commencing
Assumption 2	National ILW repository will be available before the end of the onsite ILW store building design period (before the end of this century)
Assumption 3	National HLW (spent fuel) repository will be available before the end of the design period of the onsite spent fuel store (before the end of this century)
Assumption 4	No major changes in legislation during the operational period of the AP1000 and the associated onsite waste facilities.
Assumption 5	Planning permissions for the spent fuel store and the extensions to the ILW store will be granted.
Assumption 6	No major restrictive changes to discharge limits during the operational period of the AP1000
Exclusion 1	External hazards and events that could cause major disruptions other than those already assumed in the safety case
Exclusion 2	Post-closure monitoring, requirements are not specified here.
Exclusion 3	Post-closure management, requirements are not specified here.
Exclusion 4	Variations in discharge

Table 26-2. Calculated Annual Limits for Air Emissions (Ref. 26.1, Table 6.1-5)

Air Effluent Input	Representative 12-month Plant Discharge (TBq/y)	Worst-Case Plant Annual Discharges (TBq/y)	Calculated Annual Limit (TBq/y)
Radioiodines(1)	5.95E-04	9.82E-04	1E-03
Noble gases(2)	8.099	13.363	13

27 DECOMMISSIONING AND END-OF-LIFE ASPECTS

27.1 INTRODUCTION

The objective of this chapter is to demonstrate that the generic design of the AP1000 plant can be safely decommissioned at the end of its operational life in accordance with United Kingdom (UK) strategy and regulations. Site-specific issues, including site delicensing, are not discussed as they will be the responsibility of the licensee. Although decommissioning is the last stage in the life cycle of a nuclear facility, licensees are required to make and implement adequate arrangements for the safe decommissioning of the site in accordance with national strategy, site licence condition (SLC) 35 (Reference 27.1).

The AP1000 design incorporates a number of features to facilitate decommissioning and to reduce the risk from decommissioning activities. Steps have been taken to minimise the amount of waste produced. The basis for decommissioning is based on current available techniques; dose management is considered to be as low as reasonably practicable (ALARP). These principles are described in Section 27.2.

Section 27.3 outlines the decommissioning strategy that has been developed for the AP1000 plant, describes the reasoning behind the timing of decommissioning, and provides more detail on the operations that will be carried out during decommissioning. It discusses the factors that affect the timing of decommissioning. Assumptions have been made that will be subject to review over time as detailed site-specific information becomes known. For example, use of the site after operations have ceased and local stakeholders' views will be important factors to consider when final decommissioning plans are being constructed.

A plan for implementing the decommissioning operations has been developed based on the chosen decommissioning strategy. This is described in Section 27.4, where further details on the safety management arrangements and decommissioning operations are given to enable the safe and systematic reduction of hazard from the AP1000 plant after operations finish.

Land remediation is a requirement of the operator and is not considered at this stage. However, anticipated regulator requirements are summarised in Section 27.5.

During generic design assessment (GDA), one single-unit AP1000 plant per site is assumed. Locating multiple plants on a site does not affect the logistics of decommissioning the nuclear island (NI), because each NI on a site will operate independently and can be decommissioned independently. However, if the waste treatment facilities are shared, the decommissioning plan must ensure that the decommissioning waste does not affect units still operating and that the decommissioning waste does not exceed the capacity of the waste facility.

Conclusions and references are presented in Sections 27.6 and 27.7.

27.1.1 Decommissioning Principles

The decommissioning strategy and plan developed in this chapter are based on the following principles:

- Systematic and progressive risk reduction
- Dose minimisation
- Waste minimisation
- Passively safe storage of wastes

Application of these four principles is discussed in the following sections.

27.1.1.1 Risk Reduction

Risk reduction is achieved using a staged approach to decommissioning. Three stages are identified, each one reducing the highest-risk items in turn; all three stages follow International Atomic Energy Agency (IAEA) guidance (Reference 27.2).

Stage 1 is to remove the fuel from the reactor and from the spent fuel pool, following an appropriate period of cooling. Spent fuel is put into dry storage canisters and transported to the onsite spent fuel stores. Checks are carried out to ensure that containment is maintained. After the fuel is removed, the primary circuit is decontaminated using existing primary circuit systems.

In Stage 2, preparatory work will be carried out to enable the remaining decommissioning activities. This includes conversion of the fuel-handling area for processing decommissioning waste; Surveys of the facility will be carried out and decommissioning plans and safety cases will be finalised. Service systems not required for decommissioning activities will be removed

In Stage 3, remaining radioactive materials will be removed in a systematic manner that reduces risk until there are no radiological restrictions on the site. This is the radiological end point for the site.

These three stages of decommissioning are discussed further in Section 27.3. The stages of decommissioning could overlap if appropriate but, for the sake of clarity, are considered as three distinct stages.

27.1.1.2 Dose Minimisation

Dose to decommissioning operators will be reduced to levels that are ALARP. Methods to achieve ALARP include design features to minimise dose; assessing potential options and choosing the arrangements that are ALARP; reducing the dose rate, for example, by decontamination or shielding or remote working; and reducing the time spent close to the source, for example, through modular construction that allows multiple components to be removed together from the reactor and then dismantled in a lower-dose area.

27.1.1.3 Waste Minimisation

The waste management hierarchy is integrated into the design, operation, and decommissioning plans for the AP1000 plant. In line with the requirements of the waste hierarchy, prevention, re-use, and recycling features are incorporated into the design. Decommissioning will be planned so as to avoid the production of unnecessary wastes. The number of approaches that will be used to minimise decommissioning waste are described below.

The integrated waste strategy (IWS) (Reference 27.3) will be reviewed during the operational phase and prior to and during the decommissioning phase to maximise reuse and recycling; disposal will be chosen only if other options are not practicable. The use of new and more appropriate waste routes for the decommissioning phase will be assessed.

A thorough characterisation of the physical, chemical, biological, and radiological properties of the plant will be carried out after defueling and decontamination of the primary circuit. The drivers for this characterisation are to establish plant conditions so that decommissioning

can be carried out safely and waste can be minimised, for example, by decontamination and separation. Operational radiological monitoring records will provide input for the characterisation.

Decontamination will be used where practicable to recover wastes that can, in line with the requirements of the waste hierarchy, be reused, recycled, or disposed of by conventional nonradioactive routes.

Segregation of different waste types will be carried out to allow optimum use of the waste routes available at the time of decommissioning. Segregation, minimisation, and disposal techniques are detailed in the IWS document (Reference 27.3), which will be updated as required by the operator to continuously improve waste minimisation.

27.1.1.4 Passively Safe Storage of Wastes

It is recognised that disposal routes for higher-activity materials will not be available immediately when that waste is processed. Therefore, a period of interim storage on site is envisaged. The waste will be stored on the site in appropriately designed facilities in a passively safe condition; that is, one that will not require active safety systems during the interim storage period. The use of an interim passively safe storage system will not compromise disposability.

27.1.2 Decommissioning End Point

The aim of decommissioning is to remove hazards so that the site does not present an unacceptable level of risk to human health or the wider environment. The end point includes the decommissioning of all facilities, including the interim storage facilities. The physical end point will be determined to a large extent by the future use of the site. In making a decision on the end point, the operators will take into account factors such as the planning conditions and the views of the regulators, local authority, and stakeholders. Therefore, the physical site end point will be determined later by the operator, taking into account local stakeholders' views but subject to the overriding requirement that there is no unacceptable risk to human health or the wider environment. The decommissioning end point is discussed further in Section 27.4.2, where an assumed end point is given for planning purposes.

27.2 DESIGN FOR DECOMMISSIONING

27.2.1 Overview

The design of the AP1000 plant incorporates features that support safe decommissioning, and minimise the amount and category of wastes produced from decommissioning as well as human and environmental impact. These principles are discussed in this section, along with the features incorporated into the design to aid decommissioning and to reduce waste volumes.

27.2.1.1 Design Principles

Regulatory Guidance

The design of the AP1000 plant facilitates and minimises decommissioning and associated waste management operations and costs. The principles underpinning the design are consistent with the UK government policy on decommissioning, the Office for Nuclear

Regulation (ONR) safety assessment principles (SAPs) for Nuclear Facilities and the Environment Agency (EA) Radioactive Substances Regulation – Environmental Principles.

SAP DC.1 states that "facilities should be designed and operated so that they can be safely decommissioned" (Reference 27.4). The adoption of this principle ensures that decommissioning and waste retrieval requirements are incorporated into plant design. Measures that demonstrate the adoption of this principle include the following:

- Design measures to minimise activation and contamination, for example, selection of materials around the reactor to prevent large quantities of long lived radionuclide's forming (e.g., using low cobalt steel)
- Physical and procedural methods to prevent the spread of contamination
- Control of activation (e.g., by control of primary circuit water chemistry)
- Design features to facilitate decommissioning and to reduce dose uptake by decommissioning workers
- Consideration of the implications for decommissioning when modifications to and experiments on the facility are proposed
- Identification of reasonably practicable changes to the facility to facilitate or accelerate decommissioning
- Minimising the generation of radioactive waste

Additionally, SAP RW.2 states that "the generation of radioactive waste should be prevented or, where this is not reasonably practicable, minimised in terms of quantity and activity". This principle may be adopted through specific design provisions, construction methods and commissioning, operational and decommissioning arrangements that avoid the creation of radioactive waste or reduce to the minimum radioactive waste generated throughout the facility lifetime.

As well as the SAPs, the EA Radioactive Substances Regulation – Environmental Principles also provide guidance on how decommissioning and waste minimisation may be incorporated into plant design. Principle DEDP3, Considering Decommissioning during Design and Operation, states that "facilities should be designed, built and operated using the best available techniques (BATs) to minimise the impacts on people and the environment of decommissioning operations and the management of decommissioning wastes" (Reference 27.5). In addition principle DEDP4, Discharges during Decommissioning, states that "aerial or liquid radioactive discharges to the environment during decommissioning should be kept to the minimum consistent with the decommissioning strategy for the site".

The following sections describe how the design of the AP1000 plant addresses these principles.

Minimising the Generation of Radioactive Waste

The current design of the AP1000 plant is the result of a design philosophy and design process that emphasised safety and simplicity. The design process used throughout the development of the AP1000 plant is to create a safe nuclear power plant with costs, radiation exposures and radioactive discharges ALARP.

The AP1000 design minimises the creation of radioactive waste during operations and decommissioning as the AP1000 plant was designed with fewer valves, pipes, and other components so less waste will be generated during maintenance activities (repair and replacement) and decommissioning compared to plants of a similar size. When compared to similar nuclear power plants, the AP1000 plant has roughly 50 percent fewer valves, 35 percent fewer pumps, 80 percent less piping, and 80 percent fewer heating, ventilation, and air-conditioning systems. Considering these characteristics, the decommissioning phase of the AP1000 plant should be shorter and the decommissioning activities may produce smaller quantities of activated/contaminated material that should be treated and conditioned for interim storage and final disposal as radioactive waste. This lends itself to more simple strategies, shorter decommissioning timescales and lower requirements for funding of the decommissioning phase.

In addition to the reduced building volumes and plant inventory, many features have been incorporated into the AP1000 design that are intended primarily to reduce the production of activated corrosion products. Such measures include the selection of materials used in the design and controls imposed upon the construction. A consequence is a reduction of operational radiation exposure during the normal operational life of the plant. A direct result of this is the reduction of the radioactive inventory and a reduction in the residual mass of active materials at the time of decommissioning.

The only effective course of action to reduce activation of fixed structures is to control material composition and attempt to reduce major element concentrations. Each of the materials in and around the core has a major element concentration that cannot be removed. For steels, these include iron and nickel, and for concrete, calcium. Efforts to reduce trace elements are of little benefit since their contribution to the total is minimal in comparison with the contribution from the major elements to the radioactive inventory.

One case where the control of a trace element is appropriate is steel where the reduction in cobalt has significant benefits. Activation of Co-59 produces Co-60, which is the largest contributor to occupational radiation exposure on pressurised water reactors (PWRs). The most highly activated structures in the plant will be the reactor internals. The level of cobalt in these structures has been restricted to below 0.05 percent by weight.

The UK AP1000 Environment Report describes in detail ways in which the AP1000 design minimises radioactive waste generated during operation, in particular (Reference 27.7):

- Section 2.6 gives further examples of AP1000 design decisions related to waste minimisation, waste generation, and waste disposal that reinforce the concept of safety through simplicity, ALARP, and BAT.

- Section 3.2 describes several ways in which the release of radioactive emissions from the AP1000 plant is reduced at source.

- Section 3.3 describes the handling and treatment of gaseous radioactive waste and gives details of the BAT assessments carried out for the treatment of gaseous radwaste.

- Section 3.4 describes the handling and treatment of liquid radioactive waste and gives details of the BAT assessments carried out for the treatment of liquid radwaste.

- Section 3.5.4 describes how waste minimisation, storage and disposal principles have been incorporated into all stages of the AP1000 plant life cycle including design, construction, operation and decommissioning.

- Table 3.1-1, Nuclear BAT Management Factors and AP1000 features, outlines the ways generation of radioactive waste is minimised, resources are used efficiently, emissions are reduced and waste is stored in a passively safe and retrievable form.

Preventing the Spread of Contamination

The AP1000 design provides features for protection against the occurrence, spread, and thus potential personnel exposure to radioactive contamination. The major contributor to the contamination of surfaces is activated corrosion products. The following steps have been taken in the design of the AP1000 plant to limit the generation of corrosion products:

- The injection of zinc acetate into the primary system has the effect of inhibiting general corrosion and primary water stress corrosion cracking. Corrosion rates of the materials can be reduced by up to a factor of three or more with the addition of 20 ppb of zinc.

- Primary circuit water chemistry will be maintained at pH levels of 6.9 to 7.4 to again mitigate the effects of activated corrosion products.

- Primary and auxiliary materials selected for use in the AP1000 plant have a cobalt content of less than 0.2 percent by weight or even lower depending on component. High cobalt stellite alloys are not used in primary circuit components.

The spread of contamination is also limited by a structural design that incorporates a number of structural modules. These are composite structures comprising concrete filled steel plate where face of the steel plate forms the walls of rooms. They are easily decontaminated and prevent the possible leaching of water borne contaminants into the concrete. In the limited areas where there are concrete walls exposed to potential contamination, such walls are coated with a coating that can be decontaminated. All steel surfaces exposed to potential contamination will also be provided with surface finishes that will prevent penetration and facilitate decontamination.

The incorporation of thicker and larger plates in the spent fuel pool also limits the spread of contamination. Where possible, this plate becomes the formwork. This eliminates the potential for voids between the plates and the concrete, which eliminates the potential for unsupported areas of plate and thus potential for high stress areas. The larger plates significantly reduce the amount of welds and particularly in situ welding. In addition, reduction in the weld surfaces reduces the damage to the plate surface finish making decontamination easier. Leaks in the spent fuel pool are primarily associated with welds that have been significantly reduced in quantity in this design. In addition, leak chases are provided. These provide for evidence of leakage and direct any contaminated leakage flow to the waste handling systems. They also prevent the leaching of active fluid into the concrete should a leak occur. The same advantages are also applicable to the refuelling water storage tank and the reactor cavity.

Spread of contamination is also limited by the provision of heating, ventilation, and air conditioning (HVAC) within the secondary containment areas.

The Environment Report (Reference 27.7, Section 2.9.5) gives further details of how the potential for leakage and spread of radioactive contamination from the AP1000 plant is minimised by using structure, system, and component designs and operational procedures. The principles that will be considered in the design of the radwaste and intermediate-level waste (ILW) store buildings with respect to decommissioning are outlined in the

UK AP1000 Radioactive Waste Arisings, Management and Disposal report (Reference 27.8). These include:

- Surfaces exposed to contamination will be minimised wherever practicable, and their surface coatings will be impermeable and readily decontaminated. For example inside containment:
  - Carbon steel and structural modules within the containment are coated with either inorganic zinc with an epoxy top coat or self-priming high solids epoxy (SPHSE).
  - Where practical, miscellaneous carbon steel items (such as stairs, ceilings, gratings, ladders, railings, conduit, duct, and cable tray) are hot-dip galvanised.
- Steel surfaces subject to immersion during normal plant operation (such as sumps and gutters) are stainless steel or are coated with SPHSE applied directly to the carbon steel without an inorganic zinc coating.
- Exposed concrete surfaces inside containment are coated with an epoxy sealer to help bind the concrete surface together and reduce dust that can become contaminated and airborne.
- Floors subject to heavy traffic or contaminated liquid spills are coated with self-levelling epoxy or SPHSE floor coating.
- The plant will be designed for the containment and recovery of possible spillage of active material.
- To prevent the spread of airborne contamination during operations, the ventilation system will be designed using depression gradients, such that the flow of air is from areas of low contamination to areas of potentially high contamination.
- Cabinets (e.g., sample cabinets) will be of robust construction and made as small as practicable, where used whilst still fulfilling their design function.
- Both internal and external surfaces of cabinets will be smooth and free from cracks, sharp edge projections and recesses, where contamination could collect.
- All cabinets will be vented via the active ventilation system and maintained at a depression, to prevent the potential spread of airborne contamination to the operating areas.

Design Features that Facilitate Decommissioning

As well as minimising decommissioning waste and contamination, the AP1000 design incorporates features which facilitate decommissioning. These are described later in Section 27.2.2.3.

In addition to the design features which minimise waste, reduce contamination and facilitate decommissioning, the plant containment and structures will be designed to retain their integrity for the expected operational life and the subsequent decommissioning period. The life of the radwaste building will be extended beyond the assumed 60 year operation period to allow the building to be used to support decommissioning. The operational period for the ILW store building is 100 years.

27.2.1.2 Operation and Maintenance Principles

Regulatory Compliance

Ultimate responsibility for plant operation and maintenance will belong to the licensee. When operating the plant the licensee must follow regulatory requirements that are informed by the policy and regulatory guidance provided by the UK government, ONR, EA, and international bodies such as the IAEA.

As Low As Reasonably Practicable

The licensee should ensure that the principle of ALARP is considered in all operational and maintenance tasks which are important to safety, radioactive waste management and decommissioning.

Best Available Technique

The licensee should ensure that the principle of BAT is adopted in the management of radioactive substances and radioactive waste to provide an optimal level of protection to human health, wildlife, organisms and the wider environment. The implementation of BAT during operations should result in reduced amounts of waste and radioactive contamination to be dealt with during decommissioning.

Operation and Maintenance

The licensee will need to establish preventive maintenance programmes to ensure the continual safe operation of the AP1000 plant. These programmes will include surveillance, inspection and maintenance of systems, structures, or components (SSCs) in accordance with appropriate safety margins, engineering practices and quality levels.

The way in which a plant is operated and maintained will also have a significant impact on the decommissioning strategies that can be implemented and the nature and amounts of waste that will have to be dealt with. For example, the operational procedures and good housekeeping must ensure that radioactive contamination does not spread throughout the plant and that provision is made to carry out maintenance with the minimum spread of contamination. It is also important that the plant is decontaminated throughout its operating lifetime, as this will minimise the potential operator dose uptake during decommissioning operations.

To ensure a high level of plant safety as the plant ages, the licensee should develop an inspection and maintenance programme to manage SSC ageing effectively and proactively. As the plant ages, there is an increased probability of both single component failures and common-cause failures. Operating experience has shown many SSC failures have occurred as a result of ageing mechanisms such as general and local corrosion, erosion–corrosion, radiation and thermal embrittlement, fatigue, creep, vibration and wear (Reference 27.9). These failures can affect plant safety through abnormalities of process systems. The programme should cover the entire lifetime of the plant including the decommissioning period which may extend over many years. The objective is to provide for the timely detection and mitigation of significant ageing effects in nuclear power plant SSCs important to plant safety and reliability during operation and decommissioning (Reference 27.10).

Waste Minimisation

The basic AP1000 design principles that minimise the creation of radwaste during operations and decommissioning are well established (Reference 27.7 and 27.8). These principles, which include good housekeeping, optimisation of plant shutdowns, waste segregation and volume reduction, should be followed by the licensee.

The operational procedures used by the licensee should take into account waste minimisation and best practice to prevent additional secondary waste arisings during operation of the plant. This will ensure that all wastes can be disposed of by already proven or planned routes when the plant is eventually decommissioned.

The onsite waste inventory should be minimised before decommissioning by the prompt transfer of waste to the available national waste disposal repositories, if these are available and have capacity to accept new build waste. Some ILW and high-level waste (HLW) may have to be transferred to onsite waste stores before this transfer is possible.

Plant Modification

If the licensee should modify the plant during the operational life, then the effect on decommissioning, such as future access, should be taken into consideration.

Data Collection, Record Management and Corporate Memory

SAP DC.6 states that "Documents and records that may be required for decommissioning purposes should be identified, prepared, updated, retained, and owned so that they will be available when needed" (Reference 27.4).

The adoption of this principle requires the licensee to develop robust data collection and record management procedures to handle the large amount of monitoring, process equipment and maintenance information that needs to be retained to facilitate decommissioning. This includes records of any design or materials changes and any extensive maintenance or refurbishment work carried out. These records are important to document the plant condition prior to the transition from operation to decommissioning and to ensure minimal loss of corporate memory before the decommissioning phase begins.

27.2.1.3 Learning from Experience Principles

National and International Experience

International experience is an important source of information on best practice. Learning from experience (LFE) is published by international organisations (e.g., IAEA, Western European Nuclear Regulators Association (WENRA), Nuclear Energy Association (NEA), European union (EU)), regulatory bodies (e.g., ONR, NRC), and in scientific and technical publications and conference proceedings. Westinghouse and the licensee will monitor these resources as part of their normal business practice. Relevant information will be appropriately recorded.

The IAEA has established a decommissioning network, which will bring together organisations with specific experience and competence in decommissioning and that are willing to share their experience with other organisations.

Licensee Experience

The licensee will likely have accumulated its own operating and decommissioning experience from operating and decommissioning other nuclear power plant facilities. The licensee will use this experience together with experience gained from the specialist decommissioning contractors that it employs to inform the decommissioning of the AP1000 plant.

Westinghouse Experience

Westinghouse will engage with the licensee with the LFE processes which Westinghouse has in place, for example the Corrective Action Process and the Lessons Learned database. The decommissioning of early Westinghouse PWR plants and the first AP1000 plants (e.g., China and US) that are likely to be decommissioned ahead of any UK plants will provide LFE resources that can be made available to the licensee to assist in their decommissioning plans. The requirements to alert and involve licensees in the discussion and resolution of learning events, which have relevance to safety or the environment, is built into the Westinghouse management arrangements.

27.2.2 Design Features for Decommissioning

27.2.2.1 General

The most effective time to minimise the decommissioning hazards and liabilities is during the design phase. Westinghouse has designed a number of features into the AP1000 plant that reduce the hazards associated with decommissioning and the liabilities that must be managed after the end of operations. These features are grouped into two categories:

- Minimising the volume and activity of waste
- Enabling decommissioning

The following sections describe each specific design feature incorporated into the AP1000 plant that minimises decommissioning liabilities, facilitate the decommissioning operations, and minimise the dose to operators.

27.2.2.2 Reducing Waste Volumes and Activity by Design

Minimising Materials

A very effective method of reducing decommissioning liabilities is to minimise the amount of materials and number of components that have to be decommissioned. At the design stage, Westinghouse reviewed the components used in previous designs and made significant reductions in materials without compromising safety or operational performance. Compared with similar nuclear power plants, the AP1000 plant has approximately 50 percent fewer valves, 35 percent fewer pumps, 80 percent less piping, and 80 percent fewer HVAC systems. As a result, the decommissioning phase of the AP1000 plant should be shorter and the decommissioning activities will produce less activated and contaminated material that must be treated and conditioned for interim storage and final disposal as radioactive waste. This should result in less decommissioning work to carry out and ultimately produce less waste to dispose of during decommissioning. A reduced dose may also result from having to decommission fewer components, which may result in less time working in active areas. The use of lower numbers of components also minimises the number of potential leakage pathways.

Selecting Materials for Low Activation

Activation of steels can have a significant impact on decommissioning liabilities, as activation products increase dose rates around the plant and can increase the category of waste. Westinghouse took an effective course of action during the design phase that reduces dose for decommissioning operations by carefully selecting materials to control composition and attempting to reduce activation products. In particular, a significant effort has been made to reduce cobalt-based alloys and/or lower the acceptable level of cobalt in the materials.

Reducing the amount of cobalt in structural materials is an example of the particular benefits of materials selection. Activation of Co-59 produces Co-60, which is the largest contributor to occupational radiation exposure on PWRs. The most highly activated structures in the plant will be the reactor internals. The level of cobalt in these structures has been restricted to below 0.05 percent by weight, thus reducing Co-60 production. Other primary and auxiliary materials selected for use in the AP1000 design have cobalt content of less than 0.2 percent by weight. Additionally, for the steam generator (SG) tubes, adoption of 690TT allows a reduction in cobalt generation because of the reduction in nickel content, and cobalt in 690TT for the SG tubes is limited to 0.015 percent by weight. Use of stellite alloys for hard facing of valves and other components has been significantly reduced.

Each material in and around the core has elements that generate problematic activation products, and these cannot always be eliminated. For steels, these include iron and nickel, and for concrete, calcium. Even where these materials cannot be eliminated, steps have been taken to minimise the quantity present, including simplifying the design and reducing the number of components.

Minimising Corrosion

Activated corrosion products are the major contributor to the contamination of surfaces in the primary circuit. The following steps have been taken in the design of the AP1000 plant to limit their generation:

- The injection of zinc acetate into the primary system has the effect of inhibiting general corrosion and primary water stress corrosion cracking. Corrosion rates of the materials can be reduced by up to a factor of three or more with the addition of 20 ppb of zinc.

- Corrosion products and other contaminants will be removed by the chemical and volume control system during the operational phase, which will reduce contamination levels and dose for operators during decommissioning.

- Primary circuit water chemistry will be maintained at a pH between 6.9 and 7.4 to again mitigate the effects of activated corrosion products.

Decontaminating Primary Circuit

The majority of the primary circuit is designed in stainless steel with limited use of Inconel™. At this time, an oxidative process system has been identified for the decontamination of potentially active or contaminated piping circuits although other processes (e.g., oxidative/reductive processes) may be considered. Decontamination factors of up to ten for stainless steel and two to three for Inconel are expected for the initial phases.

This method of decontamination will require the provision of dedicated reagent tanks, pumps, and associated equipment. It may be possible to use existing operational plant and equipment.

This gives the operator the option to decontaminate the primary circuits before dismantling if the conditions at the time suggest that it would represent the ALARP option.

Selecting Surface Materials

The AP1000 structural design incorporates a number of structural modules that are plate structures filled with concrete, the whole acting as a composite structure. They present a steel plate face forming the walls of rooms. In addition, concrete surfaces that will potentially be exposed to contamination will be covered with steel plates that can be decontaminated. Where these steel surfaces could be exposed to potential contamination, they will be provided with surface finishes to facilitate decontamination. This is an improvement over existing PWRs, where a large amount of concrete is exposed to contamination that is more difficult to decontaminate. The outer steel surface also prevents the possible transfer of waterborne contaminants into the concrete.

Reducing Leakage Pathways

The AP1000 design has a number of design features to reduce leakage pathways. Reducing the number of leakage pathways reduces the spread of contamination and thus potentially the amount of radioactive waste produced, as well as the amount of work and dose for decommissioning operatives. The measures for reducing leakage pathways are discussed below.

Penetrations through the primary containment are designed to be leaktight assemblies whilst allowing pipes and cables to pass through the containment vessel boundary. Very often, in previous designs, they are the sites of small leakage pathways and so have been minimised in the AP1000 design.

One of the fundamental design objectives for passive cooling of the AP1000 reactor is to isolate containment during a design basis accident so that only energy passes through the containment boundary, not fluids. This minimises the number of penetrations and reduces design, inspection, and maintenance burdens, and, therefore, waste arisings that could result from these activities.

Penetrations have been minimised by implementing a variety of innovative techniques:

- Service systems in containment, for example, component cooling water or compressed air, are split and routed inside containment, resulting in only one supply or return penetration for each service.

- Some intermittent services with common fluids share common penetrations. For example, both chilled water and hot water heating services to HVAC in containment share common penetrations since they will not be used at the same time. The fire protection water and containment spray supply systems also share a common penetration.

- Instrumentation and control penetrations are reduced by taking advantage of digital data highway technology. Multiplexing cabinets are located such that instrumentation and control signals share a common highway penetration in lieu of multiple individual signal penetrations.

All floor drains in radioactive areas are grouted into the surrounding concrete to provide secondary containment: this ensures that any leakage will be collected in the floor drain and

not bypass the drain, therefore potentially reducing the spread of contamination should the drain leak. This reduces the amount of work and waste during decommissioning.

The spent fuel pool and connected pools are designed to eliminate unidentified leakage to the groundwater. The design includes construction using high-quality modular techniques, reduced numbers of welds using advanced welding techniques, welds equipped with leak chases, and a zoned pool leak detection system. To the extent possible, these pools are located entirely inside the auxiliary and containment building, so that any theoretical leakage from the tanks would accumulate in the building, reducing the potential spread of contamination and decommissioning liabilities. Further details can be found in the Environment Report (Reference 27.7, Section 2.9.5.5).

27.2.2.3 Features Enabling Decommissioning

The AP1000 design includes the following features that enable decommissioning to be carried out more quickly, more safely, and to minimise dose to operators.

Modular Dismantling Philosophy

The AP1000 plant is designed and built in modules, which aids the construction and quality of build, and makes decommissioning easier. Modules can be removed in a similar manner to the way that they were installed, although some segmentation of modules may be required to facilitate lifting operations due to the additional weight of concrete added during the construction process. The decommissioning sequence depends on the way the individual modules interact to provide the overall structural integrity of the facility during decommissioning. Some individual modules can be partly decommissioned in parallel if individual modules are structurally independent, and can be separated and removed to the waste processing area for further dismantling, decontamination, packaging and disposal. This allows some of the decommissioning to be carried out away from the original position and source of dose, in a facility designed and built specifically for dismantling, decontamination, size reduction, and packaging for disposal. This approach reduces risk and dose to operators.

Polar Crane Available for Decommissioning

The polar crane in the containment is designed for lifting large items from the reactor such as the SGs, reactor coolant pump (RCP) motor/impeller assemblies, and reactor vessel head to a place where they can be set down and prepared for transfer to the waste facility. It will be available for lifting these large reactor components during the decommissioning phase. In addition, an auxiliary hook can be used for assisting with large lifts or on its own for lifts of smaller components.

Reactor Pressure Vessel

The AP1000 design is such that the reactor pressure vessel (RPV) can be removed in one piece. This should significantly reduce the doses received by decommissioning staff and reduce costs. Further processing such as decontamination and size reduction would be required to make the RPV suitable for disposal in the UK. This will be done in a specifically designed facility should the operator choose to use this option.

Logistics of Waste Movements

Once the polar crane has lifted items or minor modules for transfer to the waste processing facility, they must be removed from the plant. The plant has been designed with pathways that facilitate the movement of equipment. These routes will be used during decommissioning

operations to install decommissioning equipment and they will allow for removal of whole plant items and modules as they are being decommissioned.

Floor slabs of the auxiliary building and shield building are strengthened and structurally connected, providing not only seismic protection but also allowing movement of the heavier modules and plant items.

Heating, Ventilation, and Air-Conditioning Systems Support Decommissioning

During operations, facilities at risk of potential contamination are provided with ventilation systems that provide extraction and filtration. The ventilation systems will also be used in facilities where there is a contamination risk during decommissioning. This will provide local ventilation to reduce airborne contamination, thus reducing the spread of contamination and the risk of internal dose to operators.

It is expected that local modifications to the HVAC system will be required during the decommissioning phase. This will depend on the operating experience, decommissioning plans, and safety case developed closer to the time by the operator.

Operational Shielding Suitable for Decommissioning

Operational shielding has been designed in a way that will facilitate decommissioning operations. Some examples are described below.

The shield building is a structure that surrounds the containment vessel and provides shielding for the containment vessel and other radioactive systems located in the containment building. This will be maintained during the decommissioning phases to reduce doses to decommissioning staff. Some modifications to the shielding are expected to allow access for decommissioning equipment and revised shielding assessments will be carried out as part of the decommissioning safety case. These changes are not expected to adversely affect the protection offered by the shielding. Any modifications made to shielding will ensure that doses to decommissioning staff will be ALARP.

The shroud that provides shielding to the control rod drive mechanism can be used for removal of the system during decommissioning to reduce dose to operators.

Removable shielding is provided for piping systems that require inspection during the operational phase. This will allow quick access for size reduction and isolation of pipework during decommissioning. The removable shielding can also be reused on other sections of pipework, thus reducing dose to decommissioning operators.

Shielding is provided to separate equipment such as demineralisers and filters from nonradioactive equipment. Uncontaminated items can therefore be removed with minimal dose to operators when making space to decommission the radioactive equipment.

Shielding provided between radiation sources and access areas for operations will continue to be used during decommissioning.

Equipment that requires minimal maintenance is enclosed in shielded compartments. Removable access hatches are fitted to allow access for decommissioning whilst maintaining shielding around the components.

Shielding is provided to manually operated valves that can become contaminated, and will reduce dose to operators during decommissioning.

Recovery of Residual Operational Waste

The AP1000 plant is designed so that operational wastes such as those from the condensate polishing plant can be removed and processed in the waste handling building during the operational phases. Some operational wastes, such as the residue of operational wastes in vessels, will have to be removed during decommissioning. The shielded hatches that allow access to the vessels for maintenance during operations can also be used for decommissioning; either by providing access for remotely operated tooling or allowing man access if dose rates within the vessels permit.

Isolation and Decommissioning of Sections of the Plant

The plant design allows sections of plant to be isolated and decommissioned independently of others where appropriate. In particular service systems will be provided with isolation valves to allow areas to be decommissioned and taken out of service without affecting ongoing service supplies needed elsewhere. Also, prior to decommissioning, a new electrical supply to the ILW store will be installed which will also supply the radwaste building. This will allow the main NI to be dismantled whilst retaining the use of the radwaste building.

27.3 DECOMMISSIONING STRATEGY OF THE AP1000 DESIGN

27.3.1 Introduction

This section provides a high-level decommissioning strategy appropriate to this stage of the approval process. At the appropriate time, it can be used as the basis of a standalone decommissioning strategy document. This decommissioning strategy document will be updated by the operator at appropriate intervals agreed upon with the regulator, or after significant changes, to ensure that it remains current as required under SLC 35 (Reference 27.1). The decommissioning strategy document is also subject to periodic regulator review (ONR and EA) as may be required by government policy (Reference 27.11) and SLC 15 (Reference 27.1).

This strategy is consistent with UK government regulations, policies, and strategies; and with IAEA guidelines on decommissioning nuclear power plants (Reference 27.2).

This section gives details on the activities that will be carried out during decommissioning, and the sequence and duration of those activities.

Timing of decommissioning is an operator’s decision but a number of factors will affect the choice between immediate and deferred decommissioning. The sensitivity of the decision to those factors is discussed. One of the significant factors in deciding when to decommission is the predicted use of the site after operations, which also affects the site end point and land remediation strategy. Each of these in turn is influenced by local stakeholders as well as regulatory requirements. Stakeholder engagement and the site end point are therefore also considered in this section. Planning and other matters related to implementation of the strategy are discussed in Section 27.4.

27.3.2 Generic Decommissioning Strategy

27.3.2.1 General

The IAEA has recognised the following three primary decommissioning strategies in developing IAEA safety standards (Reference 27.2):

- **Immediate dismantling** – Dismantling begins soon after shutdown of the plant (typically within 5 years) with radioactive material being removed.

- **Deferred dismantling or safe enclosure ("safe store")** – Those parts of the facility containing radioactivity are processed or brought into a condition such that they can be stored and maintained safely (e.g., liquids are drained from the system and irradiated fuel and operational waste materials removed). The facility is placed in long-term storage (for, say, 50 years) before final dismantling.

- **Entombment** – As with the deferred dismantling option, liquids and waste are removed. The remaining radioactive material is encased onsite (normally in concrete). Essentially, the site becomes a near-surface waste repository.

All the options above could be implemented for the AP1000 plant. The strategy of entombment is, however, highly unlikely to be acceptable to the public for nuclear power plants in Western Europe as it is effectively onsite disposal of HLW, which is not in line with declared government policy.

The choice therefore lies between prompt and deferred decommissioning. However, whichever option is adopted, spent fuel would be discharged from the core and kept in an interim store onsite at the end of station operation before disposal once a facility is available.

The factor that influences the two considered options, immediate or deferred decommissioning, is effectively a choice about timing. The advantages and disadvantages of immediate or deferred decommissioning are considered with respect to the AP1000 design below in Sections 27.3.2.2 to 27.3.2.6. Unless deferral can be substantiated, then immediate decommissioning is the default position.

27.3.2.2 Radioactive Waste Minimisation and Operator Exposure

Deferring decommissioning may be the most appropriate option if it allows primary circuit materials to decay to the point where waste volumes or categories are reduced, or dose to operators is significantly reduced.

Waste generation will be minimised in an AP1000 due to material selection. For example, the level of cobalt in reactor internal structures is limited to below 0.05 weight percent, and in primary and auxiliary materials to less than 0.2 weight percent, however, there is still some activation of the steel producing Co-60 in the RPV. Some concrete will also become activated, for example from module CA-04. It is expected that decommissioning of the RPV will have to be delayed for at least 8 to 10 years after cessation of plant operations to allow activity levels to drop sufficiently so that the dismantled components can be transported within the regulations applicable at that time. This delay will allow the Co-60 to decay by approximately two half-lives and the dose due to this nuclide to reduce by a factor of approximately four. Remote decommissioning methods, however, will still be required for the RPV decommissioning whether an immediate or deferred decommissioning strategy is chosen.

The inventories of activated materials for the AP1000 plant after 10, 50, and 100 years have been determined (see Appendix 27A, Table 27A-1). The data show that the reduction in activity in the period between 10 and 50 years after shutdown is relatively modest; clearly, the categorisation of the activated waste materials is unlikely to change significantly in that time.

It is concluded that, from the perspective of radioactive waste minimisation and operator radiation exposure, there is no significant benefit to be gained by deferring decommissioning.

27.3.2.3 Radioactive Waste Management and Available Disposal Routes

Disposability of Intermediate-Level Waste and Spent Fuel

The ILW and the spent fuel from the AP1000 plant at a burnup of 65 GWd/t have been assessed to be disposable in the UK (Reference 27.12). In addition, the low-level waste repository (LLWR) has agreed in principle to accept low-level waste (LLW) from AP1000 installations (Reference 27.13).

It is recognised that spent fuel will have to be allowed to cool for 100 years before it can be placed in the geological disposal facility (GDF). This is allowed for in the design.

The GDF is not yet available but the current plan is for it to be available for disposal of waste from this generation of nuclear power plants. The AP1000 design allows for passive safe storage of ILW and spent fuel until the proposed GDF becomes available.

The unavailability of the GDF at the end of the AP1000 plant operation should not delay immediate decommissioning of the reactor as the design allows for passive safe storage of ILW and spent fuel, and other wastes can be disposed of as they arise. However, the decommissioning strategy and timing of decommissioning should be reviewed if changes to either of the repositories' plans occur.

As the disposability of the spent fuel and ILW is effectively neutral in determining the decommissioning timeframe, immediate decommissioning, as the default position, remains the preferred option.

27.3.2.4 Maintenance of the Organisation and Corporate Memory

Immediate dismantling is advantageous because the workforce and management structure, and hence the corporate memory, will essentially be in place, allowing work to flow from operations to decommissioning without loss of that corporate memory.

The spent fuel store decommissioning will have to be deferred until the fuel has cooled sufficiently to be disposed of and therefore requires maintaining the organisation for a considerable period, 100 years or more. This period exceeds the decommissioning period for the AP1000 reactor itself, and so does not affect decommissioning of the power plant.

There may or may not be a substantial delay to waste store decommissioning. However, delaying reactor decommissioning (where corporate memory helps) to aid store decommissioning (where corporate memory will be much less of an issue) is not advantageous.

Based on this criterion, prompt reactor decommissioning is therefore favoured.

27.3.2.5 National and International Experience

There is a wealth of international experience now developing on the timing of decommissioning and actual decommissioning. This international experience suggests that prompt decommissioning is preferred for PWRs (Reference 27.14, Summary of Session 3).

The advantages of prompt decommissioning include the availability of an existing workforce with detailed knowledge of the plant, continuation and maintenance of the organisation, and corporate memory. Prompt decommissioning is consistent with sustainability. The most compelling reasons for deferral are considered to be immature waste management and disposal facilities and inadequate funding.

Current international practice for PWRs calls for prompt decommissioning strategies.

27.3.2.6 Conclusion of Technical Arguments on Generic Decommissioning Strategy

Based on the considerations of the various technical factors discussed above, it is concluded that the bulk of the plant and facilities will be subject to immediate decommissioning at the end of operations. However, the spent fuel and ILW will be placed into passive safe storage, spent fuel so that it can cool sufficiently to allow transfer to the GDF and ILW until the GDF becomes available.

27.3.2.7 Stakeholder Engagement and Decommissioning End Point

In addition to the technical arguments on the preferred decommissioning strategy set forth above, it is important to consider nontechnical arguments. These are likely to focus on the future use of the site and the views of a variety of stakeholders, and will develop with time. It is inappropriate to forecast these arguments at this point, but they will be taken into account by the operator closer to the time when operations cease.

27.3.3 Stages of Decommissioning

The decommissioning strategy is designed for progressive and systematic reduction of hazard, and this is achieved through a number of stages of decommissioning. The three stages of decommissioning are summarised as follows (Reference 27.3); they could overlap if appropriate but, for the sake of clarity, are considered as three distinct stages.

27.3.3.1 Stage 1

The principal activities to be accomplished during Stage 1 are as follows:

- Maintenance of buildings and systems until dismantling
- Removal of fuel from the reactor to the spent fuel pool and disposal per the established practices
- Removal of radioactive inventory from the reactor system and non-decommissioning service systems
- Contamination mapping
- Post-operational clean out and in-situ decontamination (e.g., chemical decontamination of potentially active or contaminated circuits) of non-decommissioning service systems and reactor system

- Establishment of new radiation control areas based on the above actions as work progresses
- Review configuration of service systems (e.g., electrical, piping, HVAC, radwaste, drainage, monitoring) and plan for their use/modification in decommissioning activities
- Removal of fuel from the spent fuel pool to the spent fuel store

It is expected that this phase of work will last 10 years.

27.3.3.2 Stage 2

The principal activities to be accomplished during Stage 2 are as follows:

- Modification of existing service systems and installation of temporary service systems to meet decommissioning requirements (e.g., shielding, monitoring, ventilation systems)
- Removal of radioactive inventory from the spent fuel pool system and fuel handling system
- Dismantling of non-radioactive, non-decommissioning service systems from the turbine building and disposal/recycling of inert waste
- Post-operational clean out and in-situ decontamination of spent fuel pool system and fuel handling system
- Conversion of fuel handling area, within the auxiliary building, into an interim waste storage, decontamination, waste reduction, packaging, and processing area for ILW
- Contamination mapping of radioactive, non-decommissioning service systems
- Dismantling of potentially radioactive, non-decommissioning service systems
- Ex-situ decontamination of dismantled radioactive, non-decommissioning service systems (e.g., in decommissioning building, spent fuel pool, fuel handling area, hot machine shop, radwaste building)
- Treatment, packaging and disposal of waste from potentially radioactive, non-decommissioning service systems
- Contamination mapping of potentially radioactive systems in containment

It is expected that this phase of work will last 6 years.

27.3.3.3 Stage 3

The principal activities to be accomplished during Stage 3 are as follows:

- Dismantling of reactor system. Assessment of activity levels of dismantled equipment and secure protection for transportation to waste handling areas
- Removal of radioactive inventory from residual radioactive systems in containment

- Contamination mapping of other potentially radioactive systems, the containment building, and shield building
- Dismantling of decommissioning service, non-radioactive systems from turbine building and yard. Replacement with temporary decommissioning service systems, as required
- Decontamination of dismantled reactor system ex-situ (e.g., in decommissioning building, spent fuel pool, fuel handling area)
- Post-operational clean out and in-situ decontamination of other radioactive systems in containment, the containment building (including cutting, processing, and removal of active concrete in the containment building), and the shield building
- Removal of radioactive inventory from residual radioactive systems in auxiliary building
- Disposal/recycling of inert waste from non-radioactive systems from turbine building and yard
- Packaging and disposal of radioactive waste from reactor system
- Post-operational clean out and in-situ decontamination of residual radioactive systems in auxiliary building
- Dismantling and removal of residual radioactive systems from containment
- Dismantling and removal of containment building, shield building, and turbine building,
- Ex-situ decontamination of dismantled radioactive systems from containment, and the dismantled active components of the containment building and shield building
- Disposal of inert waste from dismantled turbine building
- Dismantling and removal of remaining non-radioactive, decommissioning service systems and residual radioactive systems in the auxiliary building
- Dismantling and removal of remaining potentially radioactive, decommissioning service systems and the auxiliary building, radwaste building, decommissioning building, and LLW store. Replace with temporary systems as required.
- Ex-situ decontamination of potentially radioactive, decommissioning service systems and the auxiliary building, radwaste building, decommissioning building, and LLW store.
- Treatment, packaging, and disposal of radioactive waste from dismantled radioactive systems from containment and the dismantled active components of the containment building and shield building
- Disposal/recycling of inert waste from dismantling non-radioactive, decommissioning service systems and residual radioactive systems in the auxiliary building
- Dismantling and removal of temporary decommissioning service systems, wastewater system, annex building, and diesel generator building

- Treatment, packaging and disposal of radioactive waste from potentially radioactive decommissioning service systems, including temporary service systems.

- Disposal/recycling of inert waste from temporary decommissioning service systems, wastewater system, annex building, and diesel generator building

- Maintenance of ILW and HLW stores

It is expected that this phase of work will last 6 years.

This sequence of decommissioning works is presented in Figure 27-3.

27.3.3.4 Interim Waste Stores

The interim waste stores will be decommissioned and dismantled once all decommissioning waste has been removed from the stores and transported to the appropriate national repository or offsite waste storage facility if the repository is not available.

27.4 DECOMMISSIONING PLANNING AND IMPLEMENTATION FOR THE AP1000 DESIGN

27.4.1 Planning Overview

This section gives greater details on the implementation of the decommissioning strategy based on an assumed plant status at the end of the operational phase and an assumed target end point for decommissioning. The decommissioning operations, waste management, and safety management arrangements are also described in this section.

The operator will be responsible for updating decommissioning plans as required if UK legislation or best practise changes or if there are any changes to the assumptions made in this document.

At appropriate periods in the future, detailed decommissioning plans will be developed by the operators. During the preparation of these detailed decommissioning plans, the operator will also develop or revise the following documents prior to decommissioning operations:

- Detailed decommissioning plans (for individual plant/facilities)

- Decommissioning safety cases

- Health physics and environmental monitoring strategies

- BAT and ALARP studies (including decommissioning waste routes and waste minimisation strategies)

- Environmental impact assessment and environmental statement as required by The Environmental Impact Assessment for Decommissioning Regulations (EIADR)

- Decommissioning hazard identification

- Radioactive waste management case

- The IWS (Reference 27.3)

27.4.2 Assumed Target Decommissioning End Point

The main objectives of decommissioning any industrial site, including a nuclear power plant, are as follows:

- To ensure that the decommissioned site does not present unacceptable risks to human health or the wider environment
- To allow the release of the site for future use (e.g., for redevelopment or use as open space)

It has been assumed for the purposes of the plan that, as a minimum, the decommissioning operations would include the following:

- Removal of all hazardous materials (including wastes)
- Dismantling of plant/machinery
- Demolition of structures to 1 m below ground level

To achieve these objectives, the overriding requirement would be the safe removal of radioactive materials (to include spent fuel, radioactive wastes, and activated plant components).

The intended decommissioning end point and the subsequent management of contaminated land, if appropriate, will be addressed by the licensee as part of their update of the Decommissioning Strategy document. The assumed target decommissioning end point is described below:

- Plant and equipment will be decontaminated and radioactive materials removed and disposed of via the appropriate route.
- Structures will be de-planted and demolished during final site clearance (FSC).
- Buildings will be removed to a depth of 1 m below ground level.
- Roads, car parks, underground services, and similar structures, will be removed.
- The active drains and outfall will be removed and foul and surface water drains will be removed if less than 1 m below ground level.
- Basements, if present, will be demolished to 1 m below ground level and any remaining subsurface structures punctured to assist drainage.
- Land requiring remediation will be identified and treated appropriately.
- Ground will be appropriately landscaped, and land drains installed if required.
- After FSC, the site will be released from its Nuclear Site Licence if it is deemed appropriate.

It is noted that the eventual end use will be subject to consultation and rationalisation with UK government policy at the time and may also be subject to conditions attached to the original planning consent.

27.4.3 Assumed Plant Status at the End of Operational Life

The status of the facility at the end of its operational life and therefore the start of the decommissioning phase, the decommissioning plant status (DPS), has been assessed.

In determining the DPS, a number of assumptions have been made about the operations of the plant:

- The reactor will be operated for 60 years.
- Plant SSC will have been well maintained during its operational life through the implementation by the licensee of an effective inspection and maintenance programme
- All necessary plant support facilities (e.g., power, utilities, cooling, shielding, ventilation systems, effluent treatment, drainage, security) will be operational and maintained.
- Chemical inventories onsite will be at low levels and tanks will contain residual unused chemicals.
- Some accumulation of potentially radioactive corrosion products is to be expected in the radioactive water systems.
- Irradiated fuel will be kept in the cooling ponds after defueling. The spent fuel will then be dried and then stored for up to 100 years onsite, at which point it will be disposed of in the GDF.
- Operational ILW will be packaged in a form suitable for disposal offsite. There will be an interim passively safe storage period onsite for the waste.
- LLW will be packaged onsite for disposal. After packaging, waste disposal containers will be sent to appropriate disposal sites. It is assumed that current disposal routes (or routes similar to them) will remain available during the operational and decommissioning phases.
- A repository for spent fuel will be available.
- A disposal facility for ILW will be available.
- Any unplanned operational events that might have occurred during the operating life of the plant will have been fully remediated.
- No significant changes have been made to the design or operation of the plant.
- The radiological conditions of the main items of the plant are those shown in Appendix 27A.
- The radiological and contamination zoning of areas will be the same as that outlined in Chapter 24.

27.4.4 Decommissioning Operations and Waste Management

27.4.4.1 Decommissioning Sequence and Methodology

The stages of decommissioning have been outlined previously in Section 27.3.3. The outline decommissioning methodology for each of these stages and for the decommissioning of the site interim waste stores is outlined in the following sections. This information has been based on Sections 5.1.2 to 5.1.5 of the UK AP1000 Decommissioning Plan (Reference 27.20).

27.4.4.2 Stage 1 Decommissioning

Stage 1 decommissioning addresses:

Maintenance of buildings and systems until dismantling

- Following cessation of power generation operations, all buildings and systems will be maintained as required until they are ready to be dismantled
- Remove fuel from the reactor to the spent fuel pool
- Removal and transport of spent fuel from the reactor to the spent fuel pool as per the processes established at that time. Spent fuel will remain in the spent fuel pool until the heat output from the fuel has reduced sufficiently to meet the requirements for placement in a dry spent fuel storage container.
- Remove radioactive inventory from the reactor system and non-decommissioning service systems
- The radioactive inventory of the reactor system and the non-decommissioning service systems will be removed and treated by the existing plant radwaste systems. The term radioactive inventory refers to the radioactive contents of vessels, tanks, pipes, etc., such as water, chemicals, settled solids, ion exchange resins, and filter cartridges. There will be no removal of fixed contaminated equipment at this stage.

Contamination mapping

- Contamination mapping of all radioactive and potentially radioactive systems will be carried out to ensure that the health and safety risks associated with maintenance and dismantling of the radioactive systems are understood and the decontamination and radioactive waste treatment options can be assessed.
- Post-operational clean out and in-situ decontamination (e.g., chemical decontamination of contaminated circuits) of non-decommissioning service systems and reactor system
- The reactor cavity and radioactive, mechanical and fluid systems that are not required for decommissioning will be decontaminated and cleaned in line with the decontamination strategy described in the UK AP1000 Decontamination Considerations (Reference 27.21). Contaminated piping circuits will likely be decontaminated by an oxidative decontamination process, although other processes (e.g., oxidative/reductive processes) may be considered. The oxidative process involves ion exchange. Anion and cation resins will be used, will become active, and must be treated as active waste. It is anticipated that the AP1000 circuits will be significantly less contaminated due to the

chemistry and the addition of zinc acetate. This method of decontamination will require the provision of dedicated reagent tanks, pump skid, and the like. It may be possible to utilise existing plant equipment or alternatively explore the option of using mobile equipment during the development of the final decommissioning plan. All waste, active or not, will be treated in accordance with the requirements in force at the time of decommissioning. The system will be designed to minimise exposure and limit the potential for active water to leak and contaminate surfaces.

Establishment of new radiation control areas

- At the time the plant enters the decommissioning phase, the existing radiological control areas will remain in place. As work progresses and activity levels permit, the boundaries will be successively reduced.

Review of requirements of decommissioning service systems

- The decommissioning requirements for all service systems will be reviewed. Service systems may need to be modified according to decommissioning work package requirements. The need for temporary service systems will be identified (e.g., electrical, piping, ventilation, monitoring, and shielding systems). The existing plant radwaste systems will remain in use for as long as possible during decommissioning. The treatment of decontamination and active drain reagents may be achieved using the auxiliary building ion exchange facility. The treatment route will be assessed to determine if further treatment units (e.g., neutralising, filtration) will be required to achieve required discharge consents. Final effluent disposal will either be by routing to the site effluent treatment facility, discharge to outfall, or by collection and transfer to a designated waste effluent treatment facility, operated by a contractor. A mobile encapsulation plant will be used as far as practicable for the decommissioning and disposal of solid waste (e.g., high-efficiency particulate air (HEPA) filters, spent resins, etc.). When the auxiliary building and in particular the liquid radwaste facilities are to be decommissioned it will be possible to re-locate the encapsulation plant to either the radwaste building, or the temporary decommissioning structure for further use. The liquid radwaste equipment could then be cleaned, size reduced, and encapsulated if needed. The point at which the existing plant radwaste systems will be decommissioned will be defined in the final decommissioning plan. However, it is assumed it will be during Stage 3.

Removal of fuel from the spent fuel pool to spent fuel store

- Once the remaining spent fuel in the spent fuel pool has cooled sufficiently, the spent fuel assemblies will be transferred from the spent fuel pool to the cask loading pit by the fuel transfer system. Here they will be placed into dry storage canisters which are filled with inert gas and sealed. The sealed canisters will then be cleaned and decontaminated before being transferred to the spent fuel store using an appropriate transport vehicle.

27.4.4.3 Stage 2 Decommissioning

Stage 2 decommissioning addresses:

Modify existing service systems and install temporary service systems to meet decommissioning requirements (e.g., shielding, monitoring, ventilation systems).

Modifying existing service systems and supply temporary service systems to meet decommissioning requirements in line with the plans developed during the Stage 1 review.

Removal of radioactive inventory from spent fuel pool system and fuel handling system.

- The radioactive inventory of the spent fuel pool system and the fuel handling system will be removed and treated by the existing plant radwaste systems. Contamination mapping will be carried out to assess the decontamination and cleaning requirements and the health and safety risks associated with maintenance and dismantling of the radioactive systems.

Dismantling of non-radioactive, non-decommissioning service systems from the turbine building and dispose/recycle inert waste.

- Non-radioactive service systems (for example, circulating water cooling system) that are no longer needed to support decommissioning activities will be dismantled and removed as per the schedule established at that time. Temporary lifting and handling equipment to support plant dismantling will be brought in and installed. The active drain system will remain in operation. All waste is expected to be non-radioactive and will be disposed of/recycled by the procedures in place at that time.

Post-operational clean out and in-situ decontamination of spent fuel pool system and fuel handling system.

- The spent fuel pool, fuel handling system, and other associated areas will be decontaminated and cleaned as required in line with the decontamination strategy described in the UK AP1000 Decontamination Considerations (Reference 27.21). The treatment of decontamination and active drain reagents may be achieved using the existing ion exchange facility as described in Stage 1.

Conversion of the fuel handling building

- All fuel from the reactor and the spent fuel pool will have been removed during Stage 1 of decommissioning. The spent fuel racks will be dismantled and the pool will be cleaned and decontaminated. The HVAC systems will remain in operation. The fuel handling building will then be used as a decontamination and waste reduction area. This building, together with the temporary facility described earlier, will be sufficient to store all of the dismantled equipment removed from the plant during decommissioning. The basic premise is that there is significantly less building volume and equipment and that less of this reduced volume will be active. As items are confirmed as clean, they will be removed from the site and disposed. This facility will be used for processing ILW waste. Items will be reduced in size to accommodate their disposal in the standard waste casks (e.g., radioactive waste management (RWM) boxes and drums (Reference 27.24)) in use at that time for that waste level. Equipment to perform cutting and volume reduction activities will be installed in this building. The reduction process will be designed to minimise personnel exposure, and minimise and contain the generation of dust and the like.

- Contamination mapping of potentially radioactive, non-decommissioning service systems.

- Contamination mapping of all radioactive and potentially radioactive systems will be carried out to ensure that the health and safety risks associated with maintenance and dismantling of the radioactive systems are understood and the decontamination and radioactive waste treatment options can be assessed.

Dismantling of radioactive, non-decommissioning service systems.

- Detailed plans for the dismantling of all major equipment will be developed in the final decommissioning plan. Such plans will include provisions for limiting personnel hazards (see Section 27.4.6.2). Installed in-cell handlers will be used to remove large plant items. Remote in-cell handling equipment will be provided, where there is no man access, to facilitate dismantling of the plant.

- For removal of large plant items and modules, plans will be developed cognisant of the technical guidance such as IAEA Technical Report "Heavy Component Replacement in Nuclear Power Plants: Experience and Guidelines" (Reference 27.25). This report describes the organisational requirements necessary for large and complex removal projects, and describes suitable strategies and sequences for the removal of specific heavy components.

- Examples of outline sequences for removing large items, contaminated items and difficult to access items are provided in Section 5.1.7 of Reference 27.20.

- Before transportation to the LLW or ILW areas, dismantled equipment will be packaged and examined to determine activity levels and to confirm packages are securely protected for transportation. Stations will be set up in the auxiliary and containment buildings to provide this function. Items determined to be clean will be routed to an interim clean storage area where they will await dispatch.

Ex-situ decontamination of dismantled radioactive, non-decommissioning service systems.

- Decontamination of dismantled radioactive components will take place ex-situ in the various facilities provided (e.g., converted spent fuel pool/fuel handling area, the decommissioning facility, the health physics and hot machine shop, the radwaste building).

- Treat, package and dispose of waste from radioactive, non-decommissioning service systems.

- Radioactive waste will be classified, treated and disposed following established procedures for operational LLW and ILW as described in the UK AP1000 Radioactive Waste Arisings, Management and Disposal (Reference 27.8).

Contamination mapping of potentially radioactive systems in containment.

- Contamination mapping of potentially radioactive systems within the containment building will be carried out to ensure that the health and safety risks associated with maintenance and dismantling of the radioactive systems are understood and the decontamination and radioactive waste treatment options can be assessed.

27.4.4.4 Stage 3 Decommissioning

Stage 3 decommissioning addresses:

Dismantling of reactor system. Assess activity levels of dismantled equipment and securely protect for transportation to waste handling areas.

- The reactor system will be dismantled and components will be removed and transported to the waste processing facilities. The activity levels of the reactor pressure vessel should have dropped sufficiently so that the dismantled components can be transported within the regulations applicable at that time. The hot and cold legs will be remotely cut and removed using techniques that minimise personnel exposure. The reactor pressure vessel will be disconnected from its supports, and all piping will have been previously cut and removed. The details of this operation will be included in the final decommissioning plan. A temporary shielding structure will be produced which will cover the reactor pressure vessel and internals during lifting, upending, and transport to the processing facility. The polar crane will be used for the lifting and upending to and on the 135' (41.15m) level. The reactor pressure vessel and its transport shield can then be passed through the new opening to the jacking tower, lowered to the transporter and then taken to the processing facility. These activities can be largely completed remotely.

- An option for the reactor pressure vessel will be to dismember it in situ, package it in the approved containers, and then remove the individual containers. This will require the provision of temporary shielding and cutting processes, which will allow for flooding the reactor vessel compartments to provide additional shielding. Alternatively, reactor vessels in the United States have been disposed intact. The internals will have been removed, decontaminated, wrapped, and taken to the processing area. The transport route will be through the opening provided at the 135' (41.15m) elevation.

Removing radioactive inventory from residual radioactive systems in containment.

- Some of the systems within the containment building are expected to be radioactive (this will have been confirmed by the contamination mapping carried out at the end of Stage 2). The radioactive inventory of these systems will be removed and treated by the existing plant radwaste systems.

Contamination mapping of other potentially radioactive systems and buildings.

- Contamination mapping of the remaining radioactive decommissioning service systems will be carried out prior to commencing cleaning, decontamination, and dismantling of these systems. Contamination mapping of the containment building and shield building, auxiliary building, radwaste building, and the temporary decommissioning facility will also be carried out to assess if any of the structures or concrete are active or contaminated prior to dismantling the buildings.

Dismantling of and removal of non-radioactive decommissioning service systems.

- The non-radioactive decommissioning service systems within the turbine building will be dismantled and removed as per the schedule established at that time. Temporary lifting and handling equipment to support plant dismantling will be brought in and installed. Temporary service systems will be provided to facilitate ongoing decommissioning activities as required.

- Decontaminate dismantled reactor system ex-situ (e.g., in decommissioning building, spent fuel pool, fuel handling area).

- Decontamination of radioactive dismantled reactor components will take place ex-situ in the various facilities provided (e.g., converted spent fuel pool/fuel handling area, the decommissioning building, the health physics and hot machine shop, the radwaste building).

- Post-operational clean out and in-situ decontamination of radioactive systems in containment, the containment building (including cutting, processing, and removal of active concrete in the containment building), and the shield building.

- The radioactive systems within the containment building will be cleaned and decontaminated in line with the decontamination strategy described in the UK AP1000 Decontamination Considerations (Reference 27.21). Active concrete within the containment building will be cut, processed and removed. Concrete is considered to be active no more than 3' (0.9m) from the exposed outer edges. The cutting programme may use a diamond wire sawing technique, which will cut through the steel facing. Any active concrete will be removed under controlled conditions and processed separately. The diamond wire sawing is relatively clean in that dust can be controlled and the limited quantities of water needed can be controlled and maintained within a closed circuit. Typically blocks of concrete are cut and the active pieces removed. The removed pieces are sized for packaging to suit the approved disposal containers. Once the wire is passed around the area to be cut, the machine can be located away from the active area and shielded to minimise personnel exposure. It is anticipated that the only active concrete will be local to the reactor pressure vessel and possibly the spent fuel pool area. The same techniques will be used in both areas. Following the removal of active concrete, the containment and shield buildings will be cleaned and decontaminated as required.

Removal of radioactive inventory from residual radioactive systems in auxiliary building.

- The existing plant radwaste systems in the auxiliary building will be the last radioactive decommissioning service systems to be decommissioned. The radioactive inventory of these systems will be removed and treated by temporary service systems.

Disposing/recycling of active and inert waste.

- As decommissioning progresses, wastes from dismantled non-radioactive systems and non-radioactive wastes segregated from dismantled decontaminated radioactive systems will be disposed/recycled/recovered by the procedures in place at that time. Active wastes will be classified, treated, and disposed following established procedures for operational LLW and ILW as described in the UK AP1000 Radioactive Waste Arisings, Management and Disposal (Reference 27.8). The order in which waste from specific systems will be disposed can be seen in Figure 27.3.

- Post-operational clean out and in-situ decontamination of radioactive decommissioning service systems in auxiliary building.

- The radioactive decommissioning service systems in the auxiliary building will be cleaned and decontaminated in line with the decontamination strategy described in the UK AP1000 Decontamination Considerations (Reference 27.21).

Dismantling and removal of residual radioactive systems from containment.

- The residual radioactive systems within the containment building will be dismantled. Dismantled components will be examined to determine activity levels, securely packaged, and transported to the appropriate waste processing facilities.

Dismantling and removal of containment building, shield building, and turbine building.

- At this point the dismantling of buildings will begin. The removal of the containment building, shield building, and turbine building is a bulk material removal undertaking. This is simplified by the fact that the structures are freestanding and can be systematically removed from the top. The containment building steel pressure vessel will be stable throughout the dismantling process and can support significant weight in terms of access attachments for personnel and cutting equipment. During the removal process, individual sections of plate will need to be stabilised. Waste will be monitored prior to transportation but, as none of it should be active, it is expected that it will go directly to the clean waste areas.

Ex-situ decontamination of dismantled radioactive systems from containment and the dismantled active building components.

- Ex-situ decontamination of dismantled radioactive decommissioning systems and the dismantled active components of the containment building and shield building will take place in the various waste handling facilities (e.g., in the decommissioning building, radwaste building).

Dismantling and removal of remaining radioactive and non-radioactive decommissioning service systems and residual radioactive systems in the auxiliary building.

- The radioactive and non-radioactive decommissioning systems in the auxiliary building will be dismantled and removed as per the schedule established at that time. Temporary lifting and handling equipment to support plant dismantling will be brought in and installed as required. Dismantled equipment will be packaged and examined to determine activity levels and to confirm packages are securely protected for transportation to the waste processing areas.

Decontaminating, dismantling and removal of the auxiliary building.

- The auxiliary building will be systematically removed by cutting through the composite steel/concrete structure. Temporary HVAC together with temporary sealing for openings will ensure that airflow is controlled and inward only. None of this concrete will be active; however, some may be contaminated. Significant areas of the walls are steel faced and can be readily decontaminated. A mobile decontamination unit will be used for this purpose. It is recognised that, due to access considerations, the tanks in the lower auxiliary building may need to be first removed to a local decontamination area and then taken to the processing facility. Such items, due to access considerations, may need to be disassembled prior to removal. This then allows work to decontaminate the walls in the lower auxiliary building to proceed. Explosive removal of concrete has not been considered in the nuclear island. Floor slabs will be supported, cut, and systematically removed to expose the equipment within the rooms. Much of this equipment will be active and will be removed, packaged for local transport, and taken to the waste

processing area. Work to disconnect this equipment, most of which are modules from their systems, will have been previously completed. Dismantled components will be packaged and examined to determine activity levels and to confirm packages are securely protected for transportation to the temporary decommissioning facility.

Decontaminating, dismantling, and removal of the radwaste building.

- Prior to dismantling, the radwaste building will be manually cleaned and decontaminated as required. The building HVAC system will be maintained to minimise dust released and equipment will be manually dismantled and size reduced. The HVAC system will then be decommissioned in a similar manner, and the building cladding removed, followed by demolition of the structure itself. All wastes will be surveyed by Health Physics prior to disposal but it is anticipated this waste will be free release discharge.

Decontaminating, dismantling, and removal of the LLW store.

- The LLW store will be manually cleaned as required. It is not expected to be contaminated but decontamination may be carried out if required. A temporary HVAC system will be provided to minimise dust released and equipment will be manually dismantled and size reduced. All wastes will be surveyed by Health Physics prior to disposal but it is anticipated this waste will be free release discharge.

- Ex-situ decontamination of dismantled radioactive, decommissioning service systems and auxiliary building components.

- Ex-situ decontamination of radioactive components from the decommissioning service systems and the dismantled auxiliary building will take place in the temporary decommissioning facility.

- Treat, package and dispose of radioactive waste from dismantled radioactive decommissioning service systems and buildings.

- All remaining radioactive waste from dismantled radioactive decommissioning service systems and buildings will be treated, and packaged in the temporary decommissioning facility. Waste packages will be examined to determine activity levels and to confirm packages are securely protected for transportation to interim stores/disposal facilities/free-release as appropriate.

- In-situ decontamination and dismantling of the decommissioning building.

- Following processing of radioactive waste from dismantled radioactive decommissioning service systems and buildings, the temporary decommissioning facility will be decontaminated and decommissioned. The HVAC system will be operated while the remaining equipment is cleaned and dismantled, using the mobile decontamination unit. The HVAC system will then be shut down, cleaned, surveyed, etc., with spent filter cartridges being disposed of as ILW waste. All the equipment and structures will be surveyed prior to disposal and it is anticipated it will be LLW or free discharge. Temporary waste handling and processing facilities will be provided.

Dismantling and removal of temporary decommissioning service systems.

- The temporary decommissioning service systems provided to facilitate decommissioning of the existing systems and buildings will be decontaminated and decommissioned.

Dismantled components will be packaged and examined to determine activity levels and to confirm packages are securely protected for transportation to the temporary waste handling and processing facilities. Here the dismantled components will be treated and packaged. Waste packages will be examined to determine activity levels and to confirm packages are securely protected for transportation to interim stores/disposal facilities/free-release as appropriate.

Dismantling and removal of waste water system, diesel generator building, and annex building.

- At this stage, the waste water system, diesel generator building, and annex building will be dismantled. All waste is expected to be non-radioactive and will be disposed of by the procedures in place at that time.

Disposing of radwaste and non-radioactive waste.

- All radioactive waste generated during the final building and systems dismantling will be processed, packaged, and transported to interim storage as described in Section 27.1.1.4. Non-radioactive waste will be disposed of by the procedures in place at that time.

Maintaining ILW and spent fuel stores.

- The interim ILW and spent fuel stores will be required until the respective national repositories are available to receive waste packages for final disposal. In addition to this, spent fuel will need to remain in the spent fuel store until the heat output from the fuel has reduced sufficiently to meet the current RWM criterion for acceptance. Consequently, the ILW and spent fuel stores will need to be maintained until all waste packages have been transported off the site for final disposal.

27.4.5 Decommissioning of Waste Stores

Dismantling of ILW Store

- The store design life is substantially longer than that of the power generation facility and as such the ILW store will be a standalone structure supported by its own services and utilities. If the national ILW repository is available before the end of AP1000 operations, ILW decommissioning waste could be shipped direct to the repository without interim storage onsite. Having the national ILW repository available before the end of AP1000 operations will also allow the decommissioning and dismantlement of the on-site ILW store using the decommissioning facilities created for the AP1000.

- Once all the stored waste packages have been removed from the ILW store to off-site storage (national ILW repository or other appropriate storage facility) the building can be decommissioned. The building HVAC and effluent collection systems will continue to operate to minimise dust and effluent releases. The vault crane will be moved to the maintenance bay for decontamination. It will then be used for the lifting and removal of equipment from the building. Equipment will be decontaminated and the reagents used collected in the effluent collection system. The effluents will be routed to a temporary mobile treatment facility (e.g., filtration, ion exchange, pH neutralisation) before discharge to site drainage. Most of the equipment will be located outside of the vault and is expected to be clean. A Health Physics survey will be carried out and the waste characterised as either LLW or free discharge. Dismantling, cutting, etc., will be

performed manually. Once the equipment has been removed the effluent collection system will be drained and flushed and decommissioned in a similar manner. Any contamination will be removed by scabbling or other suitable techniques (e.g., peelable coatings), and disposed of as LLW or ILW, as required. The HVAC system will then be decommissioned, decontaminated, and surveyed, with spent cartridges being disposed of as ILW using a temporary mobile encapsulation facility. The remaining building structure will be demolished, monitored and anticipated to be free discharge to landfill or, to be used on site as backfill.

Dismantling of Spent Fuel Store

- The on-site spent fuel store will be decommissioned following the transfer of stored spent fuel to the national HLW repository (once available). On-site storage up to 160 years after plant start up may be required to allow all the fuel to decay before shipment to the national HLW repository (see Reference 27.20, Section 10.1.2). The decommissioning facilities created to handle the AP1000 and the ILW store arisings will need to be dismantled and disposed of following a period of decontamination.

- When the HLW repository is available, the spent fuel will be shipped to it and the spent fuel store can be decommissioned. This will require the use of temporary facilities to handle the wastes arising as a result of the dismantlement of the spent fuel store. Based upon the Holtec dry storage system, these wastes will comprise the steel closure lid, steel container and divider shells, the concrete support foundation and top surface pad (Reference 27.7, Section 3.5.8). Holtec's dry storage system materials were selected to ensure no chemical, galvanic, or other reactions among the materials of the HI-STORM 100U System, their contents, and the operating environment. The HLW store comprises a number of subterranean cylindrical steel and concrete cavities (see Section 27.4.5.7.4) which are expected to be free from contamination. This will be confirmed by a survey of surface radioactivity. If necessary, the cavities will be decontaminated and any active waste arising from decontamination will be handled and disposed of as LLW or ILW using a temporary mobile encapsulation facility. Following decontamination, the remaining waste materials will be characterised as either LLW or free discharge.

27.4.5.1 Shielding and Containment

Existing Shielding and Containment

The AP1000 design incorporates significant shielding and containment that is designed to be effective under all conditions anticipated in the plant life cycle.

The containment building is an integral part of the overall containment system with the functions of containing the release of airborne radioactivity following postulated design basis accidents and providing shielding for the reactor core and the reactor coolant system during normal operations. Access to the containment is provided through personnel airlocks and equipment and maintenance hatches. Access to the containment can be controlled by the health physics office in the annex building. The control room is shielded against radiation so that continued occupancy under accident conditions is possible. The fuel handling and storage facility is designed to prevent inadvertent criticality and to maintain shielding and cooling of spent fuel.

The shield building provides shielding for the containment vessel and the radioactive systems and components located in the containment building. During accident conditions, the shield building provides the required shielding for radioactive airborne materials that may be

dispersed in the containment as well as radioactive particles in the water distributed throughout the containment. The cylindrical section of the shield building also protects the containment building from external events and is a key component of the passive containment cooling system.

The auxiliary building provides protection and separation for the seismic Category I mechanical and electrical equipment located outside the containment building. It provides protection for the safety-related equipment against the consequences of internal or external events and it also provides shielding for the radioactive equipment and piping that is housed within the building. Within the auxiliary building, the fuel-handling area is designed to prevent inadvertent criticality, to maintain shielding and cooling of spent fuel and to provide protection for the spent fuel assemblies, the new fuel assemblies and the associated radioactive systems from external events. Also, the fuel-handling area is constructed so that the release of airborne radiation following any postulated design basis accident that could result in damage to the fuel assemblies or associated radioactive systems does not result in unacceptable site boundary radiation levels. Also within the auxiliary building, the control room is shielded against radiation so that continued occupancy under accident conditions is possible.

Certain areas of the annex building, such as the hot machine shop and the control support area are provided with shielding for protection against low level radiation from either internal sources or external sources under accident conditions. This is accomplished by either reinforced concrete walls or reinforced masonry walls.

Wherever possible, the existing shielding and containment in each section of the plant will remain in place until all the active equipment has been removed and all required decontamination has been completed.

Some modifications are expected to the shielding to allow access for decommissioning equipment. Revised shielding assessments will be carried out as part of the decommissioning safety assessment to ensure that any changes meet ALARP considerations.

Temporary Shielding and Containment

Whilst the shielding and containment incorporated into the design of the AP1000 plant will be retained for as long as possible during decommissioning, there will be some requirements for the provision of temporary shielding and containment. These will include:

- Shielding and containment for the temporary decommissioning facility. The facility will be designed to provide the maximum opportunities for remote working during the processing and handling of decommissioning waste in order to reduce personnel exposure.

- A temporary HVAC system and a mobile decontamination unit will be needed for the decommissioning of the auxiliary building.

- A temporary HVAC system and a mobile decontamination unit will be needed for the decommissioning of the temporary decommissioning facility.

- Provision of temporary covers and shielding of open pipe and vessel ends exposed during cutting operations and dismantling.

- A temporary shielding structure will be produced to cover the RPV and internals during lifting, upending, and transport to the processing facility.

- Temporary enclosures and tents with HVAC facilities may be used around dismantling works where there is a risk of generating airborne radioactive material.

Remote Operations

Where possible, dismantling operations for highly radioactive components will be performed remotely in order to reduce the occupational radiation exposure. Remote dismantling operations may take place behind shielding barriers, underwater, in fume hoods and in inaccessible areas.

27.4.5.2 Progressive and Systematic Reduction of the Hazard

Decommissioning plans have been developed that ensure progressive and systematic reduction of the hazard. This is achieved by the three-stage process described in Sections 27.3.3.1 to 27.3.3.3.

Stage 1 Decommissioning

The components of the plant with the highest residual activity are the fuel rods. Removal of the fuel rods from the reactor to the spent fuel pool is the first step of Stage 1 decommissioning. The reactor cavity and other areas that have been directly exposed to the fuel will have the next highest residual activity and consequently decontamination of these areas is the next step of the decommissioning sequence. Residual activity levels will be reduced by removing the radioactive inventory of service systems that are no longer needed for decommissioning.

Contamination mapping of potentially active systems and structures will be carried out to ensure that the health and safety risks associated with maintenance and dismantling of the radioactive systems are understood and the decontamination and radioactive waste treatment options can be assessed. The results of these surveys will inform the selection of cleaning and decontamination processes of the non-decommissioning service systems. The decontamination of active circuits will further reduce residual activity levels prior to the commencement of active component removal.

As decommissioning progresses, the radiological control boundaries will be successively reduced in line with the progressive reduction in hazards.

Throughout the decommissioning process ILW and LLW will continue to be generated. For this reason it is logical to retain the existing plant radwaste systems for as long as possible. Whilst at this stage the precise time at which the radwaste systems will be decommissioned cannot be specified, it is assumed it will be during Stage 3.

As soon as it has cooled sufficiently, the remaining spent fuel will be placed into dry storage canisters and transported to the spent fuel store.

Stage 2 Decommissioning

In order to meet the requirements of decommissioning activities, existing service systems will be modified and temporary service systems will be installed.

As soon as possible, following the removal of the final spent fuel, the radioactive inventory of the spent fuel pool system and fuel handling system will be removed and post-operational clean out and in-situ decontamination will be carried out. This will ensure that residual activity levels are ALARP prior to conversion of the fuel handling building to an ILW waste

processing facility. This is in line with the principle of converting existing parts of the plant to facilitate decommissioning. The spent fuel racks will be dismantled and the pool will be cleaned and decontaminated allowing the area to be used as a decontamination and waste reduction area. Potential hazards associated with these decontamination and waste reduction processes will also be reduced. For example, the volume reduction process will be designed to minimise personnel exposure, and minimise and contain the generation of dust.

Easily removable non-radioactive systems and service systems which are not required for decommissioning will be the first systems to be dismantled. This reduces hazards associated with subsequent decommissioning activities by removing potential obstructions and creating space.

Further contamination mapping will be carried out prior to the dismantling of radioactive, non-decommissioning service systems. At this point, the components with the highest residual activity are the reactor pressure vessel and internals. However, the removal of these components will be deferred to Stage 3 to allow activity levels to drop to the point where the dismembered pieces can be transported within the regulations applicable at that time. The sequence of removal of active non-decommissioned service systems will continue to follow the principle of removing components with the highest residual activity. The sequence for removal of the steam generators is outlined in Section 5.1.7 of the UK AP1000 Decommissioning Plan (Reference 27.20).

Radiation and security controls will be implemented to determine the activity levels of dismantled equipment and to confirm it is securely protected for transportation. This will allow clean equipment to be routed to an interim clean storage area. This will reduce the volume of waste sent to the temporary decommissioning facility, the radwaste building, and the converted fuel handling building. Radioactive components will be transported to the appropriate waste handling area for decontamination, processing, and packaging.

Stage 3 Decommissioning

Contamination mapping of the remaining potentially radioactive systems and buildings will be carried out at the end of Stage 2 and beginning of Stage 3.

By this point the activity levels of the RPV and the internals should have dropped sufficiently to allow them to be removed. The internals will be removed, wrapped, and taken to the processing area for decontamination and processing. The RPV will be removed following the procedure outlined in Section 5.1.4 of the UK AP1000 Decommissioning Plan (Reference 27.20).

Following removal of the RPV, non-radioactive decommissioning service systems will be dismantled and removed and replaced by temporary service systems as required. The non-radioactive systems will be removed first as this work will be easier than the removal of the radioactive systems. The radioactive decommissioning systems will be systematically decommissioned as specified in Section 5.1.4 of the UK AP1000 Decommissioning Plan (Reference 27.20). Residual hazards will be progressively reduced for each system by removing the radioactive inventory, post-operational clean out, in-situ-decontamination, and dismantling and removal of components to the waste processing areas. Here ex-situ decontamination will be carried out as appropriate and the waste will be processed, packaged, and transported to the appropriate interim store or final disposal repository, if available.

At this time the only potential activity or contamination remaining will be in structures and concrete in the containment building, shield building, auxiliary building, radwaste building, and the temporary decommissioning facility. This will have been established by the

contamination mapping carried out at the beginning of Stage 3. Any activated concrete will be removed under controlled conditions and processed separately.

Following the removal of active concrete, the containment building, shield building, and turbine building will be decontaminated in-situ and dismantled. Active and contaminated components from the containment and shield buildings will undergo ex-situ decontamination, processing, packaging, and disposal. It should be noted that the turbine building could be dismantled during Stage 2 as the systems within the building are not expected to be active and will be dismantled and disposed of during the first two years of Stage 2 decommissioning. However, it is expected that the decommissioning of other plant areas that present a greater residual risk will be carried out first and so dismantling of the turbine building will be delayed until the containment and shield buildings are ready to be dismantled.

The last potentially active or contaminated buildings to be dismantled will be the auxiliary building, radwaste building, and the temporary decommissioning facility. This will allow the waste processing and handling facilities in these buildings to remain in service as long as possible. The auxiliary and radwaste buildings will be dismantled first and active waste will be transported to the decommissioning facility for decontamination, processing, and packaging. Temporary decommissioning service systems and a mobile decontamination unit will be provided to facilitate this work. The decommissioning facility will be the last potentially active or contaminated building to be dismantled. It will be decontaminated in-situ prior to dismantling and waste will be classified and disposed of via appropriate routes.

The remaining buildings and systems will all be non-active and will be disposed of by the procedures in place at the time.

When all the active waste has been transferred from the appropriate interim store (LLW/ILW/HLW) to offsite storage, the store will be decommissioned, again following the principle of progressive and systematic reduction of the hazard.

27.4.5.3 Enabling Works

Stage 1 could begin as soon as the plant ceases to generate power, however, there is a need to allow the core barrel radioactivity levels to decay to a level where it can be safely dismantled and packaged in accordance with the requirements in force at that time. It is expected that Stage 1 will last approximately 10 years to ensure that the spent fuel has sufficient cooling time before it is transferred to dry storage. Decommissioning Stages 2 and 3 will be approximately 6 years each. These durations may be reduced and activities implemented in parallel when the final decommissioning plan is generated.

The existing plant radwaste systems will remain in use while Stage 1 and possibly Stage 2 are in progress. The point at which they will be decommissioned will be defined in the detailed decommissioning plan; it is assumed that this will be during Stage 3.

The preferred process for decommissioning is to remove major components and modules for transfer and subsequent processing in the purpose-built waste facility; this is in close proximity to, but away from, the plant. Waste processing and volume reduction activities will be conducted in the reactor building only where necessary. This will provide the maximum opportunities for remote applications for cutting and handling in a facility specifically designed for it. This will also provide opportunities to implement measures to reduce personnel exposure to ALARP.

Before any dismantling work is begun, the fuel handling area within the auxiliary building will be converted to service dismantling, decontamination, and packaging of decommissioning waste. In addition to the fuel handling area a decommissioning facility will be set up large enough to allow storage of at least two SGs, one reactor vessel, and sundry other equipment; and will include a remote handling and waste reduction process area. Equipment to perform cutting, decontamination, volume reduction, and waste packaging activities will be installed in this building.

Throughout the decommissioning process, wastes will be characterised and packaged, with size reduction as necessary. Items will be reduced in size to accommodate their disposal in the standard containers agreed upon with the RWM. The active waste packages will be placed either in passive safe storage (spent fuel and ILW) onsite, or dispatched offsite for disposal at the LLWR. Further details can be found in Section 26.7.2.3 of Chapter 26 and the Radioactive Waste Management Case Evidence Reports for ILW and HLW (References 27.22 and 27.23).

ILW will also be stored and processed in the modified spent fuel handling area in Stage 2. This cannot take place until the last of the spent fuel is removed from the spent fuel pool and the pool has been converted. Stage 1 requires the removal of all fuel from the reactor and the spent fuel area. Once this has been accomplished, the spent fuel racks will be dismantled and the pit will be cleaned and decontaminated. The HVAC systems will remain in operation.

The drainage and ventilations systems may have to be extended or adapted to meet the requirements of the decommissioning process. These changes will be addressed in the detailed decommissioning plans for the individual plant and facilities.

The modified spent fuel handling area, together with the temporary decommissioning facility, will be sufficient to store all the dismantled equipment removed from the plant during decommissioning. With significantly less building volume and equipment, less of this reduced volume will be active. As items are confirmed as clean, they will be removed from the site and disposed of.

27.4.5.4 Decommissioning Operations

The technologies to decommission the AP1000 plant currently exist. However, when the plant is due to be decommissioned, it will be the operator's responsibility to review the techniques available and to select the most appropriate one. The currently recognised techniques for decommissioning and decontamination are summarised below; further details can be found in the Radioactive Waste Arisings, Management and Disposal document (Reference 27.8, Section 5.2.4) and the Decontamination Considerations document (Reference 27.21).

- Decommissioning techniques:
  - Cutting
  - Shearing
  - Demolition
  - Fixing contamination (sealing loose contamination before dismantling)
- Decontamination techniques:
  - Chemical dissolution
  - Electrochemical
  - Abrasion

- Dry surface cleaning
- Wet surface cleaning
- Mechanical surface removal
- Liquefaction
- Degradation

Size Reduction of Large Items

The large solid radioactive waste items that will require decommissioning are the SGs, reactor head and the RPV. A number of options for removing and reducing the size of the SGs have been incorporated into their design:

- Removing the upper noncontaminated sections and lowering the remaining contaminated sections using the polar crane.

- Removing steel work and concrete to allow all of the SGs to be lowered to the ground for size reduction.

- Removing the top of the containment to remove the whole SG using an external crane.

It is expected that the SGs will be radioactive but with an activity level that will fall into the LLW category (as will be case for the other large items). It is intended that these items are handled as they arise and are reduced in size, the pieces being decontaminated to the extent practicable. Decontaminated pieces that are no longer radioactive will be released to conventional waste handling facilities for recycling or disposal. Decontaminated pieces that remain radioactive will be wrapped before placement into half-height International Organisation for Standardisation (ISO) (HHISO) containers and sent for disposal at the LLWR.

Because the upper section of the SGs may have become contaminated during operations, before wastes from these structures are disposed of, decontamination may be appropriate

Decontamination materials are expected to be similar in nature to those previously used for operating AP1000 plant LLW arisings as dealt with in the standard AP1000 plant radwaste building, and so will be packaged and disposed of in the same manner. To facilitate this disposal route, a temporary decommissioning facility will be erected, for example a tent with mobile HVAC. Laydown areas have been provided for protecting and wrapping potentially contaminated equipment prior to transfer to the waste handling facility. The area currently allocated for the temporary decommissioning facility for the GDA site is identified in Figure 27-1, Item 27.

One possible sequence for the decommissioning of the steam generators is outlined in Section 5.1.7 of the UK AP1000 Decommissioning Plan (Reference 27.20).

Other large items such as the reactor vessel, RCPs, and reactor head can be disposed of using techniques similar to those used for SGs, and are therefore not considered further here.

27.4.5.5 Feasibility Reviews

Licensee Reviews

The licensee will carry out feasibility reviews to validate methodology/techniques used in the decommissioning of the AP1000 plant. The initial decommissioning plan will be reviewed

and updated throughout the operational phase; the final decommissioning plan will be reviewed and updated during decommissioning.

Reviews of the arrangements for managing decommissioning activities will also be conducted regularly as part of the licensee's compliance with the construction design and management (CDM) regulations (Reference 27.15). These reviews will ensure that:

- Construction, dismantling and demolition work is carried out, so far as is reasonably practicable, without risk to the health and safety of any person.
- The standard of welfare facilities is adequate for all persons throughout the duration of decommissioning.
- Any structure designed for use as a workplace has been designed taking account of the provisions of the Workplace (Health, Safety and Welfare) Regulations 1992.

Office for Nuclear Regulation Reviews

In accordance with current UK government policy the ONR carries out reviews of certain licensees' decommissioning strategies to ensure that they remain soundly based as circumstances change. Guidance on the quinquennial reviews process is provided in ONR NS-TAST-GD-026 (Reference 27.16).

The licensee will also be regulated by the Nuclear Decommissioning Authority (NDA), a department within the Department of Energy & Climate Change (DECC).

27.4.5.6 Strategy for Safety Systems

27.4.5.6.1 Safety Systems Incorporated in the Design

The AP1000 design incorporates a range of engineered safety features (ESFs) which protect the public in the event of an accidental release of radioactive fission products from the reactor coolant system (Section 6.5). The ESFs include:

- Passive containment cooling system
- Passive core cooling system
- Containment isolation system
- Containment hydrogen control system
- Containment leak rate test system
- Main control room (MCR) emergency habitability systems
- Fission product removal and control systems

Each of these systems will remain active whilst fuel remains in the reactor. The MCR emergency habitability systems will be maintained whilst the control room function is required.

In addition to the ESFs, the AP1000 plant has a number of auxiliary systems that provide safety and support functions during decommissioning:

- Fuel storage and handling
- Water systems

- Process auxiliaries – compressed air, plant gas, sampling systems, drainage, chemical volume control system
- Air-conditioning, heating, cooling, and ventilation systems
- Fire protection system
- Communication system
- Plant lighting system
- Standby diesel generators and diesel fuel oil system

The fuel storage and handling systems will remain operational until all fuel is removed to dry storage. The other systems will remain active during decommissioning while their services are required and the residual risks they are designed to mitigate are still present. Where the above systems cannot be decommissioned progressively, then it may be necessary to bring in temporary equipment to provide these services. These requirements will be assessed in detail in the final decommissioning plan.

The AP1000 plant has Emergency Response Facilities (see Section 25.4) that include the MCR, the operational support centre, and the technical support centre. These areas provide communication and assembly points for staff during an emergency. The technical support centre also provides plant management and technical support to operating staff during an emergency. These facilities will be retained during decommissioning for as long as possible. If necessary, they will be replaced by appropriate temporary facilities to ensure that effective emergency response facilities are available throughout decommissioning.

27.4.5.6.2 Plant Management Safety Systems

In addition to the safety systems incorporated into the design, the licensee will need to implement appropriate plant management safety systems to cover the decommissioning activities. The licensee will be responsible for safety and environmental management of the plant through the operating life and eventual decommissioning of the plant. Westinghouse will liaise with the site licensee, regarding safety and environmental management throughout all phases of the plant life cycle (Reference 27.7).

Westinghouse can support the licensee by providing technical and design information that is relevant to decommissioning and that will assist the licensee in choosing the decommissioning strategy and preparing the initial decommissioning plan, as well as the CDM file for the decommissioning work packages.

It is anticipated that knowledge transfer and the management arrangements developed to support operation of the AP1000 plant will provide the foundations of the arrangements required for the decommissioning process. However, a review of this will be carried out during the creation of the operational management arrangements to ensure that this is true. It is expected that the decommissioning arrangements will be reviewed every 5 years.

27.4.5.6.3 Other Safety Systems Required During Decommissioning

In addition to the plant safety systems incorporated into the design (Section 27.4.5.6.1) and plant management safety systems (Section 27.4.5.6.2), the decommissioning activities may require the modification of safety systems as the dismantling progresses or the addition of

other safety systems for temporary decommissioning facilities. These requirements will be identified in the final decommissioning plan.

27.4.5.7 Decommissioning Waste Management and Disposal

To facilitate safe and effective management of wastes, they will be characterised and duly segregated according to their activity and other physical and chemical properties. This will essentially involve segregation into streams of nonradioactive waste, LLW and ILW, although further segregation within these categories may be necessary to meet the needs of the most appropriate disposal routes. After separation and segregation during decontamination and decommissioning operations, confirmatory monitoring will be undertaken prior to final consignment. The method of operational and confirmatory monitoring will be developed during the detailed decommissioning planning stage.

Application of BAT to waste management requires that all reasonable opportunities should be taken for waste minimisation, reuse, and recycling. Where possible, wastes will be declassified by segregation and cleaning to free-release standards.

27.4.5.7.1 Nonradioactive Wastes

Once segregated, these wastes will be recycled or disposed of via conventional routes. A storage facility for nonradioactive waste is provided in the AP1000 design (Figure 27-1, Item 28).

27.4.5.7.2 Low-Level Wastes

Both the radwaste building (Figure 27-1, Item 5) and the temporary decommissioning facility (Figure 27-1, Item 27) erected for LLW/ILW decommissioning processing, as described in Section 5.1.3 of the UK AP1000 Decommissioning Plan (Reference 27.20), will be used to handle LLW generated during decommissioning.

LLW will be collected and transferred to either the radwaste building or the temporary decommissioning building. The waste will then be processed. This could include decontamination, size reduction, characterisation, and further sorting, repackaging, and immobilisation.

The waste will be packaged in HHISO containers, transported to the buffer store, and finally sent to the LLWR in Cumbria for final disposal. However it is expected that this facility will close during the operating life of the first AP1000 plant. Consequently, any LLW decommissioning waste that will be generated following cessation of operation of the first AP1000 plant will need to be disposed of at a future LLWR that has not yet been specified.

The waste management strategy requires LLW to be shipped for disposal routinely according to schedules agreed to by the plant operator and the UK NDA. The LLW buffer storage area (Figure 27-1, Item 29) will be available to store LLW during periods when waste cannot be received by the LLW disposal facility. This is a covered area comprising a concrete hard standing area with a steel framed canopy. The storage area will have the capability of storing up to 2 years generation of operational LLW. The decommissioning LLW volume may require a larger LLW buffer storage area to accommodate 2 years of generation. If this is the case the storage area and canopy may need to be extended. Due to the construction of the LLW buffer store, it can be dismantled when not needed or relocated to a more convenient location onsite. A final LLW buffer store will only be dismantled upon completion of all radioactive decommissioning activities.

Further information can be found in Section 26.7.5.1 of Chapter 26 of this PCSR and the IWS (Reference 27.3, Sections 6.6 and 6.9).

27.4.5.7.3 Intermediate-Level Wastes

The strategy for dealing with ILW waste arisings is to process the waste into a stable form and then store it onsite in the ILW store.

ILW will be collected and transferred to either the radwaste building or the temporary building before treatment in the mobile encapsulation unit. Treatment could include decontamination, size reduction, characterisation; and further sorting, repackaging, and immobilisation.

Once the ILW has been encapsulated in waste packages acceptable to RWM (e.g., 500-litre drum, 3-m^3 drum and box), the boxes and drums will be transported to an onsite ILW store (see Figure 27-1, Items 21, 25, and 26), where they will be stored in a passively safe condition until a national intermediate-level waste repository becomes available. The ILW store is a reinforced concrete structure consisting of a waste package reception area and a shielded vault serviced by a certified nuclear crane. The seismic assessment has determined that the AP1000 plant ILW store does not need to be seismically qualified from the perspective of radiological consequence. The ILW store will be an independent facility that can remain operational even if the rest of the site has been decommissioned, providing that the essential infrastructure is maintained.

Further information can be found in Section 26.7.5.2 of Chapter 26 and the IWS (Reference 27.3, Sections 6.7 and 6.9).

It has been assumed that ILW will have to be stored onsite until suitable disposal facilities become available. If alternative offsite storage facilities become available, then the potential for their use will be addressed in the IWS and decommissioning strategy documents.

27.4.5.7.4 Spent Fuel

After spent fuel is removed from the reactor, it will be stored in the fuel storage pool. Because spent fuel is not expected to be reprocessed, the HI-STORM 100U System (or another equivalent cask system) is proposed to dry-store it once it has been removed from the spent fuel pool and dried using helium. The spent fuel assemblies will then be transferred from their dry cask storage to the national GDF once it is available, with repackaging carried out as appropriate.

The dry spent fuel storage is a seismically qualified, below-ground dry-storage facility with design features considered to minimise unauthorised intrusion and to provide radiation shielding. The location of the spent fuel store is shown in Figure 27-1, Items 22 to 24. The spent fuel store will be an independent facility that can remain operational even if the rest of the site has been decommissioned, providing that the essential infrastructure is maintained.

It has been assumed that spent fuel will have to be stored onsite until suitable disposal facilities become available. If alternative offsite storage facilities become available, then the potential for their use will be addressed in the IWS and decommissioning strategy documents.

Further information on radioactive waste management can be found in Chapter 26 (in which Section 26.7 addresses the solid radwaste system).

27.4.5.7.5 RWM Disposability Assessment

RWM has concluded that ILW and spent fuel from operation and decommissioning of an AP1000 plant should be compatible with plans for transport and geological disposal of higher activity wastes and spent fuel (Reference 27.12).

RWM expect that these conclusions eventually would be supported and substantiated by future refinements of the assumed radionuclide inventories of the higher activity wastes and spent fuel, complemented by the development of more detailed proposals for the packaging of the wastes and spent fuel and better understanding of the expected performance of the waste packages (Reference 27.12). This information would be developed as part of the detailed site specific decommissioning plan that would be prepared by the licensee during the operational phase of the AP1000 plant.

On the basis of the GDA Disposability Assessment for the AP1000, RWM has concluded that, compared with legacy wastes and existing spent fuel, no new issues arise that challenge the fundamental disposability of the wastes and spent fuel expected to arise from operation of such a reactor (Reference 27.12).

27.4.5.7.6 Volumes of Decommissioning Wastes

The total ILW decommissioning waste associated with large-volume components and waste from decontamination operations is estimated to be about 800 m^3. The total LLW associated with decommissioning large- and small-volume components, compactable dry active waste, and demolition waste is estimated to be about 5500 to 6000 m^3. Further details can be found in Appendix 27A, Tables 27A-2 to 27A-5.

A typical schematic for the treatment of decommissioning waste is shown in Figure 27-2. The management of decommissioning waste is being planned with the expectation that the LLW, ILW, and spent fuel waste streams can be disposed of in NDA facilities.

27.4.5.8 Sensitivity of the Waste Streams to Decommissioning Processes

27.4.5.8.1 Effectiveness of Decontamination

Decontamination processes will be adopted with the aim of changing the classification of the decommissioning waste to the lowest level possible. The aim will be to reduce, where possible, ILW to LLW and LLW to free release material. Effective monitoring of activity pre and post decontamination is important in confirming the waste classification and reducing quantities of ILW and LLW produced during decommissioning.

The mass of decommissioning waste in each ILW and LLW waste classification is sensitive to the effectiveness of the selected decontamination techniques (see Section 27.4.5.9).

27.4.5.8.2 Waste Form

The waste streams produced during decommissioning are sensitive to different decommissioning processes because different processes may result in different forms of waste being produced. For example:

- Different size-reduction processes may generate different amounts of active fines which may produce wastes that require stabilisation or dusts that require filtration.
- Different decontamination processes may produce different solid or liquid secondary wastes (see Section 27.4.5.4).
- For ILW the stabilisation techniques and grout addition rates may vary according to the form of the waste and this will affect the total number of waste packages generated.

27.4.5.8.3 Waste Volume

The waste volume generated during decommissioning is sensitive to the decommissioning processes adopted. For example:

- The adoption of refined cutting techniques (e.g., diamond wire sawing) can remove contaminated concrete to a specific depth of contamination and can be used to minimise the amount of concrete that is classified as radioactive waste.
- Disposal of large items without size reduction may be possible but would result in disposal of a much larger volume of waste.
- The selection of compaction or super compaction will affect the volume of LLW produced.

The mass of the radioactive components that require being decommissioned as identified in the disposability assessment (Reference 27.12) is unlikely to vary significantly as a function of different decommissioning methods. However, the volume of the waste radioactive components is sensitive to the size reduction and packaging techniques that may be employed.

27.4.5.9 Impact of Decontamination on Primary Waste Volumes

Decontamination will be used to reduce the contamination levels of decommissioned materials where BAT and ALARP analyses indicate that it is beneficial. For example, where practicable, decontamination will be used to recover wastes so that they can be reused or recycled. Decontamination may also allow the radiological waste classification of primary wastes to be reduced from ILW to LLW or LLW to free release for disposal by conventional nonradioactive routes. Wastes generated during decommissioning will be segregated into different waste types to allow optimum use of the various decontamination routes available at the time of decommissioning.

The majority of the waste arisings from the decommissioning of small and large volume components, as identified in appendices A3 and A4 of the AP1000 UK Environment Report (Reference 27.7), will undergo swabbing/monitoring to determine their activity and, if necessary, will be subject to decontamination. The aim is to reduce the waste activation level so that it may be reclassified. The wastes will be monitored to assess if this has been achieved

and further decontamination will be carried out if necessary. This process will result in reductions in the volumes of ILW and LLW requiring processing and disposal.

Also, prior to demolition, plant modules will be monitored to assess the contamination levels of the steel and concrete. Decontamination of the modules will be carried out in order to reduce the activation levels from LLW to free release levels where possible. The decontamination will be aided by the use of concrete walls with decontaminable coating and steel surfaces with surface finishes that will prevent penetration of contamination.

No credit has been taken in the disposability assessment (Reference 27.12) for the effect of decontamination on the estimated ILW and LLW arisings. At this stage no estimate has been made of the benefit that decontamination processes may provide in reducing the quantities of ILW and LLW decommissioning waste.

27.4.5.10 Generation of Secondary Wastes

27.4.5.10.1 Liquid Wastes

Some decontamination operations will produce secondary liquid wastes. These may include the following:

- **Detergent wastes** – Wet surface cleaning operations may produce detergent wastes. These will be collected and monitored to assess activity levels. When the activity levels are above acceptable limits, the wastes will be treated through the existing plant radwaste systems but if this is not possible processing will be carried out using mobile equipment. Processing will typically involve a concentration step (e.g., evaporation or reverse osmosis) in order to reduce the volume of waste to the extent necessary to allow an encapsulation plant to immobilise the concentrate in a cementitious grout. The liquids remaining after the concentration step (condensed evaporator distillate or reverse osmosis permeate) will be monitored to assess if further treatment is required prior to discharge.

- **Chemical wastes** – Decontamination processes such as chemical dissolution will produce chemical wastes. These will be collected in the chemical waste tank and pH and other chemical adjustment will take place as required. The wastes will be monitored and if the activity levels are deemed to be above acceptable limits, the waste will be processed using mobile equipment or combined with detergent wastes and processed as detergent waste.

27.4.5.10.2 Solid Wastes

Some decontamination operations will produce secondary solid wastes. These may include:

- **Filters** – Some decontamination and decommissioning operations will produce airborne particulates. These operations include cutting, abrasion, mechanical surface removal (e.g., scabbling) and demolition. These operations will be carried out using the BAT and ALARP techniques so that the amount of dust produced is minimised. However some dust capture by air filtration will be necessary and this will generate spent filters as a secondary waste. The spent filters will be monitored to assess activity levels so they can be processed and disposed of appropriately.

- **Swabs** – Dry surface cleaning will generate contaminated swabs as secondary waste. These will be monitored, classified and disposed of appropriately.

- **Activated resins** – Decontamination of active piping circuits will likely be carried out by an oxidative decontamination process. This involves an ion exchange process using anion and cation resins to absorb activation released by the process. These resins will become active and will be encapsulated in a cementitious grout in a similar way to operational ion exchange resins.

27.4.5.10.3 Quantity of Secondary Wastes

The quantity of secondary wastes that will be generated from the decontamination processes will be dependent on the methods employed and the extent of their use. This will need to be defined as the initial decommissioning plan is developed in detail, but no estimates have been made at this time.

27.4.5.11 Use of Best Available Technique and Waste Management Hierarchy in Decommissioning

27.4.5.11.1 Waste Hierarchy

The licensee will implement the principles of the waste hierarchy (avoid, minimise, recycle/reuse, abate) during decommissioning operations. Throughout the plant operational life and during decommissioning, the AP1000 Integrated Waste Strategy (Reference 27.3) will be reviewed by the licensee to maximise waste reuse and recycling wherever possible.

The AP1000 design includes features that avoid and minimise waste production (Section 27.2.2.2). Decontamination techniques will be selected to minimise the waste produced and to reduce the radiological waste classification during decommissioning (Section 27.4.5.9).

Where waste is produced it will be treated by appropriate techniques (e.g., segregation, size reduction, encapsulation, packaging) to ensure that the waste is in the most appropriate form for disposal.

27.4.5.11.2 Best Available Technique Assessment and Implementation

The plant has design features that avoid the early foreclosure of decommissioning options, and will be operated and maintained, so as to avoid the early foreclosure of decommissioning options which may restrict the implementation of BAT.

The licensee will carry out regular reviews of the methodology/techniques used in the decommissioning of the AP1000 throughout the life cycle of the plant (Section 27.4.5.5). As part of these reviews, the methodology and techniques that are considered to be BAT will be regularly assessed. By deferring the design and construction of the decommissioning facilities towards the end of operations, it will be possible to ensure that the techniques associated with the most up to date BAT assessment are built into the decommissioning facilities that are constructed.

27.4.5.12 Timescale and Programme

The estimated decommissioning timescales for the active facilities are:

- Stage 1 – 10 years
- Stage 2 – 6 years
- Stage 3 – 6 years

The stages of decommissioning could overlap if appropriate but, for the sake of clarity, are considered as three distinct stages.

RWM calculations have indicated that for the limiting irradiation fuel (i.e., at highest burnup), a cooling period of 100 years would be needed to allow disposal in their generic intended design concept. Therefore, the spent fuel may have to be stored in passive safety onsite for that length of time.

ILW will have to be stored onsite in a passively safe state until the future GDF is available to receive ILW.

It has been estimated that a period of 10 years will be required to transfer all the spent fuel to the GDF with another 10 years required to complete decontamination and decommissioning of the spent fuel storage facilities. Similarly, it has been assumed that a period of 10 years will be required to transfer all the ILW to the GDF and to decontaminate and decommission the ILW storage facilities. Given that there is currently a lack of a definitive GDF design and that these timescales will not affect the initial decommissioning programme, these estimates seem reasonable.

This programme of decommissioning works is presented in Figure 27-4.

This programme will be further developed by the operator as the decommissioning strategy and detailed decommissioning plans are reviewed during the lifetime of the AP1000 plant operation.

The passively safe storage facilities for spent fuel and ILW will be designed for 100 years. If after this period there is no GDF (or centralised storage facility) available, or if longer cooling periods are required, then the facilities will be assessed for life extensions and appropriate actions taken to ensure continued safe storage.

27.4.6 Safety Management Arrangements

Organisational safety management arrangements will be the responsibility of the operator. The operator will be responsible for ensuring that organisational arrangements are established and maintained to ensure safe and effective decommissioning of facilities. This responsibility includes a requirement to identify in the safety cases for operation and decommissioning an appropriate management organisation and resource for safe operation and decommissioning. The organisation is likely to change at the end of operations and the start of decommissioning. The organisation should be designed to achieve the activities being undertaken at the time; this organisation may change during the different decommissioning stages and should be reviewed if activities change. The operator is responsible for ensuring that its staff and contractors receive suitable training for roles that they will be required to undertake during decommissioning, which could be different from their previous roles in the operational phase.

The decommissioning safety case will be updated towards the end of reactor operations and before decommissioning starts. It will also be amended as necessary during the decommissioning process to take into account changes in both facilities and hazards. The decommissioning safety case will address existing and new hazards that will be present during decommissioning. The level of detail included will be proportionate to the radiological hazard.

Prior to decommissioning, a fault analysis review will be undertaken. The review will specifically target new faults or operational changes that could arise from decommissioning and is not applicable to current operations.

A review of the hazards that may be encountered during decommissioning should be carried out before decommissioning commences as part of decommissioning planning and safety case preparation. Any changes to the plant required for decommissioning should be substantiated before implementation, and should take into account the following:

- Safety function categorisation
- Examination, inspection, maintenance, and testing arrangements
- Onsite and offsite emergency plans
- Onsite and offsite monitoring programmes

External contractors are likely to be employed during decommissioning operations. The operator will be responsible for maintaining the function of intelligent customer during these operations to ensure that decommissioning operations are carried out safely. The operator is also responsible for ensuring that contractors are suitably qualified and experienced for the work that they are to perform.

The operator will be responsible for determining how these safety arrangements will be managed, but it is likely that the decommissioning arrangements will build upon and be consistent with the operational arrangements.

27.4.6.1 Experience of Decommissioning and Hazards Encountered

Westinghouse has a wealth of experience in nuclear decommissioning, including decommissioning of PWRs as well as other reactor types. Westinghouse will draw upon this experience to assist the licensee to develop a safe and cost-effective decommissioning strategy for the AP1000 plant.

A nonexhaustive list of Westinghouse's global decommissioning experience includes:

- Fort St Vrain (United States (US))
- Vandellos 1 (Spain)
- Zorita (Spain) (PWR)
- CIEMAT Research Facilities (Spain)
- Three Mile Island (TMI) 2 (US) (PWR)
- Yankee Rowe (US) (PWR)
- Trojan (US) (PWR)
- Qinshan (China) (PWR)
- Connecticut Yankee (US) (PWR)
- San Onofre (US) (PWR)
- Shoreham (US)
- Fukushima 2 (Japan)
- Forsmark 1/2/3 (Sweden)
- Oskarshamn 1/2 (Sweden)
- TVO Olkiluoto 1/2 (Finland)
- Chooz A (France) (PWR)
- KNK (Germany)

Past experience indicates that record keeping and plant knowledge are important in facilitating the decommissioning process. The decommissioning plan should reflect that retention of this knowledge base would be a major contributor to a safe, efficient and cost effective decommissioning process.

Westinghouse believes the decommissioning experience accumulated thus far all indicates that the most appropriate philosophy for decommissioning is the same as that embodied in the AP1000 plant construction plan which is to remove components/modules as complete units as far as possible (Reference 27.17).

The first AP1000 plants are under construction in China and the US. It is probable that these plants will reach the end of their operational life before any plant built in the UK. If these plants are subject to immediate dismantling, then there will be lessons learnt from their decommissioning that may benefit the final decommissioning plan required for any UK AP1000 plant.

27.4.6.2 Decommissioning Hazards

27.4.6.2.1 Significant Hazards

The major hazards anticipated during the decommissioning process are industrial and radiological. From past decommissioning experience, these two hazards can interact and complicate each other, for example, inadequate consideration of decommissioning activities during structural design has led to difficulties in retrieving radioactive waste and in some cases hampered sampling to determine the hazardous radiological characteristics.

The major anticipated hazards are as follows:

Radiation Hazards

- Direct radiation
- Radionuclide inhalation/ingestion
- Loss of containment
- Radioactive waste

Industrial Hazards

- Heavy/dropped loads
- Working at height
- Tripping/falling
- Fire
- Noise
- Vibration
- Dust
- Electric shock
- High temperatures
- High pressures
- Enclosed spaces

Toxic Materials

- Residual chemicals
- Decontamination chemicals

- Nonradioactive waste

27.4.6.2.2 Identification of Hazards

Referring to the final decommissioning plan, a decommissioning safety case will be developed by the operator. During decommissioning, the safety case will be updated when necessary to reflect the impact of modifications to the facilities and to address the changing nature of the hazard.

The PCSR uses a number of checklists to identify hazards for consideration in the AP1000 Design Basis Assessment, Probabilistic Risk Assessment, Severe Accident Analysis and assessment of internal and external hazards (see Chapters 9 through 12). Collectively these checklists provide comprehensive and systematic hazard identification. These checklists will be reviewed and hazards assessed for their applicability to the decommissioning operations.

The final decommissioning plan will identify a number of individual decommissioning work packages. The implementation of CDM through the operator's or decommissioning contractor's management system will ensure that the hazards associated with each individual decommissioning work package will be fully evaluated before the project is initiated. A key aim of CDM is to identify hazards early on, so they can be eliminated or reduced at the design or planning stage and the remaining risks can be properly managed.

A survey of radiological and nonradiological hazards will be made as an important input to the safety assessment for decommissioning and for implementing a safe approach during the work. The survey should be conducted to identify the inventory and location of radioactive materials and other hazardous materials. Special attention will be paid during the characterisation of any fissile material that may be left in the plant. Uncertainty about the amounts of fissile material could have severe consequences if assessments for criticality are incomplete or wrong (Reference 27.18).

The radiation and contamination surveys determine the radionuclides, maximum and average dose rates, and contamination levels for inner and outer surfaces throughout the facility. Contamination mapping may then be used to plot the location of the hazards in order to facilitate the development of appropriate safety precautions and to help prioritise the decommissioning works.

Particular decommissioning challenges are associated with removal of heavy components, for example:

- SGs
- Reactor vessel head
- Reactor vessel internals
- Pressuriser
- Reactor coolant piping/recirculation piping

Radiation hazards associated with decommissioning these heavy items may arise during decontamination operations and when the internal active surfaces are exposed during opening or cutting operations. Other radiation exposures may occur during the preparation of containment openings and handling of large items in the designated laydown areas. The safe, hoisting and handling of these large items presents a significant industrial hazard. Lifting engineers will be used to prepare lifting plans to minimise the risks associated with such operations.

The polar crane used during the operation of the site will be retained ready for use during the decommissioning of heavy items. The polar crane structure has sufficient capacity to handle heavy equipment with the addition of a larger capacity hoist module. In addition the polar crane can accommodate the upper assembly of the SGs between the girders.

27.4.6.2.3 Protection Measures

The measures to protect against the significant hazards are similar to the control measures identified in Section 27.4.6.3.

27.4.6.3 Control Measures

The control measures required for each individual decommissioning work package will be developed as part of the final decommissioning plan and related decommissioning safety case and project specific implementation of the CDM. For each activity consideration will be given to:

- ALARP/BAT
- Skills/training
- Written procedures
- Area classification
- Decontamination (chemical/mechanical)
- Access/egress
- Ventilation
- Shielding
- Remote operations/robotics
- Scaffolding/safe lifting/cranes
- Temporary facilities
- Personal protective equipment
- Dose rate/occupancy factors
- Fire safety
- Noise reduction
- Monitoring
- Laydown areas
- Waste treatment/packaging

During Stage 1 decommissioning the first contamination barrier is kept as it was during operation, but the mechanical opening systems are permanently blocked and sealed (e.g., with valves or plugs). This allows the decommissioning and removal of ancillary systems to reduce the hazards from minor systems, whilst making use of radioactive decay in the main hazards to naturally reduce the potential dose uptake from activities.

Equipment will be removed floor by floor such that activities are controlled within a particular plant area and can be easily supervised. Work will be carried out away from access/egress points where practicable. Where such work is unavoidable, consideration will be given to scheduling this work last, again, if practicable. Remaining, contaminated items will then be surveyed, and as before, appropriate systems of work put in place to enable their safe removal.

27.4.6.4 Manual and Remote Tasks

Remote Operations

The decision to select human or robotic decommissioning methods will largely be determined by the outcome of the contamination mapping exercise (see Section 27.4.6.2.2). This information will be used to assess the predicted cumulative dose for the task with the available shielding layout. Other important factors in the selection of human or robotic tasks are design and availability of robotic equipment and the accessibility of the working area.

Where possible, dismantling operations for highly radioactive components will be performed remotely in order to reduce the occupational radiation exposure. For example, removal of the RPV and internals is a task which has been carried out remotely by Westinghouse at several nuclear sites (e.g., Fukushima 2, San Onofre, Yankee Rowe).

Examples of operations that could be done also manually in lower active areas but are typically undertaken remotely in highly active areas include:

- Mechanical, thermal or hydraulic cutting (e.g., diamond wire cutting, band saw, abrasive water jet cutting, plasma arc cutting)
- Grinding, blasting, welding, hammering
- Lifting, jacking
- Disassembly of small components
- Sludge recovery
- Decontamination
- Monitoring (e.g., TV cameras, radiation)
- Handling of radioactive waste (ILW and HLW)

Manual Operations

There will be many manual tasks which need to be undertaken to decommission the facility. It is envisaged that skilled personnel will be engaged to assess, plan and safely execute the required tasks under controlled systems of work. This may include removal of smaller items such as pumps and pipe work and some decontamination and size-reduction operations carried out in the radwaste building, for example.

Manual dismantling may be aided at certain stages by means of the partial or total decontamination of the structures or systems to be dismantled to reduce the level of radiological controls required.

Low activity or clean plant and equipment are assumed to be removed manually, by a suitably qualified and experienced person (SQEP).

Removal of steelwork and concrete structures may involve the use of both SQEP and remotely operated equipment.

27.4.6.5 Industrial Safety Hazards

The industrial safety hazards are identified in Section 27.4.6.2.1 and control measures are shown in Section 27.4.6.3. The anticipated significant nonradioactive hazards may include:

- **Access** – Provisions for items such as access routes/equipment hatches/removable gratings/lifting equipment have been included in the design, and would be subject to routine monitoring and controlled under a written system of work to ensure that unnecessary dose is not accrued by e.g., transient workers.

- **Building integrity** – The buildings will have stood for over 60 years and therefore need to be regularly inspected to ensure their integrity remains, and no unacceptable hazards arise during the decommissioning works. Where new access points need to be provided, assessments will be made to ensure that the building structural integrity is not compromised.

- **Environment** – Environmental conditions (e.g., flood risk) may change over time. Therefore, periodic reviews of external risks to site integrity posed by the environment will be undertaken to assess the impact (if any) on proposed decommissioning activities.

- **Lifting activities** – Lifts will be assessed to determine their potential to impact on safety critical systems should a failure under load occur. It is expected that during decommissioning activities there will be an increased number of lifts compared to operational activities.

- **Manual operations** – Skilled trades such as scaffolding/welding/fitting would be required to do much of the decommissioning work. Controlling the tasks using a safe system of work, pursuant to CDM will ensure that risks to personnel are reduced to tolerable levels. Working at height can pose a particular risk from falls, or dropped objects. A high standard of safety principles and clear expectations will supplement the safe approach to decommissioning.

27.4.6.6 Record Management for Decommissioning

There are specific records that must be maintained during the operational life of the plant for the subsequent decommissioning phase, and the design documents that form a basis for this will be transferred from the vendor to the licensee when the licensee takes plant ownership. This information will include the following:

- A full set of design drawings
- Pre-Operation Safety Report
- A record of regulator discussions and agreements

The operator will be responsible for procuring the plant and for establishing a full set of as-built drawings for the plant. Westinghouse will be available to assist with this and to review any suggested design changes to the plant to ensure that they are not detrimental to the operation and decommissioning of the plant. Further details can be found in the Plant Life Cycle Safety Report (Reference 27.19, Sections 4 and 9.3.5).

During the operational phase of the plant, the operator will be responsible for maintaining records of the plant for use during decommissioning; these records will include the following information:

- Plant modifications
- Operational history
- Incident records
- Radiological surveys
- Radioactive substances and radioactive waste quantities, locations, condition, and ownership, with specific focus at the end of normal operations
- Waste treatment and disposal records
- Safety cases for operations, decommissioning, and waste management
- Regulator interactions and agreements
- The physical condition of the facility, including examination, maintenance, inspection, and testing records

During the decommissioning phase of the project, the operator will be responsible for keeping records of the following:

- The history of decommissioning operations
- Decommissioning reports to show how the objectives of the decommissioning plan, including the planned end-state for the facility, have been achieved
- Waste disposal records

The operator will be responsible for the generation, retention, and ownership of documents and records. The very long timescales involved in the operations and decommissioning of the AP1000 plant will be a major consideration in determining the form and manner in which documents and records are generated and retained.

27.4.6.7 Knowledge from Other Occurrences

As stated above in Section 27.4.3, a number of assumptions have been made when determining the suggested decommissioning strategy. So that the effects on decommissioning of other occurrences can be determined, the plant operators will review the impact of operational events and design changes on decommissioning plant status. These events may have an impact on decommissioning in a number of ways including the following:

- Practicalities of decommissioning such as access and dismantling techniques that can be used
- Dose to operators during decommissioning
- Radiological conditions of the DPS
- Waste volumes

When any significant changes occur, then the plant operator will be responsible for reviewing and updating as necessary the decommissioning strategy, plans, and safety case.

27.4.7 Stakeholder Engagement

The plant operators will be responsible for developing a stakeholder engagement process for decommissioning. This engagement process will be designed to ensure a wide ranging and inclusive consultation on relevant issues. The process will be flexible to allow engagement on any topics determined by the plant operator and should also allow alignment with other stakeholder processes. The stakeholder engagement process developed for the specific site must incorporate:

- Independence
- Transparency
- Openness
- Clarity
- Accessibility

During development, the stakeholder engagement process should consider diverse mechanisms to ensure that information is effectively communicated and that stakeholders have adequate opportunity for engagement. The following are examples of such mechanisms:

- Engagement workshops
- Plant operator website
- Posted information in local public buildings
- Site visitor centre
- Local liaison committee meetings held regularly throughout the year

Because the decommissioning strategy will be a living document developed throughout the life of an operating AP1000 plant, stakeholder involvement will be sought at all pertinent opportunities.

Typical stakeholders could comprise:

- Local authorities and bodies, for example: town, parish, district, and county councils
- Local organisations, for example: landowners' associations, national farmers' union, business associations, local members of parliament, and local residents
- Emergency and health services, for example: Civil Nuclear and County Constabularies, and county fire and rescue services
- Government agencies and regulators, for example: EA, Food Standards Agency, , NDA and ONR.
- AP1000 plant operators

27.5 LAND REMEDIATION

A contaminated land strategy is not required until a specific site has been identified. The operator will be required, however, to provide a strategy that sets out measures to detect radioactively contaminated land and to manage any such land that is identified. This strategy should be integrated with other relevant strategies.

The operator of the plant will be required to establish the following:

- Routine health physics surveys of ground at intervals appropriate to the level of risk in the survey areas.

- Boundary groundwater monitoring. This would include bore holes to intercept all groundwater horizons downstream of any potential contamination sources, and bore holes upstream to give background data. These would be sampled at appropriate intervals.

- Procedures required if spills occur.

If any contamination were to be found, it would need to be characterised, recorded, monitored, controlled, and remediated as appropriate.

27.6 CONCLUSIONS

The design of the AP1000 plant supports safe decommissioning. Steps have been taken to minimise the amount of waste generated during this process. Assumptions have been made about the status of the plant at the end of operations based on the design and operational guidance set out in this document.

The decommissioning strategy identifies the principles on which the AP1000 plant will be decommissioned and describes the reasoning behind the timing of decommissioning, which is proposed to be immediate. Ultimately, however, the operator will review this decision, taking into consideration conditions at the time.

A decommissioning plan has been developed based on this strategy (Reference 27.20). It is based on current available techniques; dose management is considered to be ALARP. The plan meets UK regulatory requirements and international best practice.

The design minimises waste volumes and activities. It is recognised that disposal routes for higher-activity materials will not be available immediately when that waste is processed. Therefore, a period of interim storage onsite is envisaged. The waste will be stored onsite in specifically designed facilities in a passively safe condition. An interim passively safe storage system will not compromise disposability.

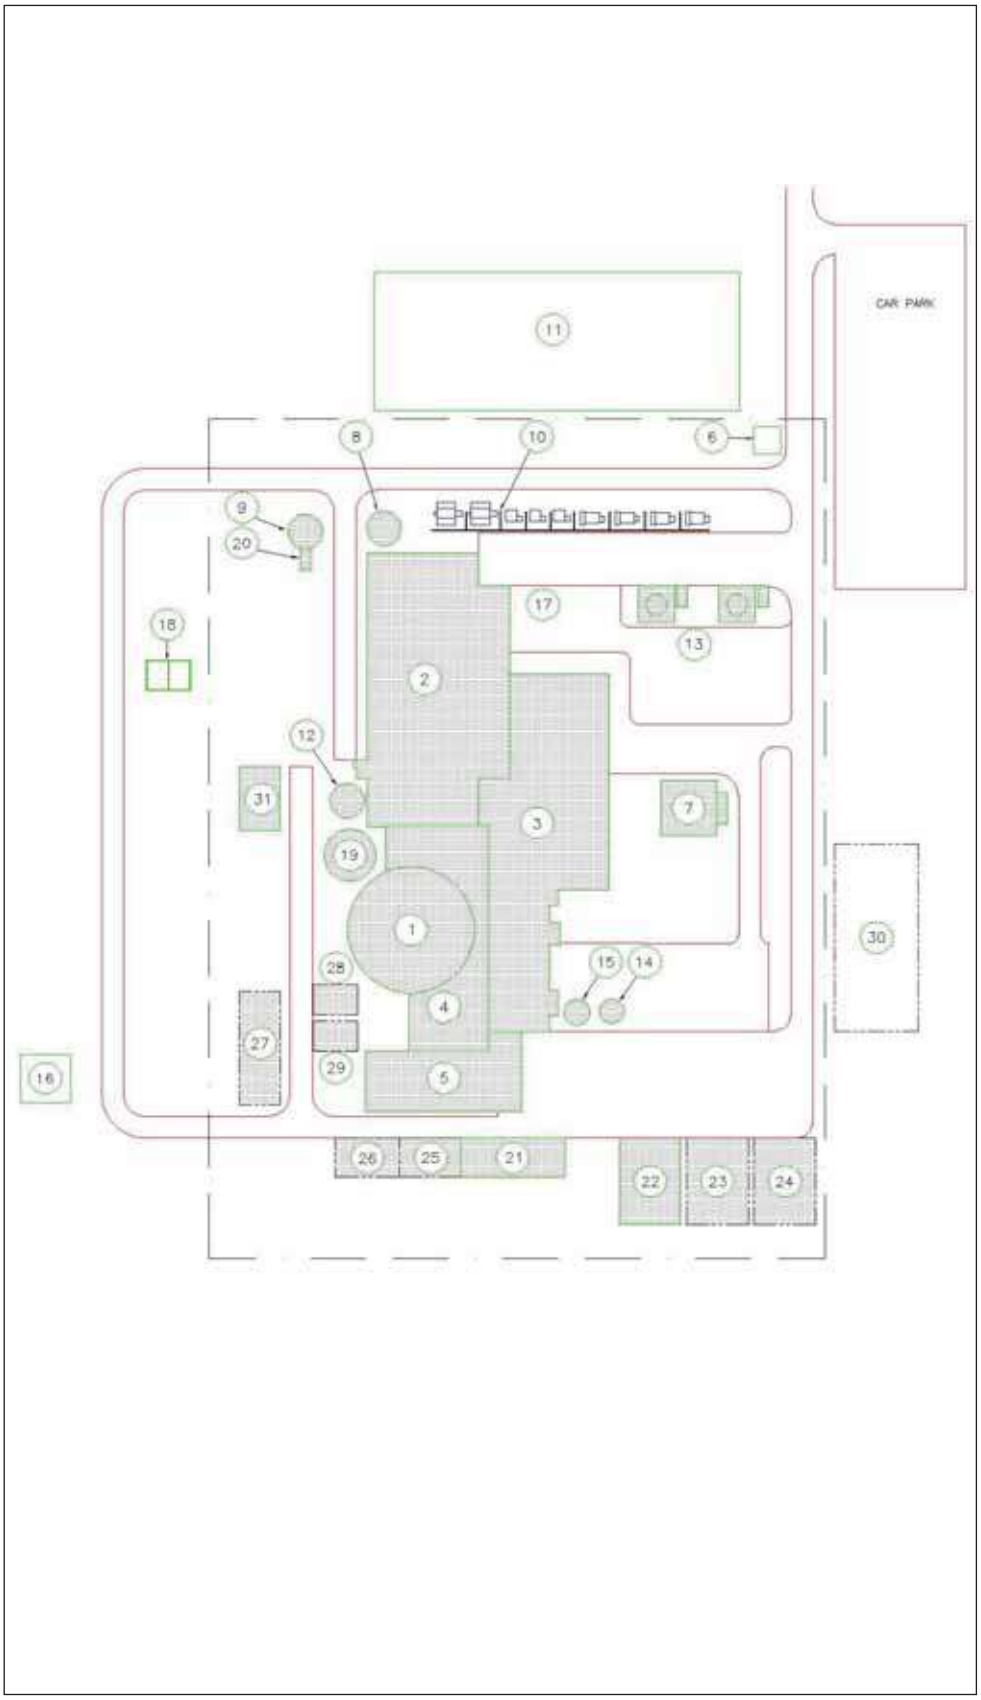

Figure 27-1. Typical AP1000 Design Plot Plan (Page 1 of 2)

Item	Description
1	Containment shield building
2	Turbine building
3	Annex building
4	Auxiliary building (contains fuel handling area)
5	Radwaste building
6	Plant entrance
7	Diesel generator building
8	Fire water/clearwell storage tank
9	Fire water storage tank
10	Transformer area
11	Switch yard
12	Condensate storage tank
13	Diesel generator fuel oil storage tanks
14	Demineralised water
15	Boric acid storage tank
16	Hydrogen storage tank area
17	Turbine building letdown area
18	Waste water retention basis
19	Passive containment cooling ancillary water storage tank
20	Diesel-driven fire pump/enclosure
21	ILW store (20 years)
22	Spent fuel store (20 years' storage)
23	Spent fuel store extension 1 (40 years)
24	Spent fuel store extension 2 (60 years)
25	ILW store extension 1 (40 years)
26	ILW store extension 2 (60 years)
27	Decommissioning facility (future)
28	Storage area for nonradioactive waste
29	Storage area low-level waste
30	Area for contractors' compound
31	Area for storage of large radioactive components

APPENDIX 27A
INVENTORIES OF ACTIVATED MATERIALS AND RADIOACTIVE WASTE ARISINGS

Table 27A-1 summarises the inventory of activated material after 10, 50, and 100 years of decay. A conservative approach has been taken, and basic data regarding activity levels for a typical PWR has been used with the estimated quantities for the AP1000 plant.

Tables 27A-2 to 27A-5 are taken from the Environment Report (Reference 27.7, Table 3.5-10, Appendices A4, A5, and A6) and estimate the radioactive waste arisings from decommissioning.

Table 27A-1. Summary of Inventory of Activated Material After 10, 50, and 100 Years' Decay

Component	Material	Mass (t)	Decay Time (y)	Isotopic Activity (MBq)											Total Activity (MBq)	Mean Specific Activity (MBq/t)
				H-3	Fe-55	Co-60	Ni-59	Ni-63	Nb-93m	C-14	Ca-41	Sm-151	Eu-152	Ho-166m		
Radial Shield																
Baffle, barrel, neutron pads and formers	Stainless steel	66	10		1.3E+10	4.3E+9	9.4E+7	1.5E+10	4.3E+8						3.3E+10	5.0E+8
			50				9.4E+7	1.1E+10							1.2E+10	1.8E+8
			100				9.4E+7	8.0E+9							8.2E+9	1.2E+8
Vessel and vessel cladding	Mild/ stainless steel	333	10	1.8E+6	2.7E+7	7.2E+6	9.3E+4	9.0E+6						4.5E+7		1.4E+5

Table 27A-4. Key for Preconditioning and Disposal Methods

Pre-conditioning Method	
1.	Immobilisation in a cementitious grout within a $3m^3$ RWM approved drum
2.	Immobilisation in a cementitious grout within a $3m^3$ RWM approved box
3.	Compacted (Possible super compaction) into a 200L RWM approved drum and placed into HHISO container
4.	Placed in “baskets” in the RWM (possibly grouted), e.g., 4 m box
5.	Collection and passed to monitoring and sampling tanks with filtration/IX
6.	Passed to WGS delay beds
7.	Collection and storage in oil tanks
8.	Sorted dependent on size/type
9.	Monitoring and swabbing (over period of time) with potential cleaning/decontamination or size reduction
10.	Potential quenching, filtration, chemical treatment, and ion exchange, as necessary
11.	Size reduction and placed in HHISO
12.	Placed in HOLTEC flask
13.	Collect and store
14.	Collect in a chemical waste tank and de-water (cross flow filtration)
15.	Collect in 200L Drum
Disposal Method	
A.	Site ILW store until UK repository becomes available
B.	Sent to LLW repository for storage
C.	Recycle or free issue
D.	Discharge to site drain
E.	Discharge to atmosphere
F.	Incineration
G.	Discharge via site effluent treatment
H.	Underground HLW storage facility
I.	Offsite contractor (e.g., NSG Environmental Ltd)
J.	Send to Inutec for drying and disposal at LLWR

Table 27A-5. Steel and Concrete Rubble from Demolishing Various Modules

Module	Waste Description	LLW/ILW/ HLW/Mixed	Physical/Chemical Description	Waste Form	Steel Mass	Steel Volume[(1)]	Concrete Mass	Concrete Volume[(1)]
					Tonne	m^3	Tonne	m^3
CA01	Concrete/Steel	LLW	Steel framework filled with concrete	Solid	907	118	4315	1796
CA02	Concrete/Steel	LLW	Steel framework filled with concrete	Solid	30	4	142	59
CA03	Stainless Steel	LLW	Reinforced curved tank wall section	Solid	191	25	N/A	N/A
CA04	Concrete/Steel	LLW	Barrel shaped octagonal structure houses reactor vessel	Solid	28	4	478	199[(2)]
	Lead/Titanium	LLW	Lead encased titanium tubes	Solid	4	0	N/A	N/A
CA05	Carbon Steel	LLW	Steel framework filled with concrete	Solid	56	7	268	111

Notes:

1. Demolished volume is based on density of 7700 kg/m^3 for steel and 2400 kg/m^3 for concrete and 11000 kg/m^3 for lead filled titanium tubes. Provisions should be included in storage facilities to accommodate packaged waste that may require two to three times demolished volume. With proper decontamination prior to demolition, most of this waste will be essentially all VLLW.
2. Concrete volume based on the assumption that a concentric section around the reactor vessel cavity in the vicinity of the core will contain enough activation products to be treated as an LLW.

28 CONCLUSIONS

28.1 Introduction

This chapter summarises the main conclusions from the Pre-Construction Safety Report (PCSR) for the Westinghouse AP1000 nuclear power plant submitted under the Office for Nuclear Regulation (ONR) generic design assessment (GDA) process (Reference 28.1).

28.2 Setting the Pre-Construction Safety Report in Context

Chapter 1 of Volume 1 sets the PCSR in the context of the evolution of the AP1000 design, and of the United Kingdom (UK) regulatory regime in general and the GDA process in particular.

Chapter 1 also introduces the overall safety claims that the implementation of passive safety features and the simplification of the design significantly contribute to the improved safety and reliability of the plant over existing plants; that the AP1000 design, construction, and operation fully meet UK licensing requirements and safety assessment principles (SAPs) (Reference 28.2); and that levels of public, worker, and environmental risk from all modes of operation and all parts of the plant life cycle are as low as reasonably practicable (ALARP).

Chapter 2 then gives an overview of the safety case developed in the subsequent volumes and chapters of this PCSR that demonstrates that these overall safety claims are justified. The structure of the safety case presented in this PCSR is based on the following claims introduced in Chapter 2:

- Safety is managed throughout the plant life cycle.
- Safety is achieved through simple, passive design and defence in depth.
- Design and operation are tolerant to faults and risks are ALARP.
- Engineering solutions are fully substantiated.
- Radiological releases are minimised in normal and abnormal operating conditions.

28.3 Safety Is Managed throughout the Plant Life Cycle

The Westinghouse Global Management System (WGMS) discussed in Chapter 3 ensures that documented quality and safety procedures are in place, and that they are robust, managed, and monitored in accordance with statutory, legal, and regulatory requirements. The WGMS meets the requirements of UK and international regulations and good practice. Post-GDA, the WGMS also ensures that Westinghouse safety management arrangements are appropriately transferred and integrated into the safety management systems of the licensees, who become responsible for safety once the Design Acceptance Confirmation is received from the ONR and a Statement of Design Acceptance is received from the EA. The arrangements ensure that safety-important information is available, as appropriate, throughout the construction, commissioning and operating phases and eventual decommissioning.

An integral part of this process is adapting the safety case presented in this PCSR, which is based on the UK generic site described in Chapter 4 to the actual site(s) where the design is to be built. The Plant Life Cycle Safety Report (PLSR) (Reference 28.3) describes the process by which the knowledge within the AP1000 safety case can be most comprehensively transferred to the potential licensee and outlines the Westinghouse assumption about any licensee's management system. Plant life cycle issues related to engineering (for example,

commissioning, maintenance, ageing, and decommissioning) are addressed in Chapter 7 as discussed below in Section 28.4.

In these chapters, Westinghouse safety management is shown to be a continuous process from design through construction and commissioning to operation and ultimate decommissioning.

28.3.1 Safety Management Conclusions

The principles underlying the management of safety ensure that the design, construction, commissioning, operation, and decommissioning fully meet UK regulatory expectations and best practice and that the public, worker, and environmental risks associated with the above phases of the plant life cycle are ALARP.

28.4 Safety Is Achieved through Simple, Passive Design and Defence in Depth

Volume 2 describes the AP1000 design and operation.

Chapter 5 introduces the engineering principles that underlie the AP1000 design. In particular, it gives the scheme for categorising safety functions and classifying the systems, structures, and components (SSCs) that provide them. This categorisation and classification scheme is the basis on which appropriate codes and standards are applied, how maintenance and testing regimes are determined, and how the equipment is qualified, commensurate with the safety importance of each SSC. The categorisation and classification scheme provides a coherent framework for developing and substantiating the safety case for the design.

Where the AP1000 plant departs from conventional PWRs is in the use of passive means of providing essential safety functions to protect against faults. These passive safety features rely solely on natural mechanisms such as natural convection and driving forces derived from compressed gases rather than active pumped systems; therefore, safety is substantially enhanced. Further, there is no reliance on alternating current (ac) power to bring the reactor to a safe shutdown condition or to keep it there. More conventional active systems provide defence in depth by reducing the probability that the passive safety features will be actuated.

All of these features and their operation are described in Chapter 6. The design described in Chapter 6 draws together information specified by the Design Reference Point (DRP) (Reference 28.4) and supporting safety case information. The information presented in Chapter 6 is used as the basis for all the assessments presented in the PCSR and covers the following:

- Reactor systems
- Steam and power conversion systems
- Normal operations
- Passive safety systems
- Control and instrumentation (C&I)
- Essential electrical systems
- Auxiliary systems
- Containment and ventilation systems
- Fuel handling and radwaste systems
- Civil structures

Chapter 7 discusses how the engineering aspects are managed through the life cycle, including during power operations. It recognises that the AP1000 plant design, build, test and maintenance activities can influence the safety of the AP1000 plant throughout life and that there is a requirement for Westinghouse to work with the operator to ensure the continued safety of the reactor. However, it is also accepted that the delivery of Westinghouse's arrangements post-design acceptance and on a licensed site will be under and in agreement with the licensee's arrangements.

Chapter 7 also outlines the long-term approach to the management of the ageing mechanisms to ensure the plant remains safe and risks remain ALARP for the duration of the plant life cycle. It also sets out the approach to the periodic safety review process.

28.4.1 Design Conclusions

In many respects, the AP1000 reactor is a conventional PWR. However, the above chapters demonstrate that the implementation of passive safety features, simplification of the design, and defence in depth significantly contribute to a high level of safety and reliability.

28.5 Design and Operation Are Tolerant to Faults and Risks Are As Low As Reasonably Practicable

Volume 3 presents the fault and accident analysis that demonstrates the fault tolerance of the AP1000 design and operation. The methodology used is outlined in Chapter 8.

Possible faults have been identified in a systematic, auditable, and comprehensive way for the reference design, including all operating modes of the reactor and all inventories of radioactive material on the site. The list of faults is presented in Chapter 8, Appendix 8A. The list of faults is comprehensive, but some of the individual faults may be bounded by other faults whose behaviour is similar and have similar provision of safety functions.

The fault list also details the hazards arising onsite or offsite (internal and external hazards, respectively).

28.5.1 Design Basis Analysis

The design basis (DB) analysis of each of the fault groups is given in turn in Chapter 9. For each, several faults are identified and analysed that produce the most onerous demand on the design safety systems. The main fault types analysed in Chapter 9 are the following:

- Main steam line break
- Increase in heat removal faults (excluding main steam line break)
- Feed line break
- Decrease in heat removal faults (excluding main feed line break)
- Major mechanical failure of a single reactor coolant pump (RCP)
- Decrease in reactor coolant flow faults (excluding major mechanical failure of a single RCP)
- Reactivity and power distribution faults (excluding control rod ejection)

- Ejection of a rod cluster control assembly (RCCA) from the core
- Inadvertent operation of a core makeup tank (CMT)
- Chemical and volume control system (CVS) malfunction that increases reactor coolant inventory
- Steam generator tube rupture (SGTR)
- Large-break loss–of-coolant accidents (LOCAs)
- Medium-break LOCA
- Small-break LOCA
- Safety injection line break
- CMT line break
- Passive residual heat removal tube rupture
- Reactor coolant leakage
- Large cold leg break in Mode 4 operation
- Loss of normal residual heat removal system (RNS) in Modes 4 and 5 with RCS intact
- Loss of RNS in Mode 5 with RCS open
- Criticality faults during refuelling and spent fuel storage
- Loss of heat removal during refuelling and spent fuel storage
- Dropped fuel cask in loading bay
- Dropped fuel assembly onto other fuel
- Operator falls into flooded refuelling cavity or fuel storage pool
- Water-level fall in refuelling cavity or fuel storage pool (shielding lost)
- Failure of filters in heating, ventilation, and air conditioning (HVAC) system
- Dropped filters
- Reduced HVAC airflow
- Loss of containment of spent resin
- Dropping of radioactive exchangeable items
- Failure of small lines carrying primary coolant outside the containment

The DB response of the system and the corresponding SSCs to the analysed faults in each of these groups demonstrates that the applicable acceptance criteria is met (including the dose targets given in the SAPs, Reference 28.2, Target 4. The set of SSCs required to ensure that the criteria are met are assigned to the appropriate class and the corresponding safety function(s) to the appropriate category, using the scheme described in Chapter 5.

Where the fault falls into the category of frequent faults (initiating event frequency $>10^{-3}$/yr), alternative means of providing the necessary safety functions are also identified to comply with the SAP requirement that frequent faults should have diverse means of providing the necessary safety functions. These faults are analysed to demonstrate that the diverse SSCs listed can mitigate the event and satisfy the applicable acceptance criteria.

Also as part of this process, as required under site licence condition (SLC) 23, limits and conditions are identified which may be candidates for operating rules or which may have operating rules associated with them. Similarly, required operating instructions (e.g., to manually initiate safety systems) are identified. These operating instructions are considered in Chapter 13 as outlined below in Section 28.5.4. Finally, other SSCs are identified that may provide defence in depth and contribute to ALARP.

Chapter 9 demonstrates that, for all but one of the above fault groups, with the identified SSCs operating and identified limits and conditions met, the calculated doses are below the basic safety objective (BSO) for the corresponding DB dose target (SAP Target 4) (Reference 28.2). For the one fault where this is not the case (SGTR), the calculated doses are still well below the basic safety level (BSL) for the corresponding dose target. Further, for all of the fault groups, the risks from all modes of normal operation and fault conditions are shown to be ALARP.

28.5.2 Probabilistic Safety Assessment

The probabilistic safety assessment (PSA) discussed in Chapter 10 takes the same reactor and spent fuel pool fault groups as in Chapter 9 and assesses the progression of events if the safety systems fail or do not operate as designed. Each fault group is assigned an initiating event frequency, normally based on operating experience for other PWRs or from reliability assessments and a set of sequences developed representing the failure of safety systems. Each sequence has a frequency calculated from the initiating event frequency and the reliabilities of the mitigating systems. Consequences for each sequence are calculated from transient or other analyses.

The PSA gives the required analysis of severe accidents (i.e., sequences that lead to offsite doses above the DB dose targets or that lead to damage of the reactor core).

Two main parameters constitute the output of the PSA: the core damage frequency (CDF) and the large release frequency (LRF). For at-power internal events, these are assessed to have values of 1.7×10^{-7}/yr and 1.7×10^{-8}/yr, respectively. Both parameters are several orders of magnitude lower than for conventional PWRs of similar power output. Accidents in shutdown conditions make a contribution to these parameters that are comparable to the at-power values.

The SAPs (Reference 28.2) give a number of probabilistic targets to be met by the plant. The PSA gives the results relevant to internally initiated reactor faults and, as such, makes a major contribution to the demonstration that these targets are met. However, other parts of the fault and accident analysis also make a contribution so the consideration of probabilistic targets is

postponed until Chapter 14 (see Section 28.5.5 below), which gives the overall conclusions of the fault and accident analysis.

28.5.3 Internal and External Hazards

Internal and external hazards and the risks from operator errors and other human factors have been assessed separately.

Internal hazards are those that arise onsite but outside the nuclear systems that have the potential to affect the safety of the AP1000 plant. Internal hazards have been identified in a systematic, auditable and comprehensive way, and the following are assessed in Chapter 11:

- Internal fires
- Internal flood
- Pressure part failure
- Internal explosions
- Internal missiles
- Release of toxic, corrosive, or flammable material
- Dropped loads and load mishandling
- Biological agents
- Onsite transport
- Electromagnetic interference (EMI)

The focus of the Internal Hazard assessment is to demonstrate that the Class 1 SSCs delivering the Category A safety functions are adequately protected from design basis internal hazards or that there is sufficient redundancy that if some equipment is lost, the safety function can still be delivered. Protection from internal hazards of Class 2 SSCs delivering Category A safety functions and providing defence in depth and Class 2 SSCs delivering supporting Category B safety functions have also been assessed, where operation of such Class 2 SSCs is credited. Where relevant, the effect of combined and consequential hazards has been reviewed and assessed.

The assessment in each of the Internal Hazard areas has confirmed that the DB hazard does not prevent the delivery of the Category A safety functions or any supporting Category B safety functions. The conclusion is, therefore, that the AP1000 design is tolerant to faults arising from internal hazards and that the designed safety measures are effective.

External hazards are those naturally occurring and man-made hazards that may arise offsite. Examples include earthquakes, extreme weather, and aircraft crash. The following external hazards for the generic site described in Chapter 4 are assessed in Chapter 12:

- Earthquakes
- External flooding
- Accidental aircraft crash
- External explosion
- Extreme ambient temperatures
- Meteorology
- Extreme wind
- Offsite fire and smoke
- Offsite missiles
- Biological fouling

- EMI and lightning

The majority of the external hazards assessed in this assessment fall within the bounds of the generic site parameters given in Chapter 4 and thus may be regarded as within the DB of the plant. This is mainly due to the inherent robustness of the AP1000 design.

The analysis is similar to that done for internal hazards, and this chapter demonstrates that the delivery of the Category A safety functions by Class 1 SSCs is not compromised by design basis external hazards and that the AP1000 design measures are effective.

A number of site-specific assessment requirements have been identified, which will need to be addressed in any site-specific PCSR, and there are a number of overall site requirements including accident/incident management and emergency preparedness that will need further consideration at the appropriate stage.

28.5.4 Human Factors

Chapter 13 describes how an integrated and managed Human Factors (HF) Engineering programme has been rigorously and systematically applied throughout the concept, analysis and design phases of the Standard AP1000 Plant design. The measured and proportional application of HF processes and methodologies has ensured that the design considers at all times the role of the human operator in the safe and efficient operation of AP1000.

The HF design of the AP1000 Plant has been based upon a set of internationally recognised Standards and Codes and on industry experience and guidance that can be deemed as relevant good practice in the UK.

The difference between the role of the operator in the AP1000 plant and in current plants is one of degree, and not a fundamental change in character. The use of passive safety systems, simplification of the design, and appropriate use of automated systems mean that the operators are responsible for assessing plant status and verifying the availability and operability of, and the need for actuation or termination of the plant's defence in depth and passive safety systems. The HSI includes displays that integrate information to facilitate assessment of plant state and supervisory control of automated and passive systems, and a computerised procedure system that facilitates execution of the AOPs and EOPs. It is therefore easier to place the plant into a safe condition and maintain it in a safe state under post-fault conditions. The Human Factors programme has provided guidance to ensure that functions have been allocated appropriately between automatic systems and human operators. Where operator action is required, the corresponding action is strictly controlled through the use of plant procedures with supervision and verification monitoring from the main control room (MCR) supervisor, and crew performance is governed by the plant conduct of operations. The combined effect of these provisions is to minimise the likelihood of operator errors that might affect plant safety. The design evolution of AP1000 is consistent with the ONR's expectations for the demonstration of ALARP with respect to new commercial reactor designs.

It is recognised that, even with the best design from a human factors perspective, operator errors may still occur. Chapter 13 demonstrates that the risk from operator errors is small and reduced to a level that is ALARP. This demonstration consists of a systematic identification of operator errors, that is, the failure of operators to perform actions required to ensure nuclear safety correctly, and the assessment of these errors to show that their contribution to risk is reduced to levels that are low and ALARP.

The following three types of operator errors identified by the International Atomic Energy Agency (IAEA) are assessed:

- **Type A** – Operator actions that degrade or prevent systems from performing their safety functions (maintenance latent errors)

- **Type B** – Operator actions that induce initiating events (operator induced initiating events and maintenance induced initiating events)

- **Type C** – Post-fault operator actions that prevent the mitigation of the initiating event or make it worse

Human errors of these three types are identified from both the DB analysis presented in Chapter 9 and the PSA in Chapter 10. These errors are screened according to their risk significance, and those considered to be risk-significant are analysed and documented in a uniform and systematic way in accordance with current good human factors analysis practice for the purpose of this PCSR.

Acknowledged gaps in the human factors safety case substantiation for GDA have been identified and will need to be further progressed during the site licensing phase. These shortfall areas are:

- Completion of the resolution process currently in progress for the human engineering discrepancy (HED) and HED issues arising from the HF verification and validation activity conducted for standard AP1000 plant design.

- Completing the plant start-up C&I HF verification activity described in Reference 13.61.

- Complete human error analysis process at a cognitive-level for all screened-in, risk-significant operator actions, as demonstrated on a sample of actions for GDA, and provide these as input into the site PSA.

- Completion of the HF maintenance and maintainability assessments for local plant maintenance, testing, inspection, and surveillance activities.

- Implementation of a site-specific HF integration plan as part of the overall AP1000 programme plan.

The conclusion of the human factors assessment is that, as a consequence of the AP1000 plant operating philosophy, the design, and the human factors programme, the role of the operators in ensuring nuclear safety in the AP1000 plant has been optimized, andthe risk due to human error is reduced ALARP for GDA.

28.5.5 Conclusions from Fault and Accident Analysis

Chapter 14 summarises and consolidates the results of the chapters in Volume 3 (Chapters 8 to 13) so that comparisons can be made with the other SAP targets.

The chapter lists all of the SSCs that have been identified in the fault and accident analysis as being important to safety, giving their classification and performance and reliability claims made in the safety case.

SAP Targets 5 and 7 are probabilistic targets for risk of individual death for workers and public, respectively. Both have the same BSL ($1.0x10^{-4}$/yr) and BSO ($1.0x10^{-6}$/yr). The PSA doesn't give this value explicitly, but Chapter 14 argues that, for reactor faults, the CDF provides a reasonable surrogate and has a value well below the BSO. Other faults only provide a minor contribution to these targets.

Targets 6 and 8 give frequency-dose targets for the plant as a whole for the workforce and public, respectively. Bringing the information together from the various chapters shows that the targets are easily met.

Finally, Target 9 is a societal risk target, giving BSL and BSO for the risk of 100 or more fatalities. Chapter 14 argues that the LRF, which is significantly below the BSO, is a reasonable surrogate for this.

Chapter 14 brings together the various ALARP assessments that have been done in the past and the individual ALARP assessments coming from the fault and hazard assessments in this PCSR to demonstrate that the risks from AP1000 design and operation are ALARP.

During the development of the AP1000 plant, design choices have been made that reduce fault frequencies, removing some faults common to existing plants altogether. The passive design of protection systems and defence in depth contribute significantly to a design that is extremely tolerant to faults.

The designers of the AP1000 plant have sought means of further reducing risk during every part of the design and safety assessment possesses. The designers have also used available tools such as the PSA and severe accident assessment to identify risk-reduction measures that might be reasonably practicable to implement. Many design decisions and design changes have been implemented as a result, which contribute to the overall risk being ALARP.

28.6 Engineering Solutions Are Fully Substantiated

The SSCs that have been identified in the fault and accident analysis as being important to safety, their classification, and the performance and reliability claims made for them in the safety case are listed in the Engineering Schedule in Appendix 15A.

Chapter 15 lists the sources of claims on SSCs in the safety case and the requirements on SSC performance that are implied by them. These requirements come from the following sources:

- Performance requirements from the transient analysis performed as part of the DB assessment
- Survivability and operability requirements arising from the need to operate in normal plant environmental conditions and the environmental conditions following a design basis accident (DBA)
- Reliability requirements from the probabilistic assessment of DB faults and the PSA
- Separation and segregation requirements from the internal hazard assessments
- Seismic qualification requirements arising from the external hazards assessment

- Quality requirements for design, manufacturing, installation, commissioning, maintenance, and testing

- Durability requirements related to expected plant service life

The remaining chapters of Volume 4 (Chapters 16 to 23) provide the evidence that the SSCs identified in the fault assessments can meet the requirements arising from the claims made on them in the safety case through their design and by the way they are tested and maintained throughout the life of the plant.

28.6.1 Civil Engineering

Chapter 16 summarises the generic design information, which is used to justify that the civil engineering structures will withstand the loads arising from normal operations, internal hazards, external hazards, and internal plant faults.

The civil engineering safety case clearly has a dependency on site-specific information. However, the AP1000 international design is based on external hazard data representative of a worst-case site. This leads to structures having robust load resisting systems capable of withstanding the generally more benign UK environments.

The approach to construction acknowledges that the achievement of the design intent has some dependency on the site, as well as the organisations with responsibilities for construction, and that it would be inappropriate for the construction processes to be fully defined before the site-specific PCSR is developed. While still complying with the codes and standards identified in this chapter, choices remain relating to the specification and methods of construction.

The design has taken into account the 60-year design life. It is concluded that there will be no erosion of the capability of the civil engineering structures to withstand the loads required by the nuclear safety case, provided the appropriate maintenance, examination, inspections, and testing are undertaken. Beyond 60 years, it is likely that the nuclear island structures will still need to provide safety functions until such time as decommissioning has removed all the significant nuclear materials. Replacing the nuclear island civil engineering structures is generally not an option, which can be a possibility when considering internal plant; therefore, the nuclear island structures will need to have a working life well in excess of 60 years, with the exception of some of the water storage structures that may no longer be needed following cessation of power operation. The nuclear island is constructed from a combination of reinforced concrete, structural steelwork, and SC-constructed elements. A working life of 120 years is achievable in line with normal civil engineering criteria

It is concluded that the AP1000 design demonstrates that the deterministic justifications of the civil engineering structures are appropriate to their safety function and class, and that the necessary normal and hazard loads will be withstood as required, subject to appropriate investigations and confirmations being provided relevant to a particular site.

28.6.2 Mechanical Engineering

Chapter 17 considers the mechanical systems, which largely provide safety functions to prevent fuel damage and the consequent release of radioactivity. Analysis of these systems has therefore been carried out to review their requirements against three primary safety functions: reactivity control, residual heat removal, and containment.

The role of each mechanical system in normal and abnormal operation is discussed, and the primary safety functions to which the system contributes are identified. A description of each mechanical system is provided that shows how the SSCs that make up the system contribute to the relevant primary safety functions.

The chapter provides evidence that each SSC can meet the requirements placed on it by the safety case in terms of performance and reliability appropriate to its importance for safety as characterised by its safety classification. The evidence consists of design criteria, discussion of applicable codes and standards, and deterministic analysis, as appropriate.

The conclusion of the chapter is that the mechanical design fully meets the requirements of the safety case in that the individual SSCs assessed are designed, manufactured, installed, tested, and maintained according to the appropriate codes and standards and in a manner consistent with their safety importance as identified in the safety case and appropriate to their safety classification.

28.6.3 Essential Electrical Systems

Chapter 18 describes the design of the electrical power systems of the AP1000 plant, including essential supplies, main and standby generation, auxiliary supplies, main export grid connection, and maintenance grid connection.

A distinguishing feature of the AP1000 plant is that it is designed to be able to achieve a safe shutdown without offsite ac power supplies or standby diesel generators; although defence in depth considerations mean that the plant is normally operated and shut down with ac power available.

The AP1000 electrical system fulfils a number of functions that are important to nuclear safety, contributing to the provision of the primary safety functions of heat removal, containment, and criticality control identified in the safety case. It also contributes to defence in depth.

To reflect the relative importance of each function and the system to deliver that function, the AP1000 plant electrical system is classified according to the scheme given in Chapter 5. Chapter 18 references evidence that the electrical system has been designed in accordance with international nuclear safety standards and follows the principles of diversity, redundancy, segregation, defence in depth, and quality of design and equipment commensurate with the classification of the corresponding SSCs and can meet the performance and reliability requirements placed on it by the safety case.

The conclusion of the chapter is that the design of the electrical systems fully meets the requirements of the safety case by supporting the provision of the main safety functions and by providing defence in depth.

28.6.4 Control and Instrumentation

Chapter 19 discusses the AP1000 C&I systems, which form a fundamental part of the safety systems used to shut down the reactor following DB transients and which maintain the reactor in the shutdown state. Provision is made for continued monitoring in the main control room (MCR) and from the remote shutdown room (RSR). The MCR remains habitable following DBA. The C&I systems are also important for the provision of the reactivity control, residual heat removal and containment safety functions and are classified in accordance with their safety importance in the same way as other systems.

The Class 1 protection and safety monitoring system (PMS) is designed to respond automatically so that specified limiting conditions are not transgressed. The Class 2 diverse actuation system (DAS) provides backup to the PMS in actuating Class 1 safety systems. The plant control system (PLS) which is a Class 2 system provides the main closed loop controls necessary for plant operation and mitigation for plant transients in advance of Class 1 system actuation. The data display and processing system (DDS) which is Class 3 provides the plant monitoring and control interface for the duty system and as subset of the systems important to safety. The DAS is included to support the AP1000 design risk goals by reducing the probability of core damage or a severe accident, which potentially results from the unlikely coincidence of postulated transients and postulated common-mode failure in the PMS and the PLS.

Bases of safety justifications have been produced for the principal C&I systems i.e. the PMS, DAS, PLS and DDS. The PMS basis of safety justification refers to lower tier safety justifications where specific aspects of the system are further substantiated.

Three supporting documents have been produced for Chapter 19 to provide further justification and substantiation of the overall C&I architecture and include:

- an ALARP justification
- SAPs Conformance Assessment
- an IEC 61513 safety Life Cycle Conformance Assessment

The conclusion of the chapter is that the design of the principal AP1000 C&I systems will meet the requirements of the safety case by supporting the provision of the main safety functions and by providing defence in depth, once the identified gaps in compliance and the associated compensating measures have been completed.

28.6.5 Structural Integrity

Chapter 20 provides a safety justification of AP1000 components at the design stage in support of the GDA. It provides component safety reports that provide safety arguments to establish that the structural reliability of each major AP1000 primary pressure boundary component (e.g., reactor pressure vessel, steam generators, and pressuriser) is commensurate with the consequences of gross failure.

Assurance that the safety functional requirements of individual components will be met at all times is provided by substantiating structural integrity against appropriate structural reliability targets depending on the structural integrity classification of the component. Detailed substantiation of the safety claims made on each major structural component is provided in the individual component safety reports.

The chapter concludes that the safety arguments presented identify a suitable and sufficient diversity of evidence to substantiate the structural reliability claimed for the AP1000 components addressed.

28.6.6 Reactor Chemistry

Chapter 21 describes the application of chemical controls and treatments in the AP1000 plant design. It also describes and assesses the systems involved in the provision of chemical controls, principally the CVS.

A number of systems in the AP1000 design contain fluids that are essential to their functions, including heat transfer and control of core reactivity. The quality of these fluids and their interactions with system components and materials can substantially impact the reliable and safe operation of the individual systems or the reactor as a whole. Chemical additives are employed to optimise the performance of the fluids and minimise potential negative effects e.g., corrosion of materials. Chemistry is also used as a means to mitigate impacts in accident and fault conditions, principally by controlling levels of radioactivity in the primary and secondary coolant.

To achieve these aims, chemical controls are in place in the primary circuit to provide the following functions:

- Control reactivity of the core to within operating limits (control of boron levels)
- Maintain integrity of the primary circuit and the fuel cladding (control of oxygen levels and pH)
- Minimise build up of radioactivity on plant outside the core region due to the irradiation and transport of corrosion products (control of crud formation and transport)

The detailed chemistry control strategy is the responsibility of the plant operator, but Westinghouse endorses operating within Electric Power Research Institute (EPRI) guidelines on reactor chemistry, which are developed from accumulated industry-wide research and operating experience and are an authoritative guide to best practice. The AP1000 plant is designed to operate safely within these guidelines and the chemistry operating specifications and technical specifications reflect the EPRI standards.

This chapter provides evidence that the AP1000 reactor chemistry and chemistry control systems support the overall safety claims by aiding control of core reactivity, controlling the integrity of the pressure boundary, and controlling the quantity, distribution, and containment of radioactive materials, thereby ensuring safe operation of the reactor.

The conclusion of the chapter is that the chemical controls in the design significantly contribute to safe operation of the plant and reduce releases to the environment in accident conditions.

28.6.7 Fuel Design

Chapter 22 provides a safety justification of the fuel assemblies in the AP1000 reactor. For normal operation, this means that all reasonable steps are taken to minimise the failure of the fuel rod cladding and thus minimise the release of radioactive fission products into the coolant. For fault conditions, the definition of satisfactory performance depends on the frequency with which the fault is expected to occur.

This chapter presents the safety case for the standard fuel element design in the AP1000 PWR. The safety case consists of a justification that the nuclear, thermal, and hydraulic design of the fuel meets the design bases, functional requirements, and safety performance required for normal operation and during transients and in accident conditions.

A number of fundamental safety criteria are defined in terms of the ability to shut the reactor down, avoidance of fuel damage or fuel failure, and limits to release to the environment. The mechanical design of the core components and their physical arrangement, together with the

corrective actions of the reactor control, protection, and emergency cooling systems, ensure that in any fault these criteria are met.

These safety criteria together define a number of safety design bases.

During normal operation, following any operational transient or following any fault expected to occur during the lifetime of the fuel, the following apply:

- The number of clad failures must be small so that the safety criteria are clearly met.
- The fuel and in-core components suffer no deterioration that could prejudice their performance in subsequent, more severe faults.

In addition, a number of design bases for design basis fault sequences have been identified. These safety design bases lead to limiting conditions (for example, minimum departure from nucleate boiling ratio or critical heat flux) within which the fuel can operate safely during both normal and fault conditions.

The conclusion of the chapter is that none of the design bases or limiting conditions is exceeded when the fuel is subjected to the full range of operational and fault conditions considered in Chapter 9.

28.6.8 Containment and Ventilation

Chapter 23 provides the evidence that the design of the containment and nuclear ventilation systems in the AP1000 plant is adequate to meet the safety claims placed upon these systems in other parts of the safety case, both for normal operations and under fault conditions.

The containment and ventilation systems largely support the primary safety functions of the containment of radioactive substances and heat transfer/residual heat removal, and provide environmental support to SSCs, which contribute to primary safety functions. Analysis of the containment and ventilation systems has therefore been carried out to review their requirements against the primary safety functions.

The chapter provides evidence that each SSC can meet the requirements placed on it by the safety case in terms of performance and reliability appropriate to its importance for safety as characterised by its safety classification. The evidence consists of design criteria, discussion of applicable codes and standards, and deterministic analysis, as appropriate.

The conclusion of the chapter is that the mechanical design fully meets the requirements of the safety case in that the individual SSCs assessed are designed, manufactured, installed, tested, and maintained according to the appropriate codes and standards and in a manner consistent with their safety importance as identified in the safety case and appropriate to their safety classification. The justification against these safety functions demonstrates that the risks have been reduced to a level that can be considered to be ALARP.

28.6.9 Engineering Substantiation Conclusions

The tolerance to faults and demonstration that risk is ALARP rely on claims made on the SSCs that make up the design and on assumptions regarding fuel design and reactor chemistry. The chapters that make up the engineering substantiation volume provide the arguments and evidence that substantiate the claims made on SSCs in the other parts of the safety case.

28.7 Radiological Releases Are Minimised in Normal and Abnormal Operating Conditions

The safety of pre-power operation, power operation and post-power operation activities for the AP1000 plant are based on risk reduction, dose minimisation, waste minimisation, and safe storage. Volume 4 addresses control of radiation in this context. The principle of ALARP is applied in addition in all of these cases.

28.7.1 Radiological Protection

Chapter 24 covers the protection of workers and members of the public against exposure to ionising radiation in normal operations and protection of essential workers following a major accident.

Radiation protection from external radiation under normal operating conditions, including routine maintenance, is achieved in the design by reducing the sources of radiation so far as is reasonably practicable (SFAIRP). Where sources cannot reasonably be reduced further, exposure to radiation is controlled by means of shielding and by controlling the duration of exposure.

The design of the AP1000 plant has taken account of utility requirements for reliability, safe operation and maintenance, and reduction in operator dose. Experience from the continuing improvements in operating plants has been incorporated into the design (e.g., materials selection, plant layout) and operating regime (e.g., reactivity control, water chemistry) to reduce radiation levels from the plant. In areas where exposure to external radiation are likely, suitable and sufficient shielding is provided to protect workers during normal operations, maintenance, and fault conditions. Features have been incorporated into the design that reduce the outage time for refuelling and, as a result, reduce the duration of worker exposure to radiation. Where applicable, remote inspection and maintenance systems have been developed to further reduce exposures during shutdown.

Protection from radioactive contamination is achieved by reducing the activity present in dispersible form, provision of suitable containment and ventilation, layout of areas, control of access, monitoring, and personal protective equipment.

In fault and accident conditions, the design allows the reactor to be brought to safe shutdown without any release of radioactivity and systems are in place to maintain the integrity of the containment systems for at least 72 hours without the need for standby systems. In the unlikely event that a release does occur, the MCR is provided with an uncontaminated supply of air from pressurised cylinders and shielding calculations demonstrate that the dose to workers in the MCR during this period will be limited. Pre-defined routes are provided to locations that need to be accessed in a major emergency.

The conclusion of this chapter is that everything has been done to ensure that risks from radiation in normal operation and risks to operators during accidents have been reduced to levels that are ALARP.

28.7.2 Accident Management

Chapter 25 complements the assessment in Chapter 24 in that it discusses protection of the public during fault and accident conditions.

By necessity, accident management arrangements will be site-specific, but the chapter addresses requirements for emergency response to a nuclear incident and emergency. It also

identifies the provisions available in the current AP1000 design to respond to a nuclear incident or an emergency, as well as identifies the requirement for contingency plans, which will be fully integrated with the environmental monitoring programme.

The chapter concludes that the AP1000 design facilitates the management of an incident or emergency by the provision of the MCR, technical support centre (TSC), RSR, and operational support centre (OSC).

28.7.3 Radioactive Waste Management

Chapter 26 provides evidence that Westinghouse has produced an integrated waste strategy to address the radioactive wastes and spent fuel produced by AP1000 plant, which is appropriate for the assessment of a generic design and contributes to the minimisation of radiation doses to the operators and public.

The design of the plant is such that the generation of radioactive wastes are minimised. Any wastes that are generated are contained, and cooled where necessary. As far as can be ascertained during the GDA process, all wastes generated during operation will be able to be packaged and disposed of offsite, with discharges that respect agreed annual limits.

28.7.4 Decommissioning

Chapter 27 identifies the principles that define the AP1000 plant decommissioning strategy.

The AP1000 plant has been designed so that it can be safely decommissioned, with steps being taken at the design stage to minimise the amount of waste generated during the process.

Assumptions have been made on the status of the plant at the end of operations based on the design and operational guidance set out in this document. A decommissioning plan, which meets UK regulatory requirements and international best practice, has been developed based on this strategy and assumptions regarding current available techniques. Dose management is assessed to be ALARP.

Waste volumes and activities have been minimised by design. It is recognised that a period of interim storage onsite may be required for some items before ultimate disposal is possible. The waste will be stored on-site in specifically designed facilities in a passively safe condition. The interim passively safe storage system will not compromise disposability.

28.7.5 Radiation Control Conclusions

Simplifications in the design mean that operator doses during normal operations and during fault conditions are significantly below regulatory and legal limits, and reduced to levels that are ALARP. Operator doses and routine releases to the environment from radioactive waste management onsite are minimised. Decommissioning activities are expected to produce less activated or contaminated material than for existing plants.

28.8 Summary

This PCSR demonstrates that the AP1000 design, construction, commissioning, operation, and ultimate decommissioning fully meet UK licensing requirements and fulfil the requirements of the SAPs (Reference 28.2). In particular, the PCSR demonstrates that normal operating limits are complied with, that risk and consequence targets are met, and that the risks arising from all modes of operation and all parts of the plant life cycle are ALARP.

The safety case presented in this PCSR that provides this demonstration is summarised by the five safety claims introduced in Chapter 2:

- Safety is managed throughout the plant life cycle.
- Safety is achieved through simple, passive design and defence in depth.
- Design and operation are tolerant to faults and risks are ALARP.
- Engineering solutions are fully substantiated.
- Radiological releases are minimised in normal and abnormal operating conditions.

The overall conclusions are that these claims are fully justified. In addition, it is concluded that:

- The use of passive systems and defence in depth makes the AP1000 plant extremely tolerant to faults as demonstrated by at-power internal events CDF of 1.7×10^{-7}/yr and an LRF of 1.7×10^{-8}/yr.

- For most fault conditions, the calculated doses and risks are significantly below the BSO of the relevant SAPs target. In the small number of cases where this is not so, the doses or risks are still significantly below the BSL.

- Risk reduction has been carried out systematically and comprehensively during every part of the design and safety assessment to the point that the risks from the AP1000 design and operation are ALARP.
