1 INTRODUCTION

This chapter describes the contents of the Pre-Construction Safety Report (PCSR) for the Westinghouse AP1000 nuclear power plant (NPP or AP1000), submitted through the Office for Nuclear Regulation (ONR) and the Environment Agency (EA) generic design assessment (GDA) process. It provides an introduction to the GDA process, a summary of the content of the PCSR, and a high-level overview of the AP1000 design approach including its innovative safety features and capabilities.

The PCSR demonstrates that the AP1000 design, construction, operation and ultimate decommissioning fully meet United Kingdom (UK) regulatory requirements and fulfil the requirements of the ONR safety assessment principles (SAPs) (Reference 1.1).

1.1 BACKGROUND

The UK nuclear regulators, the ONR (previously the Health and Safety Executive-Nuclear Directorate [HSE-ND]), and the EA, have jointly established the UK GDA process (Reference 1.4), described in Section 2.3, to assess the safety, security, and environmental implications of particular generic reactor designs before an application is made for the permission to build a new nuclear reactor at a specific site. The complete licensing process is two phases, namely Phase 1 (GDA) and Phase 2 (nuclear site licensing). The GDA provides a coordinated approach by the regulators for the pre-licensing/pre-authorisation phase. If positive, the outcome of the GDA process will be the publication of a Design Acceptance Confirmation (DAC) and an EA Statement of Design Acceptability (SoDA) for the generic design. It is envisaged that the DAC and SoDA will form the basis of any application to build the corresponding reactor on a specific site.

Westinghouse is a requesting party (RP) in the GDA process, as it seeks the DAC from the ONR and a SoDA from the EA for its AP1000 standard design. Since the start of Phase 1, Westinghouse has submitted a number of documents to the ONR/HSE-ND and EA as required under the GDA. In summary, the submission and outcome of the four steps in Phase 1 are as follows:

- Step 1 (Q1 to Q3, 2007) was the preparatory design assessment process during which there were discussions to establish a full understanding of the requirements and processes that would be applied. A number of documents including, but not limited to, UK Compliance Document for AP1000 Design (Reference 1.5), UK AP1000 Safety and Environment Report (Reference 1.6), and the UK AP1000 Probabilistic Risk Assessment (Reference 1.7) were submitted for assessment by the HSE-ND and the EA. Step 1 was completed in August 2007, and the HSE-ND acknowledged (Reference 1.8) that the submission met the required criteria and was eligible for GDA.

- Step 2 (Q3, 2007 to Q2, 2008) was a review of the fundamental acceptability of the proposed reactor design concept within the UK regulatory regime to identify any aspects that could prevent the proposed design from being licensed in the UK. The HSE-ND Step 2 report (Reference 1.9) issued in March 2008 concluded that the HSE-ND did not find "any safety or security shortfalls that are so serious as to rule out at this stage eventual construction of the AP1000 on licensed sites in the UK. As a result of our assessment, we see no reason why the AP1000 should not progress to GDA Step 3."

- Step 3 (Q2, 2008 to Q4, 2009) required the RP to provide a generic PCSR to the HSE-ND and an environment report to the EA detailing the safety and environment aspects of the proposed reactor design. The general intention was to move from the

fundamentals of the previous step to an analysis of the design, primarily by examination at the system level and by analysis of the RP's supporting arguments. Westinghouse submitted PCSR Rev. 1 (Reference 1.10) in August 2009 and, following comments from the HSE-ND, PCSR Rev. 2 (Reference 1.11) in December 2009. The Step 3 report (Reference 1.12) concluded that the HSE-ND believed "that the AP1000 could be suitable for construction on licensed sites in the UK" subject to resolution of a number of issues in Step 4. It was also concluded that the HSE-ND had "not identified any significant issues, or significant design or safety case changes that could impact on radioactive waste arisings or have a significant negative environmental impact." During Step 3, Westinghouse submitted a technical report to the Office for Civil Nuclear Security that described the security measures for the AP1000 design. The Step 3 security assessment report (Reference 1.13) concluded "No significant issues have been identified so far that would preclude this design from being adequately secured against malicious capabilities."

- Step 4 (Q1, 2010 to Q4, 2011) is an in-depth assessment by the ONR/HSE-ND and EA of the safety case and generic site envelope submitted. The general intention of this step is to move from the system-level assessment of Step 3 to a fully detailed examination of the evidence, on a sampling basis, given by the safety analyses. The aim of this step is to do the following:

  – Confirm that the higher-level claims, such as system functionality, are properly justified.

  – Complete a sufficiently detailed assessment to allow the ONR/HSE-ND and EA to come to a judgement whether or not a DAC and Statement of Design Acceptability can be issued.

  At the end of Step 4, GDA Issues were identified that require the RP to resolve before the issuance of a DAC and SoDA.

  In December 2011, the ONR issued an interim Design Acceptance Confirmation (iDAC) (Reference 1.18) and the EA issued an interim Statement of Design Acceptability (iSoDA) (Reference 1.19) to Westinghouse.

Within the joint regulatory GDA process described above, the EA's process is based on two steps, consisting of a preliminary and a detailed assessment of the design. This is followed by a public consultation, which reflects its normal policy. Any comments received during the public consultation will be considered by the EA as part of any site authorisation process; they will not be considered during the GDA process.

In order to meet these requirements, Westinghouse has submitted this PCSR and other supporting documents, as defined in the GDA Master Document Submission List. The previous revisions of the PCSR presented the safety claims, arguments, and evidence at a level appropriate to the step of the GDA process. This revision reflects the developments since the iDAC and incorporates changes to the safety case identified in the closure phase.

1.2 UK NUCLEAR REGULATORY REGIME

The UK nuclear regulatory regime is based on the Nuclear Installations Act 1965 (as amended). The sections of this act relating to licensing and inspection of nuclear installations are relevant statutory provisions of the Energy Act 2013.

The ONR and EA developed the GDA process in response to a request from the UK government following its 2006 Energy Review. The following principal organisations are involved in the regulation of civil NPPs in the UK:

- **Office for Nuclear Regulation** (ONR) – Responsible for the regulation of nuclear safety and security across the UK.

- **Environment Agency** (EA) – Responsible for the regulation of discharges and radioactive waste disposals from nuclear power stations and to ensure their impact on air, water, and land is acceptable and minimised.

The regulatory regime in the UK is different from many other countries in that it is not based on compliance with prescriptive regulations apart from statutory radiological worker and public dose limits for normal operation. The UK approach is based on goal setting, and the ONR has published SAPs (Reference 1.1) that it uses to assess nuclear safety cases. The safety case is required to show that the design, construction, and operation of the plant is safe, and that the risk to the public, workforce, and environment is as low as reasonably practicable (ALARP).

1.3 AP1000 PRE-CONSTRUCTION SAFETY REPORT

This PCSR is a lead document in the submission by Westinghouse for the GDA process. The development of the PCSR and the way it fits within the suite of safety documentation that forms the safety case developed throughout the AP1000 plant life is discussed in Chapter 2.

This revision of the PCSR is specific to the close-out of the GDA process. It supersedes the earlier versions (Refs. 1.10 and 1.11) produced for GDA Steps 2, 3, and 4.

This PCSR provides the overall safety case for the AP1000 design, construction, commissioning, operation, maintenance, and decommissioning. The complete safety submission is described in Chapter 2, and consists of this PCSR and a number of supporting documents. The linkage of the PCSR with key supporting documents, including the Safety and Environment Report (Reference 1.6), is presented in the Plant Life Cycle Safety Report (Reference 1.14).

This PCSR is presented in the following six volumes:

- Volume 1 – Executive Summary and Safety Case Management

- Volume 2 – Engineering Principles and Plant Overview

- Volume 3 – Faults and Accident Assessment

- Volume 4 – Engineering Substantiation

- Volume 5 – Radiation Protection, Emergency, Accident, and Waste Management

- Volume 6 – Conclusions

Acronyms used within the chapters are defined at the start of each chapter and consolidated for the whole of the PCSR in Appendix 1A.

1.3.1 Volume 1, Executive Summary and Safety Case Management

Chapter 1, Introduction – Describes the contents of the PCSR submitted under Phase 1, Step 4 of the GDA process. It also provides a high-level overview of the AP1000 design approach together with an introduction to its innovative safety features and capabilities.

Chapter 2, Safety Case – Presents the structure, content and overall logic of the safety case. The safety case itself is developed in the subsequent chapters.

Chapter 3, Management of Safety – Deals with the management of safety and quality relating to this safety case and how it provides key inputs into the site-specific safety cases required for construction, commissioning, operation, maintenance and ultimate decommissioning and how the safety case will be developed throughout the plant life.

Chapter 4, Generic Site Characteristics – Describes the UK generic site assumed in the assessment.

1.3.2 Volume 2, Engineering Principles and Plant Overview

Chapter 5, Engineering Principles – Describes the engineering principles applied within the PCSR and the approach to the classification of Safety Systems and equipment qualification and reliability.

Chapter 6, Plant Description and Operation – Presents a comprehensive, detailed description of the AP1000 plant including the primary and auxiliary systems, the passive safety systems and the civil structures.

Chapter 7, Life Cycle Engineering and Safety – Describes the approach to engineering and safety during the complete lifecycle of the reactor from design control, construction, commissioning and operation through to decommissioning. The requirements for examination, maintenance, inspection and testing and taking due cognisance of ageing and degradation are also presented.

1.3.3 Volume 3, Faults and Accident Assessment

Chapter 8, Fault and Accident Analysis – Presents the methodology for fault and consequence assessment, identification of the design basis faults and development of the fault schedule. A composite fault list that covers the full set of initiating faults addressed throughout the safety justification is provided in Appendix 8A.

Chapter 9, Internally Initiated Faults – Describes the internally initiated faults that could lead to core damage or could lead to a release of nuclear material.

Chapter 10, Reactor Faults Probabilistic Safety Assessment and Severe Accident Analysis – Presents a summary of the Probabilistic Safety Assessment (PSA) for the AP1000 design, its links to design basis accident (DBA) fault sequence groups and the approach to risk reduction and the ALARP principle.

Chapter 11, Internal Hazards – Presents the internal hazards identified for the AP1000 design including but not limited to fire, flood, explosions and missiles, dropped loads and release of toxic material. The safety case for each hazard is provided.

Chapter 12, External Hazards – Presents the identified external hazards including, but not limited to, earthquake, extreme wind and rainfall. The safety case for each hazard is provided.

Chapter 13, Human Factors – Provides a summary of the human factors input to the design and safety process including error identification methodology and classification, the screening of errors and the ALARP arguments.

Chapter 14, Results and Conclusions – Fault Analysis – Presents the results and conclusions of the analyses presented in Chapters 8 to 13 with an overall ALARP assessment demonstrating that the plant is safe to operate.

1.3.4 Volume 4, Engineering Substantiation

Chapter 15, Engineering Substantiation – Describes the approach to engineering substantiation and a summary of the Engineering Schedule.

Chapters 16, Civil Engineering – Describes the civil engineering aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 17, Mechanical Engineering – Describes the mechanical engineering aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 18, Essential Electrical Systems – Describes the essential electrical systems of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 19, Control and Instrumentation – Describes the control and instrumentation (C&I) engineering aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 20, Structural Integrity – Describes the structural integrity aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 21, Reactor Chemistry – Describes the reactor chemistry aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 22, Fuel System, Nuclear and Thermal Hydraulic Design – Describes the fuel design and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

Chapter 23, Containment and Nuclear Ventilation Systems – Describes the containment and ventilation aspects of the plant and presents evidence that the engineering provision meets the safety requirements of normal operation, fault and hazard conditions and ageing.

1.3.5 Volume 5, Radiation Protection, Emergency, Accident, and Waste Management

Chapter 24, Radiation Protection – Summarises the radiological hazards under normal and accident conditions and the protection measures to mitigate consequences of the identified hazards.

Chapter 25, Accident Management – Describes general arrangements, facilities and equipment to assist the management of emergencies currently included in the AP1000 design basis.

Chapter 26, Radioactive Waste Management – Summarises the arrangements for handling wastes arising from normal operations, the approach to waste minimisation and the approach to the segregation of wastes. The chapter draws on information provided, in particular in the Environment Report and the Integrated Waste Strategy, for the management and details of all radioactive waste and non-radioactive waste arising during operations and decommissioning.

Chapter 27, Decommissioning and End-of-Life Aspects – Presents the decommissioning strategy that demonstrates that the generic AP1000 design can be safely decommissioned at the end of its operational life. Demonstration that dose management through decommissioning will result in doses that are ALARP, and that waste volumes and activities have been minimised by design, are also presented.

1.3.6 Volume 6, Conclusions

Chapter 28, Conclusions – Draws together the overall conclusions from the previous chapters.

1.4 THE AP1000 DESIGN

1.4.1 AP1000 Design Philosophy

The Westinghouse AP1000 design is an advanced and passively safe pressurised water reactor (PWR) with an output capacity of approximately 1100 MWe (actual power output depends on site-specific conditions) and a design service life of 60 years.

The most significant aspect of the AP1000 design philosophy, and the one that sets the design apart from existing PWRs, is the use of passive means of protecting against faults. These passive safety features rely solely on natural mechanisms such as natural convection and driving forces derived from stored energy (gravity, batteries, and compressed gases) rather than active pumped systems; therefore, safety is substantially enhanced.

In comparison with PWR plants in operation today, the AP1000 design represents considerable simplifications that enhance nuclear safety and facilitate construction, operation, maintenance, and decommissioning. A general arrangement is presented in Figure 1-1.

The AP1000 design is the combination of proven design concepts and is the result of operational experience from existing PWR plants applied to a defined set of functional requirements in the most simple, effective way practicable.

The design is founded on adherence to the following inviolate principles:

- The systems providing the principal means of delivering the following safety functions will not require alternating current (ac) power:
  - Shutting down the nuclear reaction
  - Removing decay heat, which uses only natural mechanisms such as natural circulation, conduction, convection, evaporation, and condensation
  - Maintaining the reactor coolant water inventory
  - Containment isolation

  - Maintaining other safety functions such as spent fuel pool cooling, main control room (MCR) habitability, and severe accident mitigation features

- Active Class 2 systems minimise demand on passive systems and provide defence in depth.

- Multiple barriers exist to prevent release of fission products. The function of containment of radioactive materials is provided by a hierarchy of barriers, one within another. The initial barrier is the cladding of the fuel; each fuel element is clad in a tube made from a zirconium alloy. The integrity of this cladding is ensured by adequate transfer of heat to the coolant. The reactor core is contained in a high-integrity steel pressure vessel (the reactor vessel) that, together with the primary circuit, provides the next barrier. The containment building provides a final barrier and retains radioactive material in the event that the primary circuit is breached; for example, in a loss-of-coolant accident (LOCA).

- Calculated core damage frequency (CDF) and large release frequency (LRF) are minimised by eliminating failure modes by design rather than providing mitigation features. This approach ultimately results in a plant design that is safe because it has the design objective that the risk to the operators and the public is ALARP.

- Simplification of the plant with respect to design, licensing, construction, operation, inspection, and maintenance.

- Tolerance to faults by means of reducing possible faults by design and by the provision of reliable, passive, automatic mitigating systems.

1.4.2 Evolution of the AP1000 Design

1.4.2.1 Design Evolution

Westinghouse has been involved with PWRs since the early days of commercial nuclear power in the 1950s. Westinghouse has designed and delivered more than 100 commercial NPPs and nearly 50 percent of the world's 440 nuclear plants are based on Westinghouse technology. The AP1000 design is the culmination of this design, build, and operating experience. Eight AP1000 plants are currently under construction in the United States (US) and China, with dozens more planned around the world.

The AP1000 design is an evolution of the AP600 design originally developed by Westinghouse during the 1980s and early 1990s as part of the cooperative US Department of Energy (DOE) and Electric Power Research Institute (EPRI) advanced light water reactor (ALWR) programme. The purpose of the programme was to design a new plant with levels of safety that were significantly improved over existing plants by using the lessons learned from the operating experience gained over the previous three decades.

Designed to satisfy the standards defined in the ALWR Utility Requirements Document (URD) (Reference 1.15), the Westinghouse AP600 design is a combination of innovative passive safety systems that rely on dependable natural forces and proven conventional technology. The ALWR URD contains a large number of design improvements for safety and reliability, many of which were implemented or improved upon in the AP600 design. The implementation of some features exceeded the URD requirements; for example, post-accident reliance on ac power is eliminated rather than just reduced. Following a DBA, the passive safety systems and equipment are sufficient to automatically establish and maintain core cooling and containment integrity indefinitely, by reliance exclusively on natural forces and stored energy (see Section 1.4.2.3).

When the AP600 design received US Design Certification, it was the safest, simplest, and lowest-cost nuclear reactor on the market. However, this also coincided with a period of relatively low oil and gas prices that made the AP600 design uneconomic in comparison with a fossil fuel plant.

Making a significant reduction in the cost of the AP600 design was not possible by making small system and component improvements. The solution was to increase the power output of the plant which would reduce the cost per megawatt below that of a natural gas plant; this would require some components to increase in size/capacity however the cost increase was much less than power increase. The power increase was achieved by increasing the height of the reactor vessel and the containment structure such that the general arrangement of the plant did not have to change. Other changes included a larger turbine and other plant equipment as appropriate to provide the larger power output and to maintain safety margins. This new design, capable of generating over 1000 MWe, is the AP1000 design. The AP1000 design primary circuit components are shown in Figure 1-2.

The AP1000 design maintains the large safety margins of the AP600 design. No new concepts or changes to fundamental principles were introduced to the proven components chosen for the AP600 design. The test data obtained for the AP600 design were shown to be applicable to the AP1000 design. The changes to the AP600 Design Control Document (DCD) were minimised and the AP1000 design retains compliance with the US utilities' requirements as expressed in the ALWR URD (Reference 1.15). The AP1000 design safety analysis is documented Chapter 9 and the risk to the public is documented in the probabilistic safety assessment (PSA) (Chapter 10), which together demonstrates that large safety margins are maintained for the AP1000 design. It also shows that the AP1000 design improves on the probability of large release goals for advanced reactor designs in the event of a severe accident scenario retaining the molten core within the reactor vessel.

1.4.2.2 Use of Proven Components and Technology in the AP1000 Design

The use of proven components and technology greatly facilitates the construction, operation, and maintenance of the AP1000 design. The AP1000 core and major reactor internal components are designs proven by their use in currently operating PWRs supplied by Westinghouse:

- The AP1000 core uses a design for the fuel used in current Westinghouse reactors.
- The control rod drive mechanisms are the same as in existing Westinghouse reactors.
- The AP1000 steam generator design is based on 30 years of operating experience, including design features incorporated in the latest Westinghouse replacement steam generator designs.
- Construction materials for components in the AP1000 design have been selected based on lessons learned from operating experience in existing plants.
- The development of digital C&I systems for back-fitting to currently operating plants has allowed such systems to be incorporated into the AP1000 design with a level of safety proven by practical experience and extensive computer software verification and validation.

Furthermore, several important enhancements, all based on existing technology, improve the safety performance characteristics of the design relative to currently operating PWRs:

- The AP1000 reactor coolant pumps do not have seals. Their design is based on proven seal-less motor pump technology that has been used in naval PWRs and various non-nuclear commercial applications. This eliminates the potential for LOCAs due to seal failure, enhancing safety by removing the major contributor to small LOCAs.

- The AP1000 design reactor coolant system (RCS) piping with an outside diameter of 10 cm or more has been designed to reduce the probability of their gross failure. Evaluations have concluded that elimination many of the pipe whip restraints is ALARP considering improvements in the ability to perform in-service inspection and also reduces operators' radiation exposures associated with such inspections. The number of welds in the primary circuit has been reduced in comparison with earlier designs.

- The number of containment penetrations has been reduced by half and the containment isolation valves have been replaced by types that are less likely to leak than those used on previous PWRs.

- The AP1000 design features an advanced MCR, as required by the ALWR URD (Reference 1.15). Incorporating human factors assessment in the design and testing of the MCR reduces the likelihood of the operators either inadvertently causing initiation of a fault sequence or performing the wrong actions during a fault sequence.

1.4.2.3 Use of Innovative Safety Features and Capabilities in the AP1000 Design

The distinguishing safety enhancement of the AP1000 design over existing PWR technology is the adoption of passive protective safety measures, which operate during fault sequences in the event that normal duty systems have failed. These systems are regarded as passive because they rely on natural physical processes for their operation with no reliance on active components such as pumps, fans, or diesel generators; and they are designed to function without Class 1 support systems such as ac power and component cooling water. The only requirement for initiating these passive systems is the one-time realignment of valves which can be achieved with high reliability.

These passive systems provide a means of controlling reactivity and removing decay heat for the first 72 hours in design basis accident scenarios.

- The core makeup tanks (CMTs) provide borated water by gravity feed to provide additional coolant and to control reactivity.

- The automatic depressurisation system (ADS) depressurises the primary circuit to allow for safety injection. The accumulators are connected to the primary circuit with non-return valves and contain water under pressure from compressed gas. They provide additional coolant automatically once the primary pressure drops below the gas pressure that forces the borated water through the non-return valves.

- The passive residual heat removal (PRHR) system uses a heat exchanger in the in-containment refuelling water storage tank (IRWST) to remove heat from the primary circuit by natural circulation.

- The passive containment cooling system (PCS) uses water flowing under gravity and natural circulation of air to cool the outside of the containment vessel (CV). Heat is transferred to the CV from the reactor by evaporation of water that condenses on the inside of the CV and then runs back to the IRWST.

- The PCS and passive core cooling system (PXS) provide means for long-term core cooling and containment heat removal.

The operation of these passive systems has been verified using highly developed thermal-hydraulic computer codes, which in turn are verified against real systems tests and extensive rig testing. Computer simulations using these codes have enabled the AP1000 design to demonstrate that these innovative passive features substantially enhance its nuclear safety capability. A summary of the technical support documents that support the AP1000 design are presented in Chapter 2.

The PXS shown in Figure 1-3 comprises the CMTs, ADS, accumulators, IRWST, and PRHR system. The PCS is shown in Figure 1-4.

The primary means of satisfying Category A safety functions is using passive Class 1 systems, structures, or components (SSCs). In addition to the passive systems outlined above, a number of Class 1 and Class 2, SSC's support the passive components and provide defence in depth by adding additional redundancy and diversity to the AP1000 design.

For C&I systems:

- The protection and safety monitoring system (PMS) provides detection of abnormal conditions and actuation of the appropriate Class 1 systems necessary to achieve and maintain the plant in a safe shutdown condition.

- The diverse actuation system (DAS) is a Class 2 system that provides diverse backup actuation of the Class 1 passive features. The DAS also provides manual actuation capability for a number of systems.

- The plant control system (PLS) provides Class 2 actuation of the active defence-in-depth (DiD) systems.

- The essential electrical supply system (IDS), referred to as the essential power supply in this PCSR, consists of four static battery-backed divisions. The IDS provides reliable power for the Class 1 equipment required for the plant instrumentation, control, monitoring, and other vital functions needed for shutdown of the plant. In addition, the IDS provides power to the normal and emergency lighting in the MCR and the remote shutdown workstation.

For mechanical systems:

- The plant Class 1 passive features such as the PRHR HX, CMTs and PCS.

- For more frequent events, other Class 1 passive features provide backup to these passive features such as passive feed and bleed (ADS, Accumulators, IRWST injection and containment recirculation)

- A number of active Class 2 systems provide additional backup for frequent events.

    - The startup feedwater system (SFW) supplies feedwater to the steam generators during plant startup, hot standby, and shutdown conditions.

    - The chemical and volume control system (CVS) consists of two centrifugal makeup pumps providing makeup flow to the reactor primary circuit.

- The normal residual heat removal system (RNS) removes heat from the core and RCS and provides RCS low-temperature overpressure protection (LTOP) at reduced RCS pressure and temperature conditions after shutdown.

- The component cooling water system (CCS) is a closed-loop cooling system that supports the RNS during fault conditions.

- The service water system (SWS) supplies cooling water to remove heat from the CCS heat exchangers in the turbine building.

- The Class 2 dc and Uninterruptible Power Supply System (EDS) provides dc and uninterruptible ac electrical power to the Class 2 components above.

- The main ac power system (ECS) provides electrical ac power to the Class 2 components above.

- The onsite standby power system (ZOS) consists of two onsite Class 2 standby diesel generator units and support systems that support EDS functions.

The quality assurance requirements associated with the Class 1 and Class 2 SSCs outlined above are presented in Chapter 5.

1.4.3 Standardisation of the AP1000 Design

The evolution of the AP1000 design has been built on the design philosophy which emphasised safety and simplicity. Another important aspect of the AP1000 plant design approach is standardisation across multiple sites around the world. This approach of using a standard design has been welcomed in the U.S. and around the world in applications to other regulatory authorities. Standardisation brings large benefits in the minimization of the chance of design, analysis, licensing, construction, and operation errors by advoiding repetition of design activities and sharing operational experience amongst licensing agencies and operating utilities in the future.

The Design Reference Point document (Reference 1.17) defines the UK design reference point for the AP1000 design that is relevant to the GDA application. Further discussion on the AP1000 design reference point is presented in Chapter 6 together with a detailed description of the plant and operation.

Following initial approval, design documentation is placed under configuration control. Once under configuration control, changes to the design documentation can only be made through the design change proposal process (Reference 1.17). Design change control is discussed further in Chapter 7.

1.5 KEY SAFETY ATTRIBUTES

In many respects, the AP1000 design is a conventional PWR. However, the implementation of passive safety features and the simplification of the design significantly contribute to the improved safety and reliability of the plant. A summary of the key safety attributes is presented here, with the full detail covered in the remainder of the PCSR:

- The use of proven technology and evolutionary design means plant operation is highly reliable in all plant operating modes (startup, power operation, standby, and refuelling) and throughout plant life (construction, commissioning, operation, maintenance, and

decommissioning) with the fault rates for many types of common or anticipated faults being significantly lower than for existing plants.

- Passive systems are available to supply all essential safety functions following a fault, with more conventional systems providing defence in depth. This makes the AP1000 design and operation extremely tolerant to faults with risk to the public, workers, and environment being significantly reduced over existing plants and being reduced to levels that are ALARP; for example, CDF and LRF are several orders of magnitude lower than existing plants.

- The use of modular construction techniques means that the construction process is safer, simpler, and more predictable, leading to higher quality construction. This form of construction also aids decommissioning.

- All design basis and probabilistic targets are met using passive Class 1 safety systems backed up by other Class 1 systems and also by active Class 2 systems providing defence in depth.

- Separation, segregation, redundancy, and diversity provided by the design minimise the effects of internal and external hazards and human errors.

- Simplifications in the design mean that operator doses are significantly reduced during operation, maintenance, and inspection activities. Operational release of activity is well within the authorised limits, and doses will be kept below the basic safety level (BSL), the legal limit, and, where practicable, the basic safety objective (BSO), and ALARP; e.g., targets 1, 2, and 3 of the ONR SAPs (Reference 1.1). Best practicable means (BPM) are used to minimise discharges to the environment and to minimise radioactive wastes arisings, including those from operations, maintenance, decommissioning, and site restoration.

- Simplification of the design will have a major impact on decommissioning. Compared with similarly sized NPPs, the AP1000 design has roughly 50 percent fewer valves; 35 percent fewer pumps; 80 percent less piping; and 80 percent fewer heating, ventilation, and air conditioning (HVAC) systems. Therefore, the decommissioning phase of the AP1000 design is expected to be shorter, and decommissioning activities are expected to produce less activated or contaminated material, resulting in simpler strategies and lower funding requirements.

1.6 SUMMARY

This PCSR is one of the lead documents in the safety submission for the AP1000 design, construction, operation, and maintenance. Subject to obtaining a successful DAC, and a SoDA from the EA, the PCSR will be updated with site-specific licensing requirements for Nuclear Site Licensing. The complete safety submission is described in Chapter 2, and consists of this PCSR and a number of supporting documents.

The safety case detailed in subsequent chapters demonstrates that the AP1000 design, construction, and operation meet UK licensing requirements and safety principles; have safety levels in excess of nuclear plants currently in operation; and have levels of public, worker, and environmental risk that are ALARP.

2 SAFETY CASE

2.1 INTRODUCTION

This chapter gives an overview of the safety case presented in this Pre-Construction Safety Report (PCSR) for the AP1000 design within the context of the United Kingdom (UK) regulatory regime in general and the generic design assessment (GDA) process in particular.

2.2 UNITED KINGDOM REGULATORY REGIME

The UK nuclear regulatory regime is described in Chapter 1 whereby the onus is on the licensee to demonstrate that the design, construction, commissioning and operation of the plant is safe and that the risk to the public, workforce and the environment is as low as reasonably practicable (ALARP). The Office for Nuclear Regulation (ONR) safety assessment principles (SAPs) (Reference 2.1) are used to assess applications from licensees.

2.3 GENERIC DESIGN ASSESSMENT PROCESS

The GDA provides a coordinated approach by the safety, security, and environmental regulators for the pre-licensing/preauthorisation phase. The complete licensing process has been split into the following two phases:

- **Phase 1: GDA** – The assessment of the safety case for a generic design, leading to the issue of a Design Acceptance Confirmation (DAC) and an Environment Agency (EA) Statement of Design Acceptability (SoDA) if the outcome is positive. Phase 1 has four steps, which are explained in detail in Section 1.1.

- **Phase 2: Nuclear site licensing** – The assessment of the application for a nuclear site licence, which is site, reactor design, and operator specific.

This PCSR and its supporting documentation constitute Westinghouse's submission under GDA Closeout and the basis for the development of the site-specific safety cases that will be presented in Phase 2 of the licensing process. The safety case is currently owned by Westinghouse, the requesting party for GDA. A key feature is that once the DAC and the SoDA are received, the operating organisations that become the licensees will own the safety case and will be responsible for any changes and future reviews of that design, and Westinghouse will transition to the role of responsible designer and continue to support the licensee.

The safety case presented in this PCSR for submission under GDA Closeout is for a generic site which is described in Chapter 4. It is based on the design reference point (DRP) (Reference 2.4), which is described in Chapter 6. The DRP lists the design documentation that specifies the AP1000 plant's detailed design that forms the basis of this PCSR.

2.4 AP1000 DESIGN SAFETY CASE OVERVIEW

2.4.1 AP1000 Design Safety Case

This section provides an overview of the scope and purpose of the safety case and how the safety case is developed throughout the life of the AP1000 plant. Throughout the various phases of the AP1000 project, the safety case will be reviewed and revised and will consider at each stage the relevant safety, engineering, and management information. It is understood that the regulatory bodies, the ONR or the EA, may specify regulatory "hold points" beyond

which the licensee may not proceed without regulatory agreement or consent. Westinghouse would expect that the safety case at each stage will demonstrate the safety of the design prior to the conclusion of the phase. The expected phases of the AP1000 project and the purpose of the associated safety reports are provided below, starting with this PCSR.

2.4.1.1 Pre-Construction Safety Report

According to the Plant Life Cycle Safety Report (Reference 2.5), the purpose of this PCSR is to do the following:

- Demonstrate prior to non-active construction that the detailed design proposal will meet regulatory dose-frequency targets and that risks are as low as reasonably practicable.
- Specify generic safety functions and design requirements for all structures, systems and components important for safety and provide evidence to substantiate the design.
- Demonstrate that the plant can be built to an appropriate quality and that it can be operated safely and within safe operating limits throughout life, including decommissioning.

2.4.1.2 Site-Specific Pre-Construction Safety Report

The main purpose of the site-specific PCSR is similar to that of this PCSR, but it is also to address any site-specific issues that were not specifically covered by this PCSR. The site-specific PCSR will be required by the potential licensee as part of the licensing phase of the project.

2.4.1.3 Pre-Commissioning Safety Report

This may be split into two separate phases of inactive and active commissioning. The purpose of the pre-inactive commissioning phase is to do the following:

- Demonstrate that the plant as built will meet the safety criteria and standards set in the PCSR and show that it can be operated safely.
- Define the extent of the inactive commissioning and that it will demonstrate the proper functioning of safety systems, procedures, and equipment via safety commissioning schedules.
- Justify the safety of nonactive commissioning operations.

The pre-active commissioning phase will do the following:

- Sentence any shortfalls revealed during inactive commissioning.
- Demonstrate that the inactive commissioned plant continues to meet relevant safety criteria and is capable of safe operation.
- Demonstrate that the active commissioning activities can and will be carried out safely and that the operating procedures for commissioning are supported by the safety case.
- Enable the production of a programme of safety commissioning activities that will demonstrate the proper functioning of systems, procedures, and equipment.
- Demonstrate that all identified aspects of safety have been demonstrated prior to active commissioning.
- Identify limits and conditions necessary in the interest of safety.
- Demonstrate compliance with the legal duty to reduce risks to workers and the public (so far as is reasonably practicable (SFAIRP).

2.4.1.4 Pre-Operational Safety Report

The main purpose of the pre-operational safety report is to do the following:

- Demonstrate that the plant (as built and commissioned) meets the safety standards and criteria set down in the PCSR.
- Demonstrate that detailed analysis has been undertaken to provide support of the safety case.
- Demonstrate that all necessary pre-operational actions have been completed, validated, and implemented.
- Identify limits and conditions necessary in the interest of safety.
- Demonstrate compliance with the legal duty to reduce risks to workers and the public SFAIRP.

2.4.1.5 Plant Operational Safety Report

The main purpose of the plant operational safety report is to do the following:

- Demonstrate operation of the plant meets the safety standards and criteria set down in the PCSR.
- Demonstrate compliance with the legal duty to reduce risks to workers and the public SFAIRP.
- Take account of experience to review and changes that have been necessary, and that the safety case is still valid.

- Review the safety adequacy of the plant in light of its current and projected conditions and against modern safety standards and expectations.

- Take a strategic look forward to consider facility lifetime and contingency requirements.

As part of the transfer of information from Westinghouse to the licensees, any assumptions made in the safety case documentation will be highlighted. These aspects will form part of the training of licensee personnel. The aim of the knowledge transfer process is to ensure that potential licensees have the capability to secure and maintain safety of the facility and that, where necessary, the licensee has the means to perform as an intelligent customer (IC). The knowledge transfer process is described in detail in Chapter 7 of this PCSR.

Arrangements for future safety case production, approval, independent nuclear safety assessment, and periodic review will be part of the licensee's own arrangements.

2.4.2 Development of the AP1000 Design Pre-Construction Safety Report

This PCSR is one of the lead documents in the submission to the ONR and the EA for DAC. It provides the overall safety case for AP1000 design, construction, and operation.

For the AP1000 design, the intent is that its lifetime should consist of design, construction, commissioning, and 60 years of operations followed by decommissioning and long-term storage of spent fuel. Ageing considerations are presented in Chapter 7.

The safety case developed in this PCSR has a number of elements to demonstrate that the AP1000 design as constructed and operated meets statutory dose limits in normal operation, that it meets specified dose targets in design basis fault conditions, and that the risks to workers, the public, and the environment are ALARP in all normal operational and fault conditions and throughout plant life.

Volume 1: Safety is managed throughout the plant life cycle.

Chapter 1 is the overall introduction to the PCSR, and Chapter 2 (this chapter) gives an overview of the safety case. Chapter 3 lays out the principles and processes underlying the management of safety. These principles and processes ensure that safety important information is passed on from the design stage, through construction and commissioning to power operation and ultimately to decommissioning. The principles and processes also describe Westinghouse's expectations of the licensees' systems that will be in place during operation to ensure continuity from the design process throughout the life cycle of the plant.

The safety management process described ensures that design, construction, commissioning, operation, and decommissioning fully meet UK licensing standards and best practices, specifically that the levels of safety exceed those of most currently operating nuclear plants, and that the public, worker and environmental risks associated with all phases of the plant's life cycle are ALARP.

The safety case described in this PCSR is based on a generic site, which is described in Chapter 4. The information presented there will form the starting point for the development of site-specific PCSRs required for site licensing in the future.

Volume 2: Safety is achieved through simple, passive design and defence in depth.

The basic engineering principles that underlie the design process are described in Chapter 5 with the major systems, structures, and components (SSCs) that make up the AP1000 design described in Chapter 6. The significant difference between the AP1000 design and other existing pressurised water reactors (PWRs) is in the use of Class 1 passive safety systems; that is, safety systems that rely solely on natural phenomena such as gravity, natural convection cooling, or the energy stored in pressurised gases. The AP1000 design passive systems are also significantly simpler than the active protection systems in conventional PWRs.

The implementation of passive safety features and simplification of the design significantly contribute to the improved safety and reliability compared with existing plants.

Design simplification also contributes to the reliability, extended design life of the plant, and reduced decommissioning efforts. Chapter 7 describes the engineering processes that are in place to maintain high levels of reliability throughout the plant's life and to protect against the effects of ageing.

Volume 3: Design and operation are tolerant to faults and risks are ALARP.

During the development of the AP1000 design, design choices have been made that reduce fault frequencies, thereby removing some faults common to existing plants altogether. The fault analysis presented in this volume shows that the passive design of the protection systems significantly improves the response of the plant to faults with the risks to the public, workforce and environment being considerably reduced over those associated with existing plants.

Chapter 8 describes the methodology used in the identification and assessment of faults, as well as provides a list of all the faults identified and the grouping used to analyse them. Chapter 9 provides the design basis assessment, and Chapter 10 provides the probabilistic assessment that allows the design to be compared with UK dose and risk targets. Chapters 11 and 12, respectively, provide the corresponding analysis of internal and external hazards. Human factors and the tolerance of the plant to human errors are presented in Chapter 13.

The analysis presented in Volume 3 leads to the identification of safety functions that are required to maintain safety in all of the identified life cycle phases and operating conditions, and the SSCs of the design that provide them.

Chapter 14 consolidates the results of the previous chapters to demonstrate that design targets are met with considerable margin. Chapter 14 also demonstrates that, throughout the development of the AP1000 design, the designers have systematically sought means of further reducing risk. The designers have also used available tools such as the probabilistic safety assessment (PSA) and severe accident assessment to identify risk-reduction measures. Many design decisions and design changes have been implemented as a result, which contribute to the overall risk being ALARP.

Volume 4: Engineering solutions are fully substantiated. The SSCs of the design are fully able to satisfy the claims made on them and are able to provide the safety functions identified in the fault analysis.

Chapter 15 lists the sources of claims on SSCs in the safety case and the requirements on SSC performance that are implied by them. The evidence that the SSCs fulfil these requirements is presented in Chapters 16 to 23 of this PCSR.

Volume 5: Radiological releases are minimised in normal and abnormal operating conditions.

Chapter 24 demonstrates that simplifications in the design mean that operator doses during normal operations and during fault conditions are significantly reduced over those from existing PWRs. Chapter 25 Describes general arrangements, facilities and equipment to assist the management of emergencies currently included in the design basis for the AP1000. Chapter 26 demonstrates that operator doses and routine releases to the environment from radioactive waste management on the site are minimised, and Chapter 27 shows that decommissioning activities are expected to produce less activated or contaminated material than for existing plants.

Volume 6: Conclusions.

Chapter 28 is the only chapter in this volume. It draws together the overall conclusions from the previous chapters and makes general conclusions relating to regulatory targets and risk that is ALARP.

2.4.3 Compliance with Dose and Frequency Targets

The ONR SAPs have a number of dose and frequency targets for normal operation, including legal limits, and for accident conditions. The targets are addressed in this PCSR as follows:

Target 1	Doses and legal limits for normal operation – any person on the site	Chapter 24
Target 2	Doses for normal operation – any group on the site	Chapter 24
Target 3	Doses and legal limits for normal operation – any person off the site	Chapter 24
Target 4	Frequency dose targets for design basis sequences – any person	Chapters 9 and 14
Target 5	Individual risk of death – any person on the site	Chapters 10 and 14
Target 6	Frequency dose targets for any single accident – any person on the site	Chapter 14
Target 7	Individual risk of death – any person off the site	Chapters 10 and 14
Target 8	Frequency dose targets for any single accident – any person off the site	Chapters 10 and 14
Target 9	Total risk of 100 or more fatalities	Chapters 10 and 14

2.5 AP1000 DESIGN GENERIC DESIGN ASSESSMENT DOCUMENTATION

The safety submission provided for the GDA process consists of this PCSR and a number of supporting documents. Supporting documents are included in the reference section for each PCSR Chapter. The principal supporting documents are summarised in this section.

2.5.1 Topic Reports

- Internal Hazards

  The following Internal Hazards Topic Reports support Chapter 11:

  - Flooding Topic Report, UKP-GW-GLR-107 (Reference 2.21), presents the safety case in determining the effects to SSCs resulting from a flood within the AP1000 plant.
  - Dropped Loads Topic Report, UKP-GW-GLR-110 (Reference 2.22), presents the safety case in determing the effects to SSCs resulting from a dropped load.
  - Fire Protection Topic Report, UKP-GW-GLR-111 (Reference 2.23), presents the safety case in determining the effects to SSCs resulting from a fire within the AP1000 plant.
  - Internal Missiles Topic Report, UKP-GW-GLR-108 (Reference 2.24), presents the safety case in determining the effects to SSCs resulting from an internally generated missile within the AP1000 plant.
  - Pressure Part Failure Topic Report, UKP-GW-GLR-114 (Reference 2.25), presents the safety case in determining the effects to SSCs resulting from the failure of pressure-retaining fluid systems within the AP1000 plant.
  - Explosions Topic Report, UKP-GW-GLR-109 (Reference 2.26), presents the safety case in determining the effects to SSCs resulting from an explosion within the AP1000 plant.
  - Combined Hazards Topic Report, UKP-GW-GLR-036 (Reference 2.27), presents the safety case in determining the effects to SSCs resulting from combined hazards.

2.5.2 Basis of Safety Case Documents

- Control and Instrumentation

The following Basis of Safety Case (BSC) documents support Chapter 19:

- Plant Control System (PLS) BSC, UKP-PLS-GLR-001 (Reference 2.28)
- Data Display and Processing System (DDS) BSC, UKP-DDS-GLR-001 (Reference 2.29)
- Diverse Actuation System (DAS) BSC, UKP-DAS-GLR-001 (Reference 2.30)
- Protection and Safety Monitoring System (PMS) BSC, UKP-PMS-GLR-001 (Reference 2.31)

- BEACON Core Monitoring System BSC, UKP-GW-GL-162 (Reference 2.32)

- Electrical

  - Electrical BSC, UKP-GW-GL-163 (Reference 2.33), supports Chapter 18.

2.5.3 Other Supporting Documents for United Kingdom Safety Case

- AP1000 Design Reference Point for UK GDA

  UKP-GW-GL-060 (Reference 2.4) specifies the documents that define the DRP to which this safety case applies. The DRP is dated 31st March 2016, and any design changes subsequent to that date are subject to design change control with respect to this safety case (Section 6.1.1).

- Categorisation and Classification Methodology

  UKP-GW-GL-044 (Reference 2.9) describes the scheme adopted for the AP1000 design in the UK for the categorisation of safety functions and the classification of SSCs. This is summarised in Chapter 5.

- Classification of SSCs

  Appendix 15A lists the safety classification for each SSC claimed in the safety case, together with an outline of its functional and reliability requirements and applicable design codes and standards.

- Equivalence/Maturity Study of US Codes and Standards

  UKP-GW-GL-045 (Reference 2.11) provides evidence for the suitability of the codes and standards used in the AP1000 design as compared to current European codes and standards.

- Human Factors

  The Human Factors Qualitative Error Analysis Report (Reference 2.7) provides evidence for the substantiation of the AP1000 plant human factors safety case and demonstrates an appropriate human error analysis process.

- Limits and Conditions

  The Limits and Condition Process Description (Reference 2.35) describes the operating rules, the methodology for development, and the process for transition into the operating phase.

  The Generic Technical Specifications (Reference 2.36) are a dynamic set of plant parameters, associated limits and conditions for plant operation, and associated SSCs, including high integrity items, that provide the delivery of important safety functions for the AP1000 plant.

- Plant Life Cycle Safety Report

The Plant Life Cycle Safety Report (Reference 2.5) describes the safety programmes to support plant owners throughout the design, construction, and operation of the AP1000 reactor. Chapter 7 discusses the plant life cycle.

- Environment Report

  The Environment Report (Reference 2.13) consolidates and summarises the environmental information to demonstrate that the AP1000 design meets the environmental requirements of the GDA process. Chapter 4 discusses the environmental aspects of the safety case.

- Structural Integrity Classification

  The Structural Integrity Classification Report (Reference 2.20) describes the process used to determine the structural integrity classification of the AP1000 plants components which was used in the development of the safety case presented in Chapter 20.

- ALARP

  APP-GW-GER-005 (Reference 2.17) is the main supporting document that demonstrates the derivation of the low-risk AP1000 design. This is discussed in detail in Appendix 6A.

In addition to the documents listed above, there are a number of other documents produced in support of the Environment Report, which are listed in the AP1000 DRP document together with a further list of detailed design documents (Reference 2.4).

2.6 WESTINGHOUSE QUALITY MANAGEMENT SYSTEM

To control the process for submission of the PCSR, Westinghouse operates a Quality Management System (QMS) that assures, maintains, and improves all areas of critical support operations such as safety, health, environmental, quality, technical, operational, and commercial, combining all functional requirements into one corporate framework. It extends from high-level policy documentation and regulatory compliance processes to detailed guidance documents and others, incorporating detailed work instructions and taking full cognisance of recognised standards throughout all corporate disciplines.

The QMS is based on the model devised by the European Foundation for Quality Management (EFQM) Excellence Model, certified to International Organisation for Standardisation (ISO) 9001:2008, and designed to work in tandem with specific external required processes, which include but are not limited to the following:

- ISO 9001:2008 Quality Management Systems – Requirements
- ISO 10006 Guidelines for Quality Management
- ISO 19011 Guidelines for Quality and Environmental Management Systems Auditing
- ISO 90003 Software Engineering Quality Management Standard
- GQAS General Quality Assurance Specifications
- BS OHSAS 18001 Occupational Health and Safety

- BS 7000 series Design Management Systems
- ANSI/ASME NQA-1 Quality Assurance Requirements for Nuclear Facilities
- IAEA GS-R-3 The Management System for Facilities and Activities
- IAEA GS-G-3.1 Safety Guide
- IAEA SF-1 Fundamental Safety Principles

The Westinghouse QMS provides an approach that is consistent with the ONR SAPs (Reference 2.1), the Ionising Radiations Regulations (IRRs) (Reference 2.18), and the site licence condition (SLC) requirements through a documented assessment programme. The following SLCs are considered:

- SLC 6 Documents, Records, Authorities and Certificates
- SLC 12 Duly Authorised and Other Suitably Qualified and Experienced Persons
- SLC 14 Safety Documentation
- SLC 15 Periodic Review
- SLC 17 Management Systems
- SLC 19 Construction or Installation of New Plant
- SLC 20 Modification to Design of Plant Under Construction
- SLC 23 Operating Rules
- SLC 36 Organisational Capability

The role of the QMS is not only to ensure full control of the contents the PCSR and the process of its submission to governing bodies, but also to ensure that the highest levels of communication, innovation, performance management, and teamwork are being comprehensively delivered. Among the benefits of the QMS are the increased confidence that requirements will be met, greater assurance that processes are under control, and evidence that a culture of continuous improvement is in place. These assurances are reached by following robust procedures. Those procedures that are relevant to the PCSR are included in Table 2-1.

2.6.1 Control of the Development of the Safety Case

In respect of any operation that may affect nuclear safety, it is a requirement to make and implement adequate arrangements for the production and assessment of all documentation relating to the safety case. This safety case justifies and documents safety at all phases of the life cycle including design, manufacture, construction, commissioning, operation and decommissioning.

The safety case comprises the complete safety justification for the operation within the scope of this case. This safety case is considered to be the totality of claims, arguments, and evidence that substantiates the safety of the plant, activity, operation, or modification in question.

Prior to commencement of safety case development, a Project Quality Plan (PQP) (Reference 2.14) was produced. This detailed the scope, boundary, and interfaces of the PCSR and how it is intended to produce and manage the safety case.

The PQP and supporting procedures held within the QMS ensure that the proposed design can meet regulatory safety requirements and that the safety case is supported with all the

documentary evidence that is needed to be able to construct, maintain, and operate the plant in accordance with the intent assumed in the safety case. The nuclear site licence holder will ensure the safety of all facilities and activities on the site. The interface between Westinghouse and the utilities is described in more detail in Chapter 3.

This PCSR provides a baseline for configuration management against which all future phases of the plant life cycle can be measured; suitable audit trails are maintained throughout all phases of the life cycle (see Chapter 7 for more detail on the plant life cycle). The Westinghouse QMS provides an approach that is consistent with the ONR SAPs, SLCs, International Atomic Energy Agency (IAEA) GS-R-3 (Reference 2.19), and Ionising Radiations Regulations 1999 (IRR99) (Reference 2.18) requirements through a robust and documented assessment programme. During the GDA process, if there is a requirement to update safety case documentation that can impact the site-specific PCSR, then where there are potential licensees, they will be invited to be part of that review process. In moving to an operational regime, the safety case will be owned by the licensee, and an operational safety case will be required.

Safety documentation is classified according to safety significance and is to be subject to the prescribed due process for UK licensing, including independent nuclear review (INR). Once approved, no alteration or amendment must be made to the safety case unless the verification process has approved such alteration or amendment.

The safety case provides deterministic safety arguments and design substantiations against the range of hazards identified. These are supported by appropriate ALARP justifications. In particular, the Westinghouse QMS gives assurance that the safety case does the following:

- Demonstrates that there is a benefit from affecting the operation or operating the plant that outweighs the risks arising from the activity.
- Confirms that all relevant standards have been met and that risks have been reduced to levels that are ALARP.
- Presents the bases and assumptions used in estimating risks and ensures that they are defined and maintained during the plant life cycle, including emergency arrangements.
- Demonstrates that suitable safety management arrangements (SMAs) are in place or are credibly planned to affect the various activities required during the plant life cycle.

The safety case demonstrates that the AP1000 plant can be operated such that the risks to the operators, site workers, public, and environment are ALARP.

All stages of the development of the safety case consider interactions with interfacing safety justifications and other stakeholder systems if deemed necessary, e.g., transport, fire and conventional hazards. The flow of information across all identified boundaries is managed throughout the plant life cycle (see Chapter 3).

The complete safety case is presented to and accepted by the ONR prior to implementation; and, once produced the adequate arrangements are to be put in place by the licensee for its periodic and systematic review and reassessment.

2.6.2 Control of the Quality of the Pre-Construction Safety Report Production

A safety case is mandatory for all operations required to be performed throughout the plant life cycle. The development of a safe design is an iterative process involving complex

interactions between safety, design, and safety case documentation (see Section 2.6.1). It is imperative that the scope of the safety case is clearly defined at the commencement of any project. This requires definition of the physical (e.g., system/equipment) boundaries of the safety case, organisational boundaries, and the provenance and appropriateness of information that crosses such boundaries.

The function of the safety case is to demonstrate that the plant can be operated safely throughout the plant life cycle. Additionally, it must balance the functional requirement of the design with the requirement to deliver the function safely. The safety case must recognise that the optimum design may be a balance between nuclear safety and other constraints, such as conventional health and safety or environmental issues. This applies whether considering new designs, modifications to existing or as yet unbuilt designs, or on modifications to extant plant.

Due to the size and complexity of PCSR production, detailed planning was considered at the start of the production process to facilitate the presentation of the safety case in a clear, well-structured, and logical manner.

Implicit in the production of the PCSR is a requirement that Westinghouse, as the design authority (DA), has the responsibility for, and the requisite knowledge to support maintenance of the design integrity and the overall basis for safety of its nuclear facilities over its entire life cycle, from design to decommissioning. The DA also has responsibility to maintain the design intent of the AP1000 plant throughout its life cycle. At a suitable point, the DA role will be handed over to the licensee, and Westinghouse will become the responsible designer while continuing to support the licensee.

Robust documented procedures contained within the Westinghouse QMS (Chapter 3) detail those requirements that enable the ONR to gain adequate confidence that the AP1000 design is being designed, procured, constructed, and commissioned to meet the design intent, including the fuel and the neutron sources, and thus operate safely. These procedures do the following:

- Comply with the fundamentals of nuclear safety to be applied to safety cases, derived with due cognisance to the IAEA guidance.
- Ensure that the resulting designs are acceptable when judged against the SAPs and complementary safety case methodologies that assist authors and technical leads in the production of safety cases to the required standards. They also ensure that the resulting safety cases present the key elements normally expected in any safety case and facilitate the production of a case compliant with relevant principles.
- Provide prescription and guidance on the purpose, content, and structure of a safety case including the PCSR, and describe each of the reports that may be employed to present the AP1000 design safety case throughout the design and build project stage.
- Mandate the classification of all documentation comprising the safety case (including the PCSR) and prescribe the AP1000 design approval route.

2.6.3 Control of the Quality of Safety Case Documentation

The Westinghouse QMS contains arrangements specifying particular skills and experience required of individuals to deliver key roles in the organisation and the project delivery framework. Management is responsible for determining the necessary personnel competencies in terms of skill, education, and experience requirements for the activities affecting quality, and the supply chain is carefully monitored through a rigorous audit procedure to ensure competence levels are met, maintained, and exceeded.

Documented arrangements, along with a full suite of training and competency records, are held within the QMS to give assurance and confidence to the ONR that the safety case is of the required quality. These complement the records that will be kept by the licensee later in the process to ensure the suitability of staff who construct, commission, operate, examine, maintain, inspect, test, and modify the SSCs that make up the plant.

Fundamental to complying with SLC 12 is the ability to demonstrate to the ONR that Westinghouse has suitable and sufficient SMAs in place to ensure that only suitably qualified and experienced persons conduct functions that may have an effect on nuclear or radiological safety during the production of the PCSR.

Compliance with SLC 12 ensures that the licensee applies quality assurance to all activities associated with the design, construction, manufacture, commissioning, operation, and decommissioning of the installations on the site, including the preparation and review of safety documentation. The licensee's arrangements are expected to include the provision of a quality assurance (QA) function to oversee the specification, audit and review of QA arrangements.

3 MANAGEMENT OF SAFETY

3.1 INTRODUCTION

Safety is paramount within the Westinghouse management system, overriding all other demands. All levels of Westinghouse management and workforce are focused on achieving a high level of safety and ensuring Westinghouse remains a high-reliability organisation. This is facilitated through the Westinghouse Global Management System (WGMS) (Reference 3.47). The main aim of the management system is to achieve and enhance safety by doing the following (Reference 3.2):

- Bringing together in a coherent manner all the requirements for managing the organisation.
- Describing the planned and systematic actions necessary to provide adequate confidence that all these requirements are satisfied.
- Ensuring that health, environmental, security, quality, and economic requirements are not considered separately from safety requirements, to help preclude possible negative impact on safety.

The WGMS ensures that documented quality and safety procedures are in place; that they are followed; and that they are robust, managed, and monitored in accordance with statutory, legal, and regulatory requirements. The AP1000 design has in place a robust safety management framework that meets the requirements of United Kingdom (UK) and international regulations and good practices (References 3.2, 3.3, and 3.4).

During the design phase, the safety case is owned by Westinghouse, the requesting party for Phase 1 of the UK New Build licensing process; i.e., the generic design assessment (GDA) process. During the life cycle of the AP1000 plant, safety responsibilities will transfer from Westinghouse to the site licensee who will have prime responsibility for safety when the plant is operational. Once the Design Acceptance Confirmation (DAC) is received, the operating organisations that become licensees will own the safety cases and will be responsible for any changes and future reviews of that design, albeit with input from Westinghouse where deemed appropriate by both parties. Westinghouse will implement its safety and quality management systems:

- Up to the end of the UK New Build licensing process, phase 2; i.e., Nuclear Site Licensing
- During subsequent plant construction
- During the commissioning phase prior to product acceptance handover to the operating organisation’s licensee

The function of the WGMS is to define the safety and quality management framework, ensure that safety and quality management arrangements are adhered to, and ensure that an effective safety culture is maintained. The WGMS also ensures that Westinghouse safety management arrangements are appropriately transferred and integrated into the safety and quality management systems of the licensee.

The scope of this chapter is to do the following:

- Describe the WGMS structure applied to the AP1000 project, and the safety fundamentals, safety requirements, and safety guides that it addresses.

- Specify the details of the quality assurance programme (Reference 3.5) that Westinghouse will use to meet its stated objectives for providing the necessary technical information and documentation for the Office for Nuclear Regulation (ONR) and Environment Agency (EA) to conduct a complete GDA of the AP1000 design.

3.2 SAFETY MANAGEMENT FRAMEWORK

3.2.1 General Arrangements

Westinghouse operates its WGMS (Reference 3.47) in order to manage, maintain, and continuously improve all areas of safety, including technical, operational, commercial, and management. The quality policy of Westinghouse is:

> *To provide products and services that fully satisfy customer and regulatory requirements.*

Among the benefits of the WGMS are the following:

- Increased confidence that requirements will be met.

- Greater assurance that processes are appropriately managed.

- Motivation to recognise opportunities for improvement, with a high degree of importance being placed upon nuclear safety issues, error reporting, feedback, and lessons learned.

The WGMS comprises high-level policy documentation, procedures, and guidance documents (incorporating detailed work instructions), and takes full account of the required standards in all disciplines. The three QMS levels follow:

- Level 1: QMS, Westinghouse Quality Management System Manual (Reference 3.1); EHS-MS, Environmental, Health, and Safety Management System (Reference 3.48)

- Level 2: Westinghouse and Operational Organisation Policies and Procedures

- Level 3: Function/Department/Plant Procedures and Work Instructions

The Westinghouse QMS is certified to ISO 9001:2008 and is designed to be fully compatible and work in juxtaposition with specific externally required processes, as detailed throughout this chapter. Section 5.4 explains the levels of quality assurance (QA) required in relation to the equipment classification and the associated codes and standards.

Each level of the WGMS is populated with policies and procedures. The arrangements for those are detailed in the Westinghouse Management System Document Administration document (Reference 3.6), which identifies compliance, implementation, processes, and work instructions that have been developed and implemented. These procedures are focused on the following:

- Ensuring safety is considered as the key aspect in all activities
- Ensuring effectiveness and improvement through a process- and risk-based approach
- Ensuring a robust safety culture is embedded
- Conducting projects according to a specific project quality plan
- Delivering a quality product safely

The maintenance and continual improvement of Westinghouse procedures and processes are achieved through a comprehensive audit programme that acts as a catalyst for driving safety improvement and that is operated under Westinghouse procedures for quality assurance audits (Reference 3.7), self-assessments (Reference 3.8), and control of purchased items and services (Reference 3.9). Using suitably qualified and experienced quality auditors (Reference 3.10), the findings from these audits are actioned in accordance with documented procedures for corrective actions (References 3.11 and 3.12). The Westinghouse quality assurance records procedure (Reference 3.13) explains the method by which the creation of, validation of, and changes to Westinghouse documents are managed.

The audit process allows the organisation to discern clearly its strengths and areas in which safety and quality improvements can be made, and culminates in planned improvement actions that are then monitored for progress. A Westinghouse management review (Reference 3.14) assesses how the performance and outcomes compare with processes, procedures, and targets that were set. This assessment then demonstrates the suitability, adequacy, and effectiveness of the WGMS.

The audit process ensures that the most important controls are in place and that the root causes of errors, problems, and areas of weakness are fully addressed and corrected. It also ensures that the potential problems are identified before they become an issue. Emphasis is placed on preventive action and the trending process included in the Westinghouse procedure for the corrective action program (Reference 3.11), root cause analysis (Reference 3.16), and apparent cause analysis (Reference 3.17).

The function of the WGMS within this project is not only to ensure adherence to the requirements of governing bodies and Westinghouse procedures but also to ensure that communication, innovation, performance management, and safety culture are integrated into the safety and quality management systems of the licensee in order to help the licensee produce a robust QMS that maintains and improves upon safety and international good practices.

There are eight fundamental principles (FP.1 through FP.8) within the ONR safety assessment principles (SAPs) (Reference 3.19). Together with SAP MS.1, meeting the expectations of these SAPs is essential for the licensee to produce an acceptable, robust QMS that maintains and improves upon safety and international good practices. These SAPs will be used by the ONR to judge the acceptability of the design during the plant life cycle and therefore must be considered by both Westinghouse during design and construction and the site licensee during plant operation. The SAPs follow:

- FP.1 – Responsibility for Safety
- FP.2 – Leadership and Management for Safety
- FP.3 – Optimisation of Protection
- FP.4 – Safety Assessment
- FP.5 – Limitation of Risks to Individuals
- FP.6 – Prevention of Accidents
- FP.7 – Emergency Preparedness and Response
- FP.8 – Protection of Present and Future Generations
- MS.1 – Leadership

The control of the WGMS is the responsibility of the Westinghouse management, and changes are reviewed and approved by Westinghouse in accordance with management review procedures (Reference 3.14 and Reference 3.6).

Site licensees will be required to demonstrate that similar arrangements are in place for all above aspects of their management system prior to acceptance handover.

3.2.2 Arrangements Specific to the Generic Design Assessment Process

The current quality management system arrangements for the AP1000 GDA project are detailed in the Project Quality Plan for the UK GDA (Reference 3.5). The purpose of the project quality plan is to specify how the quality objectives for the GDA are met. This quality plan also details the QA programme for the GDA and makes reference to UK guidance documents used throughout the GDA, together with Westinghouse Level 2 policies and procedures, and Westinghouse Level 3 procedures specific to the UK GDA.

The Plant Life Cycle Safety Report (Reference 3.20) outlines the safety programmes developed by Westinghouse to support plant owners throughout the design, construction, commissioning, operation, and decommissioning of the AP1000 plant, and sets out the following safety philosophy policy statement:

> *It is the Westinghouse policy to design, produce, market, and distribute our products and services and to conduct our operations in an environmentally sound and socially responsible manner. Westinghouse considers the impact our actions may have on the environment and the health and safety of our employees, subcontractors, customers, and public.*

Section 3.4 discusses the management of safety through the plant life cycle in more detail.

As part of the GDA assessment process, the ONR has raised regulatory queries (RQs), regulatory issues (RIs), regulatory observations (ROs), and technical queries (TQs). These have been processed, and responded to in accordance with Westinghouse procedures (References 3.24, 3.25, and 3.49).

3.3 ARRANGEMENTS FOR THE INTERFACE WITH UTILITIES

3.3.1 Key Roles in the Project Life Cycle

The nuclear site licence holder (Reference 3.26) ensures the safety of all facilities and activities on the site, in part, by assuming the responsibility of the intelligent customer (IC) for the purchase of all equipment and services associated with it. Prior to the issuance of a site licence, the IC is also responsible for ensuring that the aspects of the pre-work impacting nuclear safety and environmental protection are brought together with the same rigour as if a site licence had been in place.

Westinghouse, as design authority (DA) for the AP1000 design, has assumed the position of IC for the purposes of the GDA. Ownership of the IC role will change during the life cycle of the plant. At some time during the licensing process the licence holder will take on the role. In addition, the role of DA will also transfer from Westinghouse to the licensee. The interfaces between Westinghouse, the utilities, and other stakeholders (e.g., contractors) over the life cycle of the plant are described in detail in Chapter 7.

3.3.2 Interfaces between Westinghouse and the Utilities

Westinghouse has worked with potential utility licensees during the GDA process concerning submissions to the UK regulators with the purpose of ensuring that an acceptable safety case has been made for the AP1000 design. A formal interface exists with potential utilities, which is covered in the Project Quality Plan (Reference 3.5). This ensures that the safety of the AP1000 design is understood and maintained during its life cycle, and that a systematic approach has been undertaken to ensure the competency of the utilities at technical, operational, and managerial levels.

Representatives from the utilities attend regular GDA progress meetings. This ensures concerns raised throughout the review process by all parties are promulgated, addressed, and discussed. This should also facilitate any future licensing application for construction and operation of AP1000 reactors.

Fundamental to the success of the interface between Westinghouse and the utilities is for all parties to implement safety requirements appropriate to their role at each phase of the project. This includes the management of contractors and development (and delivery) of appropriate integrated safety standards.

Steps have been taken to build confidence that there is a robust interface with stakeholders on the Pre-Construction Safety Report (PCSR). The Project Quality Plan (Reference 3.5) requires that all employees performing work on the UK GDA project be responsible for the quality of their own work and comply with Westinghouse policies, procedures, and work instructions.

In accordance with SLC 36, Organisational Capability (Reference 3.26), a strong nuclear safety culture is being developed between Westinghouse and the utilities, the aim of which is to ensure a common understanding of the key aspects of nuclear safety within their respective organisations. This will aid the formal demonstration to the regulatory bodies that procedure compliance has been achieved.

Each utility manager or appointed person designated to determine plant safety will ensure that a strong safety culture is developed within their section/department in order to establish, maintain, and continually improve the safety management system requirements in accordance with those identified by the IC and in accordance with regulatory requirements and SLCs. Strong emphasis will be placed on continuous improvement and ensuring that lessons learned are implemented, monitored, and fully documented.

3.3.3 Security Arrangements

The GDA process and safety case submissions will require the transfer of detailed knowledge in document form between Westinghouse, vendors, stakeholders, and utilities, the confidentiality of which is paramount. The procedure for creating, handling, and processing protectively marked documents (Reference 3.27) ensures that all documents are marked appropriately with the correct level of security classification and handled in accordance with ONR Civil Nuclear Security (ONR CNS) requirements (Reference 3.28).

3.4 MANAGEMENT OF SAFETY THROUGH THE PLANT LIFE CYCLE

The management of safety in the plant life cycle begins with the design process (Reference 3.20). The input to the design process incorporates safety principles, assessments, codes, and standards that will continue through the life of the plant. Regulations require the management of safety to be fully documented. Design, construction, commissioning, operation, and decommissioning phases will each have appropriate documentation in order to demonstrate how the regulations are intended to be implemented, managed, and monitored.

Westinghouse will be the DA until at a suitable point, this role will be transitioned over to the licensee, and Westinghouse will become the responsible designer. Westinghouse will provide support to the licensee until agreed otherwise, and formal procedures will be established between Westinghouse and the licensee to define the responsibilities throughout the development of the AP1000 design, procurement, construction, installation, and commissioning phases.

Chapter 7 discusses the plant life cycle in more detail with reference to the Plant Life Cycle Safety Report (Reference 3.20). The key aspects of the safety management of each project phase are discussed in the following sections.

3.4.1 Design

The fundamental principles of plant design ensure that the design meets the required specification, is capable of delivering and maintaining required safety functions, is fit for purpose, and all mitigating risks have been identified and reflected in the design. The involvement of suitably qualified and experienced persons (SQEPs) from the IC, utilities, and other stakeholders should ensure that all aspects of the specification are fully reviewed prior to incorporation in the design.

Well-established procedures within Level 2 and Level 3 of the WGMS regulate the design process and ensure compliance with regulatory requirements and those of the potential utility. These procedures are subject to audit in accordance with internal quality assurance audits procedure (Reference 3.7) and reviewed if necessary during GDA progress meetings.

To ensure a well-established design process is formally documented and implemented, the following examples of Westinghouse procedures have been reviewed in the preparation of the Project Quality Plan (Reference 3.5):

- Design and Development (Reference 3.29)
- Safety Classification (Reference 3.30)
- Design Analysis (Reference 3.31)
- Design Reviews (Reference 3.32)
- Safety Analysis Reports (Reference 3.33)
- Functional Specifications (Reference 3.34)
- Design Specifications (Reference 3.35)

In accordance with the WGMS (Reference 3.47), training records of the Westinghouse design management team are required to confirm the competence of SQEPs and to identify relevant training when required (Reference 3.36). Contracted key personnel used by Westinghouse during the GDA process have been confirmed as SQEPs; their records of qualification have been verified. Processes aligned to the requirements of SLC 36, Organisational Capability (Reference 3.26), have been adhered to following changes to personnel. The knowledge transfer process associated with the transfer of the IC role to the site licensee will involve incorporation of this PCSR into the licensee safety case and acceptance of a joint suite of procedures that define clearly the ongoing roles and responsibilities of both parties. These procedures will be fully documented within both the site licensee and the WGMS. During the design, construction, and commissioning phases when Westinghouse is the DA, some elements may be assigned to other responsible designers. However, the responsibility of the overall design integrity will remain with Westinghouse, which has sufficient in-house knowledge to understand the impact of subcontracted work. The formal arrangements will be addressed in the appropriate level of the WGMS. The licensee will also be required to have suitable arrangements to maintain design integrity. When the site licence has been granted, any changes will be carried out in accordance with the licensee's arrangements for making modifications, under SLC 20, Modification to Design of Plant Under Construction (Reference 3.26). Section 7.3 describes in more detail the management of design change control with reference to the plant life cycle (Reference 3.20).

The AP1000 design has been reviewed to determine safety classification of systems, structures, and components (SSCs) based on the safety function of the SSC. The safety class dictates the level of integrity required of that system or equipment (often expressed as a specified reliability or probability of failure on demand), and Chapter 5 discusses the UK equipment classification scheme in detail. Such information is useful early in the design process as it can facilitate the choice of design options and, where necessary, assist in the procurement of long-lead items.

The GDA process recognised that the implied reliability and safety margins were developed using standards from outside the UK/Europe. The governing AP1000 codes and standards document (Reference 3.37) was, therefore, reviewed to take account of those codes and standards that have been applied during the design of the AP1000. The AP1000 Equivalence/Maturity Study of the U.S. Codes and Standards (Reference 3.38) has been produced by Westinghouse to ensure the UK SSC requirements have been met. This is discussed in more detail in Section 5.3.

Westinghouse has also introduced a design reference point (DRP) document (Reference 3.39), that is used to define a known (baseline) status for every document and activity associated with the design, against which the GDA can be carried out. The GDA process will result in the issuance of a DAC for the generic AP1000 design that will comprise the DRP and other supporting documentation. The identification and assessment of any future safety-significant changes with regard to the DAC will be referenced in an application and issuance of any nuclear site licence for the construction and operation of the AP1000 design in the UK.

3.4.2 Construction

The modular design of the AP1000 plant allows a portion of construction to be undertaken in a factory environment. This allows quality and safety to be more closely monitored within a more securely controlled environment than in a traditional build approach. It also reduces the potential environmental risks associated with large civil construction.

Westinghouse will work closely with the licensee during the construction stage and ensure that technical information is provided to the licensee; e.g., for verification purposes. Account will be taken of the requirements of the licensee set out in SLC 19, Construction or Installation of New Plant (Reference 3.26).

The prime construction contractor will be required to have a fully functional site safety manual that includes a safety policy statement covering all aspects of site safety, e.g., fire protection, accident reporting and feedback, planning, and training.

Controls of purchased items and services are established to ensure that applicable technical and quality requirements are met by subcontractors (Reference 3.9). Procurement activities are controlled through documented procedures and instructions that include requirements for bid evaluation, selection and qualification of suppliers, communication of requirements to suppliers, evaluation of supplier performance, and resolution of nonconformances. Where Westinghouse has procured services outside their organisation, under the Westinghouse procedure for control of purchased items and services (Reference 3.9), they remain wholly responsible for the control and provision of SQEPs to ensure output is delivered efficiently and the appropriate level of safety management is used. Westinghouse will perform surveillance activities at a supplier's facility during manufacturing, inspection, testing, and release of items, as appropriate and as specified in procurement documents in accordance with the Westinghouse supplier oversight procedure (Reference 3.40) and quality oversight at resident facilities (Reference 3.41). The management of nonconformances is executed in accordance with Reference 3.42.

A construction verification process (which includes information on inspections, tests, analyses, and acceptance criteria to demonstrate the condition of the plant) is aligned with the intended design, which is identified as an essential component of plant safety (Reference 3.20). The process requires that the prime construction contractor provides evidence that processes are established to ensure that build quality is in accordance with the design intent. It also requires demonstration that modifications during the build are controlled and approved. When the build is complete, the constructor or consortium is required to produce appropriate documentation giving a detailed demonstration that the plant has been built to meet the design intent.

The overall build programme (material procurement, component manufacture, construction, and commissioning) for the plant is controlled by a series of hold points, where the preceding activity is examined for completion/adequacy before the activity in the following phase is permitted. An element of this permission is demonstrating that the plant build complies with the design intent. Hold points will also be applied throughout the design and build phase to assist in the management of risks. Hold points are typically set at stages where there are significant changes in the levels of risk associated with the project, e.g., where the foreclosure of options occurs, or where the design baseline can be set to facilitate configuration management. Hold point control documents define the hold point logic for the project and present the nuclear-safety-implicated activities associated with each hold point, together with the criteria and deliverables for release.

Management of the construction process and an overview of the construction verification process and its objectives are discussed in Section 7.4.

3.4.3 Commissioning

The overall objective of commissioning is to demonstrate that the plant has been constructed as designed, that the systems perform in a manner consistent with the plant design, and that activities culminating in operation at full power, including initial fuel load, initial criticality, and power ascension, are performed in a controlled and safe manner.

Westinghouse has established an initial test programme (ITP) that will be further developed to incorporate the expectations of a Pre-Commissioning Safety Report (PCmSR), which will address both inactive and active commissioning. Its primary purpose is to present firm evidence that the plant has been constructed in accordance with the design intent and that sufficient and appropriate tests will be conducted to support the future operational safety case.

The ITP demonstrates that the construction and installation test programmes, pre-operational test programmes, and startup test programmes have been developed in sufficient detail to allow the commissioning tests to be carried out without undue risk to operators, site workers, and the public, and in accordance with statutory health and safety requirements. This implies that the future operating infrastructure must be in place and approved, at least for active commissioning, and demonstrates that the commissioning trials will not compromise the future safe operation of the plant.

During commissioning the licensee has the responsibility under SLC 21, Commissioning (Reference 3.26), to have in place and implement adequate arrangements to ensure safety. In accordance with SLC 20, Modification to Design of Plant under Construction (Reference 3.26), the licensee is required to ensure that management arrangements are in place in order to maintain design integrity and to define a baseline statement for the safety of the plant through the remaining life cycle of the facility.

A detailed description of the commissioning phases of the project is discussed in Section 7.5.

3.4.4 Operation

During operation, the responsibility for the safety of the plant lies with the licensee. The licensee must demonstrate that adequate management arrangements are in place, and that examination, inspection, monitoring, and testing of the plant and assets, through a series of comprehensive and systematic audit process of safety assessments, are fully documented.

Westinghouse will supply technical and operational information, through specifications as detailed within the Plant Life Cycle Safety Report (Reference 3.20), that prescribes the manner with which the licensee will operate the plant. The supplied technical and operational information will include or will provide input to:

- Technical specifications and operating limits,
- Examination, maintenance, inspection, and testing schedules,
- Procedures for normal operation, emergency conditions, and accident management,
- Training programmes,
- Radiation protection arrangements for operators, and
- Emergency preparedness

This ensures that the requirements of the safety case, and the assumptions on which the safety case is based, are captured and communicated to operating utilities and incorporated into the operating regime.

The AP1000 Technical Specifications (Tech Specs) compile the equipment conditions, signals, and operational requirements from all of the identified accident conditions. Each requirement within the Tech Specs comprises the limiting condition for operation and the surveillance requirements.

Westinghouse may have a DA capability within the licensee's organisation (dependent upon the licensee), under which any design changes must undergo due process in accordance with SLC 22, Modification or Experiment on Existing Plant (Reference 3.26), and SLC 23, Operating Rules (Reference 3.26). The general principles of design change control as detailed in the ONR technical assessment guide Design Safety Assurance (Reference 3.43) are as follows:

- Recognition of change
- Understanding the safety impact of change
- Agreement of change at the correct authority level
- Controlled implementation and communication of change
- Update of necessary documentation

3.4.5 Decommissioning

The licensee has a requirement to produce a decommissioning safety case to give confidence to the governing bodies that the decommissioning of the plant will be in accordance with regulatory requirements and under the auspices of a robust set of management arrangements. The safe decommissioning of the plant has been taken into account since the initial planning stage, the dismantling of the structure and the removal of hazardous material has been reviewed, and the risks to the general public and the environment have been identified and reduced to a level that can be demonstrated to be as low as reasonably practicable (ALARP) at all stages of decommissioning.

Westinghouse involvement will be determined through due process as either a design consultant or an external contractor, and in accordance with the licensee's requirements, with any such involvement being documented in the decommissioning safety case. High-level information on decommissioning is available from the design work to date, which is reflected in the detailed liaison requirements for Westinghouse and the potential licensees, to ensure that due process for the plant end of life is fully considered. The level of detail in this PCSR is proportionate with the current stage of the AP1000 design.

Management and disposal of waste is described more fully in the integrated waste strategy (Reference 3.44) and supporting documents (References 3.45 and 3.46).

A detailed description of the decommissioning stages of the project is discussed in Section 7.9 and in Chapter 27.

3.5 ROLE PROFILES

The safety of the plant is dependent on the abilities and attitudes of the individuals who design, construct, commission, operate, examine, maintain, inspect, test, and modify the SSCs that make up the plant. Management is responsible for determining the necessary personnel competencies in terms of skills, education, and experience requirements for the activities affecting quality.

Westinghouse has produced a procedure regarding individual training and competency requirements (Reference 3.36).

Top-level management within Westinghouse has the ultimate responsibility for the training and development of competent persons, and to ensure that procedures implemented within the WGMS are managed, maintained, and continuously improved in accordance with regulatory requirements and company quality policies. Westinghouse will liaise closely with utilities and licensees to ensure these levels are met and maintained within their organisations.

Where Westinghouse has procured services outside their organisation, under the Westinghouse procedure for control of purchased items and services (Reference 3.9), they remain wholly responsible for the control and provision of adequate SQEPs to ensure that output is delivered efficiently and that safety management controls are in place.

3.6 DESIGN RELIABILITY ASSURANCE PROGRAMME

Westinghouse has implemented the Design Reliability Assurance Programme (D-RAP), which gives confidence that through-life reliability is designed into the AP1000 plant. The D-RAP comprises the following three phases:

Phase 1 Identifies and evaluates risk-significant SSCs

Phase 2 Post-Design Certification process that develops component maintenance recommendations for plant operation

Phase 3 Relates to advice to the licensee on plant operation

Section 5.9.1.2.1 discusses the D-RAP programme in more detail.

4 GENERIC SITE CHARACTERISTICS

4.1 Introduction

The UK generic design assessment (GDA) process requires that the suitability of the AP1000 plant for application to sites in the UK be assessed before a specific location for such a plant has been identified. This includes an early assessment of the potential impact of the AP1000 design to members of the public and the surrounding environment. To allow such assessments to be undertaken, a UK generic site has been defined. This generic site does not represent any particular location in the UK, but rather reflects a conservative set of conditions for a credible UK site. Early consideration of the characteristics of a UK generic site is important for the following reasons:

- The assessment of radiological risk to the local population depends on the location and characteristics of that population as well as those local factors that affect the dispersion of activity released into the environment.

- It is important to understand and, if necessary, mitigate those hazards over which an operator has no effective control. These "external hazards" could have an impact on the safe construction or operation of the plant.

- It is essential to assess the suitability of a site to support the engineering and infrastructure requirements of the design.

The intention of this chapter is primarily to provide confidence that the generic site characteristics in the UK will not lead to materially increased radiological risk to people from the AP1000 design throughout the life cycle of the nuclear site. A detailed assessment of external hazards can be found in Chapter 12. An assessment of the engineering and infrastructure requirements can be found in Volume 4. The impact of the AP1000 plant on the wider environment is described in the UK AP1000 Environment Report (Reference 4.1, Section 5.3). This includes the consideration of nonhuman species and sensitive habitats.

This chapter has the following structure.

UK Strategic Siting Assessment

In parallel with the GDA process, and independent of it, in 2010 the UK government undertook a process to identify strategically suitable sites for possible new build. This process is known as the Strategic Siting Assessment (SSA). As part of this process a number of strategically suitable sites for possible new build were identified. The SSA process is described in Section 4.2.

UK Generic Site Characteristics

For the purpose of carrying out radiological impact assessments for the GDA process, a generic UK site was defined. The characteristics of that generic site are summarised in Section 4.3.

Design Parameter Assessment against Generic Site Characteristics

The AP1000 plant is a standardised nuclear power plant designed for construction and operation at sites meeting a broad range of parameters (see Table 4-9). The site design parameters relevant in the context of this chapter are presented in Section 4.4 to demonstrate

that potential UK sites are acceptable for the operation of an AP1000 plant from a radiological perspective.

Monitoring of Site-Specific Parameters

The outline of a suitable monitoring programme of site-specific parameters is given in Section 4.5.

The siting characteristics are covered here from a generic UK perspective. A number of the siting criteria discussed in this chapter are dependent on local conditions of a specific site. In such cases, detailed assessments are expected to form part of any future site licence application.

4.2 Strategic Siting Assessment

Details of the SSA process undertaken by the UK government are provided in the National Policy Statement (NPS) for Nuclear Power Generation (Reference 4.3). As part of the SSA process, criteria have been developed against which the strategic suitability of possible sites can be judged. These criteria relate to nuclear safety, environmental protection, societal issues, and operational requirements, and are presented in Part 5 of the NPS for Nuclear Power Generation (Reference 4.3).

The conclusion of the SSA is that ten of the nominated sites are potentially suitable for the deployment of new nuclear power stations. The sites are listed and details provided in the NPS for Nuclear Power Generation (Reference 4.3).

The GDA generic site assessment, as the focus of this chapter, is not geared towards any particular candidate site in the UK. Nevertheless, a consideration of the general characteristics of the candidate sites identified through the SSA process is useful. For example, the site boundaries for the SSA-nominated sites enclose areas of between 75 hectares (185 acres) and 298 hectares (714 acres). Of the ten potential sites, eight are located adjacent to existing nuclear power stations (either operational or in a decommissioning phase). The other two nominated sites are located on the west coast of Cumbria, within the wider locality of Sellafield. All ten sites are located on the UK seacoast or on major estuaries.

4.3 UK Generic Site Characteristics

4.3.1 Introduction

The GDA process requires that the suitability of the AP1000 design for application to sites in the UK be assessed. This necessitates some assumptions be made on the local environment surrounding the AP1000 plant. To allow for such assessments to be undertaken in the absence of a specific location for the plant, a UK generic site has been defined. The UK generic site has a number of characteristics that relate to the distribution of population centres and parameters that influence the dispersion of radionuclides in the environment. The UK generic site characteristics are based on data obtained from a number of existing coastal nuclear power stations in the UK and are given in the following subsections. It has generally been assumed that the generic site characteristics remain constant over the life cycle of the nuclear plant. Details on the impact of a future climate change on meteorological and hydrological data are discussed in Chapter 12.

A number of the UK generic site characteristics data are taken from an Environment Agency (EA) assessment method report (Reference 4.4). This includes exposure group characteristics as well as atmospheric and marine dispersion conditions. Other UK generic data have been

derived from the environmental data from five existing UK nuclear power station sites: Dungeness, Hartlepool, Heysham, Hinkley, and Sizewell. These include the distribution of population centres, topography, geology, meteorology, flooding, tidal ranges, and coastal water depths. The values derived for the UK generic site from data for those sites are normally conservative values, represented by maximum and minimum values, or 80 and 20 percentile values. More details on how these site characteristics were derived can be found in the UK Generic Site Report (Reference 4.5). Details on the environmental assessments undertaken to support the AP1000 build in the UK are presented in the UK AP1000 Environment Report (Reference 4.1).

4.3.2 Human Population

It has been assumed that the population centres of a given size are located at the nearest distance recorded for the five existing nuclear power stations. The density of population centres is based on the 80 percentile distribution for the five sites. Population centres are present within 2 km (1.2 mi), 10 km (6.2 mi), and 20 km (12.4 mi) of the site; individual properties/farms are also present within 2 km (1.2 mi) of the UK generic site. Details are shown in Table 4-1.

Members of the public who have the potential to receive an offsite dose of radioactive discharges from the operation of a nuclear power plant can only be characterised on a site-specific basis. For a general assessment of the impact of radioactive discharges at a generic coastal site the default methodology is to consider the following potential exposure groups: a local resident family and a fisherman family. The local resident family represents members of the public primarily exposed to atmospheric releases through external exposure to activity in the plume and deposited to the ground, inhalation of activity in the plume, and ingestion of activity transferred to terrestrial foodstuffs. The fisherman family represents members of the public primarily exposed to liquid releases through external exposure to activity in beach sediments and ingestion of marine seafood. Habit data for the local resident and fisherman families are shown in Tables 4-2 and 4-3, respectively.

4.3.3 Water Environment

The nearby foreshore and marine environment supports a fishery, wildfowl, and seabirds. It has been assumed that the intertidal zone of the generic site contains a wide range of substrates within 10 km (6.2 mi) of the site. These may include sand, gravel, mud, rocky outcrops, and made ground.

Tidal ranges are shown in Table 4-4. This UK generic site data is based on five existing nuclear sites and assumes the 80 percentile value for high tides and the 20 percentile value for low tides. Limiting water depths off the coast of five existing nuclear sites are shown in Table 4-5. The UK generic site is assumed to have the shallowest depth.

For the purpose of radiological impact assessments, a conservative volumetric water exchange rate of 130 m^3/s (2.1E6 gpm) has been adopted to characterise the flushing of the local marine water compartment. This is based on the lowest value at existing UK coastal nuclear sites. A low value leads to higher activity concentrations in beach sediments and marine biota in the local compartment and hence to higher doses to members of the relevant exposure group.

4.3.4 Terrestrial Environment

Within the five existing nuclear sites, the highest ground elevation within 2 km (1.2 mi) of the UK generic site is 30 m (98 ft), and within 10 km (6.2 mi) is 358 m (1,174 ft). Land cover

within 5 km (3.1 mi) includes arable and grassland, dune vegetation, and some woodland. A surface roughness length of 0.3 m (1 ft) is applicable for atmospheric dispersion modelling purposes. It is assumed that the land is stable and that the presence of faults is minimal.

4.3.5 Meteorological Data

Ranges of temperature, wind speed, and rainfall for the UK generic site are shown in Table 4-6. These data are based on five existing nuclear sites. They do not represent extreme weather conditions in the whole of the UK and are therefore not directly comparable with the meteorological data considered in the external hazard assessment (Chapter 12).

The distribution of atmospheric stability categories and atmospheric deposition rates for the generic site are given in Tables 4-7 and 4-8, respectively.

4.4 Design Parameter Assessment against Generic Site Characteristics

4.4.1 Introduction

This section provides a demonstration that the natural environmental conditions for a generic site in the UK are consistent with the safe operation of the AP1000 plant and will not lead to elevated risk to people. Consideration is also given to anthropogenic factors that could have an impact on the safety features of the AP1000 plant.

A review of relevant criteria has been carried out. These are based on site characteristics considered in the AP1000 human risk assessment reported in the UK AP1000 Environment Report (Reference 4.1, Section 5.2). Consideration has also been given to external hazard criteria relevant to human risk assessments in Chapter 12 and the SSA criteria considered in the NPS for Nuclear Power Generation (Reference 4.3). The relevant parameters can be grouped as follows:

- Meteorological conditions
- Geological and hydrogeological conditions
- Topography
- Hydrological conditions
- Access to suitable sources for cooling
- Human populations
- Potentially hazardous man-made installations or hazardous human activities
- Site dimension

The impacts of meteorological, geological, hydrogeological, and hydrological conditions encountered in the UK as well as the potential impact of hazardous installations or activities on the safe operation of the AP1000 standard plant have been assessed in detail in Chapter 12. The AP1000 plant design parameters relevant to the criteria assessed here are shown in Table 4-9.

Generally, in the context of siting, the site-specific characteristics of natural and man-made external hazards need to be confirmed in detail at the site-licensing stage to ensure that the safe operation of the AP1000 plant at a specific location is not compromised. As demonstrated by the assessments reported in Chapter 12, the AP1000 design incorporates adequate and sufficient defences to ensure that the delivery of Category A safety functions are not compromised by the potential effects of the range of external hazards that are likely to be encountered at a candidate site in the UK.

In addition to ensuring that the characteristics of a specific site do not compromise the safe operation of the AP1000 plant, a number of other site-specific parameters need to be established at the detailed site investigation stage. This includes an investigation into historical land use (to determine whether there could be any existing contamination in the ground), protected or sensitive habitats, and the presence of archaeological remains.

A summary comparison between the bounding design parameters of the AP1000 plant and the ranges of naturally occurring environmental conditions in the UK, as well as the potential impacts from man-made installations or activities, is presented in the following subsections. In addition the AP1000 plant design parameters are compared to the characteristics of the UK generic site defined in Section 4.3.

4.4.2 Meteorology

Extreme ranges of temperature, wind, snow, and rainfall in the UK and their potential impact on the AP1000 plant are presented in Chapter 12, where it is demonstrated that the safe operation of the plant would not be compromised. This includes an assessment of the likely impact of a climate change on these parameters over the expected lifetime of the plant.

Comparing the meteorological design parameters for temperature and wind shown in Table 4-9 with those of the UK generic site shown in Table 4-6 shows that the AP1000 plant design parameters encompass the UK generic site conditions for those parameters.

Meteorological parameters that influence the atmospheric dispersion of aerial emissions are not related to plant design, but are based on the atmospheric conditions prevalent at a specific site. Therefore, these must be considered further at the site-specific planning phase in conjunction with detailed site-specific modelling of gaseous radioactive emissions. A generic assessment of the dispersion of operational atmospheric emissions and related doses to the public is summarised in the UK AP1000 Environment Report (Reference 4.1, Section 5.2). This assessment is based on the meteorological parameters assumed for the GDA generic site, as described in Section 4.3. The conclusion from the assessment of the impact of atmospheric emissions is that applying UK generic site dispersion factors results in very low doses to the local exposure group.

The AP1000 plant is suitable for the range of meteorological conditions likely to be encountered at sites in the UK.

4.4.3 Geology and Hydrogeology

The potential impact of seismic hazards on Class 1 systems, structures, and components (SSCs) is considered in Chapter 12. The effects of drought and associated changes in groundwater levels on the stability of foundations and the availability of water for plant systems and fire protection are also considered. It is concluded that for conditions that can be expected in the UK the safety features of the AP1000 plant would not be compromised.

The AP1000 plant is designed for a normal groundwater elevation to within 0.6 m (2 ft) of the plant grade elevation (see Table 4-9). For the UK generic site, groundwater is assumed to occur at 2 m (6.6 ft) below the surface (Reference 4.5). As a result the AP1000 plant design parameter is more conservative than the UK generic site characteristics.

Geotechnical engineering parameters for soils (e.g., bearing capacities) to support the generic design are considered in Chapter 16. Foundation design will need to be considered further at the site-specific design stage, including the definition of appropriate ground engineering

options. This will require geotechnical ground investigation to determine soil types and their engineering properties and will include investigation of groundwater level and variability.

Possible coastal erosion and other landscape changes over the lifetime of the plant, including long-term fuel storage after operations have ceased, have to be assessed on a site-specific basis.

In addition, the following site-specific geological, seismological, and geophysical information will need to be considered at the site licensing stage:

- Structural geology of the site
- Seismicity of the site
- Correlation of earthquake activity with seismic sources
- Seismic wave transmission characteristics of the site
- Geological history
- Evidence of paleoseismicity
- Site stratigraphy and lithology
- Engineering significance of geological features
- Site groundwater conditions
- Dynamic behaviour during prior earthquakes
- Zones of alteration, irregular weathering, or structural weakness
- Unrelieved residual stresses in bedrock
- Materials that could be unstable because of mineralogy or unstable physical properties
- Effect of human activities in the area (e.g., mining, drilling)

4.4.4 Topography

The local topography around a nuclear site can influence the extent and characteristics of local transport routes. This needs to be considered for the initial construction of the plant, for the normal operations of the plant (e.g., movement of goods to and from the site), in the context of emergency responses (e.g., evacuation routes, movement of emergency response units), as well as for future decommissioning activities. A detailed analysis of access from a site to local transport routes and of any restrictions imposed on transport routes by the local topography needs to be carried out at the site licensing stage.

In addition, the topography around a nuclear plant can influence the dispersion of radionuclides emitted from the plant. For example aerial effluents can become trapped in local valleys in certain atmospheric conditions and the topography can influence the local wind field.

4.4.5 Hydrology

Ranges of external flooding from elevated rivers and sea levels, high tides, storm surges, and tsunamis in the UK and their potential impact on the AP1000 plant are presented in Chapter 12. This includes an assessment of the likely impact of a climate change on the sea level rise over the anticipated lifetime of the plant in Section 12.7.

This assessment demonstrates that the design of the plant prevents the loss of key safety functions in any credible inundation event. Further confirmation that this is the case will be provided by site-specific flood risk assessments required at the site licensing stage. These assessments will include defining maximum predictable flood levels, taking into account local coastal defences already in place. In addition, site-specific issues will be identified that could lead to local flooding such as surface run-off and upstream dam failure.

For such issues site-specific flood protection beyond that provided by the AP1000 standard plant may need to be provided.

A number of local water body characteristics that are not related to plant design may influence the dispersion of liquid emissions and the radiological impact on the local population. This includes seawater volumetric exchange rates for the local area, tidal range, water depth, characteristics of the bed sediments, and details of aquatic biota. A generic assessment of liquid effluents and related doses to the public is presented in the UK AP1000 Environment Report (Reference 4.1, Section 5.2). This assessment was carried out based on parameters assumed for the GDA generic site, as described in Section 4.3.

The characteristics of the marine environment of the UK generic site were based on an analysis of conditions at existing nuclear sites in the UK with the most conservative chosen for this assessment.

The conclusion from the assessment of the liquid emissions impact is that the characteristics of the UK generic site do not adversely affect the radiological risk to the local population. Therefore, it can be established that the AP1000 standard plant is suitable for the range of hydrological conditions likely to be encountered at sites in the UK.

4.4.6 Sources of Cooling

The generic site has access to seawater for balance of plant heat removal. This is consistent with the preliminary conclusions of the SSA, as shown in Section 4.2. The AP1000 standard design for the UK is based on indirect cooling of the circulating water system (CWS) and service water system (SWS) where nonradiological water is passed through cooling towers and water vapour is discharged to the atmosphere. Water can also be used to provide direct cooling of the CWS and SWS in which the same cooling water for the plant is discharged back to the marine environment.

An assessment of the generic impact of cooling water discharge on the marine environment is provided in the generic assessment of the impacts of cooling options (Reference 4.6).

Historically, a cooling water problem encountered by plants in coastal locations using seawater cooling has been due to marine organisms blocking the cooling water inlet screens. The potential external hazard associated with biological fouling of cooling water inlets is considered in Chapter 12. Protective features of the air and water inlet systems have been designed to resist biological fouling. These features will need to be supplemented with routine inspections and surveillance by the operators.

Considering the factors discussed above, it can be established that seawater cooling presents a viable option for the AP1000 design in the UK. Further consideration of the cooling water system will be necessary at the site-specific planning and design stages.

The circulating water system is not required to be used as the ultimate heat sink in response to an accident.

4.4.7 Human Populations

It is important that the characteristics of the population of a site be taken into account to ensure that an appropriate response can be made to an emergency extending beyond the boundaries of the site. It must be possible to apply emergency offsite measures on an appropriate timescale. As these measures may include evacuation, it is necessary to make particular arrangements to cover institutions housing significant numbers of relatively immobile people.

The characteristics of the population local to the site need to be considered in detail at the site licensing stage. Regarding the UK generic site, individual dwellings and small population centres are present within a couple of kilometres of the UK generic site, with larger towns typically situated further afield (see Table 4-1).

From this perspective, there are significant advantages in locating AP1000 plants on candidate sites adjacent to existing nuclear facilities. The emergency arrangements for the existing plants will have been agreed by the Office for Nuclear Regulation (ONR) and the relevant statutory consultees. There will have been regular exercises to test the arrangements. The offsite civil agencies will have been involved in these exercises. Further consideration will be necessary at the site-specific planning and design stages, particularly in response to external hazards that could simultaneously impact neighbouring sites.

4.4.8 Potentially Hazardous Installations or Activities

A number of installations and activities should be considered, including:

- Hazardous industrial facilities for example those that fall under the Control of Major Accidents and Hazards (COMAH) Regulations (Reference 4.7)
- Proximity to other nuclear installations
- Proximity to civil aircraft movements
- Proximity to military installations or operations
- Transport of hazardous materials

There are two aspects to the consideration of nearby potentially hazardous installations or activities. First, these could present hazards to the safe operation of the nuclear facility. These hazards are primarily either physical (resulting, for example, from fire, explosion, or impact) or chemotoxic (resulting from the release of gases or vapours). Second, the neighbouring hazardous installations and activities might be affected by an incident at the nuclear facility. Careful consideration of potentially hazardous installations is important for complex sites, where several facilities exist close to one another.

The potential impact of physical and chemotoxic hazards on the safety functions of the AP1000 design are considered in detail in Chapter 12 with the conclusions outlined in the following sections.

External Explosions

For the AP1000 plant, all SSCs required for nuclear safety are located on the robust reinforced concrete nuclear island structure which provides a level of protection from explosions outside of the nuclear island. The AP1000 site security system is designed to protect the AP1000 nuclear island from credible external explosions.

Accidental Aircraft Crash

Civil aircraft movements can present a hazard in the case of an accidental aircraft crash (see Section 12.8). UK legislation restricts flying in the vicinity of UK nuclear sites. The predicted frequency of an accidental aircraft crash away from flight paths and airfields has been calculated for a range of aircraft types. Malicious aircraft crashes are outside the scope of this review due to their sensitive nature. It should be confirmed on a site-specific basis that accidental aircraft crash frequencies and UK legislation that restricts flying in the vicinity of existing UK nuclear sites is applicable to the specific site under consideration.

External Fire

The AP1000 standard plant will withstand the effects of external smoke, heat, or fumes caused by external fires to an extent that is sufficient to ensure that they would not compromise either the control of core reactivity or the removal of heat from the core, and would not, therefore, result in the uncontrolled dispersion of radioactivity or the uncontrolled exposure of plant personnel or the public to radiation.

External Toxic Gases

Any smoke or toxic gases that penetrate the AP1000 site boundary are considered in the context of internal or external hazards (Chapter 11 or 12, respectively). The AP1000 plant main control room is designed to provide isolation from toxic smoke and gases generated onsite. The main control room is pressurised to a positive pressure using compressed air for a period of 72 hours which prevent toxic gases from entering.

Further consideration of these issues will be necessary to confirm that the assumptions and data presented in Chapters 11 and 12 remain applicable on a site-specific basis. In addition an assessment will need to be undertaken on whether any hazardous installations in the vicinity could be affected by an incident at the AP1000 plant.

4.4.9 Site Dimension

The required land area for the construction, operation, and decommissioning of the AP1000 plant needs to be considered and compared with available sites in the UK.

A typical layout for the AP1000 standard plant is presented in Chapter 6. With the exception of the parking area, the entire facility is contained within a perimeter fence that encloses approximately 10 hectares (2.5 acres). The site boundaries for the SSA-nominated sites enclose areas between 75 hectares (185 acres) and 298 hectares (714 acres) (Section 4.2). Hence, all of the nominated sites have sufficient land area available for at least one AP1000 nuclear power station.

The finalised layout will need to accommodate both generic and site-specific requirements and meet with the approval of the regulators. As part of that, the finalised layout will need to ensure that the constructed AP1000 plant can be operated in a safe and secure manner, with access to the site and nuclear materials strictly controlled.

4.4.10 Grid Connection

A distinguishing feature of the AP1000 plant is that it is designed to be able to achieve a safe shutdown without site ac power supplies or standby diesel generators. The grid connection type and reliability for the UK generic site do not adversely affect the radiological risk to the local population. As a result, redundant grid connections are not required.

4.5 Monitoring of Site-Specific Parameters

The monitoring of site-specific parameters is part of the environmental management system for environmental protection purposes. With regard to the site-specific criteria noted in this chapter, the parameters to be monitored on a site-specific basis should include, but not be restricted to the following:

- Meteorological conditions and tidal cycles/height (both in advance and to identify any longer-term changes)
- Groundwater levels
- Signs of coastal erosion
- Structural integrity and effectiveness of any flood protection systems at the plant

In addition changes in the characteristics of the local populations, in infrastructure and in neighbouring industries, are likely during the life cycle of the plant. As a result these data need to be monitored periodically and the safety case updated if necessary.

Monitoring will begin prior to construction in order to develop a baseline against which to judge any changes that occur. The collation of baseline data is required as part of an environmental impact assessment to support an application for planning consent.

As the development programme moves into the construction phase, any changes in the baseline will need to be identified and an assessment made of whether revisions of either plant design or construction methodologies are required. Likewise, monitoring will be continued throughout the licensing period, to include the operational phase and decommissioning phases, to identify whether any revisions are necessary to operational procedures or facility engineering.

More details on the environmental management system can be found in the UK AP1000 Environment Report (Reference 4.1, Section 6.2).

Throughout the full life cycle of the plant, the operating organisation and other responsible parties that will vary throughout the life cycle (e.g., during decommissioning) will be required to keep themselves appraised of any developments in the vicinity of the plant that could affect plant safety or emergency planning arrangements. For example, any new housing developments in the vicinity of the plant could affect the emergency planning assumptions.

4.6 Conclusions

In this chapter, an overview is given on general siting topics and how they apply to the AP1000 plant. The foremost intent of this chapter is to establish that characteristics of a generic UK site will not lead to increased risks to the population from the AP1000 design.

This chapter's overview provides confidence that the generic site characteristics in the UK will not lead to materially increased radiological or other risks from the AP1000 design throughout the life cycle of the nuclear site. The evaluations forming this confidence are based on the assessment of relevant AP1000 plant parameters against UK generic site data, with consideration of the following critical areas as forming the basis for defining a UK generic site:

- Meteorological conditions
- Geological and hydrogeological conditions
- Topography
- Hydrological conditions
- Access to suitable sources for cooling
- Human populations
- Potentially hazardous man-made installations or hazardous human activities
- Site dimension

Additionally, supporting detailed assessment of site external hazards can be found in Chapter 12, including an assessment of the potential impact of a future climate change. The influence and interactions of the AP1000 plant on the wider environment is described in the UK AP1000 Environment Report (Reference 4.1, Section 5.3), including consideration of nonhuman species and sensitive habitats.

From these assessments, assurance is provided that the natural environmental conditions for a generic site in the UK are consistent with the safe operation of the AP1000 plant and will not lead to elevated risk to either the human population or local environs.

Further, a set of key site environmental parameters associated with the UK generic site has been presented. This chapter then sets out the arguments that establish that the UK generic site concept is a suitable basis for a generic assessment of the AP1000 design and will form a sound basis for any future specific site licensing.

Wind Speed	
Operating basis	64.82 m/sec (145 mph) (3-second gust); importance factor 1.15 (Class 1), 1.0 (non-Class 1); exposure C; topographic factor 1.0
Tornado	134.11 m/sec (300 mph)
Seismic	
Certified seismic design response spectra	0.30g peak ground acceleration [c]
Fault displacement potential	No potential fault displacement considered beneath the Seismic Category I and Seismic Category II structures and immediate surrounding area. The immediate surrounding area includes the effective soil-supporting media associated with the Seismic Category I and Seismic Category II structures.
Soil	
Average allowable static bearing capacity	The allowable bearing capacity, including a factor of safety appropriate for the design load combination, shall be greater than or equal to the average bearing demand of 426.1 kPa (8900 lb/ft²) over the footprint of the nuclear island at its excavation depth.
Dynamic bearing capacity for normal plus safe shutdown earthquake	The allowable bearing capacity, including a factor of safety appropriate for the design load combination, shall be greater than or equal to the maximum bearing demand of 1675.8 kPa (35000 lb/ft²) at the edge of the nuclear island at its excavation depth. or Site-specific analyses demonstrate a factor of safety appropriate for normal plus safe shutdown earthquake loads.
Shear wave velocity	Greater than or equal to 304.8 m/sec (1000 ft/s) based on minimum low-strain soil properties over the footprint of the nuclear island at its excavation depth.

Table 4-9. AP1000 Standard Site Design Parameters (cont.)

Soil (cont.)	
Lateral variability	Soils supporting the nuclear island should not have extreme variations in subgrade stiffness. This may be demonstrated by one of the following: 1. Soils supporting the nuclear island are uniform in accordance with Regulatory Guide 1.132 if the geologic and stratigraphic features at depths less than 36.58 m (120 ft) below grade can be correlated from one boring or sounding location to the next with relatively smooth variations in thicknesses or properties of the geologic units. 2. Site-specific assessment of subsurface conditions demonstrates that the bearing pressures below the nuclear island do not exceed 120% of those from the generic analyses of the nuclear island at a uniform site. 3. Site-specific analysis of the nuclear island basemat demonstrates that the site-specific demand is within the capacity of the basemat. As an example of sites that are considered uniform, the variation of shear wave velocity in the material below the foundation to a depth of 36.58 m (120 ft) below finished grade within the nuclear island footprint and 12.19 m (40 ft) beyond the boundaries of the nuclear island footprint meets the criteria in the case outlined below: Case 1: For a layer with a low strain shear wave velocity greater than or equal to 762 m/sec (2500 ft/s), the layer should have approximately uniform thickness, should have a dip not greater than 20 degrees, and should have less than 20% variation in the shear wave velocity from the average velocity in any layer.
Liquefaction potential	No liquefaction considered beneath the Seismic Category I and Seismic Category II structures and immediate surrounding area. The immediate surrounding area includes the effective soil-supporting media associated with the Seismic Category I and Seismic Category II structures.
Minimum soil angle of internal friction	Greater than or equal to 35 degrees below footprint of nuclear island at its excavation depth.
Missiles	
Tornado	1814.4 kg (4000 lb) automobile at 46.94 m/sec (105 mph) horizontal, 33.1 m/sec (74 mph) vertical 124.7 kg (275 lb), 203.2 mm (8 in) shell at 46.94 m/sec (105 mph) horizontal, 33.1 m/sec (74 mph) vertical 25.4 mm (1 in) diameter steel ball at 46.94 m/sec (105 mph) horizontal and vertical

Table 4-9. AP1000 Standard Site Design Parameters (cont.)

Flood Level	Less than plant elevation 100.0 m (100 ft)
Ground Water Level	Less than plant elevation 99.39 m (98 ft)
Plant Grade Elevation	Less than plant elevation 100.0 m (100 ft) except for portion at a higher elevation adjacent to the annex building
Precipitation	
Rain	525.8 mm/hr (20.7 in/hr) [1-hr 2.6 km^2 (1-mi^2)PMP]
Snow/ice	3.6 kPa (75 lb/ft^2) on ground with exposure factor of 1.0 and importance factors of 1.2 (Class 1) and 1.0 (non-Class 1)
Atmospheric Dispersion Values - χ/Q(e)	
Site boundary (0 – 2 hr)	$\leq 5.85 \times 10^{-4}$ sec/m^3
Site boundary (annual average)	$\leq 2.0 \times 10^{-5}$ sec/m^3
Low population zone boundary 0 – 8 hr 8 – 24 hr 24 – 96 hr 96 – 720 hr	 $\leq 2.2 \times 10^{-4}$ sec/m^3 $\leq 1.6 \times 10^{-4}$ sec/m^3 $\leq 1.0 \times 10^{-4}$ sec/m^3 $\leq 8.0 \times 10^{-5}$ sec/m^3
Population Distribution	
Exclusion area (site)	0.8 km (0.5 mi)

Notes:

(a) Maximum and minimum safety values are based on historical data and exclude peaks of less than 2 hours duration. Class 1 SSCs are designed for maximum and minimum safety values.

(b) The maximum normal value is the 1 percent seasonal exceedance temperature. The minimum normal value is the 99 percent seasonal exceedance temperature. The minimum temperature is for the months of December, January, and February in the northern hemisphere. The maximum temperature is for the months of June through September in the northern hemisphere. The 1 percent seasonal exceedance is approximately equivalent to the annual 0.4 percent exceedance. The 99 percent seasonal exceedance is approximately equivalent to the annual 99.6 percent exceedance.

(c) See Chapter 16.

(d) The noncoincident wet bulb temperature is applicable to the cooling tower only.

(e) For the AP1000 plant, the terms “site boundary” and “exclusion area boundary” are used interchangeably. Thus, the χ/Q specified for the site boundary applies whenever a discussion refers to the exclusion area boundary.

(f) Not Used.

(g) The containment pressure response analysis is based on a conservative set of dry bulb and wet bulb temperatures. These results envelop any conditions where the dry bulb temperature is 46.11°C (115°F) or less and the wet bulb temperature of less than or equal to 30.06°C (86.1°F).

5 ENGINEERING PRINCIPLES

5.1 Introduction

Chapter 6 describes the systems that make up the AP1000 design. The design is based on sound engineering principles and extensive operating experience with similar plants.

The purpose of this chapter is to describe the measures used to demonstrate that the systems, structures, or components (SSCs) provided by the AP1000 design are fit for purpose – that they are designed, manufactured, installed, commissioned, maintained, and tested in accordance with their safety importance.

The safety importance of an SSC is determined by fault studies (see Chapter 8 & 9), probabilistic safety assessment (PSA) (see Chapter 10), Internal Hazards (see Chapter 11) and External Hazards assessments (see Chapter 12). These studies assign the functions provided by an SSC to a safety function category and the SSC itself to a safety class or assign the function and its SSCs as general non-safety (GNS). The categorisation and classification scheme used for the AP1000 plant in the United Kingdom (UK) is described in Section 5.2.

Codes and standards for design, manufacture, installation, commissioning, maintenance, and testing are specified as appropriate to each safety class. This is the mechanism that allows SSCs to be treated throughout their life in a way that is commensurate with their safety importance. Many of the SSCs in the AP1000 plant have been designed using United States (US) codes and standards. As part of the development of this Pre-Construction Safety Report (PCSR), an exercise has been undertaken to demonstrate that those codes and standards are appropriate to support the design, construction, manufacture and future safe operation of AP1000 reactor plants in the UK. Codes and standards are the subject of Section 5.3.

Required SSCs have to be able to meet their performance requirements (i.e., provide their safety functions) in both normal and abnormal conditions. The equipment qualification programme provides confidence that the relied upon SSCs can meet their performance requirements under normal operating conditions and in the environmental conditions expected to occur in a design basis event (DBE), including seismic events. The equipment qualification programme used for the AP1000 plant is described briefly in Section 5.8.

SSCs also need to perform reliably. The methodology used to assess the reliability of SSCs is described in Section 5.9. Particular attention is paid to passive systems in Section 5.10, since these are different from the systems normally associated with pressurised water reactors (PWRs).

The substantiation of the claims made against individual SSCs is the subject of Chapter 8 of this PCSR.

5.2 United Kingdom Categorisation and Classification Methodology

This section identifies the criteria used to classify the AP1000 plant SSCs that play an important part in ensuring nuclear safety in terms that are consistent with the ONR safety assessment principles.

Classification of SSCs defines the quality requirements placed on those SSCs during design, manufacture, and through life. In particular, the safety class of a given SSC is used to determine which codes, standards, and seismic design considerations are appropriate to the design and manufacture of that SSC.

The relevant ONR safety assessment principles for nuclear safety are used to categorise the safety functions required to maintain safety in the event of specific fault sequences by identifying which SSCs deliver these safety functions and classifying them accordingly.

5.2.1 Categorisation of Safety Functions

Relevant ONR safety assessment principles for nuclear safety recommend that the method for categorising safety functions takes the following into account:

- The consequence of failing to deliver the safety function, including both the direct consequence and the potential for a functional failure to initiate further faults or exacerbate the consequences of existing faults.
- The extent to which the function is required, either directly or indirectly, to prevent, protect against, or mitigate the consequences of initiating faults.
- The likelihood that the function will be called upon.

The categorisation of safety functions is functional. It is not affected by how the safety function is delivered by the design. Categorisation is also not affected by whether there is redundancy, diversity, or independence within the design.

The categorisation process for the AP1000 plant is performed by identifying the high-level safety function that the specific SSC delivers or supports. These safety functions are categorised A to C, based on the nuclear safety significance of delivery failure (Reference 5.2).

5.2.1.1 Category A Safety Functions

A Category A safety function is a principal means of maintaining nuclear safety. Category A safety functions are those utilised to achieve and maintain a nonhazardous, stable state for at least 72 hours following an initiating event. Category A safety functions are fulfilled by those systems analysed in the plant design basis accident (DBA) and those systems identified as having some importance to safety as discussed in Section 5.9.1. Failure to maintain a Category A safety function has the potential to result in significant core damage, radiation exposure >20 mSv to onsite personnel, or radiation exposure >1 mSv to the offsite population.

It should be noted that onsite personnel radiation exposure is affected by plant design, operation, and radiological access controls. These efforts form an integrated approach to minimising onsite personnel exposure and meeting Category A dose limits.

Examples of Category A safety functions include the following:

- Removing the nuclear core decay (or residual) heat from the reactor coolant during normal operations and accident conditions (including those SSCs that provide the heat sink for the removal of decay heat from the reactor coolant).
- Maintaining the integrity of the reactor coolant system (RCS) pressure boundary, including mitigating RCS overpressure during normal operations and accident conditions.
- Maintaining the integrity of the containment, thereby minimising the release of radioactive material from the containment.
- Controlling subcritical reactivity of the fuel in the reactor core and the spent nuclear fuel in the spent fuel pool and associated structures during normal operations and accident conditions.
- Maintaining reactor coolant inventory.
- Maintaining habitability of the main control room.
- Maintaining spent fuel integrity such that significant radioactive releases do not occur (as a result of impacts or overheating).
- Protecting SSCs from internal/external hazards that would directly and inevitably result in loss of a principal means of fulfilling a Category A safety function.
- Functions that prevent unacceptable consequences due to the failure or spurious actuation of an SSC and for which no other Category A function exists.
- Functions required to provide information and control capabilities that allow specified manual actions necessary to reach the nonhazardous stable state.
- Functions to warn personnel or to ensure personnel safety during or following events that involve or result in release of radioactivity, or risk of radiation exposure >20 mSv.
- Permanently installed structures used to provide shielding per the plant design basis to meet exposure requirements.

5.2.1.2 Category B Safety Functions

A Category B safety function is a significant contributor to nuclear safety. Category B safety functions are utilised to do the following:

- Maintain the nonhazardous stable state after 72 hours following an accident.
- Prevent radiological exposure to onsite personnel and the offsite population from exceeding the design basis limits.
- Mitigate beyond DBAs.

Alternatively, failure to maintain the safety function may reduce safety margins significantly, with radiation exposure less than Category A limits, but greater than normal operating limits.

Examples of Category B safety functions include the following:

- Preventing the release of radioactive waste material from onsite radioactive waste systems.
- Protecting against internal/external hazards that could, as part of a sequence of failures, result in the loss of one of the Category B safety functions, such as preventing the spread of fire such that the ability to deliver a specific Category B function is lost.
- Maintaining Category A safety functions after 72 hours following an accident.
- Controlling levels of radioactivity released into the environment.
- Functions that provide a backup or alternate actuation of a Category A safety function.
- Functions that considerably reduce the frequency of an initiating event, as identified by the DBA analysis.
- Functions provided to reach and maintain a stable state beyond DBAs, as specified in station operating procedures.
- Functions provided to minimise the consequences of severe accidents in accordance with the system design basis.
- Plant process control functions that maintain the main process variables within the limits assumed in the safety analysis. Failure of this function could lead directly to the actuation or operation of an SSC that delivers a Category A safety function.
- Functions that continuously monitor the availability of Category A safety functions for proper operation or alert control room staff of failures.

5.2.1.3 Category C Safety Functions

Category C safety functions are those safety functions that may make a contribution to nuclear safety, but are not categorised as Category A or Category B. Since the removal of nuclear heat during normal operation prevents reactor trips and the actuation of Category A and Category B functions, these normally operating duty systems are recognised as being important to safety.

Examples of Category C safety functions include the following:

- Removing nuclear heat from the reactor coolant during normal operation (including providing a heat sink for those systems involved in the removal of heat from the reactor coolant during normal operation). Failure of this function would result in a short-term power manoeuvre, thus affecting nuclear safety.
- Controlling reactivity to support normal power operation.
- Providing long-term support of Category A or B functions.

- Controlling the level of radioactivity within the reactor coolant.
- Monitoring radioactivity released into the environment.
- Functions that provide continuous or intermittent tests or monitoring of Category B functions to indicate their continued availability for operation and to alert control room staff to failures.
- Functions that monitor for the occurrence of, and alert personnel to take mitigating action following, internal hazards events (e.g., fire, flood).
- Functions that alert personnel of, or ensure personnel safety during or following, events that involve or result in the release of radioactivity, or the risk of radiation exposure <20 mSv.
- Functions that monitor for the occurrence of, and alert personnel to take mitigating action following, natural events (e.g., seismic disturbance, extreme wind).
- Functions that provide access control for the nuclear power plant.

5.2.2 Classification of Systems, Structures, and Components

Relevant ONR safety assessment principles require that the method for classifying the safety significance of an SSC be primarily based on deterministic methods, complemented where appropriate by probabilistic methods and engineering judgment, with account taken of factors such as the following:

- The category of safety function(s) to be performed by the SSC.
- The consequences of the failure of the SSC to perform its function.
- The probability that the SSC will be called upon to perform a safety function.
- The time following any initiating fault at which, or the period throughout which, the SSC will be called upon to operate.

Appropriately designed interfaces should be provided between SSCs of different categories and classes to ensure that any failure in a lower-class SSC will not propagate to an SSC of a higher class. SSCs providing the function to prevent the propagation of failures should be assigned to the higher class.

Auxiliary services that support components of a system important to safety should be considered part of that system and should be classified accordingly unless failure does not prejudice successful delivery of the safety function.

For the AP1000 plant, once a safety function category has been assigned to a specific SSC in line with the safety function it delivers (or supports the delivery of), the SSC is assigned a Safety Class between 1 and 3. The safety class takes the safety category into account, and considers the extent to which the SSC supports the safety function with which the safety category is associated. At this point, consideration is given to functional defence-in-depth, diversity, and redundancy in the plant design.

It should be noted the wherever an SSC satisfies the requirements of multiple categories and/or classes, that SSC may be separated into functional subcomponents. This approach will minimise the amount of conflicting or redundant classifications while allowing the appropriate safety classification to be applied based on the SSC's function.

Functions that do not satisfy the criteria defined in these subsections will be considered to have no impact on nuclear safety and as a result will be classified as GNS in system documentation.

5.2.2.1 Class 1 Systems, Structures, and Components

Class 1 SSCs provide the principal means of fulfilling a Category A safety function.

These SSCs are standby or normally operating SSCs required to protect against or mitigate the consequences of DBAs consistent with the design basis safety analysis. These SSCs provide the principal means for the protection of the health and safety of the public and workforce and are selected using deterministic methods. The reliability of these features is confirmed using a probabilistic safety analysis.

5.2.2.2 Class 2 Systems, Structures, and Components

A Class 2 SSC is a principal means of fulfilling a Category B safety function or a significant contributor to fulfilling a Category A safety function.

A significant contributor is defined as an SSC that provides a supplementary capability for those SSCs utilised in the principal response to DBAs. Class 2 SSCs are identified using the AP1000 plant reliability evaluations described in Section 5.9.

5.2.2.3 Class 3 Systems, Structures, and Components

Class 3 SSCs are all other SSCs not included in Class 1 or 2 that contribute to maintaining nuclear safety, and include SSCs identified to support the operation of Classes 1 and 2 SSCs.

5.2.2.4 General Non-Safety Systems, Structures, and Components

SSCs classified as GNS are those that do not contribute to maintaining nuclear safety, as determined by the safety case.

5.2.3 Summary of the UK Safety Categorisation and Classification Methodology

Table 5-1 illustrates the UK safety category and classification combinations that can be assigned to the AP1000 plant SSCs.

In addition, SSCs that do not contribute to nuclear safety in accordance with the AP1000 plant safety case are simply referred to as GNS and will not be categorised or classified separately.

5.3 Codes and Standards

The classification methodology described in Section 5.2 provides the rationale for the application of codes and standards appropriate for the safety importance of specific SSCs.

The AP1000 Equivalence/Maturity Study of the U.S. Codes and Standards (Reference 5.5) contains a fuller discussion of the codes and standards used for Class 1 and 2 SSCs. Application of codes and standards for electrical equipment, Control and Instrumentation are described in Chapter 18 and 19 and in Reference 5.19 respectively.

5.3.1 Codes and Standards for Class 1 Systems, Structures, and Components

Class 1 SSCs use recognised nuclear industry codes and standards. The majority of Class 1 SSCs are designed and manufactured to American Society of Mechanical Engineers (ASME) Code, Section III, Class 1, 2, or 3 for mechanical applications; International Electrotechnical Commission (IEC) codes and Institute of Electrical and Electronics Engineers (IEEE) Class 1E codes are used for electrical and control and instrumentation (C&I) applications.

In some instances, no nuclear standard has been identified because of the nature of the SSC. In these cases, "manufacturer's standards" are used, meaning the capability of the SSC is developed through engineering practice. Examples of Class 1 SSCs for which this is the case include the following:

- In-containment refuelling water storage tank (IRWST) gutter
- IRWST screens
- Control rod clusters

Table 5-22 provides a representation of relevant codes and standards associated with Class 1 SSCs. Application of codes and standards for electrical equipment, Control and Instrumentation are described in Chapter 18 and 19 respectively and in Reference 5.19.

5.3.2 Codes and Standards for Class 2 Systems, Structures, and Components

Class 2 SSCs use recognised Class 2 nuclear industry codes and standards where applicable. In some cases, based on applicability, no Class 2 nuclear industry codes or standards may be identified. In these cases, recognised industry codes and standards based on the type of SSC, or "manufacturer's standards" are used. The assessment for the use of recognised industry codes and standards is provided within Reference 5.28.

Table 5-3 presents a representation of relevant codes and standards associated with Class 2 SSCs. Application of codes and standards for electrical equipment, Control and Instrumentation are described in Chapter 18 and 19 respectively and in Reference 5.19.

5.3.3 Codes and Standards for Class 3 Systems, Structures, and Components

This classification uses the recognised non-nuclear industry codes and standards such as those shown in Table 5-4.

5.4 Quality Assurance

The three levels of safety classification are associated with the use of different levels of quality assurance (QA) requirements.

1. Recognized nuclear industry QA programme

2. Enhanced industry standard QA programme
3. Industry standard QA programme

Class 1 SSCs are designed and supplied in accordance with a recognised nuclear industry QA programme, whereas Class 2 SSCs are designed and supplied in accordance with an enhanced industry standard QA programme.

This enhanced QA is applicable to the Class 2 SSCs where the QA requirements will provide a reasonable assurance of improved SSC reliability. These SSCs are typically active (for example, pumps, fans, active valves, switchgears) and have been identified through deterministic and probabilistic methods.

For those components where the application of enhanced QA is not expected to result in an appreciable increase in reliability, the application of industry standard QA is acceptable. These are typically passive components (for example, piping, tanks, and heat exchangers) and are inherently rugged.

Class 3 SSCs are designed and supplied in accordance with an industry standard QA programme.

The requirements for the various QA programmes are given in Reference 5.2.

5.5 Seismic Categorisation

AP1000 plant SSCs are categorised with respect to the requirements to withstand the effects of an earthquake and are designated as seismic Category I (C-I), seismic Category II (C-II), and non-nuclear seismic (NNS) (Reference 5.2).

Seismic C-I applies to both function and integrity; seismic C-II applies only to integrity. NNS SSCs, whose collapse could result in a loss of function of Class 1 SSCs, must be designated as seismic C-II. Additionally, seismic C-II is applied to SSCs whose failure could incapacitate plant operators in the control room.

The three levels of safety classification are associated with the application of seismic categorisation of SSCs.

5.5.1 Seismic Categorisation of Class 1 Systems, Structures, and Components

Class 1 SSCs are designated as seismic C-I components. Since the seismic C-I designation applies to SSC function and integrity, the application of seismic C-I ensures that SSCs required to mitigate plant DBAs maintain their safety function following an earthquake and following exposure to environmental conditions that result from a DBA.

Conduit embedded in concrete does not perform a safety or seismic function. The purpose of embedded conduit is only to provide a channel for cables to pass through the concrete structure. The concrete structures themselves are qualified as Seismic C-I to withstand the appropriate seismic loads and hence allow the circuits to continue to perform their intended safety function.

5.5.2 Seismic Categorisation of Class 2 Systems, Structures, and Components

Class 2 SSCs are generally categorised as NNS; however, seismic C-II designations are applied in the following instances:

- Where a Class 2 SSC provides support for a Category A function after 72 hours following an accident. Note that SSCs stored offsite provide the primary capability for these functions. They will be stored far enough away from the site that they would not be subjected to the seismic loadings and still be transported to the site within 72 hours. As a result, the purpose of the installed post 72 hour SSCs is to provide reasonable assurance that they will be available within 72 hours of a seismic event and thereby reduce the need to resort to the offsite SSCs. The identification of the SSCs that require the seismic C-II designation has been performed using the deterministic and probabilistic methods described in Section 5.9. Because of this limited purpose the seismic C-II requirements are applied as follows:
    - For SSCs that are inherently rugged, such as pumps (Passive containment cooling system (PCS) recirculation pumps), diesel generators (Ancillary Diesel Generator), pressure vessels, or piping/valves, the only requirements are that their building is seismic C-II and the connection to the building is as strong as the building.
    - For less rugged SSCs such as large atmospheric storage tanks (Ancillary Water Storage Tank), the SSC itself will be classified as seismic C-II and will be analysed for the seismic loads.
- Where seismic C-II/I conditions exist, as described in Section 5.5.4.

5.5.3 Seismic Categorisation of Class 3 Systems, Structures, and Components

Class 3 SSCs are generally categorised as NNS; however, seismic C-II designations are applied where seismic C-II/I conditions exist, as described in Section 5.5.4.

5.5.4 Seismic Category II/I

If the failure of the integrity of an SSC in the event of a seismic event can result in an unacceptable interaction with a Class 1 SSC or an incapacitating injury to occupants of the control room, the SSCs are designated as seismic C-II/I (II over I).

Seismic C-II/I is associated with the support or anchorage of SSCs and assigned as a function of plant layout. Analyses are performed in accordance with the AP1000 Design Criteria for Protection from Seismic Interaction (Reference 5.3) on a system level and do not reflect SSC design requirements. Therefore, the application of the seismic C-II/I is not required to be reflected in SSC material and equipment specifications and procurement documentation other than the SSC supports or anchors themselves.

The requirements of seismic C-II/I are superseded by those of the seismic C-I designation, which applies to both integrity and functional requirements. Therefore, the seismic C-II/I designation does not apply to Class 1 SSCs.

5.6 Limits and Conditions

The design of the AP1000 plant includes consideration for a broad spectrum of plant-level

events to protect the health, safety, and welfare of the public to a level that is as low as reasonably practicable (ALARP). To ensure the operation of the plant is consistent with the safety case, limits and conditions are required. Application of the safety case limits and conditions will be completed during design and operating phases of plant life through the development and implementation of Operating Rules (ORs).
This section provides the description of the AP1000 ORs, the methodology for development, and the process for transition into the operating phase. ORs are a dynamic set of limits and conditions for plant operation that will be subject to plant-specific development and ongoing maintenance and upkeep over plant life. Therefore, this section does not present the final complement of ORs, as this will be the ultimate responsibility of the licensee during nuclear site licensing. Rather, this section will describe processes, identify key references and supporting documentation, and demonstrate adequacy of the AP1000 ORs for safe operation of the plant.

This section is intended to provide a high-level description of the considerations taken into account in the development of the AP1000 ORs. The content will be organised in the following manner; first the overall AP1000 limits and conditions methodology will be described, including process flow diagrams. Afterwards, each OR will be described in detail including:

- a general description
- detail of interfaces between ORs
- discussion of the interface between the generic design assessment (GDA) review and Licensee actions

This process will demonstrate adequate limits and conditions have been, or will be, developed by means of the creation of ORs for safe operation of the plant. It should be noted that many ORs are site-specific, or will be customised at the discretion of the Licensee; therefore, site considerations to the ORs will be developed as a part of the nuclear site licensing process.

The limits and conditions process is described in Reference 5.25.

5.6.1 Background

This development of the AP1000 ORs provides a link between the analysis documented in the UK AP1000 safety case and the eventual limits and conditions it implies and requires for the plant to be operated in accordance with the safety case by the licensee. The key construct within the AP1000 plant safety case is based on fault studies, in particular the design basis (DB) assessments that rely on transient and other analyses to demonstrate that the dose goals are met consistent with the likelihood of the event.

These analyses make a number of assumptions relating to normal plant conditions and to the performance and reliability of SSCs provided in the design to prevent or mitigate DB events. These assumptions relate to safety analyses for all plant operating modes (operating states) and to all major sources of radioactivity (i.e., the reactor, spent fuel, and Radwaste) and constitute the limits and conditions that must be observed in order for the analyses to remain valid and applicable during the lifetime of the plant.

Arrangements for moving the UK AP1000 safety case to an operating regime require that all limits and conditions assumed in the safety analysis are captured, consolidated, and

prioritised in documentation and procedures used for plant operation, thus providing the link between the analysis documented in the safety case and eventual limits and conditions identified so that the licensee can operate the plant in accordance with the safety case.

As an integral part of the development of the standard design of the AP1000 plant, limits and conditions for operation are identified, documented, and included in the arrangements for transfer of information between the vendor and licensee for licensing and operation. Limits and conditions for the standard AP1000 design are used to validate that the operating conditions of the systems and reactor are within those analysed in their respective plant operating mode (Table 5-5).

5.6.2 Methodology

The approach for defining the required limits and conditions for safe operation of the AP1000 plant involves a three staged approach.

- Demonstration of safety case
- Evaluation of plant characteristics
- Development of AP1000 operating rules

These stages provide the framework for the Design Phase of the AP1000 plant.

5.6.2.1 Demonstration of Safety Case

The Demonstration of Safety Case stage is mainly comprised of the claims from the AP1000 fault and accident analysis as documented in PCSR Volume 3, which include DBA and PSA insights. The output of this stage of the process is identification of design requirements necessary to satisfy safety and functional performance goals.

It should be noted that there are various disciplines and analysis inputs that comprise the assessment, and the evaluation of limits and conditions is not intended to promote fault and accident analysis as the ultimate review of the adequacy of these parameters. Rather, fault and accident assessment represents an integrated view of the plant response to DB events and provides a convenient path to identify those parameters of significance that will be evaluated for inclusion into the ORs.

5.6.2.2 Evaluation of Plant Characteristics

The Evaluation of Plant Characteristics stage reviews many different characteristics identified as design requirements; i.e., “Safety & Functional Requirements”. This multi-faceted review ultimately results in the identification of plant parameters that are included in the AP1000 ORs. Characteristics reviewed for incorporation into the ORs include:

- Plant Geometry; e.g., critical dimensions
- Initial Conditions
- Fuel Design and Performance Parameters
- C&I Functions and Setpoints

- System Performance Characteristics

The limits and conditions that arise from the safety case are attributed to four (4) distinct groups:

- Initial or Bounding Conditions for Transient or Accident Analyses
- Consequences of Abnormal Events
- SSC Performance
- SSC Availability or Integrity

Development of the AP1000 ORs necessitates the review of the plant characteristics with regard to each group for consideration.

5.6.2.2.1 Initial or Boundary Conditions for Transient or Accident Analyses

The transient analyses performed as part of the DB analysis and PSA make a number of assumptions concerning initial and boundary conditions. The validity of the safety case based on these analyses depends on the plant remaining within the operating envelope defined by these limits and conditions.

Examples of such limits and conditions are reactor pressure, containment temperature, etc.

5.6.2.2.2 Consequences of Abnormal Events

In some of the fault studies presented in the safety case, the assessed consequences make assumptions about such plant characteristics as activity levels in parts of the system or fuel cladding condition. The validity of the consequence calculations, and hence compliance with dose targets, relies on the plant being operated within the envelope defined by these implied limits and conditions.

Examples of such limits and conditions are primary circuit activity levels and fuel operating limits, such as reactor coolant flow, reactor coolant loop pressure, core power shape limits, peak cladding temperature (PCT), and departure from nucleate boiling ratio (DNBR). In addition, there are limits and conditions related to safety limits and accident management derived from the severe accident assessment (SAA) and documented in plant emergency operating procedures (EOPs).

5.6.2.2.3 SSC Performance

The DB fault analyses presented in the safety case specify the operation of various SSCs within their design parameters to mitigate the effects of the transient in view. These design parameters constitute limits and conditions on the operation of the identified SSCs.

Examples of such limits and conditions are the temperature, available volume, and boron concentration of the water in the core makeup tanks (CMTs), the available volume of water in the passive containment cooling water storage tank for containment cooling, or available water inventory in the spent fuel pool for spent fuel cooling.

5.6.2.2.4 SSC Availability or Integrity

The demonstration of compliance with probabilistic targets makes claims on the availability and integrity of risk-important SSCs identified in the safety case. Availability of SSCs is dominated by examination, maintenance, inspection, and testing (EMIT) activities and implies limits and conditions on such things as test intervals and repair times. Integrity is dominated by environmental effects such as load conditions, temperature, humidity, radiation levels, or chemistry effects such as pH or oxygen levels. The control of such environmental effects implies limits and conditions on the corresponding environmental parameters.

The latter consideration is particularly important for high integrity structural items such as the reactor pressure vessel. Limits and conditions relating to EMIT activities will provide the basis of the maintenance schedule for the plant.

5.6.2.3 Development of the AP1000 Operating Rules

The Development of the AP1000 ORs stage is grouped into six (6) categories that represent design phase products and ultimately facilitate transition to the operating phase. The ORs categories are:

- Design Transients (Loading Conditions)
- Fuel Design Requirements
- Operating Technical Specifications (OTS)
- Chemical and Radiochemical Specifications
- In-Service Inspection
- Periodic Testing (PT)

When evaluating any single plant parameter, it is possible that the parameter will apply to multiple groups since the operating phase controls may be representative of various functions, disciplines, or work streams. For example, the concentration of a hypothetical chemical parameter may be a consideration for fuel design and core operation (Fuel Design Requirements), require an administrative control in the main control room (MCR) OTS, and input into a chemistry programme trend or action level (Chemical and Radiochemical Specifications). It is expected that a plant parameter will apply to multiple OR categories with an increase in complexity or safety significance.

5.6.2.3.1 Interfaces Amongst Operating Rule Groups

As plant parameters may be applicable to multiple categories of the ORs as a function of their disciplinary interfaces and complexity, it is expected that these categories of the ORs formally interface to preserve these ties and reduce the likelihood of incomplete application of the associated limits and conditions. The OTS represent the primary operator interface document and thereby contains the majority of these programmatic controls.

Examples of these interfaces are listed below:

- Surveillance Requirements (SRs)

- Administrative Programs
- Maintenance Programme and Clearance Process
- Operating Procedures

5.6.3 Operating Technical Specifications (OTS)

5.6.3.1 AP1000 Plant Application

The AP1000 plant design applies passive safety design principles as the primary means to protect the health, safety, and welfare of the plant workers and the public. Active SSCs are also used in the plant design and provide first-actuation support prior to the operation of the passive features in completion of safety functions. Therefore, the development of the OTS for the AP1000 must reflect the application of passive and active technologies consistent with the plant safety case.

To reflect the distinction between primary SSCs (Class 1), and supporting SSCs (Class 2 and Class 3), the AP1000 OTS will be maintained by the Licensee in tiers:

- Tier 1 Technical Specifications (TS)
- Tier 2 Technical Requirements Manual (TRM)
- Tier 3 General Availability Controls (GAC)

While TS are typical of conventional applications, the TRM and GAC will be characterised by less restrictive action completion times and fewer surveillance requirements consistent with the role of these SSCs in the AP1000 plant safety case.

Criteria for the TRM will reflect a combination of deterministic and probabilistic methods and will include considerations for defence in depth (DID) functions, post-72 hour operations, and severe accident conditions.

Criteria for the GAC will reflect deterministic, probabilistic, programmatic, and operating experience-based methods and will include considerations for normal plant operational conditions and the operation of Class 3 SSCs.

Due to potential for overlapping scope, commonality between DID and normal operating systems, and the lack of a primary safety function or required support function within the scope, the Licensee may opt to physically locate the TRM and GAC content within the same volume for ease of use by operators.

5.6.3.2 General Principles

The OTS align with other portions of the ORs and typically serve the role of interface control with the MCR for critical functions or those with a high-level of complexity. The objective of OTS is to identify limits and conditions to ensure that normal operation of the reactor remains consistent with the safety case. Accordingly, the OTS are assembled with the following attributes:

- Normal operating limits and conditions for critical plant parameters and associated SSCs, referred to as Limiting Conditions for Operation (LCOs)

- Applicability of the operating limit or condition based on plant operating mode
- Action requirements applicable in the event a normal operating limit or condition is exceeded.
- SRs to ensure the corresponding LCO is satisfied.

5.6.3.3 Technical Specification Selection Criteria

As discussed in Section 5.6.2, plant parameters are screened for inclusion to the ORs. Subsequently, these parameters are reviewed for inclusion into the OTS. It should be clarified that a plant parameter that is selected for the ORs will be included in at least one of the OR categories; there is no general requirement that a plant parameter be present in the OTS as these parameters are subject to an application-specific criteria.

Application of the TS selection criteria allows for the identification of applicable parameters and those SSCs required to fulfil the operating requirements. The selection criteria is applied to each operating mode to cover the range of normal plant operation.

Criterion #1

Installed instrumentation that is used to detect, and indicate in the control room, a significant abnormal degradation of the reactor coolant pressure boundary.

Criterion #2

A process variable, design feature, or operating restriction that is an initial condition of a design basis fault or accident analysis that either assumes the failure of, or presents a challenge to, the integrity of a fission product barrier.

Criterion #3

A SSC that is part of the primary success path and which functions or actuates to mitigate a design basis fault or accident that either assumes the failure of, or presents a challenge to, the integrity of a fission product barrier.

Criterion #4

A structure, system, or component which operating experience or probabilistic safety assessment has shown to be significant to public health and safety.

5.6.3.4 Technical Requirements Manual Selection Criteria

TRM content is selected using a combination of deterministic and probabilistic criteria consistent with Appendix A of the AP1000 UK safety categorisation and classification methodology (Reference 5.2); this includes consideration of the assessment of non-Class 1 SSCs (Section 5.9.1.1) and the reliability assurance programme (Section 5.9.1.2). The criteria for TS is generally applicable, especially Criterion 4, to the selection of TRM controls, with a focus on the role of the SSC as a supporting function.

Attributes considered in the TRM selection include:

- Backup long-term plant shutdown support (Post-72 hour operation)
- SSCs that do not meet the TS risk-important criteria but do have some risk importance. This criteria applies to both core melt prevention and core melt mitigation functions.

5.6.3.5 General Availability Control Selection Criteria

GAC content is selected using a combination of deterministic, probabilistic, programmatic, and operating experience-based criteria. As the GAC is a supporting third-tier availability control, the rigour applied to the operating limitations, remedial actions, and surveillances is correspondingly reduced. Typically, GAC items consist of condition-based assessments (e.g., equipment availability) using a broad spectrum of surveillance techniques, such as instrumentation, alarms, routine EMIT tasks, and operator observations.

Examples of design features typical of GAC inclusion are:

- Fire protection programme availability controls
- Normal operating non-Class 1 ventilation functions; area temperature monitoring
- Operation of significant Class 3 SSCs
- Offsite emergency response facilities

5.6.3.6 Applicability of Limiting Conditions for Operation

The OTS criteria is applied to each plant operating mode consistent with the evaluation of DB events in the safety case. Operating modes are consistent across the plant design, as defined in Section 5.6.1.

Due to the physical nature of the plant design and the design attributes of the associated SSCs, many design features are not applicable to all operating modes; for example, passive residual heat removal (PRHR) requires a sufficient thermal gradient to produce the passive natural circulation, and therefore, is not applicable to operating modes with low temperature reactor coolant and the RCS open (e.g., refuelling).

5.6.3.7 Actions Required when Inoperable

Operability is defined as the capability of a SSC of performing its specified safety function(s). This definition considers the function of all necessary controls, instrumentation, normal or emergency electrical power, cooling and seal water, lubrication, and other auxiliary equipment that are required for the SSC to perform its specified safety function(s).

As a by-product of identifying LCOs for SSCs required to complete safety functions, the OTS process necessitates the identification of specific remedial actions in the case that the normal operating limits are exceeded; this condition is referred to as inoperable.

For each LCO, actions and completion times are defined. Actions and completion times are defined so that the plant can be maintained in a slightly degraded condition without compromising plant safety. Completion times are derived using deterministic and

probabilistic considerations. The speicified consequences of not meeting completion times varies with the safety significance of the OTS; for TS the plant is usually required to shutdown but for TRM and GAC the plant is allowed to continue operation.

For many functions, the allocation of redundant SSCs and completion time allocation is performed with consideration for regular EMIT activities. These considerations are maximized to the greatest extent practical to enable EMIT activities during normal operation and to minimize the number of activities required to be performed during shutdown operating modes.

5.6.3.8 Surveillance Requirements

SRs are requirements relating to monitoring, test, calibration, or inspections to ensure that the necessary quality of SSCs is maintained, that the facility operation will be within safety limits, and that the LCO will be met. Within the OTS, LCOs are provided with corresponding SRs that provide a prescriptive review of the plant condition for compliance with the associated LCO. Surveillances are discrete checks of compliance with the corresponding limit or condition. Failure of a surveillance indicates an inoperable condition and prompts application of the required actions.

Surveillances are used as a means of routine LCO compliance, with the frequency of the task based on the significance of the parameter, the predicted reliability of the SSC, and operating limitations imposed on the SSCs by the mode of plant operation.

Surveillances are not the sole means of inoperability identification. Operator indications, SSC performance, alarms, maintenance activities, plant conditions, and other viable sources of information are all means of entry into an LCO if the function of the SSCs can be affected.

SRs are considered a form of PT per Section 5.6.8.

5.6.3.9 Operating Technical Specifications Bases

Within the tiers of the OTS, the LCOs, SRs, remedial actions, and completion times should have a documented bases. Bases should at a minimum address the following considerations and appropriate references to support the control.

- What is the justification for the plant parameter’s inclusion into the OTS?
- What are the bases for each LCO?
- What are the reasons for the operating mode applicability of the LCO?
- What are the bases for each remedial action?
- What are the bases for each SR and the associated frequency?

The level of documentation for an OTS parameter is managed commensurate with the tier of the control.

5.6.3.10 Interfaces with other Operating Rules

Figure 5-2 shows the OTS OR Interfaces. The interfaces are described within this section.

5.6.3.10.1 Administrative Controls

The AP1000 plant design has placed selected administrative controls within the scope of the OTS due to the importance to the plant safety case (e.g., administrative programs) or to the formal operation of the plant and interface with the public and the regulator (e.g., responsibilities and organisation).

The key programs and reporting requirements:

- Offsite Dose Calculation Manual (ODCM)
- Radioactive Effluent Control Programme (RECP)
- Inservice Testing (IST) Programme
- Steam Generator (SG) Programme
- Secondary Water Chemistry Programme
- Containment Leakage Rate Testing Programme
- Component Cyclic or Transient Limit Programme
- System Level Operability Testing Programme
- Battery Monitoring and Maintenance Programme
- MCR Envelope Habitability Programme
- Ventilation Filter Testing Programme (VFTP)
- Core Operating Limits Report (COLR)
- RCS Pressure And Temperature Limits Report (PTLR)

Several of these controls are implemented by the plant operators within the MCR and under the direction of the OTS. These include:

- Safety Function Determination Programme (SFDP)

  The SFDP is an administrative control that directs the plant operators to assess the integral effect of unavailable or inoperable equipment on the plant by reviewing individual component failure for support system interactions with Class 1 functions. For example, the failure of a Class 1 direct current (dc) battery will yield the associated Class 1 SSCs unavailable to reposition if they do not fail to their safety state (i.e., motor-operated valves).

- Setpoint Programme (SP)

  The Setpoint Programme is the administrative mechanism for documentation and control of the limiting safety analysis limits, allocation of channel and setpoint statistical uncertainty, and nominal setpoint values applied to automatic Class 1 protection devices. The SP is the interface mechanism between fault and accident analysis, plant operation, and the site maintenance programme.

Finalisation and implementation of administrative controls are the responsibility of the Licensee. The OTS and associated administrative control procedures will comply with the relevant Licence Conditions (LCs).

5.6.3.10.2 Design Transients (Loading Conditions)

The OTS interfaces with the Design Transients OR through Administrative Controls.

- Component Cyclic or Transient Limit Programme

  The purpose of this administrative control is to catalogue the quantity of design transient (loading conditions) applied to Class 1 SSCs over the course of plant life to ensure the plant is continuously operated consistent with the Class 1 component design requirements and analyses.

- RCS Pressure And PTLR

  Consistent with the quantity of cycling imposed on Class 1 SSCs, consideration for material behaviours throughout the entire operating range of process conditions must be accounted for consistent with the SSC design analyses. The RCS pressure and PTLR formally documents operating limitations on the rate of change in temperature, the maximum operating pressure for a given system temperature, and the operating conditions of the low temperature overpressure protection devices to maintain compliance with ASME Code requirements.

5.6.3.10.3 Fuel Design Requirements

The OTS interfaces with the Fuel Design Requirements OR to maintain alignment between the nuclear and thermal-hydraulic design of the core design for each fuel cycle with the operating limits and controls applied in the OTS.

- COLR

  The COLR is an administrative control that is discussed in Section 5.6.5. The purpose of the COLR is to document those operating limits that must be incorporated into the OTS to ensure that the plant is operated consistent with the limiting fault and accident analyses for the duration of the fuel cycle to prevent fuel damage or DNBR. Since the core design changes each refuelling interval, the COLR is cycle-specific and the controlling operating limits must be reaffirmed reflecting the operating core configuration.

- Core Physics Testing

  To confirm the core analyses are valid, confirm refuelling activities are consistent with the cycle fuel design, and identify fuel anomalies and reactivity deviations, AP1000 plant reactor cores are subjected to physics testing during plant startup and following every refuelling operation. The completion of these physics tests do not reduce or challenge plant safety during execution and are reflected in the OTS so that the testing does not result in an inoperable condition.

Due to their unique nature, core physics testing is the subject of specific written procedures that address the required plant configuration and compliance with applicable OTS conditions.

5.6.3.10.4 Chemical and Radiochemical Specification

The OTS interfaces with the Chemistry and Radiochemistry Specifications OR to ensure the primary, secondary, and auxiliary fluid chemistries are maintained consistent with design requirements, best industry practices, and limiting fault and accident analysis assumptions.

- ODCM

  The ODCM contains the methodology and parameters used in the calculation of offsite doses resulting from radioactive gaseous and liquid effluents, in the calculation of gaseous and liquid effluent monitoring alarm and trip setpoints, and in the conduct of the radiological environmental monitoring programme. Additionally, the ODCM also contains the radioactive effluent controls and radiological environmental monitoring activities, and descriptions of the information that should be included in the site environmental and effluent reporting as required by site LCs.

- RECP

  The RECP is an administrative control applied to control radioactive effluents and for maintaining the doses to members of the public from radioactive effluents as low as reasonably achievable. The programme is contained in the ODCM, implemented by procedures, and includes remedial actions to be taken whenever the programme limits are exceeded.

  The RECP includes limitations on the capability of radioactive waste processing systems, limitations on radiological concentrations and dose, and the associated monitoring requirements.

- Secondary Water Chemistry Programme

  The secondary water chemistry programme is an administrative control applied to control and monitor secondary water chemistry to inhibit SG tube degradation and low pressure turbine disc stress corrosion cracking. Implementation of the programme includes defined process limits, monitoring provisions, and action requirements. The programme is consistent with process description and OR implementation discussed in Section 5.6.6.

- Radiation and Chemistry Limits

  The control and monitoring of both primary and secondary chemistry is a complex task that represents an interface between the OTS and the Chemical and Radiochemical Specifications categories of the ORs.

  Critical chemical input parameters used in the determination of dose assessment are contained in the OTS; e.g., primary and secondary specific activity levels. A broader scope of chemical and radiochemical controls are implemented through specific chemical and radiochemical specification documents, which are discussed in Section 5.6.6.

5.6.3.10.5 In-Service Inspection

The OTS interfaces with the In-service Inspection (ISI) OR to ensure the scope of the ISI reflects specific administrative requirements and that the overall plant conditions are acceptable for ISI activities.

- SG Programme

  The SG Programme is an administrative control applied to ensure that SG tube integrity is maintained, as the SG tube are a primary pressure boundary component. A specific control is required for the SG due to its unique nature, operating experience, and specialised inspection techniques. Inspection of SG tubes is performed as part of the ISI process.

- Plant Conditions for ISI

  The ISI OR is responsible for creation of procedures to control ISI tasks; these procedures shall consider the OTS for coordination of SSC accessibility and inspection technique selection, especially when ISI techniques require the SSCs being inspected to be inoperable. ISI is discussed in Section 5.6.7.

5.6.3.10.6 Periodic Testing (PT)

The OTS interfaces with the PT OR to coordinate required EMIT activities and ensure that the plant operation is maintained with operating limitations, even in alternate alignments or with SSCs taken out of service.

- IST Programme

  The IST programme is an administrative control applied to Safety Class 1 SSCs designed to Section III of the ASME Code. The administration of the IST programme is in accordance with the requirements of the ASME OM Code (Reference 5.21).

  Coordination is required with the OTS to ensure system alignments for IST activities do not unacceptably inhibit required safety functions. This is facilitated through alignment with the OTS SFDP as discussed above.

- Containment Leakage Rate Testing Programme

  A key assumption in the AP1000 plant fault and accident analyses are the integrity of the fission product barriers. The Containment integrity is especially critical in the calculation of worker and public doses for events that release activity into the containment. Therefore, the Containment Leakage Rate Testing Programme is required to routinely survey the Containment and its penetration assemblies to ensure that the leakage assumptions remain valid during plant life.

- Battery Monitoring and Maintenance Programme

  Due to the role and importance of the Class 1 batteries in the AP1000 plant fault and accident analyses, an administrative control is recommended to ensure the batteries are maintained consistent with governing codes and standards.

- MCR Envelope Habitability Programme

  MCR Envelope Habitability is required to protect the plant operators such that the MCR occupants can control the reactor safely under normal conditions and maintain it in a safe condition following a radiological event, hazardous chemical release, or a smoke challenge. The programme shall ensure that adequate radiation protection is provided to permit access and occupancy of the MCR under design-basis fault and accident analysis conditions without personnel receiving radiation exposures in excess of regulatory limits.

Coordination is required with OTS to ensure alignment of plant equipment for EMIT activities is consistent with the plant safety design and to verify assumptions made in normal operating OTS controls for MCR integrity.

- VFTP

  Consistent with the MCR Envelope Habitability Testing programme, the Class 1 MCR ventilation system is provided with filtration capability consistent with MCR operator accident dose assessments. Therefore, a EMIT function is required to test and replace these filters to maintain compliance with the governing assumptions.

- System-Level Operability Testing Programme

  Operability testing requirements in addition to component-level IST requirements are provided to verify that the passive safety features will operate consistent with their corresponding fault and accident analyses.

  The system level operability testing is coordinated with the OTS and documented as a SR for the affected safety functions, these include

  - Passive Containment Cooling
  - Passive Core Cooling
    - Accumulators
    - Core Makeup Tanks
    - PRHR
    - In-Containment Refuelling Water Storage Tank
    - Containment Recirculation (Long-term Core Cooling)
  - Main Control Room Habitability

- SRs

  As discussed in Section 5.6.3.7, each OTS LCO is identified with accompanying SRs, including actions and frequencies, that are implemented to provide a means of confirming the plant is being operated within the limits of the corresponding LCO. These SRs are considered periodic tests and are further discussed in Section 5.6.8.

- Plant Conditions for PT

  Coordination between the OTS and PT is required such that procedures to control PT activities account for SSC availability in accordance with applicable plant limits and conditions. This ensures that PT tasks are performed with the plant aligned with the AP1000 safety case. PT is discussed in Section 5.6.8.

5.6.3.10.7 GDA/Licensee Interface

The following items represent the interface between the scope of the AP1000 plant GDA and the Licensee submittal process for nuclear site licensing (NSL); it is anticipated that the licensee will adopt and develop these provisions in the implementation of site ORs.

- Generic plant parameters, associated limits and conditions, and associated SSCs comprising the Class 1 TS portion of the OTS will be presented to the Licensee (Reference 5.22). The Licensee will be responsible for the verification of the site application of the Class 1 TS and certification of the actions and completion times.
- Generic plant parameters, associated limits and conditions and associated SSCs comprising the Class 2TRM portion of the OTS will be presented to the Licensee (Reference 5.23). The Licensee is responsible for the verification of the site application of the Class 2 TRM and certification of the actions and completion times.
- Suggested administrative controls, programs, and reporting requirements are contained in the TS portion of the OTS. The final complement, development, and implementation of these administrative provisions are within the scope of the Licensee consistent with relevant License Conditions.
- The implementation of the OTS as described herein will be at the discretion of the Licensee and required to satisfy relevant License Conditions for the applicable units. Detailed development of the OTS and the interfacing documentation is within the scope of the Licensee.

5.6.4 Design Transients (Loading Conditions)

Pressurised Class 1 SSCs are designed in accordance with Section III of the ASME Boiler and Pressure Vessel Code (ASME Code, Reference 5.24), including consideration for evaluation of stress and fatigue behaviours (only Class 1 pressure boundaries are evaluated for fatigue on the AP1000 design). For these pressurised systems, five operating conditions are defined in the ASME Code and are considered for the design of the associated systems, including RCS components, auxiliary components, RCS component supports, and reactor internals. These five operating conditions follow:

- Level A Service Conditions – (Normal Conditions)
- Level B Service Conditions – (Upset Conditions, Incidents of Moderate Frequency)
- Level C Service Conditions – (Emergency Conditions, Infrequent Incidents)
- Level D Service Conditions – (Faulted Conditions, Limiting Faults)
- Testing Conditions

5.6.4.1 Interface with other Operating Rules

Figure 5-3 shows the Design Transients OR Interfaces. The interfaces are described within this section.

5.6.4.1.1 Fuel Design Requirements

The Design Transients interfaces with the Fuel Design Requirements OR in the form of a design input for core reload evaluation. The design of and operation of a fuel cycle is fundamentally limited by the nuclear and thermal-hydraulic capabilities of the fuel assemblies in response to normal, abnormal, and accident sequences. The Design Transient interface

provides required conditions and loading conditions for consideration in the reactor core design for compliance with the fault and accident analyses.

5.6.4.1.2 Operating Technical Specifications

Refer to Section 5.6.3.10.2

5.6.4.1.3 Chemical and Radiochemical Specifications

The interface with the Chemical and Radiochemical Specification OR is an input for programme planning and creation of procedures and processes. Changes in plant state typically result in, or require, a change in chemistry. These changes can be realised in the form of required modification to, or increased monitoring of, critical chemical parameters. Accordingly, the processing of fluids and changes in plant gaseous and liquid effluent may be affected.

5.6.4.1.4 In-Service Inspection (ISI)

The AP1000 plant ISI OR implements the provisions of Section XI of the ASME Code to pressure-retaining Class 1 SSCs. An interface with design transients is required as an input as the frequency of inspections, planning for ISI intervals, assessment of defects, and evaluation of repairs must consider the cyclic loading impact in the associated programme documentation and procedures.

5.6.4.1.5 Periodic Testing

There is no identified OR interface with Periodic Testing.

5.6.4.2 GDA/Licensee Interface

The Licensee will be provided an index of design transients and the associated number of occurrences considered in the mechanical design of the AP1000 plant Class 1 components. This index is consistent with those used in the evaluation of RCS Class 1 components in the AP1000 Structural Integrity assessment in Chapter 20.

The design transient document, coupled with the service conditions and component loading conditions constitute the interface documentation required for the Licensee to establish a cycle and transient monitoring programme for the purpose of recording the actual plant performance against the mechanical input assumptions used in the design of the Class 1 components and to ensure that the number of occurrences is not exceeded during plant life.

5.6.5 Fuel Design Requirements

The nuclear and thermal design of the AP1000 fuel is described in detail in Chapter 22.

- A detailed description of the AP1000 fuel system design consistent with the safety case is presented in Section 22.5.

- The process for the nuclear design of the AP1000 reactor core is described in Section 22.6
- The thermal-hydraulic design of the AP1000 reactor core is described in Section 22.7

Discussion in this section will be limited to the incorporation of the fuel design requirements into the operating phase and the coordination with the other ORs.

5.6.5.1 Operating Constraints

As summarised in Chapter 22, the AP1000 plant fuel system design is required to consider the broad scope of design basis events in the nuclear and thermal-hydraulic design of the core for each fuel cycle.

Specific operating limits and conditions that apply to the reactor directly interface with the OTS by means of the COLR, as required per the OTS Administrative Controls.

The COLR, along with the fuel management report for the associated cycle, document the operating limits that satisfy the plant safety analyses on a cycle-by-cycle basis; thereby validating the safety case.

5.6.5.2 Interface with other Operating Rules

Figure 5-4 shows the Fuel Design Requirements OR Interfaces. The interfaces are described within this section.

5.6.5.2.1 Design Transients (Loading Conditions)

Refer to Section 5.6.4.1.1

5.6.5.2.2 Operating Technical Specifications

Refer to Section 5.6.3.10.3

5.6.5.2.3 Chemical and Radiochemical Specifications

The Fuel Design Requirement OR section provides a critical input to the implementation of the Chemical and Radiochemical Specifications. Specifically, the design of the reactor core provides the following inputs:

- Primary Coolant Chemistry Requirements

  The design of the fuel assemblies account for nuclear and thermal-hydraulic effects, but the design must also consider the long-term chemical effects on the integrity of the first fission product barrier. Maximum chemical concentrations are identified in fuel performance documentation, which is supplier specific and finalised by the site Licensee.

- Fuel Management Report

  Accompanying the COLR, each reactor core is provided with a fuel management report that details design feature of the respective core design, including the cycle boron profile. The boron profile is used by plant operators to control the chemical content of the

primary circuit and verify operations are consistent with the reactor core design for the total fuel cycle.

5.6.5.2.4 In-Service Inspection

There is no identified OR interface with ISI.

5.6.5.2.5 Periodic Testing

Periodic testing encompasses an array of EMIT tasks that are applied to demonstrate the plant is operated and maintained in accordance with the plant safety case. EMIT activities include those that support refuelling, including fuel loading verification and core physics testing. These activities require input from the COLR and the fuel management report.

5.6.5.3 GDA/Licensee Interface

The Licensee will be provided a COLR and Fuel Management Report for the first cycle of each unit. These documents will be produced during the site licensing phase, as they are specific to a core design; it is anticipated that the licensee will adopt and develop these provisions in the implementation of site ORs.

The Licensee will be responsible for implementation of the COLR limits into the associated OTS.

5.6.6 Chemical and Radiochemical Specifications

5.6.6.1 Chemistry

The chemistry functions in the AP1000 plant are dealt with under three headings: primary system, secondary system, and auxiliary systems. The essential safety requirements of the chemistry, the various physical systems, and their design basis functions are described in Chapter 21.

Chapter 21 demonstrates compliance with the chemistry safety requirements for each operational mode of the AP1000 plant. This includes a description of the chemistry strategy and the standards that are applied. The chemical aspects of accident scenarios, the potential hazards and the hazard mitigation measures, are also discussed.

Pertinent PCSR sections that support this OR are:

- Primary Circuit (Section 21.5)
- Secondary Circuit (Section 21.6)
- Auxiliary Water Systems (Section 21.7)
- Operating Strategies (Section 21.8)
- Accident Chemistry (Section 21.9)

5.6.6.2 Radiochemistry

During normal operating conditions the following radiochemical control parameters are included in the OTS for alignment with fission product barrier design and dose assessment. Radiochemical analysis, monitoring provisions, and associated action levels are controlled by the programme outlined in Chapter 21.

5.6.6.2.1 Fuel Cladding (First Fission Product Barrier)

- Reactor coolant Iodine-131 (I-131) activity levels shall be controlled to a concentration, whereby, it would produce the committed effective dose equivalent to the quantity and isotopic mixture of iodine isotopes actually present in the coolant consistent with the safety case. This operating limit is imposed as Iodine isotopes contributed to the analysed onsite and offsite dose assessments.
- Levels of Xenon-133 (Xe-133) shall be less than a level that would produce the effective dose equivalent to the quantity and isotopic mixture of noble gases present in the reactor coolant consistent with the safety case. This operating limit is imposed as Xenon isotopes contributed to the analysed onsite and offsite dose assessments.
- The I-131 activity and ratio of I-131 and I-135 isotopes are applied as a practical approach to determine the health of the fuel cladding during normal power operation.

5.6.6.2.2 Reactor Coolant Pressure Boundary (Second Fission Product Barrier)

- The integrity of the RCS piping within the Containment (Third Fission Product Barrier) is ensured through the monitoring and limitation on leakage. Leakage is detected by diverse means of liquid collection and airborne radiation monitoring.
- RCS leakage into the secondary circuit through the SGs is continuously monitored and limited to reduce the consequences of plant transients. Leakage rates are applied in the determination of potential onsite and offsite dose assessments.
- SG dose equivalent I-131 levels shall be controlled to a concentration that consistent with the safety case and associated onsite and offsite dose assessments.

5.6.6.3 Interface with other Operating Rules

Figure 5-5 shows the Chemical and Radiochemical OR Interfaces. The interfaces are described within this section.

5.6.6.3.1 Design Transients (Loading Conditions)

Refer to Section 5.6.4.1.3

5.6.6.3.2 Fuel Design Requirements

Refer to Section 5.6.5.2.3

5.6.6.3.3 Operating Technical Specifications

Refer to Section 5.6.3.10.4

5.6.6.3.4 In-Service Inspection

There is no identified OR interface with In-Service Inspection.

5.6.6.3.5 Periodic Testing

The execution of the Chemical and Radiochemical Specifications require corresponding EMIT activities to be performed to verify compliance with prescribed chemical limits. Activities are comprised of:

- Routine sampling in accordance with the site chemistry programme
- Chemistry controls per approved chemistry procedures
- OTS SRs

5.6.6.4 GDA/Licensee Interface

In substantiation of AP1000 plant safety case claims, radiochemical limitations and fission product barrier integrity requirements will be defined. Generic AP1000 plant chemistry recommendations are provided as described in Chapter 21.

The Licensee is responsible for development and implementation of the plant Chemistry programme, a process that manages the monitoring and control of chemical parameters. The Chemistry programme will require procedures for chemical control, definition of action levels, and requisite completion times for when a threshold is exceeded.

5.6.7 In-Service Inspection (ISI)

The ISI OR is comprised of two facets; Pre-Service Inspection (PSI) of the plant prior to fuel load, and ISI of the plant during the operating life. The operation of the AP1000 plant requires inspection of Class 1 SSCs to confirm pressure boundary material conditions. The plant ISI programme provides the guidance for these examinations as well as processes for characterisation, repair, mitigation, and justification of defects identified by the inspection processes. An effective ISI programme ensures:

- The plant has been constructed consistent with the design requirements and that the integrity of Class 1 pressure retaining components is in alignment with the safety case.
- The safety of the plant is not adversely affected after the commencement of operation and throughout the operating lifetime of the plant.
- The levels of reliability and availability of all plant SSCs remain in accordance with the assumptions and intent of the design and, consequently, a cost effective electricity generation is guaranteed.

PSI is an ISI interval required to be completed prior to fuel load for the purpose of confirming acceptable material conditions prior to operation and in order to develop inspection baselines for lifetime ISI intervals.

ISI is a preventive maintenance inspection programme utilizing non-destructive examinations (NDE) for Class 1 pressure retaining SSCs.

5.6.7.1 Programme Requirements

The AP1000 plant ISI programme will be developed for the UK AP1000 plant in accordance with Section XI of the ASME Boiler and Pressure Vessel Code.

Additional considerations shall be incorporated in the development of the plant ISI programme based on the content of the AP1000 Structural Integrity assessment in Chapter 20; the Structural Integrity assessment imposes additional inspection and quality requirement for Class 1 SSCs classified as high-integrity (HI) or high safety significance (HSS).

5.6.7.2 Interface with other Operating Rules

Figure 5-6 shows the ISI OR Interfaces. The interfaces are described within this section.

5.6.7.2.1 Design Transients (Loading Conditions)

Refer to Section 5.6.4.1.4

5.6.7.2.2 Fuel Design Requirements

There is no identified OR interface with Fuel Design Requirements

5.6.7.2.3 Operating Technical Specifications

Refer to Section 5.6.3.10.5

5.6.7.2.4 Chemical and Radiochemical Specifications

There is no identified OR interface with Chemical and Radiochemical Specifications.

5.6.7.2.5 Periodic Testing

The execution of ISI activities are, by definition, EMIT activities. Although the programme planning, criteria, and procedures are contained within the ISI OR section, interface with Periodic Testing is required to ensure that work planning and the overall effect of the inspection activities on the plant are captured and controlled to within plant operating limits.

5.6.7.3 GDA/Licensee Interface

The safety case identifies the bases for the ISI programme (including PSI requirements) through adherence of Section XI of the ASME Code. The safety case confirms that equipment accessibility has been accounted for in the AP1000 design such that the required ISI is feasible. Finally, supplemental inspection requirements resulting from the AP1000 plant structural integrity assessment in Chapter 20 may be applicable to the scope of the ISI.

The detailed ISI programme will be defined by the Licensee during site licensing activities.

5.6.8 Periodic Testing

Periodic Tests are EMIT activities identified in the plant ORs and implemented in the plant operating documentation that provide assurance that the plant is operated consistent with the governing limits and conditions contained in the plant safety case.

5.6.8.1 General Principles

PTs are denoted in the AP1000 design and operating documentation as either of two (2) types:

- Surveillance Testing – Periodic tests performed to satisfy OTS SRs in order to demonstrate the plant is being operated within the LCO (See Section 5.6.3.8).
- Routine Testing – Periodic tests performed to satisfy the testing requirements of other ORs or plant programmes. Examples of routine tests may include; auxiliary system chemistry sampling, IST of active components, or ISI.

Considerations into the general requirements for PT are included in the plant design since the design of safety functions has a direct impact on the quantity, type, and frequency of PT activities. Furthermore, optimisation of the PT requirements aligned to the ORs has a direct effect on plant availability, potential worker radiation exposure requirements, and plant safety during PT operational alignments. General considerations applied to the plant design include:

- Reduction of the number of active SSCs through the application of passive safety technologies, thereby directly reducing the amount of PT required over plant life.
- Designing systems, where applicable, for PT during the power generation operating mode.
- Consolidation of ORs, where applicable, to reduce duplicate PT requirements; for example, the alignment of OTS SRs with the IST programme for active valves.
- Review of the PSA and industry operating experience for PT activities that create a greater potential for a plant-level fault to occur; for example, the testing of Safety Class 1 steam generator isolation valves are performed during refuelling outages in lieu of at power due to operating experience with valve control problems and the associated high-likelihood of a reactor trip event.
- Automation of PT sequences through the use of display and automation technologies.

AP1000 safety features acknowledged in the plant fault and accident analysis review (See Section 5.6.2) represent the scope of SSCs and parameters subject to PT. Consistent with this review, parameters subject to PT may be either functional (e.g., assurance an active component can perform its credited safety function) or conditional (e.g., tank volumes or ambient temperatures).

A safety feature is not subject to PT if the function is normally in operation and monitored consistent with its safety function; for example, the normally operating main feedwater and main steam systems.

The coordination between safety functions and PT is defined within the interfacing OR categories.

5.6.8.2 PT Frequency

The frequency of PT may be either time or condition-based. The differentiation is typically associated with the accessibility of the equipment.

- Condition-Based – PT activities specified based on the plant operating conditions such as, Cold Shutdown, a refuelling cycle basis, or an ASME in-service interval.
- Time-Based – PT assigned a recurring schedule independent of plant condition; e.g., hourly, daily, etc.

Assignment of the PT frequency is subject to an application-specific review and incorporates consideration for several properties; including alignment with an OR, conformance with a governing code or standard, application of operating experience with component types and specific manufacturers, licensing commitments and regulatory requirements, and probabilistic insights.

Over the course of plant life, the frequency of PT activities will be continuously subject to review and optimisation as part of the Maintenance Programme's effectiveness review requirements.

5.6.8.3 Interface with other Operating Rules

Figure 5-7 shows the OTS OR Interfaces. The interfaces are described within this section. A comprehensive review of OR interfaces with Periodic Testing can be obtained by a review of Sections 5.6.3 through 5.6.7.

5.6.8.4 GDA/Licensee Interface

The interface between the AP1000 plant designer and the licensee is established as follows:

- Generic SRs aligned to the TS will be provided. The application of the TS is subject to validation by the Licensee during site licensing and review of affected LCs.
- A set of analysis documentation will be made available to the Licensee for use in the identification of TRM SRs and other routine tests.
- The Licensee is responsible for the implementation of the PT process and transitioning design limits and conditions into operating documentation.
- The GDA review of the AP1000 design does not include PT frequencies as these may be site-specific based on equipment supplied and reliability assumptions applied in site analyses.

5.6.9 Inclusion of Limits and Conditions into Plant Operating Documents

The limits and conditions identified in the above process are required to transition into the Operating Phase for the plant in the form of operating documentation. This documentation will provide the basis for OTS, procedures, SRs and EMIT schedules. However, it is

recognised that these documents can only be finalised by the plant operator as they are a requirement of the site licence.

To this end, the AP1000 limits and conditions process outlines the overall documentation plan and transition process (Figure 5-8). This process provides a 'roadmap' showing how the identified limits and conditions will be included in operating documents and used in the development of EMIT schedules. The generic plant design process will stop short of producing the documents themselves as they are the ultimate responsibility of the site licensee.

Westinghouse will provide the licensee with SSC evaluations to ensure that only suitably qualified and experienced persons (SQEPs) are identified to perform work associated with the EMIT of any SSCs as per interfacing LCs.

5.6.9.1 Procedures

Consistent with the Administrative Controls accompanying the TS as generic recommended practices, written procedures shall be established, implemented, and maintained for the following functions/purposes:

- Administrative Procedures
- Normal Operating Procedures
    - General Operating Procedures (GOPs)
    - System Operating Procedures (SOPs)
- Alarm Response Procedures (ARPs)
- Abnormal Operating Procedures (AOPs)
- Emergency Operating Procedures (EOPs)
- Post-72 Hour Operating Procedures
- Severe Accident Mitigation Guidelines (SAMGs)
- EMIT Procedures
    - Surveillance Tests
    - Control/Calibration of Measuring and Test Equipment
    - Maintenance Procedures (Mechanical, Electrical, and C&I)
    - Refuelling Procedures
- Programme Procedures
    - Containment Local and Integrated Leakage Rate Testing (LLRT/ILRT) Procedures
    - Chemical and Radiochemical Control
    - ISI Procedures
    - Fire Protection Programme Procedures

- Effluent and Environmental Monitoring Procedures

The ORs are inputs to the preparation of the operating procedures so that plant component manipulations, sequences of operation, and response to alarm conditions are consistent with applicable limits and conditions of operation. These plant manipulations account for planned EMIT or programme functions, as controlled through their respective documentation. Procedure interfaces are depicted in Figure 5-1 and Figure 5-8.

During emergency operation, many operating limits are no longer a practical control since the plant is in a dynamic state. In this condition, AOPs and EOPs are provided to ensure the plant responds to the transient condition consistent with the safety analyses. When the exit conditions of AOPs and EOPs are satisfied, the plant will be in a safe and stable condition and ORs can be implemented during recovery.

5.6.9.2 Examination, Maintenance, Inspections and Testing

The plant EMIT schedules are responsible for the planning, execution, documentation, and review of the completion of plant activities, as directed by and consistent with interfacing ORs. EMIT interfaces are depicted in the limit and condition process flowchart (Figure 5-1), and the phase transition flowchart (Figure 5-8).

EMIT schedules will be developed by the Licensee, applying maintenance programme policies and practices developed to support operation. Plant maintenance is characterised by the application of predictive (PdM), preventative (PM), and corrective maintenance (CM) tasks, where the term “plant maintenance” is used to represent the spectrum of EMIT activities. EMIT schedules will be developed consistent with the site-specific SSC requirements consistent with Chapter 15, Appendix 15A.

Predictive tasks are routine condition assessment EMIT activities used to confirm compliance with ORs, ascertain SSC operating condition and readiness, and adjust EMIT schedules to optimise EMIT efficiency and equipment availability.

Preventative tasks are routine EMIT activities that are applied to confirm compliance with associated ORs and ensure SSC reliability and availability are consistent with fault and accident analysis assumptions.

Corrective tasks are reactive EMIT activities that respond to deficient conditions. Interface with ORs is essential in the execution of corrective tasks to confirm limits and conditions are satisfied and that safety functions are maintained.

Examples of predictive/preventative tasks that will be included in the EMIT schedule include:

- Surveillance Testing
- Chemical and Radiochemical Monitoring and Control
- ISI & PSI
- IST
- Containment LLRT and ILRT
- Battery Monitoring and Maintenance
- MCR Habitability Monitoring and Maintenance

- Ventilation System Filter Testing
- System-Level Operability Testing

5.7 Operator Actions

In some DBAs and other accidents, there is sometimes a requirement that operators should perform certain actions, either to manually initiate or realign a system (for example, manually activating feed and bleed cooling) or for their own protection (for example, to evacuate on the activation of an area activity alarm). Note that in the AP1000 plant, the use of passive Class 1 systems has reduced the number and the importance of such operator actions.

In both of these cases, the required operator action will be the subject of or form part of written operating procedures, supported by appropriate training and review. The importance of these actions for safety will vary in exactly the same way as the importance of different SSCs for safety.

In the case of an action to manually initiate or realign a Class 1 system providing a Category A safety function, the importance of the operator action will be the same as the corresponding SSC being actuated or realigned. The same applies to an action that would protect an operator from a radiation dose in excess of the design basis limit of 20 mSv. In both these cases, the operator action has an importance equivalent to a Class 1 SSC.

Similarly, operator actions to manually initiate or realign a Class 2 system supporting a Category

A safety function or providing a Category B safety function would have the same importance for safety as a Class 2 SSC. The same applies to an operating action that would protect an operator from a radiation dose in excess of normal operating radiation dose limits but below the design basis limit of 20 mSv.

The AP1000 plant uses symptom-based operating procedures that guide the operator through various actions depending on the state of the plant. There are three different types of operating procedures: emergency operating procedures, abnormal operating procedures, and normal operating procedures, the latter having some subdivisions. For the purpose of classification, emergency and abnormal operating procedures are considered more relevant. Both are made up of a number of actions with different importance for safety. Therefore, any given procedure may contain actions with different classifications.

5.8 Equipment Qualification

The SSCs of the AP1000 plant are designed to operate in different environmental conditions (temperature, pressure, humidity, radiation fields) depending on their duty. As part of the overall design and safety assessment, SSCs will be qualified where appropriate for the environments in which they are required to operate.

For mechanical systems, the five operating conditions defined in ASME Code, Section III are considered for the design of the RCS Class 1 components, auxiliary Class 1 components, RCS component supports, and reactor internals. These five operating conditions follow:

- Level A Service Conditions – (Normal Conditions)
- Level B Service Conditions – (Upset Conditions, Incidents of Moderate Frequency)

- Level C Service Conditions – (Emergency Conditions, Infrequent Incidents)
- Level D Service Conditions – (Faulted Conditions, Limiting Faults)
- Testing Conditions

Westinghouse Quality Management provides assurances for the dynamic testing and analysis and IST programmes relating to component qualification in these conditions. Chapter 18 describes the seismic and dynamic qualification of Seismic C-I mechanical and electrical equipment.

Class 1 electrical equipment is tested under the environmental conditions expected to occur in the event of a DBE. This testing provides a high degree of confidence in the Class 1 system performance under the limiting environmental conditions.

Three basic standards form the basis of the qualification requirements and methodology used for the AP1000 plant equipment qualification:

- IEEE Standard 323-1974 (Reference 5.6) provides revised standards for equipment qualification that are endorsed by the relevant US Regulatory Guide. In particular, IEEE Standard 323-1974 highlighted the concept of ageing and provided the basis for the development of ageing methods.

- IEEE Standard 344-1987 (Reference. 5.7) provides specific treatment of seismic qualification.

- IEEE Standard 627-1980 (Reference 5.8) generalises the principles and technical guidance of IEEE 323 and IEEE 344-1987 to the qualification of Class 1E electrical and safety-related mechanical equipment.

Compliance with IEEE Standard 323-1974 and 344-1987 requirements is the specific means of compliance with the intent of IEEE Standard 627-1980 for safety-related electrical and mechanical equipment.

The methodology adopted for the AP1000 plant equipment qualification addresses the expanded scope of IEEE Standard 627-1980 and is developed using a number of other standards; details are provided in chapter 18.

This methodology defines a number of qualification criteria, methods, and environmental conditions that comply with the above standards and applies to all Class 1 and seismic C-I electrical and mechanical equipment plus certain monitoring equipment. Class 1 electrical and mechanical equipment is typically qualified using analysis, testing, or a combination of these methods. The specific method or methods used depend on the safety-related function of the equipment type to be qualified. Class 1 mechanical equipment, such as tanks and valves, is typically qualified by analysis, with supplementary functional testing when functional operability is demonstrated only through testing, as is the case for active valves. Either testing or testing combined with analysis is the method used for environmental and seismic qualification of Class 1 electrical equipment.

Chapter 18 of this PCSR identifies qualification methods used for the AP1000 plant to demonstrate the performance of Class 1 electrical and mechanical equipment when subjected to abnormal and accident environmental conditions, including loss of ventilation systems; feedwater line, steam line, and main coolant system breaks; and seismic events, and provides the expected conditions for various locations in the AP1000 plant. General requirements for

the development of plans/procedures/reports are also provided. Application of codes and standards for electrical equipment is described in Chapter 18 and in Reference 5.19.

Performance during abnormal environmental conditions, while not specifically designated as an industry or a regulatory qualification requirement, is also addressed by the methodology. Performance during normal service conditions is demonstrated by tests and inspections addressed by the equipment specification. Electromagnetic interference (EMI) testing or analysis is not included in the qualification process and is addressed on an individual equipment basis, as necessary (e.g., if required by IEC standards and European Union (EU) directives).

AP1000 Plant Equipment Qualification Methodology document, APP-GW-G1-002 (Reference 5.20) provides guidelines, acceptable methods and procedures for the environmental, seismic, and electromagnetic compatibility (EMC) qualification of AP1000 Plant safety equipment and also provides seismic and EMC requirements that are applicable to safety-related equipment. This methodology document is applicable to the C&I. Qualification of safety and safety-related equipment for AP1000 applications is conducted in accordance with this document.

5.8.1 Equipment Qualification Data Package

The qualification methods described above are used to verify the environmental design basis and capability of the Class 1 electrical and mechanical equipment supplied for the AP1000 plant. The results of the verification, as well as the design basis for each item of equipment, are documented in an equipment qualification data package (EQDP).

The EQDP consists of the following elements:

- **Specifications** – Includes equipment identification, manufacturer, electrical requirements, safety function, environmental conditions, installation, and maintenance requirements.

- **Qualification programme** – Defines the standards-compliant programme required to demonstrate that the equipment can perform the safety function identified in the specification.

  The basic performance criterion is that the qualification test programme demonstrates the capability of the equipment to meet the Class 1 performance requirements defined in the EQDP, while subjected to the environmental conditions specified in the EQDP. Where three or more specimens are tested, failure of one of three may be considered a random failure, subject to an investigation concluding that the observed failure is not indicative of a common-mode occurrence.

  For equipment for which ageing is addressed by evaluation of appropriate mechanism(s) through a review of available material and component information, the basic acceptance criterion is that the evaluation of test data demonstrates that the effect of ageing is minor and does not affect the capability of the aged equipment to perform specified functions.

  Qualification by test – Describes any test programme identified in the qualification programme, including number and type of test and test conditions. IEEE Standard 323-1974 (Reference 5.6) recommendations for testing follow a specific sequence: burn-in test, performance extremes test, ageing simulation and testing, synergistic effects, and visual inspections/disassembly. Class 1 electrical and

electromechanical equipment for the AP1000 design equipment qualification programme is type tested according to the guidelines and requirements of IEEE Standards 323-1974 and 344-1987 (Reference 5.7). Additionally, qualification based on type tests performed according to IEEE Standards 323-1974 (Reference 5.6) and 344-1987 (Reference. 5.7), but not specifically for the AP1000 design, may be used as a qualification basis.

- **Qualification by analysis** – Describes analyses to be performed including the specification of codes and methods and acceptance criteria.

  The AP1000 design equipment qualification programme uses analysis for seismic qualification of equipment if the primary requirement is the demonstration of structural integrity during a seismic event. For equipment that performs an active or a dynamic function, seismic qualification by analysis may also be used. However, the similarity between a qualified test unit and an as-supplied unit must be demonstrated unless otherwise justified.

  Chapter 17 of this PCSR describes the qualification requirements for Class 1 mechanical equipment where a fluid pressure boundary is involved. For those mechanical components that are not pressure boundaries, analysis is performed in compliance with the applicable industry design standard. Where age-sensitive materials, such as gaskets and packing, are used in the assembly of mechanical equipment, the ageing of these materials is normally evaluated based on an item-by-item review of the ageing characteristics of the material.

- **Qualification programme conclusions and summary** – Presents the conclusions of the EQDP.

5.9 Equipment Reliability

All SSCs are expected to have a reliability that is commensurate with their safety importance. Class 1 systems, in particular, are expected to have a high level of reliability.

The reliability claims for AP1000 SSCs are based on operating experience. The AP1000 design is similar to other PWRs in many of its systems and, even where the design is novel, the components used are also used in other reactors or other industries. Equipment reliability data is therefore available from actual operating experience.

Chapter 10 discusses common cause failures and human reliability data for SSCs.

5.9.1 AP1000 Design Reliability Programmes for Systems with Safety Importance

5.9.1.1 Assessment of Non-Class 1 SSCs with Importance to Safety

In currently operating plants, active systems provide the class 1 accident mitigation capability for the plant. However, for the AP1000 design, passive systems provide the class 1 accident mitigation capability. The AP1000 has active systems that provide backup to the class 1 SSCs for some transients / accident. As a result, they are not classified as Class 1 systems.

The non-Class 1 active systems in the AP1000 design provide defence-in-depth functions and can supplement the capability of the Class 1 passive systems. Chapter 8 shows that for frequent faults, diverse mitigation is provided which in most cases is provided by diverse Class 1 passive features and not the non-class 1 active features. The most often used non-class 1 SSC is the diverse actuation system (DAS) which provides backup actuation of the

class 1 passive SSCs. The AP1000 design uses an industry defined process to evaluate the importance of the non-Class 1 systems and for identifying appropriate regulatory oversight, as necessary, of these active systems.

The assessment of the non-Class 1 SSCs includes the following three parts:

- Identification of the significant non-Class 1 SSCs
- Development of specific reliability/availability missions for the significant non-Class 1 SSCs
- Specification of proposed regulatory treatment for each of the missions developed

The results of the assessment of the non-Class 1 SSCs of the AP1000 design confirmed that portions of several non-Class 1 systems are important to safety and should have additional regulatory oversight (Appendix A of Reference 5.2).

5.9.1.1.1 Protection from Natural Phenomena

Generally, the reliability/availability missions identified for the important non-class 1 SSCs do not include protection from natural phenomena. The one area where such protection is identified is for the post-72 hour SSCs. The installed non-class 1 SSCs that provide post-72 hour passive system support should have a reasonable expectation to survive natural phenomena. The purpose of this requirement is to minimize the need to transport SSCs to the site from an offsite storage location. Since only a few, small SSCs are required, they are easily transported via smaller trucks or helicopters.

The installed post-72 hour SSCs have considerations for surviving seismic, sustained winds, wind gusts, and wind-borne missiles to provide a reasonable assurance that they will be available within 72 hours. Note that since these installed post-72 hour SSCs are not credited as the means of providing this function they are not included in the internal / external hazard assements relative to providing these functions.

5.9.1.1.2 Quality Assurance

QA requirements are applicable to all SSCs identified in the AP1000 design short-term availability controls. The QA requirements are documented in Chapter 3 of this PCSR.

5.9.1.2 Reliability Assurance Programme

The reliability assurance programme (RAP) represents a dual-staged approach to the design and operation of the AP1000 plant in order to provide increased confidence in plant reliability and the corresponding safety of the public. The first stage of the RAP is the design stage, referred to as the design reliability assurance programme (D-RAP). The second stage of the RAP is referred to as the operational reliability assurance programme (O-RAP).

5.9.1.2.1 Design Reliability Assurance Programme

This stage is described in Reference 5.2, Appendix A.

The D-RAP is implemented as an integral part of the AP1000 design process to provide confidence that reliability is designed into the plant and that the important reliability assumptions made as part of the AP1000 design PSA will remain valid.

The D-RAP is implemented in three phases. The first phase, the GDA phase, defines the overall structure of the AP1000 D-RAP, and implements those aspects of the programme that are applicable to the design process. During this phase, risk-significant SSCs are identified for inclusion in the programme using probabilistic, deterministic, and other methods. The second phase, the post-GDA process, develops component maintenance recommendations for the plant's operations and maintenance activities for the identified SSCs. The third phase is the site-specific phase, which introduces any applicable plant site-specific SSCs to the D-RAP process.

The objective of the D-RAP is to design reliability into the plant and to provide maintenance recommendations that support the AP1000 design PSA safety goals. The following goals have been established for the D-RAP:

- Provide reasonable assurance that:
  - The AP1000 plant is designed, procured, constructed, maintained, and operated in a manner consistent with the assumptions and risk insights in the AP1000 design PSA for these risk-significant SSCs.
  - The reliability of risk-significant SSCs to function when called upon does not degrade to an unacceptable level during plant operations.
  - The frequency of transients that challenge the AP1000 design risk-significant SSCs is consistent with the PSA.
- Provide a mechanism for establishing baseline reliability values for risk-significant SSCs identified by the risk determination methods used to implement the maintenance rule (or equivalent process), consistent with PSA reliability and availability design basis assumptions used for the AP1000 design.
- Provide a mechanism for establishing baseline reliability values for SSCs consistent with the defence-in-depth functions to minimise challenges to the Class 1 systems.
- Generate design and operational information to be used by a licensee for ongoing plant reliability assurance activities.

5.9.1.2.2 Operational Reliability Assurance Programme

The reliability of AP1000 design SSCs will be assured by means of the application of operational phase reliability assurance activities (OPRAAs), which are contained in various operating plant programmes. The OPRAAs are composed of site administrative, maintenance, operational, and testing programmes to enhance operational phase reliability throughout the designed plant life.

This stage is described in Reference 5.2, Appendix A.

5.10 Treatment of Passive Systems

Unlike the current generation of light water reactors, the AP1000 design uses passive Class 1 systems that rely exclusively on natural forces such as density differences, gravity, and stored energy to provide Category A safety functions for reactor faults. The passive Class 1 systems include the following:

- PRHR
- CMTs
- Accumulators
- Passive containment cooling system
- automatic depressurisation system (ADS)
- IRWST

These passive systems do not include active equipment such as pumps, fans or diesel generators. One-time alignment of Class 1 valves that normally keep the Class 1 equipment in standby, actuates the passive systems. Most of these alignments use valve operators that fail safe, such as air operators that reposition to the safeguards position on a loss of the dc power or non-Class 1 compressed air. Some of these alignments use dc motor operators with power provided by Class 1 batteries or check valves that operate by the pressure differential across the valve disc.

The operation of the Class 1 passive systems does not require alternating current (ac) electrical power. For the AP1000 design, the active systems are designated as non-Class 1 systems except for limited portions of the systems that provide Class 1 isolation functions, such as containment isolation.

The passive components are Class 1 components subject to quality, qualification, and reliability requirements as detailed for Class 1 systems in this chapter, including assessment for dependent failures and common-cause failure (CCFs). Note that component diversity is provided in the AP1000 Class 1 passive systems based on PSA insights. This diversity is credited in the mitigation of frequent faults (refer to Chapter 8) where CCF need be considered.

The actuation of the PRHR, CMTs, and PCS all have air-operated valves that fail open on loss of dc power or instrument air. These systems also have component redundancy to provide confidence that their safety functions are performed even in the unlikely event of the most limiting single failure occurring coincident with a postulated DBE. In the case of the PCS, there is also component diversity to improve the protection against CCF.

The ADS actuation involves motor-operated valves (MOVs) and squib valves, which require power from the Class 1 essential electrical supply system (IDS) to actuate. The accumulators only have non-return valves kept closed by primary circuit pressure. As soon as the primary circuit pressure drops below the pressure of the nitrogen gas in the accumulator, accumulator pressure forces these valves open and injection is initiated.

Note that some components have support systems that are not needed for their Class 1 operations and in these situations the support systems are Class 2 or Class 3. For example, compressed air is provided to the CMT isolation valves. This air supply is used to maintain the valves in their normal closed position. The Class 1 operation of these valves is to open and for this operation the air supply is not required. As a result, failure of these support

systems does not compromise the availability of the passive systems. Failure leads to a fail-safe response.

5.11 Use of Metric and US Units

The AP1000 design was developed, for the most part, in US units of measurement; however, because the design is intended for an international market, the issue of the use of metric or dual units is important.

The Westinghouse document "AP1000 Standard Plant Metrication" (Reference 5.18) defines the extent to which metrication shall apply and to what level of detail it shall reach into the design, procurement, licensing, construction, testing, information and configuration management, operation, and maintenance of AP1000 units. For this document, metrication is defined as the act of adopting metric units in the design, procurement, and construction of an AP1000 unit. The AP1000 design is "quasimetric" in that it was originally conceived in US units but will be delivered as fully metric as specified by engineering documentation, with specified and regulatory agreed-upon exceptions.

The document also identifies how future design exceptions that arise will be handled and justifies how currently identified exceptions are ALARP. Current exceptions are listed in the appendix to Reference 5.18.

This PCSR is presented in Système Internationale (SI) units. While SI units are always presented, dual units may be shown here for clarity and cross-referencing purposes.

5.12 Smart Devices

This section addresses the identification and justification of smart devices in AP1000 SSCs. Smart technology is present in many types of modern equipment such as sensors, actuators, valves, protection relays and power supplies. A smart device is defined as any component that:

a. Contains pre-developed software or programmed logic (e.g. an Hardware Description Language Programmed Device) and is a candidate for use in an application important to nuclear safety.

b. Has a primary function performed that is well-defined and applicable to only one type of application within a system, such as measuring a temperature or pressure, positioning a valve, or controlling speed of a mechanical device, or performing an alarm function.

c. The primary function performed is conceptually simple and limited in scope (although the manner of accomplishing this internally may be complex).

d. The device is not designed so that it is re-programmable after manufacturing nor can the device functions be altered in a general way so that it performs a conceptually different function: only pre-defined parameters can be configured by users.

A more extensive definition along with examples of smart devices can be found in UKP-GW-GLR-017, "AP1000 Smart Device Justification Plan" (Reference 5.26).

When a smart device is selected for use in the UK AP1000 design a smart device justification shall be performed in accordance with UKP-GW-GLR-017 (Reference 5.26) and UKP-GW-J0Y-004, "United Kingdom AP1000 Smart Device Assessment Process" (Reference 5.27).

The justification will be based on the categorization of the function important to safety being performed by the device. The UK nuclear regulatory regime requires demanding levels of safety demonstration and justification for any SSC's including smart devices that are to be used in performing Category A safety functions. The current tools and methodology available are deemed impractical to enable the successful justification of the use of Smart devices for Category A safety functions and therefore these devices shall not be used in the UK AP1000 design.

Where there is a need for a component or device to perform a Category A safety function the system designers shall select a non-smart device, select a device that has been designed to IEC nuclear standards or undertake work to specifically design a device to the IEC nuclear standards.

Data sheets or procurement requests for UK AP1000 plant components, equipment or package systems shall include definitive statements as to whether or not smart devices can be part of the delivery. Vendors supplying any equipment or package systems for a UK AP1000 plant also need to provide a definitive statement either in the purchase order or in requirements traceability documentation as to whether or not smart technology is present in what they are supplying.

6 PLANT DESCRIPTION AND OPERATION

6.1 INTRODUCTION

The Westinghouse AP1000 plant is an advanced, passively safe, 1100MWe class, pressurised water reactor (PWR) with an expected service life of 60 years. Its design includes passive safety features not present on the Generation-2 plants in service today or in other Generation-3 designs, and extensive plant simplifications to enhance nuclear safety and facilitate the construction, operation, and decommissioning of the plant. An overview of the plant is shown in Figure 6-1.

The technical characteristics of the AP1000 design are summarized in Table 6-1.

This chapter of the Pre-Construction Safety Report (PCSR) produces an overview of the evolution of the AP1000 design and describes its systems, subsystems, and components and their operation.

Normal Operations

Section 6.2 describes the six defined normal operational modes and the equipment that supports them.

Reactor System

Section 6.3 describes the reactor system (the reactor vessel (RV) and integrated head package (IHP)), reactor internals, fuel assemblies, rod cluster control assemblies (RCCA), control rod drive mechanisms (CRDM), and in-core instrumentation).

Reactor Coolant System and Connected Systems

Section 6.4 describes the reactor coolant system (RCS) the steam generators (SGs), pressuriser, and associated pumps and pipe work. Section 6.4 additionally describes systems which support RCS operation.

Steam and Power Conversion Systems

Section 6.5 describes the secondary side of the reactor systems (main steam and feed systems, turbine and condenser), which use the nuclear heat to generate electricity.

Passive Safety Systems

Section 6.6 describes the passive Class 1 engineered safety features, i.e., those subsystems and components making up the passive core cooling system (PXS); passive containment cooling system (PCS); and other passive structures, systems, and components (SSCs).

Containment and Supporting Systems

Section 6.7 describes the Containment and supporting systems.

Heating, Ventilation, and Air Conditioning Systems

Section 6.8 describes the containment system and the heating, ventilation, and air conditioning (HVAC) in controlled areas that provide the containment function in those areas.

Control and Instrumentation

Section 6.9 describes the control and instrumentation (C&I) systems that control the reactor under normal and accident conditions.

Electrical Systems

Section 6.10 describes the electrical systems that supply the Class 1 and 2 safety systems, and it describes the normal and emergency power supplies.

Fuel Handling, Fuel Storage, and Radwaste Systems

Section 6.12 describes the systems used to transfer nuclear fuel into and out of the reactor; the systems involved in storage of spent fuel, in both the short- and long-term; and the systems involved in handling and storing radioactive wastes.

Auxiliary Systems

Section 6.11 describes the auxiliary systems that support plant operation, Class 2 defence in-depth systems, and other support systems of the plant.

Summary of Systems Providing Category A and B Safety Functions and Defence in Depth

Section 6.6.5 provides a summary of which systems support passive components and class 2 SSCs providing Category A Safety Functions.

Civil Structures

Section 6.13 describes the civil structures that comprise the nuclear island, i.e., containment building, shield building, and auxiliary building; and the main plant buildings outside the nuclear island, i.e., turbine building, annex building, diesel generator building, and radwaste building.

6.1.1 AP1000 Design Reference Point

The design reference point (DRP) is defined as the revision status (configuration), at a specified moment in time, of the safety case documentation and supporting information relevant to the generic design assessment (GDA) application. The AP1000 DRP document (Reference 6.2) defines the United Kingdom (UK) design reference point for the AP1000 design; specifically, it:

- Includes a list of all the documents and their revision status that constitute the design reference point for the Westinghouse AP1000 UK GDA.
- Describes how the design reference point has been set.
- Describes how any changes will be controlled.
- Describes how the design reference point for the conclusion of GDA Step 4 will be updated.

The documents that constitute the design at that point have been used as the basis for this revision of the AP1000 plant PCSR. This facilitates the identification of any safety-

significant changes with regard to the application and issue of any future Nuclear Site Licences for construction and operation of the AP1000 design in the UK.

6.1.2 Overview of Plant Systems and Operation

The reactor core consists of 157 fuel assemblies, each consisting of 264 fuel rods arranged in a square 17×17 grid and supported on the lower core plate, which is itself supported by the core barrel. The fuel rods are clad with a zirconium alloy (ZIRLO®) which provides the first barrier to release of radioactivity. A number of fuel assemblies have moveable absorbers – either RCCAs or grey rod cluster assemblies (GRCAs) located in guide thimble tubes within the fuel assembly. A central thimble is used in some assemblies for in-core instrumentation. The fuel assembly design is similar to those being used in operating PWRs.

The RCS consists of two heat transfer circuits, each with a SG, two reactor coolant pumps (RCPs), a single hot leg, and two cold legs for circulating reactor coolant. In addition, the system includes the pressuriser, interconnecting piping, valves, and instrumentation for operational control and safeguard actuation. All RCS equipment is located in the reactor containment. During operation, the RCPs circulate pressurised water through the RV and then the SGs. The water, which serves as coolant, moderator, and solvent for boric acid (chemical shim control), is heated as it passes through the core. It is transported to the SGs, where the heat is transferred to the steam system. Then the pumps return the water to the RV to repeat the process.

The RCS is shown in Figure 6-2 and described in detail in Section 6.4.

The primary circuit boundary provides the second barrier against the release of radioactivity generated within the fuel. It is designed to provide a high degree of integrity throughout the lifetime of the plant.

With the exception of limited times during plant shutdown, the RCS pressure is controlled by the pressuriser, where water and steam are maintained at saturation within a defined pressure range by the activation of electrical heaters or a water spray. The pressure is increased through the generation of steam formed by the heaters and decreased by the condensation of steam by the water spray. Spring-loaded safety valves are installed at the top of the pressuriser and provide overpressure protection for the RCS. These valves discharge into the containment atmosphere.

The RCS interfaces with a number of fluid auxiliary systems, principally the chemical and volume control system (CVS), the normal residual heat removal system (RNS), the steam generator system (SGS), the primary sampling system (PSS), the liquid radwaste system (WLS), and the component cooling water system (CCS). The RCS also interfaces with the (PXS).

When the reactor is shut down, the SGs provide cooling until system pressure and temperature are reduced to a level that can be accommodated by the RNS. The RNS takes its suction from one of the hot legs, the one that does not have the surge line connection to the pressuriser, and returns its cooled flow into the reactor vessel via both direct vessel injection lines.

When the reactor is to be refuelled, the refuelling cavity is flooded, after which the RV closure head is removed and then placed in its storage stand. The RNS continues to cool the reactor core but now also the refuelling cavity, by virtue of the RV being open to the water in this cavity.

The sections within this chapter of the PCSR provide detailed descriptions of these systems and their operation.

6.2 NORMAL OPERATIONS

Normal operation of the reactor covers all expected modes of operation including startup, power operation, shutdown, standby, and refuelling. Below are the six modes of normal operation defined with reference to nuclear reactivity (K_{eff}), thermal power, average coolant temperature, and vessel closure:

Mode		Reactivity Condition (K_{eff})	% Rated Thermal Power[1]	Average Reactor Coolant Temperature
1	Power Operation	≥ 0.99	> 5	N/A
2	Startup	≥ 0.99	≤ 5	N/A
3	Hot standby	< 0.99	N/A	> 215.6°C (420°F)
4	Safe shutdown[2]	< 0.99	N/A	≤ 215.6°C (420°F) > 93.3°C (200°F)
5	Cold shutdown[2]	< 0.99	N/A	≤ 93.3°C (200°F)
6	Refuelling[3]	N/A	N/A	N/A

Notes:
1. Excluding decay heat
2. All RV head closure bolts fully tensioned
3. One or more RV head closure bolts less than fully tensioned

6.2.1 Power Operation

In this mode, the reactor is producing power and generating electricity through the normal steam and power conversion systems: SGs, turbine, condenser, and main feed systems.

The steam generated in the two SGs is supplied to the high-pressure turbine by the MSS. After expansion through the high-pressure turbine, the steam passes through the two Moisture Separator Reheaters (MSRs) and is then admitted to the three low-pressure turbines. A portion of the steam is extracted from the high and low pressure turbines for seven stages of feedwater heating.

Exhaust steam from the low-pressure turbines is condensed and deaerated in the main condenser. The heat rejected in the main condenser is removed by the circulating water system (CWS). The condensate pumps take suction from the condenser hot well and deliver the condensate through four stages of low-pressure closed feedwater heaters to the fifth stage: an open deaerating heater. Condensate then flows to the suction of the SG feedwater booster pump(s) and then to the main feedwater pump(s). From there it passes through two stages of high-pressure feedwater heating to the two SGs.

Normal operating conditions (at full-power conditions) are defined in the Table below.

Rated thermal power	≈3415 MWt
Nominal power output	1100 MWe Class (actual net power depends on site-specific conditions)

SG outlet steam pressure	≈56 bar (812 psi)
SG outlet steam temperature	≈271°C (520°F)
Moisture carryover limit of the exiting flow	≈0.35%
SG feedwater temperature	≈227°C (440°F)
Flow rate per SG	≈3.40 x 106 kg/hr (7.50 x 106 lbm/hr)

6.2.2 Startup

Startup mode (Mode 2) includes the operations that bring the plant from a hot standby condition (Mode 3) to power operation (Mode 1), and conversely from Mode 1 to Mode 3.

Once the RCS has been heated up to hot standby conditions (Mode 3), the CVS removes boron from the RCS, thereby increasing reactivity until the reactor K_{eff} is ≥ 0.99 and Mode 2 is entered. Further increasing reactivity with boron and control rods raises reactor power. As power increases, feedwater continues to be supplied through the startup feedwater control valves until control of feedwater is automatically transferred from the startup feedwater control valves to the main feedwater control valves. As the main feedwater control valves open and assume responsibility for maintaining the SG water level, the startup feedwater control valves close. When thermal power (excluding decay heat) becomes greater than 5 percent of rated thermal power, Mode 1 is entered.

6.2.3 Hot Standby

Hot standby mode (Mode 3) includes conditions in which the reactor is kept subcritical but otherwise near normal power operation temperature conditions (>215.6°C (420°F)). From this mode, the reactor may be returned to power operation in a short time.

During hot standby conditions, feedwater is supplied to the SGs through the startup feedwater control valves using either one or both startup feedwater pumps drawing from the condensate storage tank, or a booster/main feedwater pump drawing from the deaerator storage tank. The startup feedwater control valves operate to maintain the SG levels, and minimum flow recirculation is automatically used as required to protect the feedwater pumps in use.

The steam generators maintain core decay heat removal as required, by relieving steam via the power operated relief valves or by dumping steam to the condenser via the steam bypass valve(s).

6.2.4 Safe Shutdown

The safe shutdown mode (Mode 4) includes keeping the reactor subcritical and the reactor coolant average temperature less than or equal to 215.6°C (420°F) but greater than 93.3°C (200°F), and providing adequate coolant inventory and core cooling. During normal operations, Mode 4 conditions are entered during plant heatups and cooldowns between Mode 3 (hot standby) and Mode 5 (cold shutdown). During Mode 4 operations the transition is made between decay heat removal by the steam generators and decay heat removal by the RNS.

It is important to note that “safe shutdown mode” (Mode 4) only applies to normal operation and does not apply to the post fault condition of “safe shutdown” discussed in Appendix 9C.

6.2.5 Cold Shutdown

Cold shutdown mode (Mode 5) is the state achieved through plant cooldown when reactor coolant temperature is ≤ 93.3°C (200°F) in preparation for a refuelling or other outage, and is also the starting point for power ascension before plant heat up.

During cold shutdown, decay heat is removed from the core via the RNS and criticality is controlled by maintaining adequate boron concentration of the coolant through the CVS. The RNS provides the motive force for the CVS purification loop during shutdown.

6.2.6 Plant Cooldown (Transition from Mode 1 to 5)

Plant cooldown are the operations that bring the reactor plant between power operation conditions (Mode 1) and cold shutdown conditions (Mode 5).

The initial phase of plant cooldown consists of reactor coolant cooldown and depressurisation. Heat is transferred from the RCS via the SGs to the MSS. Depressurisation is accomplished by spraying reactor coolant into the pressuriser, which cools and condenses the pressuriser steam bubble.

Operation during power descent and shutdown is generally the reverse of operation during startup and power ascent. At low feedwater flows, control of feedwater is automatically transferred from the main feedwater control valves to the startup feedwater control valves. Feedwater is supplied by an operating booster/main feedwater pump drawing from the deaerator storage tank. Feedwater can continue to be supplied by a booster/main feedwater pump during the shutdown process; alternatively, feedwater supply can be transferred to the startup feedwater pumps when flow demand has decreased to within their capacity. Feedwater continues to be supplied until the RNS is placed in service.

When the reactor coolant temperature and pressure have been reduced to approximately 176.7°C (350°F) and 31 bar (450 psi) respectively, the second phase of plant cooldown is initiated with the RNS being placed in service. The RNS continues to cool the RCS to cold shutdown conditions and is employed throughout the shutdown to remove core decay heat and maintain the RCS at low temperature.

Before cooldown and depressurisation of the RCS are initiated, the reactor coolant boron concentration is increased to a concentration necessary to maintain shutdown margin requirements. The operator sets the reactor makeup control to “borate” and selects the volume of boric acid solution necessary to perform the boration. Correct concentration is verified by reactor coolant samples using the PSS. The operator then sets the reactor makeup control for makeup at the shutdown reactor coolant boron concentration.

Contraction of the coolant during cooldown of the RCS results in actuation of the pressuriser level control system to maintain normal pressuriser water level. Makeup continues to be automatic, with the reactor makeup pumps starting and stopping as required. RCS letdown to the WLS is initiated as required to achieve the required boron concentration.

After the cooldown operations to cold shutdown conditions and as dictated by planned outage activities, the RCS water level is reduced. For normal refuelling, when maintenance activities will be performed on the SGs, the RCS is drained to the mid-loop level to allow air to be vented into the SGs from the pressuriser to drain the SG inverted U-tubes. The RCS is then

partially refilled, after placement of nozzle dams in the SG channel heads, in preparation for removal of the reactor vessel head.

6.2.7 Refuelling

6.2.7.1 Refuelling Operations

Refuelling is achieved by removing the IHP from the RV to access the fuel assemblies. The reactor is deemed to be in the refuelling mode (Mode 6) once any of the head bolts has begun to be untensioned.

To start refuelling operations, the IHP is unbolted and removed prior to the refuelling cavity being flooded from the IRWST. The reactor upper internals are then removed and placed on a stand in the refuelling cavity. Fuel may now be removed from the core.

The fuel handling equipment is designed to handle the spent fuel assemblies underwater from the time they leave the RV through storage in the spent fuel pit and until they are placed in a container for shipment from the site. Underwater transfer of spent fuel assemblies provides an effective and transparent radiation shield, as well as a reliable cooling medium for removal of decay heat.

The refuelling cavity (inside containment) and the fuel storage area (outside containment) are connected by the fuel transfer tube, which is fitted with a quick-opening transfer tube closure (blind flange) on the refuelling cavity end and a valve on the fuel storage area end and kept full of water at all times. The closure is in place except during refuelling to provide containment integrity. Fuel is carried through the tube on an underwater transfer car.

Fuel is moved between the RV and the fuel transfer system by the refuelling machine. The fuel transfer system is used to move a fuel assembly and its associated core component between the containment building and the auxiliary building fuel handling area. After a fuel assembly is placed in the fuel basket in the fuel transfer system, the lifting arm pivots the fuel assembly to the horizontal position for passage through the fuel transfer tube. After the transfer car transports the fuel assembly through the transfer tube, the lifting arm at that end of the tube pivots the assembly to a vertical position so that it can be lifted out of the fuel basket and placed in the spent fuel storage rack.

In the fuel handling area, fuel assemblies are moved about by the fuel handling machine. Initially, a short tool is used to handle new fuel assemblies, but the new fuel elevator must be used to lower the assembly to a depth at which the fuel handling machine and associated long-handled tool can place the new fuel assemblies in or remove them from the spent fuel storage racks.

New fuel assemblies received for refuelling are removed one at a time from the shipping container and moved into the new fuel assembly inspection area. After inspection, the accepted new fuel assemblies are stored in the new fuel storage rack. For the initial core load, new fuel assemblies may be stored in the SFP.

New fuel is moved into the core using the reverse procedure of the one for removing spent fuel from the core.

The new and spent fuel storage areas are accessible to operating personnel.

6.2.7.2 Fuel Storage

The spent fuel pool (SFP) provides storage space, heat removal and shielding for the spent fuel. The pool is approximately 12.8-m (42 ft.) deep and contains borated water with a nominal boron concentration of 2700 ppm. The spent fuel is stored in high-density racks that include integral neutron-absorbing material to maintain the specified degree of subcriticality. The design of the racks is such that a fuel assembly cannot be inserted into a location other than one designed to receive an assembly. The spent fuel storage racks include storage locations for 612 fuel assemblies and five defective fuel assemblies. This capacity affords at least 10 years of cooling time before dry casking. The defective fuel cell storage locations are designed to accommodate both new and spent fuel assemblies.

The spent fuel pool cooling system (SFS) is designed to remove decay heat generated by stored fuel assemblies from the water in the SFP. This is done by pumping the heated water from within the fuel pool through a heat exchanger (HX), and then returning the cooled water to the pool. A secondary function of the SFS is clarification and purification of the water in the SFP, the transfer canal, and the refuelling water.

The SFS consist of two independent pump/HX cooling trains. During normal plant power operation, only one of two SFS cooling trains is required to operate to maintain the fuel pool temperature at or below 48.9ºC (120ºF). During refuelling operations when the spent fuel is removed from the reactor vessel, both SFS cooling trains are required to be in operation to maintain the pool temperature at ≤48.9ºC (120ºF). In addition, an RNS cooling train can be aligned to cool the spent fuel pool if additional heat removal is required; for example, when all the fuel is removed from the reactor vessel and stored in the spent fuel pool.

Water transfers from the IRWST to the refuelling cavity are performed by the SFS. This function has traditionally been performed by the RNS. That capability still exists if the need arises. To improve clarity in the refuelling cavity and reduce operational radiation exposure, the SFS is used to flood the refuelling cavity without flooding through the RV.

Both residual heat removal pumps and HXs remain operating during refuelling to remove core decay heat from the fuel that remains in the reactor vessel. As decay heat decreases and as fuel is moved to the SFP, one residual heat removal pump and HX may be taken out of service. However, the RNS valves remain aligned to the RCS should the need arise to start this pump quickly in case the operating residual heat removal pump fails.

New fuel is stored in a high-density rack that includes integral neutron-absorbing material to maintain the required degree of subcriticality. The rack is designed to store 72 fuel assemblies of the maximum design-basis enrichment.

New fuel is initially stored in the new fuel storage racks. The fuel is then moved into the SFP before being loaded into the core by the refuelling machine.

The fuel handling machine is used to handle new fuel assemblies in the rail car bay, new fuel rack, and new fuel elevator. The capacity of the fuel handling machine, while over the new fuel storage rack, is limited to lifting a fuel assembly, control rod assembly, and handling tool. The new fuel storage rack is not accessed by the cask handling crane. This precludes the movement of loads greater than fuel components over stored new fuel assemblies.

During fuel handling operations, the Radiologically Controlled Area Ventilation System (VAS) removes gaseous radioactivity from the atmosphere above the new fuel pit and spent fuel storage pool.

The Technical Specifications (Reference 6.11) detail the requisite PCS make up water flows and requisite volumes (e.g. Fuel Transfer Canal, Cask Loading Pit, Cask Washdown Pit) depending on the Containment and SFP decay heat balance.

6.2.8 Other System Operations during Shutdown

The following aspects of system operation apply to several shutdown modes. A more detailed description of design features to mitigate shutdown risks is provided in Chapter 9 of this PCSR.

- Isolation of the main steam line on a high (large) negative rate of change in steam pressure is provided to address a steam line break that could occur in Mode 3. This signal is operable during Mode 3 when a secondary side break or stuck-open valve could result in the rapid depressurisation of the steam lines. In Modes 4, 5, and 6, this function is not needed for accident detection and mitigation.

- In Modes 2, 3, and 4, when the RCPs are operating, the secondary side of the SG is cooled by steaming to the main steam system (MSS). Once the RNS is aligned and steaming to the MSS is decreased, the primary side of the SGs is cooled by operation of the RNS. However, once the RCPs are tripped, there is no forced circulation through the primary side of the tubes and the secondary side of the SGs remains at elevated temperature. With the ability to cool the secondary side via the steam generator blowdown system, the AP1000 plant design reduces the probability that an RCP would be started with the secondary side of the SG at elevated temperature. This cooling also promotes equipment availability for maintenance at the earliest time in an outage.

- The core makeup tank (CMTs) provide RCS makeup. During shutdown, the CMTs are available in Modes 3, 4, and 5 until the RCS pressure boundary is open and the pressuriser water level is reduced. During power operation, the CMTs are automatically actuated on various signals including a safeguards actuation signal (low RCS pressure, low RCS temperature, low steam line pressure, and high containment pressure) and on low pressuriser water level.

- The in containment refuelling water storage tank (IRWST) provides a means for long-term RCS makeup. During shutdown, the IRWST is available until Mode 6, when the RV upper internals are removed and the refuelling cavity flooded. At that time, the IRWST is not required because the large heat capacity of its water is in the refuelling cavity.

- The passive residual heat removal (PRHR) HX provides decay heat removal following reactor trip during power operation and is required to be available in Mode 2 and in shutdown Modes 3, 4, and 5 until the RCS is open. In these modes, the PRHR HX provides a path for passive decay heat removal. In Mode 3, the accumulators must be isolated to prevent their operation when the RCS pressure is reduced to below their operating pressure.

- In Modes 5 and 6, containment closure capability is required to be available during shutdown operations when there is fuel inside containment. Containment closure is required to maintain the containment barrier capability in the unlikely event of radiation release from the fuel.

6.3 REACTOR SYSTEM

The reactor system (RXS) generates heat by a controlled nuclear fission reaction and transfers the heat generated to the reactor coolant, provides a barrier that prevents the release of fission products to the containment atmosphere, and provides a means via the control rods to insert negative reactivity into the reactor core and to shut it down.

The RXS consists of those major items of equipment constituting the operating nuclear reactor: RV (including the part of the head vent pipe shipped with the head), core, reactor internals, flow skirt, CRDMs, incore instrumentation system (IIS), rod position sensors, and IHP. The components of the RXS are integrated in a manner which will assure safe and economical operation of the system and equipment.

Further design details of the system and its constituent components are delineated in Reference 6.12. The fuel is described in further detail in Chapter 22.

6.3.1 Reactor System Components

The reactor system consists of the following components:

- RV
- IHP
- Reactor upper and lower internals assemblies
- Fuel assemblies (157)
- Rod cluster control assemblies (53) and grey rod cluster assemblies (16)
- Discrete burnable absorber and neutron source assemblies
- Control rod drive mechanisms (69)
- In-core instrumentation (IIS)

Major components of RXS are shown in Figures 6-9, 6-10, and 6-19. The location of the RV and the IHP with respect to the layout of the major RCS components is shown in Figure 6-2.

The AP1000 plant reactor internals consist of two major assemblies: the lower internals and the upper internals. The reactor internals provide alignment and support for the core, control rods, and grey rods in order to provide safe and reliable reactor operation. In addition, the reactor internals help to accomplish the following: direct the main coolant flow to and from the fuel assemblies; absorb control rod dynamic loads, fuel assembly loads, and other loads and transmit these loads to the RV; support instrumentation within the RV; provide protection for the RV against excessive radiation exposure from the core; and position and support RV radiation surveillance specimens.

The AP1000 plant CRDM design is based on a proven Westinghouse design that has been used in many operating nuclear power plants.

The IHP combines several components in one assembly to simplify refuelling the reactor. The IHP includes: a lifting rig, seismic restraints for CRDMs; supports for reactor head vent piping, power cables, cables for in-core instrumentation, cable bridge, quickloc connectors, and cables; and the CRDM cooling shroud assembly.

The reactor core contains a matrix of fuel rods assembled into fuel assemblies using structural elements. RCCAs are normally withdrawn, inserted, or held within the fuel assemblies by the CRDMs. The CRDMs unlatch upon termination of electrical power to them, thereby releasing the RCCAs to fall by gravity into core region. During operation, the RCPs circulate

pressurised water through the RV and the SGs. The water serves as coolant, moderator, and solvent for boric acid (chemical shim control). The water is heated as it passes through the core and then flows to the SGs, where the heat is transferred to the secondary side of the SGs. The SGs produce steam that is transported to the turbine via the main steam system. The cooled water is then returned to the reactor (core) by the pumps to repeat the process.

6.3.1.1 Reactor Vessel

The RV (RCS-MV-01) is cylindrical, with a hemispherical bottom head and a removable, flanged, hemispherical upper head. The vessel contains the core, core support structures, control rods, and other parts directly associated with the core (see Figure 6-9). The vessel interfaces with the reactor internals, the IHP, and reactor coolant loop piping, and is supported on the containment building concrete structure.

The design of the AP1000 plant RV closely matches the existing vessel designs of Westinghouse three-loop plants. New features for the AP1000 plant have been incorporated without departing from the proven features of existing vessel designs.

The vessel has inlet and outlet nozzles positioned in two horizontal planes between the upper head flange and the top of the core. The nozzles are located in this configuration to provide an acceptable crossflow velocity in the vessel outlet region and to facilitate optimum layout of the RCS equipment. The vessel inlet and outlet nozzles are offset, with the inlet nozzles positioned above the outlet nozzles, to allow draining of the RCS cold legs to facilitate maintenance operations while maintaining RNS flow for core decay heat removal into the RV direct vessel injection (DVI) lines through the core to the hot leg.

A large circumferential spring is positioned on the top surface of the core barrel flange. The upper support plate rests on the top surface of the spring. The spring is compressed by installation of the RV closure head and the upper and lower core support assemblies are restrained from any axial movements.

Coolant enters the vessel through the inlet nozzles and flows down the core barrel vessel wall annulus, passes through the flow skirt, turns at the bottom, and flows up through the core to the outlet nozzles.

The RV supports and encloses the reactor core. It provides flow direction with the reactor internals through the core and maintains a volume of coolant around the core. The vessel is cylindrical, with a transition ring, hemispherical bottom head, and removable flanged hemispherical upper head. The vessel is fabricated by welding together the lower head, the transition ring, the lower shell, and the upper shell. The upper shell contains the penetrations for the inlet and outlet nozzles and direct vessel injection nozzles. The closure head is fabricated with a head dome and bolting flange. The upper head has penetrations for the CRDMs, the in-core instrumentation, and head vent; and has support lugs for the IHP.

The RV (including closure head) is approximately 12 m (40 feet) long and has an inner diameter at the core region of approximately 4 m (159 inches). The total weight of the vessel assembly (including closure head, CRDMs, studs, nuts, and washers) is approximately 408.2 tonnes (450 tons).

The RV surfaces that can become wetted during operation and refuelling are clad to a nominal 5.6 mm (0.22 inch) of thickness with a stainless-steel welded overlay that includes the upper shell top flange surface but not the stud holes. The AP1000 plant RV is designed to have a 60-year operational life considering its neutron flux exposure, design pressure and temperature (172.3 bar (2500 psi) and 343.3°C (650°F)), and operational transients.

The major factor affecting vessel life is radiation degradation of the lower shell. As a safety precaution, there are no penetrations below the top of the core.

6.3.1.2 Reactor Vessel Insulation

Stainless steel reflective insulation (RXS-MN-01) is used to insulate the RV outside surface and minimize heat losses through the wall.

In the unlikely event of a design basis accident in which the reactor cavity is flooded with water, water inlet assemblies at the bottom of the RV insulation will self-actuate to permit a water layer to form between the RV and insulation and promote heat transfer from the RV to the surrounding environment. The resultant steam-water mixture will uncap steam vent ducts located near the top of the vessel insulation and return back to the containment flood water.

For post loss of coolant accident (LOCA) long-term core cooling, the plant is designed to automatically depressurize the RCS to equilibrium pressure with the containment atmosphere and to submerge the reactor vessel up to the upper head flange elevation.

6.3.1.2.1 In-Vessel Retention

The insulation around the RV is specially designed for In Vessel Retention (IVR) of molten core debris to mitigate a severe accident (see Figure 6-18). IVR in the lower plenum of the AP1000 plant is an inherent severe accident management strategy of the passive plant. The IVR function is a passive means of providing mitigation of severe core damage accidents. In a postulated severe accident, failure of Class 1 and 2 SSCs providing the core decay heat removal or core reactivity control Category A safety functions would lead to core damage and, eventually, to core melting. The behaviour of the molten core is the subject of severe accident analysis and probabilistic risk assessment. The Reactor Vessel Cavity Reflective Insulation is Category A Class 1 equipment and is Seismic Category II (see Table 15A). This special RV insulation is also discussed in Chapter 10.

IVR of molten core debris through water cooling of the external surface of the RV is a severe accident management feature of the AP1000 design. During postulated severe accidents, the accident management strategy to depressurise the RCS and flood the reactor cavity with IRWST water submerging the RV, is credited with preventing vessel failure in the AP1000 Probabilistic safety Assessment (Chapter 10). The water cools the external surface of the vessel and prevents molten debris in the lower head from failing the vessel wall and relocating into the containment.

Retaining the debris in the RV protects containment integrity by eliminating the occurrence of ex-vessel severe accident phenomena, such as ex-vessel steam explosion and core-concrete interaction, which have large uncertainties with respect to containment integrity.

The AP1000 design provides for IVR with the following features that promote external cooling of the RV:

- The reliable multistage RCS depressurisation system results in low stresses on the vessel wall after the pressure is reduced.
- The vessel lower head has no vessel penetrations to provide a failure mode for the vessel other than creep failure of the wall itself.
- The floodable reactor cavity can submerge the vessel above the coolant loop elevation with water intentionally drained from the IRWST.

- The RV insulation provides an engineered pathway for water-cooling the vessel and for venting steam from the reactor cavity.

The phenomena associated with melting the core and relocating the molten debris to the lower plenum play an important role in the composition and configuration of the debris pool following an unprotected severe accident (Reference 6.4). In turn, the characteristics of the debris pool significantly impact the heat loading to the lower head wall and the challenge to lower head integrity (Reference 6.4). Therefore, understanding the melting and relocation scenarios plays an important role in the assessment of IVR of molten core debris in the lower plenum.

The important conclusions from the analysis of the lower plenum debris pool formation are as follows:

- The lower plenum debris bed is cooled with water during the entire relocation process prior to contact with the support plate. Transient debris configurations are not predicted to threaten vessel integrity.

- The lower plenum oxide debris subsumes the lower core support plate before dryout in the lower plenum occurs. If the relocated debris is assumed to be instantaneously quenched in the lower plenum water, the oxide debris contacts the lower support plate before the debris can return to a superheated condition. Therefore, the lower core support plate, core shroud, and a sizeable fraction of the core barrel are subsumed in the debris bed. The inclusion of these components in the debris bed provides sufficient metal to ensure adequate heat transfer surface to the vessel wall such that the focusing effect of a thin metal layer is mitigated.

- The lower plenum debris bed is predicted to form a metal layer over oxide pool configuration.

- The potential for debris interaction creating a bottom metal pool of uranium dissolved in zirconium is expected to be small.

- The earliest time to achieve the fully molten circulating debris bed in the lower plenum is several hours after event initiation.

With the cavity adequately flooded, significant margin to failure for IVR via external RV cooling is achieved provided that the following conditions are met:

- The RCS is depressurised.

- The vessel is submerged adequately to promote natural circulation of water through the annular space between the vessel insulation and the vessel lower head and sidewalls.

- RV reflective insulation remains structurally sound under the pressure loads produced by the boiling external to the RV, allows water inlet at the bottom and venting of steam at the top, and provides the proper baffling to increase the critical heat flux on the external surface of the vessel lower head.

- The RV external surface conditions do not preclude the wetting phenomena identified as the cooling mechanism in system testing.

RCS depressurisation is achieved using the automatic depressurisation system (ADS) in the event of intact RCS faults or small and medium LOCAs, or by the LOCA itself.

Reactor cavity flooding is accomplished through either operator action or the progression of the accident. The operator manually floods the cavity by opening a motor-operated valve and a squib valve in the recirculation lines between the IRWST and the containment recirculation sump. The water floods the containment by flowing out of the recirculation screens, filling the floodable region of the containment.

To achieve the high critical heat flux for the AP1000 plant lower head, the water level in containment must be sufficient for two-phase natural circulation flow. The vents from the AP1000 plant RV insulation exit to the vessel nozzle gallery.

With respect to IVR severe accident management, the goal of the RV insulation is to ensure that there will always be an adequate water layer next to the RV to promote heat transfer from it. The insulation will define an optimised flow path next to the lower head to enhance the critical heat flux. The cooling of the vessel in a severe accident is accomplished by providing the following:

- A means of allowing water-free access to the region between the RV and insulation.
- A frame that maintains the structural integrity of the insulation surrounding the lower head, which provides the annular space for the water flow next to the vessel.
- A means to vent steam generated by the water cooling the vessel wall from the insulation surrounding the RV.
- A support frame to prevent the insulation panels above the vessel lower head from breaking free and blocking water from cooling the RV exterior surface.

6.3.1.3 Integrated Head Package

The IHP (Figure 6-10) combines several components in one assembly to simplify refuelling the reactor. The IHP includes a lifting rig, seismic restraints for CRDMs, support for the reactor head vent piping, cable bridge, quickloc connectors, power cables, cables for in-core instrumentation, cable supports, and the CRDM cooling shroud assembly.

The IHP provides the ability to rapidly disconnect cables, including the CRDM power cables, digital rod position indication cables, and in-core instrument cables from the connector/penetration components on the upper head. The IHP also provides the ability to rapidly disconnect the reactor head vent system.

The IHP provides the ability to disconnect these components so that the RV upper head can be lifted and removed. In addition, the IHP provides support for the vessel head stud tensioner/detensioner during refuelling.

The purpose of the IHP is to reduce the outage time and personnel radiation exposure by combining operations associated with movement of the RV head during the refuelling outage.

In addition, the integrated head concept reduces the laydown space required in the containment. With the IHP, disconnections from and connections to the interfacing components are not made at the individual component. This applies to the CRDMs, rod position indicators (RPI), and other components within the cooling shroud assembly. The IHP consists of the following components:

- Shroud assembly
- Lifting system
- Mechanism seismic support structure
- Cable support structure
- Cables
- In-core instrumentation (IIS)

These principal elements of the IHP are described in the following paragraphs.

Shroud Assembly

The shroud assembly is a carbon steel structure that includes a shielding shroud and an air baffle. During normal operation, it directs the flow of cooling air to the CRDM coil stacks. The Rod Position Indicators are also cooled by this airflow. The duct work and air baffle are integral to, and supported by, the shroud assembly. The air-cooling fans are attached to the IHP. The shroud also provides shielding at the vessel flange region.

CRDM Cooling Fan System

The cooling of the CRDM coil stacks and digital rod position indication (DRPI) system is provided by four vane axial fans mounted 90° apart on the IHP shroud. Each fan is connected to the IHP shroud by flexible expansion joint connectors. Containment air is drawn in through multiple cut-outs located on the lower portion of the shroud and directed by baffles up through the CRDM rod travel housings. The air is then pulled through four inlet ducts located near the top of the IHP shroud positioned 90° apart, pulled through fans, and exhausted back into containment. Any two of the fans can operate to provide CRDM cooling, and two backup fans are available.

Reactor Vessel Head Lifting Rig

This apparatus supports the RV head and IHP as a single unit when it is lifted by the polar crane. The lift legs transfer the head load during a head lift from the head attachment lugs to the lift rig. The lifting system consists of lift legs, sling block, clevises, sling rods, and a lifting linkage assembly required for interfacing with the polar crane hook.

Mechanism Seismic Support Structure

This structure provides seismic restraint for the CRDMs. It is located near the top of the CRDM rod travel housings. The digital rod position indication connector plate attached to the rod travel housing interfaces with spacer plates, where required, to form a system of bumpers that interface with the mechanism seismic support structure. This support interfaces with the shroud assembly to transfer seismic loads from the mechanisms to the Reactor Vessel head.

Cable Support Structure

The cable support structure is located at an elevation above the top of the rod travel housings. It provides permanent support and routing for the CRDM power cables and RPI cables, which remain with the IHP and are normally not disturbed. These cables terminate at the connector plates, which constitute the interface with the mating cables.

Cable Bridge

The cable bridge provides support for the cables between the connector plate on the containment operating deck and the IHP. The cable bridge is attached to the IHP by a pivot-type connection, which allows upward movement of the bridge. For a refueling or other operation requiring movement of the IHP, the cables on the bridge are disconnected at the connector panel on the operating deck. Then, the bridge is swung up and away from the containment operating deck and secured to the IHP.

6.3.1.4 In-Core Instrumentation System

The IIS consists of thermocouples to measure fuel assembly coolant outlet temperature, and in-core flux thimbles containing fixed detectors to measure the neutron flux distribution within the reactor core. The in-core thimble tubes have enhanced resistance to fluid-induced vibration and wear. The thimble is stiffer than the design in previous operating plants; the gap between the thimble tube and the tubes used to guide and protect the thimble inside the RV is smaller to minimise vibration. The design of the thimble tube assembly also precludes a non-isolatable leak of reactor coolant. The thermocouples and neutron detectors are routed through the IHP. They are inserted into the core through the RV head and upper internals assembly.

The CRDMs (described in more detail later) are contained within the IHP located on top of the RV head. This assembly provides the support required for seismic restraint in conjunction with the attachment of the CRDMs to the RV head. An outer shroud (an integral portion of the head lifting system) and the seismic support plate isolate the CRDMs from the effects of ruptured high-energy lines outside the shroud, and from missiles. The shroud is also used to direct air from the cooling fans past the CRDMs. The cooling system maintains the temperature of the coils in the CRDMs below their design operating temperature.

The lines for the RV vent system are located among the CRDMs and are supported by the IHP. These lines are pressurised to RCS pressure and are considered high-energy.

6.3.1.5 Reactor Internals

The interfaces between the RV and the lower internals core barrel are such that the main coolant flow enters through the inlet nozzle and is directed down through the annulus between the RV and core barrel and through the flow skirt, and flows up through the core. The annulus is designed so that the core remains in a configuration that can be cooled for all design conditions.

Lower Internals (RXS-MI-02)

The lower core support assembly consists of the core barrel, lower core support plate, secondary core support, vortex suppression plate, core shroud, neutron panels, radial supports, and related attachment hardware. The major material for the lower internals is 300 series austenitic stainless steel. The lower core support assembly is supported at its upper flange from a ledge in the RV flange. Its lower end is restrained in its transverse movement by a support system attached to the vessel wall. The support system consists of keys attached to the lower end of the core barrel subassembly. These keys engage clevis inserts in the RV. This system restricts the lower end of the core barrel from rotational and/or translational movement, but allows for radial thermal growth and axial displacement.

The flow skirt is a perforated cylindrical ring that is an attachment to the RV bottom head. Since this structure is located within the pressure boundary, it will be described here. The

flow skirt is welded to support lugs on the inside surface of the RV bottom head. A vertical clearance is provided between the top of the flow skirt and the bottom surface of the lower core support plate to prevent contact during operation. The flow skirt provides a more uniform core inlet flow distribution.

The core shroud is located inside the core barrel and above the lower core support. This shroud forms the radial periphery of the core. The core shroud is between the lower core barrel and core, surrounding the core and forming the core cavity. The core shroud consists of formed vertical plates with fully welded vertical seams to prevent lateral flow from the fuel assemblies.

The core shroud serves to provide a transition from the round core barrel to the square fuel assemblies. Through the dimensional control of the cavity (the gap between the fuel assemblies and the shroud) and the shroud cooling flow hole inlet size, the core shroud limits the reactor coolant flow around the core periphery and maintains the required flow through the core.

During assembly, as the internals are lowered into the vessel, keys engage keyways in the axial direction. Correct positioning of the internals is provided by the installation equipment (lifting rig) guide studs and bushings. In this design, the internals have a support at the furthest extremity, and the core barrel is modelled as a beam, which is supported at the top and bottom.

Upper Internals (RXS-MI-01)

The support grid assembly establishes the spacing between the upper support and the upper core plate. The support columns are fastened at the top and bottom to these plates. The support columns transmit the mechanical loadings between the two plates; some serve the supplementary function of supporting the tubes that house the fixed in-core instrumentation.

The instrument columns housing the in-core instrumentation provide a protective path for the detectors during installation, reactor operation, and removal at refuelling outages.

The guide tube assemblies sheath and guide the control rod drive shafts and control rods. The guide tubes are fastened to the upper support and are restrained by pins in the upper core plate for proper orientation and support.

The upper core support assembly is positioned in its proper orientation, with respect to the lower core support assembly, by flat-sided pins in the core barrel. Four equally spaced flat-sided pins are located at an elevation in the core barrel where the upper core plate is positioned. Four mating sets of inserts are located in the upper core plate at the same positions. As the upper support assembly is lowered into the lower support assembly, the inserts engage the flat-sided pins in the axial direction. Lateral displacement of the plate and the upper support assembly is restricted by this design.

Fuel assembly locating pins protrude from the bottom of the upper core plate and engage the fuel assemblies as the upper assembly is lowered into place. This system of locating pins and guidance arrangement provides proper alignment of the lower core support assembly, the upper core support assembly, the fuel assemblies, and the control rods.

6.3.1.6 Fuel Assemblies and Core Components

Within the reactor core there are 157 fuel assemblies. Each fuel assembly contains 264 fuel rods, 24 guide thimble tubes, and an instrumentation thimble tube arranged to form a 17 x 17

fuel assembly (see Figure 6-11). Further design details of the fuel assemblies and its constituent components are delineated in Reference 6.12. The fuel assembly is also described in Chapter 22.

The instrumentation thimble is located in the center position and provides a channel for insertion of seven incore neutron flux detectors and one core exit thermocouple. The performance of the core is monitored by fixed neutron detectors outside the core, removable fixed neutron detectors within the core, and thermocouples at the outlet of selected fuel assemblies. The fuel assembly structure is designed to completely enclose the fuel rods and to provide a clearance between the fuel rod ends and the top and bottom nozzles of the fuel assembly structures. All fuel assemblies in the core are identical in construction.

Each fuel assembly is installed vertically in the reactor vessel and stands upright on the lower core plate, which is fitted with alignment pins to locate and orient the assembly (See Figure 6-9). Once the fuel assemblies are properly positioned in the core, the upper core plate is installed by lowering it in place over the fuel assemblies. Alignment pins, built into the upper core plate, engage and fix the upper ends of the fuel assemblies. The upper core plate then bears downward against the fuel assembly top nozzle with the holddown springs to keep the fuel assemblies in place.

The bottom nozzle serves as a bottom structural element of the fuel assembly and directs the coolant flow distribution to the assembly (see Figure 6-11). Coolant flow through the fuel assembly is directed from the plenum in the bottom nozzle upward through the penetrations in the plate to the channels between the fuel rods. The top nozzle assembly functions as the upper structural element of the fuel assembly in addition to providing a partial protective housing for the core components.

The previously mentioned 24 guide thimbles are structural members which provide channels for the RCCAs, GRCAs, wet annular burnable absorbers (WABAs), and source assemblies. The guide thimbles are fastened to the grids and end nozzles to create an integrated structure. The grid assemblies support the fuel rods and maintain the lateral spacing between the rods. Depending on the position of the assembly in the core, the guide thimbles are used for RCCAs, GRCAs, neutron source assemblies, WABA rods, or thimble plugs.

The fuel grids consist of an egg-crate arrangement of interlocked straps that maintain lateral spacing between the rods. The grid straps have spring fingers and dimples that grip and support the fuel rods. In addition, there are four intermediate flow mixing (IFM) grids that have coolant mixing vanes to provide improved departure from nucleate boiling (DNB) performance. The IFM grid straps contain support dimples and coolant mixing vanes only. The top and bottom grids and protective grid do not contain mixing vanes. The AP1000 plant fuel assembly design also includes a protective grid for enhanced debris resistance.

The bottom nozzle is a box-like structure that serves as the lower structural element of the fuel assembly and directs the coolant flow distribution to the assembly. The size of flow passages through the bottom nozzle limits the size of debris that can enter the fuel assembly.

The AP1000 plant fuel assembly design is similar in design to fuel assemblies used in legacy Westinghouse power plants. These two legacy fuel assembly designs are the 17×17 Robust and 17×17 XL Robust. The 17×17 Robust fuel assemblies have an active fuel length of 3.66 m (12 feet) and three IFM grids in the top mixing vane grid spans. The 17×17 XL Robust fuel assemblies have an active fuel length of 4.27 m (14 feet) with no IFM grids. The AP1000 plant fuel assemblies are the same as the 17×17 XL Robust fuel assemblies except that they have four IFM grids in the top mixing vane grid spans.

Core components include RCCAs, GRCAs, burnable absorbers rods (which include WABAs and integral fuel burnable absorbers (IFBAs)), thimble plugs, and source rods. A brief description of each component is provided in the following sections.

6.3.1.6.1 Fuel Rods

The fuel rods consist of uranium dioxide ceramic pellets contained in cold-worked and stress-relieved ZIRLO™ tubing, which is plugged and seal-welded at the ends to encapsulate the fuel. The rod is pressurized with an inert gas (helium) to prevent collapse under the RCS pressure. The fuel pellets are right circular cylinders consisting of slightly-enriched uranium.

The reactor contains a matrix of fuel rods assembled into mechanically identical fuel assemblies along with control and structural elements. The fuel assemblies contain various fuel enrichments, are configured into the core arrangement and are located and supported by the reactor internals.

Fuel rods are pressurised internally with helium during fabrication to reduce clad creep-down during operation and thereby prevent clad flattening. The fuel rods in the AP1000 plant fuel assemblies contain additional gas space above the fuel pellets, compared with the 17×17 Robust, 17×17 XL Robust, and other previous fuel assembly designs, to allow for increased fission gas production due to high fuel burnups.

6.3.1.6.2 Rod Cluster Control Assemblies

Each RCCAs consist of 24 absorber rodlets fastened at the top end to a common hub, or spider assembly. Each absorber rod consists of an alloy of silver-indium-cadmium (Ag-In-Cd), which is clad in stainless steel. The RCCAs are used to control relatively rapid changes in reactivity and to control the axial power distribution.

The absorber Ag-In-Cd alloy, which is essentially “black” to thermal neutrons and has sufficient additional resonance absorption to significantly increase worth. As such, these rods are sometimes referred to as “black” rods. The absorber material is in the form of solid bars sealed in cold-worked stainless-steel tubes.

The RCCAs are divided into two categories: control and shutdown. The control groups compensate for reactivity changes due to variations in operating conditions of the reactor, that is, power and temperature variations. Two nuclear design criteria have been used to select the control group. First, the total reactivity worth must be adequate to meet the nuclear requirements of the reactor. Second, in view of the fact that these rods may be partially inserted at power operation; the total power peaking factor should be low enough to confirm that the power capability is met. The control and shutdown groups provide adequate shutdown margin.

The control rods have bottom plugs with bullet-like tips to reduce the hydraulic drag during reactor trip and to guide smoothly into the dashpot section of the fuel assembly guide thimbles.

The spider assembly is in the form of a central hub with radial vanes containing cylindrical fingers from which the absorber rods are suspended. Internal groove-like profiles to facilitate handling tool and drive rod assembly connection are machined into the upper end of the hub. Coil springs inside the spider body absorb the impact energy at the end of a trip insertion. The radial vanes may either be joined to the hub by welding or brazing. The fingers are joined to the vanes by brazing, or the vanes and fingers may be integral with the spider body. A bolt,

which holds the springs and retainer, is threaded into the hub within the skirt and is welded to prevent loosening while in service.

The overall length of the RCCA is such that, when the assembly is withdrawn through its full travel, the tips of the absorber rods remain engaged in the guide thimbles so that alignment between rods and thimbles is always maintained. Because the rods are long and slender, they are relatively free to conform to any small misalignments with the guide thimble.

Each RCCA is moved independently in and out of the reactor core by CRDMs. The CRDMs operate in response to the actuation and control of the signals provided by the PLS and PMS.

6.3.1.6.3 Grey Rod Control Assemblies

Externally, the mechanical design of the GRCA is identical to the RCCA. In addition, the CRDM and the interface with the fuel assemblies and guide thimbles are identical to those of the RCCA.

The GRCAs consist of 24 rodlets fastened at the top end to a common hub or spider assembly. Geometrically, the GRCA is the same as an RCCA except that the absorber rods consist of tungsten contained within a nickel-chromium-iron Alloy 718 sleeve. Stainless steel spacers are provided at the bottom of the rodlet between the bottom of the sleeve and the bottom end plug of the stainless steel cladding. The GRCAs are used in base load operation and load follow manoeuvring. The assemblies provide a mechanical shim reactivity mechanism to minimise the need for changes to the concentration of soluble boron.

Soluble boron in the moderator/coolant serves as a neutron absorber. The concentration of boron is varied to control reactivity changes that occur relatively slowly, including the effects of fuel burnup. Burnable absorbers are also used in the initial cycle to limit the amount of soluble boron required and thereby maintain the desired negative reactivity coefficients.

Each GRCA is moved independently in and out of the reactor core by CRDMs. The CRDMs operate in response to the actuation and control of the signals provided by the plant control system (PLS) and protection and safety monitoring system (PMS).

6.3.1.6.4 Burnable Absorbers

Burnable absorbers are normally used to compensate for some of the installed excess reactivity and to ensure that a negative moderator temperature coefficient is maintained. When needed for nuclear considerations, BA assemblies are inserted into selected thimbles within fuel assemblies.

The WABAs are discrete burnable absorber rods which use aluminum oxide-boron carbide (Al_2O_3-B_4C) as an absorber material. They are attached to a holddown assembly which consists of a flat perforated base plate and a spring pack assembly. The number of absorber rods per assembly varies depending on its position in the core. The length of the absorber can also vary. The WABA rods consist of pellets of alumina-boron carbide material contained within zirconium alloy tubes. These zirconium alloy tubes, which form the outer clad for the BA rod, are plugged, pressurised with helium, and seal-welded at each end to encapsulate the stack of absorber material.

The WABA is an alternative discrete BA. The BA material is boron carbide contained in an alumina matrix.

IFBAs use a thin coating of boride on the surface of the fuel pellets, thus the absorber is said to be integral to the fuel rather than discrete. The number of fuel rods containing IFBA within a given fuel assembly can vary, as can the number of the fuel pellets in a fuel rod coated with absorber.

Discrete BA rods are designed so that the absorber temperature does not exceed 649°C (1200°F) during normal operation or an overpower transient.

6.3.1.7 Neutron Source Assemblies

The neutron sources are normally required for the initial cycle only. The neutron source rods provide a minimum base neutron level to maintain a detectable signal even under reactor shutdown conditions. The primary source contains a radioactive material which spontaneously emits neutrons during initial core loading, reactor start up, and initial operation of first core. Secondary source rods contain a stable material which is activated by neutron bombardment during reactor operation.

The purpose of a neutron source assembly is to provide a base neutron level to give confidence that the detectors are operational and responding to core multiplication neutrons. For the first core, a neutron source is placed in the reactor to provide a positive neutron count of at least two counts per second on the source range detectors attributable to core neutrons. The detectors, called source range detectors, are used primarily during subcritical modes of core operation.

Both primary and secondary neutron source rods are used. The primary source rod, containing a radioactive material, spontaneously emits neutrons during initial core loading, reactor startup, and initial operation of the first core. After the primary source rod decays beyond the desired neutron flux level, neutrons are then supplied by the secondary source rod. The secondary source rod contains a stable material, which is activated during reactor operation. The activation results in the subsequent release of neutrons.

Four source fuel assemblies are typically installed in the initial load of the reactor core: two primary source fuel assemblies and two secondary source fuel assemblies. Each primary source assembly contains one primary source rod and a number of BA rods. Each secondary source assembly contains a symmetrical grouping of secondary source rodlets.

Neutron source assemblies are employed at opposite sides of the core. The source assemblies are inserted into the rod cluster control guide thimbles in fuel assemblies at selected locations.

The primary and secondary source rods both use the same cladding material as the absorber rods. The secondary source rods contain antimony-beryllium pellets stacked to a height of approximately 2235 mm (88 inches). The primary source rods contain capsules of californium (or plutonium-beryllium as a possible alternative) source material and alumina spacers to position the source material within the cladding.

The neutron source rods are designed to withstand the following:

- The external pressure equal to RCS operating pressure with appropriate allowance for overpressure transients.
- An internal pressure equal to the pressure generated by released gases over the source rod life.

6.3.1.8 Control Rod Drive Mechanisms

CRDMs are located within the CRDM pressure housings, which penetrate through the head of the RV, and include electrically powered magnets located outside the pressure housing. They are coupled to drive rods of the RCCAs that have neutron absorber material over the active length of the control rods and the GRCAs. Externally, the GRCAs are geometrically identical to the RCCAs.

The primary function of the CRDM is to insert or withdraw, at a designated speed, 53 RCCAs and 16 GRCAs to/from the core to compensate for reactivity changes due to variation in power and temperature.

CRDMs independently move each of the RCCAs and GRCAs into and out of the reactor core.. Each cluster is in a bank used for reactivity control, axial power distribution control, or shutdown control. The control assemblies of each bank of several RCCAs or GRCAs move at the same time.

The design of the CRDMs also permits holding the RCCAs and the GRCAs at any step elevation within the range of rod travel during normal operation. The RCCAs and GRCAs have the same mechanical coupling with the CRDM.

The CRDM is a magnetically operated jack (magjack). A magjack is an arrangement of three electromagnets energised in a controlled sequence by a power cycle to insert or withdraw RCCAs and GRCAs in the reactor core in discrete steps. The CRDM is designed to release the drive rod and RCCA or GRCA during any part of the power cycle sequencing if electrical power to the magnetic coils is interrupted. When released from the CRDM, the drive rod and RCCA or GRCA fall by gravity into a fully inserted position.

The CRDM withdraws and inserts a RCCA or GRCA as shaped electrical pulses are received by the operating coils. An on or off sequence is repeated by silicon-controlled rectifiers in the power programmer and causes the control rod to be withdrawn or inserted. The drive rod and RCCA or GRCA are withdrawn by magnetic forces, or inserted by gravity.

During plant operation, the stationary gripper coil and movable gripper coil of the drive mechanism hold the RCCA in a static position until a stepping sequence is initiated, at which time the stationary gripper coil, movable gripper coil, and lift coil are energised sequentially.

The control rod position is measured by 48 discrete coils mounted on the position indicator assembly surrounding the rod travel housing. Each coil magnetically senses the entry and presence of the top of the ferromagnetic drive rod assembly as it moves through the coil centreline.

The design and construction of the CRDM include provisions to establish that gross failure of the housing sufficient to allow ejection of a control rod from the core is not credible. (Control rod ejection is discussed further in Section 9.4.)

During most of the plant operating time, the CRDMs hold the RCCAs withdrawn from the core in a static position. During most plant operation, the GRCAs are held by the CRDMs withdrawn or inserted in the core in a static position as directed by flux shape considerations. In the holding mode, two coils – stationary gripper coil A and movable gripper coil B – are energised on each mechanism. The drive rod assembly and attached RCCAs or GRCAs hang suspended from the three latches of the stationary gripper. In addition, the three latches of the movable gripper are engaged to hold the drive rod assembly in place in the event of a failure that would cause the release of the stationary gripper.

When the driveline is positioned in the last few steps, the RCCAs and GRCAs are out of the last portion of the core, although not fully withdrawn from the fuel assemblies. The rod clusters cannot be physically withdrawn from the guide tubes by the CRDMs since no additional grooves are machined in the drive rod past the last position.

If power to the stationary and movable gripper coils is cut off, the combined weights of the drive rod assembly and the RCCA or GRCA (plus the stationary gripper and movable gripper return springs) move the latches out of the drive rod assembly groove. The trip occurs as follows:

- The magnetic field, holding the stationary gripper plunger against the stationary gripper pole, collapses; the stationary gripper plunger is forced down by the stationary gripper return spring and the weight acting upon the latches.

- The magnetic field, holding the moveable gripper plunger against the movable gripper pole, collapses; the movable gripper plunger is forced down by the moveable gripper return spring and the weight acting upon the latches.

The control rod falls by gravity into the core. After the driveline is released by the mechanism, it falls freely until the control rods enter the dashpot section of the fuel assembly, where the coolant in the guide tubes slows the rate of descent until the rods are fully inserted. Figures 17A-1 through Figure 17A-7 provide further detail of the CRDM.

6.3.1.9 Control and Instrumentation

This section describes the control and instrumentation for the RV/core.

Rod Position Indicators

The only instrumentation required for the CRDM and supporting systems to operate safely is the RPI. Both the digital rod position indication (DRPI) system and the digital rod control system (DRCS) are functions of the plant control system (PLS).

The DRPI system measures the position of each control rod assembly using rod position detector assemblies. A detector assembly consists of discrete coils mounted concentrically with the rod drive pressure housing. The coils are located axially along the pressure housing and magnetically sense the entry and presence of the rod drive shaft through its centreline. The signals from the detectors are processed by the data cabinets and transmitted to the distributed controllers. The distributed controllers further process the rod position information and transmit this information to the real-time data network.

Rod Position Indication Systems

The axial position of shutdown rods and control rods is indicated by two separate and independent systems: the bank demand position indication (Bank Demand Position Indication (BDPI), also commonly called group step counters) and DRPI.

Bank Demand Position Indication System

The BDPI system counts the pulses generated in the rod control system and provides a digital readout of the demanded bank position. There is one step counter for each group of rods. Individual rods in a group all receive the same signal to move and should, therefore, all be at the same position indicated by the group step counter for that group. The BDPI system is considered highly precise (±1 step). If a rod or the group does not move one step for each

demand pulse, the step counter will still count the pulse and incorrectly reflect the position of the rod or group.

The demanded and measured rod position signals are displayed in the main control room (MCR). An alarm is generated whenever an individual rod position signal deviates from the other rods in the bank by a preset limit. The alarm is set with appropriate allowance for instrument error and within sufficiently narrow limits to prevent core design hot channel factors from being exceeded.

Digital Rod Position Indication

The DRPI system measures the position of each control rod assembly using a detector consisting of discrete coils mounted concentrically with the rod drive pressure housing. The coils are located axially along the pressure housing and magnetically sense the entry and presence of the rod drive shaft through its centreline.

The DRPI system provides an indication of actual control rod position with a lower precision than the step counters. This system is based on inductive analogue signals from a series of coils spaced along a hollow tube. To increase the reliability of the system, the inductive coils are connected alternately to data system A or B. Thus, if one data system fails, the DRPI will work on half-accuracy. The DRPI system is capable of monitoring rod position within at least ±5 steps on full accuracy.

Controls

The reactor power control system, as a function of the PLS, coordinates the responses of the various reactivity control mechanisms. The system enables daily load follow operation with a minimum of manual operator control. Load regulation and frequency control are compatible with the reactor power control system operation. The reactor power control system also performs axial nuclear power distribution control.

The rod control system (as a function of the PLS), in conjunction with the reactor power control system, maintains nuclear power and reactor coolant temperature without challenges to the protection systems during normal operating transients.

6.4 REACTOR COOLANT SYSTEM AND CONNECTED SYSTEMS

The RCS removes heat from the reactor core and transfers it to the secondary side of the SGs for power generation. The RCS contains two vertical U-tube SGs (RCS-MB-01 and RCS-MB-02), four sealless RCPs (RCS-MP-01A/B and RCS-MP-02A/B), and one pressuriser (RCS-MV-02) (See Figure 6-2).

The RCS consists of two heat transfer circuits In addition, the system includes a pressuriser, ADS, interconnecting piping, valves, and instrumentation necessary for operational control and safeguards actuation.

A description of the reactor coolant loop supports is provided in section 16.13 and 20E.

Figure 6-2 shows the main components of the RCS. The RCS pressure boundary provides a barrier against the release of radioactivity generated within the reactor and is designed to provide a high degree of integrity throughout the operation of the plant.

Spring-loaded safety valves are installed above, and connected to, the pressuriser to provide overpressure protection for the RCS. These valves discharge into the containment atmosphere.

Three stages of RCS automatic depressurisation valves are also connected to the pressuriser. These valves discharge steam and water through spargers to the IRWST of the PXS. The steam and water discharged to the spargers is condensed and cooled by being mixed with the water in the tank. The Stage 4 automatic depressurisation valves are connected by two redundant paths to each reactor coolant loop hot leg and discharge directly to the containment atmosphere.

The RCS is also served by a number of auxiliary systems, including the CVS, the PXS, the RNS, SGS, the PSS, the WLS, and the CCS.

6.4.1 Reactor Coolant System

The following SSCs are addressed in this section of the document:

- Primary Coolant Loop
- Reactor coolant piping and valves
- Pressuriser
- RCPs
- SGs

Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.26.

6.4.1.1 Primary Coolant Loop

The RCS is shown schematically in Figure 6-2. The RCS consists of two heat transfer circuits, each with a steam generator, two RCPs, a single hot leg and two cold legs, for circulating reactor coolant between the reactor and the steam generators. In addition, the system includes a pressurizer, interconnecting piping, and valves and instrumentation necessary for operational control and safeguards actuation. All system equipment is located in the reactor containment.

During operation, the RCPs circulate pressurized water through the reactor vessel and the steam generators. The pressurized water, which serves as coolant, moderator, and solvent for boric acid (used for chemical shim control), is heated as it passes through the core. It next flows to the steam generators where the heat is transferred to the SGS, and then is returned to the reactor by the reactor coolant pumps to repeat the process. The steam generators have a vertical shell and u-tube configuration with integral moisture separating equipment. The reactor coolant pumps are enhanced-inertia, high-reliability, low-maintenance, sealless-motor pumps and are integrated into the steam generator channel heads in an inverted position.

The pressurizer integrates the following subsystems: spray, heaters, safety valves, and the automatic depressurization valves (ADS). Using electrical heaters and/or a water spray, the Pressurizer controls RCS pressure by maintaining a single major water-steam interface in equilibrium under saturated conditions. The pressurizer is a vertical cylindrical vessel, with hemispherical top and bottom heads; it communicates with the RCS primary coolant loops through a surge line connected to one RCS hot leg. Electrical heaters are installed through the bottom head of the vessel and are removable for maintenance or replacement. Steam is formed by the heaters or condensed by the spray (circulated from the cold legs by the driving

head of the RCPs) to control pressure variations caused by expansion and contraction of the reactor coolant. The pressurizer pressure, temperature, and level instrumentation is provided as required by the PMS and the PLS. To allow continuous monitoring of pressurizer/hot leg reactor coolant loop level during reduced inventory operation (i.e., mid-loop), the bottom tap of the pressurizer cold-calibrated wide range level channel is connected to the bottom of the hot leg that communicates with the pressurizer. Surge line temperature is monitored to detect thermal stratification and pressurizer insurges from the RCS hot leg.

6.4.1.2 Primary Coolant Piping and Valves

RCS piping is configured with two identical main coolant loops, each of which uses a single 787-mm (31-inch) inside-diameter hot leg pipe to transport reactor coolant to a steam generator. The two RCP suction nozzles of each loop are welded directly to the outlet nozzles on the bottom of the steam generator channel head. Two 558.8-mm (22-inch) inside-diameter cold leg pipes in each loop (one per pump) transport reactor coolant back to the RV (RCS-MV-01) to complete the circuit.

Supplemental design practices have been applied to pipe systems in the AP1000 plant, including the primary loop, where an improvement in reliability has an appreciable beneficial impact on plant safety, radiation exposure, and plant examination, maintenance, inspection and testing (EMIT) activities obligations. See Chapter 20 for more detail.

RCS piping is fabricated from stainless steel. The piping is forged seamless without longitudinal or electroslag welds. The RCS piping does not contain any cast fittings. Changes in direction are accomplished in most cases using bent pipe instead of elbows to minimise the number of welds, fittings, and short-radius turns.

The RCS piping includes those sections of reactor coolant hot leg and cold leg piping interconnecting the RV, SGs, and RCPs. The RCS pressure boundary also includes piping connected to the reactor coolant loop piping and primary components.

The RCS pressure boundary includes the second of two isolation or shutoff valves and the piping between those valves.

The connected piping in the RCS includes the following:

- CVS purification return line from the system isolation valve up to the nozzle on the steam generator channel head.
- CVS purification line from the branch connection on the pressuriser spray line to the system isolation valve.
- Pressuriser spray lines from the reactor coolant cold legs up to the spray nozzle on the pressuriser vessel.
- RNS pump suction lines from one reactor coolant hot leg up to the designated isolation valves.
- RNS pump discharge lines from the designated check valves to the connections to the core makeup tank return lines to the RV direct injection nozzles.
- Accumulator lines from the designated check valves to the RV direct injection nozzles.

- PXS lines from the cold legs to the CMTs and back to the RV direct injection nozzles.
- Drain, sample, and instrument lines to the designated isolation valves.
- Pressuriser surge line from one reactor coolant loop hot leg to the pressuriser vessel surge nozzle.
- Pressuriser spray scoops, reactor coolant temperature element installation boss, and the temperature element well itself.
- All branch connection nozzles attached to reactor coolant loops.
- Pressure-relief lines in the pressuriser safety and relief valve module from the nozzles on top of the pressuriser vessel up to and including the pressuriser safety valves and ADS lines from the pressuriser relief lines to the Stage 1, 2, and 3 ADS valves.
- ADS lines from the connections to the hot legs up to the Stage 4 ADS valves.
- Auxiliary spray line from the isolation valve up to the main pressuriser spray line.
- PXS lines from one hot leg to the PRHR HX, and back to the nozzle on the steam generator channel head.
- Vent line from the RV head to the vent isolation valves.
- IRWST injection/containment recirculation lines from the designated valves to the RV direct injection nozzles.
- Level and pressure instrumentation lines.

The RCS piping accommodates the system pressures and temperatures attained under all expected modes of plant operation or anticipated system interactions. Note that level and instrumentation lines connected to the RCS water space include a 9.5-mm (3/8-inch) diameter flow limiting orifice. If one of these lines breaks, the chemical volume control makeup pumps can provide makeup flow while maintaining pressuriser water level. Also, level and instrumentation lines connected to the RCS steam space include a 6.35-mm (1/4-inch) diameter flow limiting orifice. If one of these lines breaks, the pressuriser heaters can produce sufficient steam to maintain pressuriser pressure.

6.4.1.3 Pressuriser

The AP1000 plant pressuriser (RCS-MV-02) is a principal component of the RCS pressure control system. It is a vertical, cylindrical vessel with hemispherical top and bottom heads, where liquid and vapour are maintained in equilibrium at saturated conditions.

One spray nozzle and two nozzles for connecting the safety and depressurisation valve inlet headers are located in the top head. Electrical heaters are installed through the bottom head. The heaters are removable for replacement. The bottom head contains the nozzle for attaching the surge line. This line connects the pressuriser to a hot leg, and provides for the flow of reactor coolant into and out of the pressuriser during RCS thermal expansions and contractions.

The pressuriser provides a point in the RCS where liquid and vapour are maintained in equilibrium under saturated conditions for pressure control of the RCS during steady-state operations and transients. The pressuriser provides a controlled volume from which level can be measured.

The pressuriser contains the water inventory used to maintain RCS volume in the event of a small break LOCA (SBLOCA) for a reasonable period without replenishment. (The SBLOCA fault description can be found in Chapter 9.) The pressuriser surge line connects the pressuriser to one reactor coolant hot leg. This allows continuous coolant volume and pressure adjustments between the RCS and the pressuriser.

The pressuriser is designed to meet following requirements:

- The combined saturated water volume and steam expansion volume is sufficient to provide the desired pressure response to system volume changes.
- The water volume is sufficient to prevent a reactor trip during a step-load increase of 10 percent of full power, with automatic reactor control.
- The water volume is sufficient to prevent uncovering of the heaters following reactor trip and turbine trip, with normal operation of control systems and no failures of nuclear steam supply systems.
- The steam volume is large enough to accommodate the surge resulting from a step-load reduction from 100 percent power to house loads without reactor trip, assuming normal operation of control systems.
- The steam volume is large enough to prevent water relief through the safety relief valves following a complete loss of load with the high water level initiating a reactor trip, without steam dump.
- A low pressuriser pressure-engineered safety features actuation signal will not be activated because of a reactor trip and turbine trip, assuming normal operation of control and makeup systems and no failures of the nuclear steam supply systems.

The pressuriser is sized to have sufficient volume to accomplish the preceding requirements without power-operated relief valves. The AP1000 plant pressuriser has approximately 40 percent more volume than the pressurisers for previous plants with similar power levels. This increased volume provides plant-operating flexibility and minimises challenges to the safety relief valves.

The pressuriser and surge line provide the connection from the RCS coolant loop to the safety relief valves and the ADS valves. The safety relief valves provide overpressure protection for the RCS. The ADS is provided to reduce RCS pressure in stages to allow stored water in the IRWST to flow into the RCS to provide cooling.

The pressuriser surge nozzle and the surge line between the pressuriser and one hot leg are sized to maintain the pressure drop between the RCS and the safety relief valves within allowable limits during a design discharge flow from the safety relief valves or the valves of the ADS. Requirements for the surge line and piping connecting the pressuriser to safety and automatic depressurisation valves is discussed in Chapter 17.3.

The pressuriser provides a location for high-point venting of non-condensable gases from the RCS. The gas accumulations in the pressuriser can be removed by remote manual operation of the Stage 1 ADS valves following an accident. Degassing the pressuriser using the automatic depressurisation valves will not be required on a routine basis for normal- and moderate-frequency events.

6.4.1.4 Pressuriser Safety Relief Subsystem

Overpressure protection during power operation is provided for the RCS by the pressuriser safety relief valves (V005A/B), which are spring-loaded and self-actuated with backpressure compensation. Their set pressure and combined capacity is based on not exceeding the RCS maximum pressure limit during the Level B service condition loss of load transient. This protection is afforded for the following events to envelop those credible events that could lead to overpressure of the RCS if adequate overpressure protection were not provided:

- Loss of electrical load and/or turbine trip
- Uncontrolled rod withdrawal at power
- Loss of reactor coolant flow
- Loss of normal feedwater
- Loss of offsite power to the station auxiliaries

The downstream piping directs the valve discharge away from the pressurizer, ADS valves, and safety-related equipment and into the containment atmosphere (where it is collected in either the IRWST or the containment sump). The downstream piping consists of a short length of piping fitted with a rupture disc to provide an enclosed volume (discharge chamber) in which valve leakage may cool and condense.

6.4.1.5 RCS Automatic Depressurization Subsystem

The ADS valves (RCS-PL-V001A/B, RCS-PL-V002A/B, RCS-PL-V003A/B, RCS-PL-V004A/B) act in conjunction with the PXS to mitigate design basis accidents. Their function is to reduce the RCS pressure in a controlled fashion, to allow the required safety injection flow rates from the CMTs, accumulators, and IRWST. Automatic depressurization is required primarily to mitigate small-break LOCAs.

The automatic depressurization valve subsystem consists of four different valve stages that open sequentially to reduce RCS pressure sufficiently so that long term core cooling can be provided from the PXS.

Stages 1, 2, and 3 are arranged into two identical groups. Each group has a common inlet header connected to the top of the pressurizer and a common discharge line connected to one of the spargers in the IRWST.

For Stages 1, 2, and 3, each valve stage consists of two lines, each line containing two valves in series that are both normally closed. Each stage line is arranged with an isolation valve in series with, and upstream of, a control valve. When the ADS is actuated, the isolation valve opens first, then the control valve subsequently opens to initiate and control the flow to the

IRWST. The upstream ADS isolation valves for Stages 1 through 3 are gate valves. The downstream ADS control valves are globe valves.

Stage 4 is arranged into two identical groups. Each group has a common inlet header connected to one of the hot legs. Each Stage 4 group discharges separately into a steam generator compartment at an elevation above post-accident flood up level.

6.4.1.6 Reactor Vessel Head Vent Subsystem

The reactor vessel head vent portion of the RCS provides redundant, remotely operated head vent paths to be used to prevent pressurizer overfill during certain design basis events.

Each flow path contains two normally closed, fail-closed, solenoid-operated valves (RCS-PL-V150A/B/C/D). Each valve is powered by a separate essential electrical supply system (IDS) power train. The two flow paths reconnect, and the common header traverses the refueling cavity and discharges to the IRWST through the common discharge header of one train of automatic depressurization valves.

A normally isolated, manually operated, branch line from the common discharge header is located above the reactor vessel and discharges to the containment sump so that vessel venting and filling operations during plant startup can be monitored and performed by the plant personnel at a location remote from the reactor vessel.

6.4.1.7 Reactor Coolant Pumps

The AP1000 plant RCPs (RCS-MP-01A/B and RCS-MP-02A/B) are high-inertia, high-reliability, low-maintenance, sealless pumps that circulate the reactor coolant through the RV, loop piping, and SGs. The pumps are integrated into the steam generator channel head in the inverted position. A RCP is directly connected to each of two outlet nozzles on the steam generator channel head.

Sealless pumps have an extensive operational history in both conventional and nuclear plants with a record of very good reliability and significantly reduced maintenance as compared to shaft-seal pumps. In addition, they require no support after the pumps are tripped during fault sequences.

The integration of the pump suction into the bottom of the steam generator channel head eliminates the crossover leg of coolant loop piping; reduces the loop pressure drop; simplifies the foundation and support system for the steam generator, pumps, and piping; and reduces the potential for uncovering of the core by eliminating the need to clear the loop seal during a cold leg side SBLOCA.

The AP1000 plant design uses four pumps. Two pumps are coupled with each steam generator and have shafts that rotate in the same direction.

Each AP1000 plant RCP is a vertical, single-stage centrifugal pump designed to pump at high pressures and temperatures. Because of its sealless design, it is more tolerant of off-design conditions that could adversely affect shaft seal designs. The main impeller attaches to the rotor shaft of the driving motor, which is an electric induction motor. The motor is contained within a casing that provides the pressure boundary and primary coolant circulates between the stator and rotor, obviating the need for a seal around the motor shaft. In addition, the motor bearings are lubricated by primary coolant. Thus, the motor is an integral part of the

pump. The basic pump design has been proven by many years of service in other applications.

The pump motor size is minimised through the use of a variable frequency drive to provide speed control to reduce motor power requirements during pump startup from cold conditions.

In the UK design of AP1000 plant, a variable frequency drive (VFD) is run continuously to provide a 60-Hz power supply to the pump motor. The VFD is also used to reduce the pump speed during heatup and cooldown when the reactor trip breakers are open.

A sealless pump contains the motor and all rotating components inside a pressure vessel. The RCP driving motor is a vertical, water-cooled, squirrel-cage induction motor. The pressure vessel consists of the pump casing, stator closure, stator main flange, stator shell, stator lower flange, and stator cap, which are designed for full RCS pressure. The AP1000 plant utilizes a sealless RCP design. Sealless refers to the absence of a dynamic seal where the pump shaft penetrates the pump casing. Because the shaft for the impeller and rotor is contained within the pressure boundary, seals are not required to restrict leakage from the pump into containment.

The motor and other pump internals are cooled by primary RCS coolant circulating through the motor cavity. Primary coolant used to cool the motor enters the lower end of the rotor and passes axially through the motor cavity to remove heat from the rotor and stator and circulates to an external HX. An auxiliary impeller provides the motive force for circulating the coolant. Heat from the primary coolant is transferred to component coolant water in the external HX.

The RCP also includes a cooling jacket cooled by CCS that removes heat from the upper flywheel and bearing assembly.

Flywheel assemblies provide rotating inertia that increases the coastdown time for the pump. Each flywheel assembly is of bimetallic design consisting of a heavy-metal alloy and stainless steel. Surrounding the flywheel assemblies are the heavy walls of the stator closure, casing, thermal barrier, or stator lower flange.

The materials in contact with the reactor coolant and cooling water (with the exception of the bearing material) are austenitic stainless steel, nickel-chromium-iron alloy, or equivalent corrosion-resistant material.

The RCP is equipped with a vibration monitoring system that continuously monitors pump structure (frame) vibrations. Five vibration monitors provide pump vibration information. The readout equipment includes warning alarms and high-vibration level alarms, as well as output for analytical instruments.

Four resistance temperature detectors (RTDs) monitor the motor cooling circuit water temperature. These detectors indicate anomalous bearing or motor operation. They also provide inputs to automatic reactor and RCP trips in the event of a prolonged loss of component cooling water.

A speed sensor monitors rotor speed. In addition, voltage and current sensors provide information on motor load and electrical input.

An important advantage of sealless pump designs with water-lubricated bearings is that they eliminate the following problem areas:

- No RCP seals (no “seal LOCA” and no seal maintenance)
- No seal injection, seal return, or seal leakoff systems
- No lube oil reservoirs, lube oil cooling, oil lift, oil spillage collection systems, and associated fire protection systems
- Simplified RCP operations
- No need to establish and maintain flows, pressures, and levels to support seal operation
- No need to run the oil lift pump to pressurise the lubrication system before starting the RCP

6.4.1.8 AP1000 Plant Steam Generator

The AP1000 plant SG (RCS-MB-01 and RCS-MB-02) is a vertical shell and U-tube evaporator with integral moisture separating equipment. The basic design and features of the steam generator have been proven in tests and in previous SGs, including replacement SG designs. Design enhancements include nickel-chromium-iron-alloy-690 thermally treated tubes on a triangular pitch, improved anti-vibration bars, single-tier separators, enhanced maintenance features, and a primary-side channel head design that allows for easy access and maintenance by robotic tooling. The AP1000 plant SG employs tube supports utilising a broached hole support plate design. All tubes in the SG are accessible for sleeving, if necessary.

The basic function of the AP1000 plant SG is to transfer heat from the single-phase reactor coolant water through the U-shaped HX tubes to the boiling, two-phase water/steam mixture in the secondary side of the SG. The SG separates dry, saturated steam from the boiling mixture, and delivers the steam to an outlet nozzle, from which it is delivered to the turbine. Water from the feedwater system replenishes the SG water inventory by entering the SG through a feedwater inlet nozzle and feedring.

In addition to its steady-state performance function, the SG secondary side provides a water inventory that is continuously available as a heat sink to reduce the severity of primary-side high-temperature transients or decreased heat removal transients.

On the primary side of the SG, the reactor coolant flow enters the inlet portion of the SG primary chamber or channel head via the hot leg nozzle. The lower portion of the primary chamber is an ellipsoid and merges into a cylindrical portion, which mates to the tube sheet. This arrangement provides enhanced access to all tubes, including those at the periphery of the bundle, with robotics equipment. This feature enhances the ability to inspect, replace, and repair portions of the AP1000 plant unit compared to the more spherical primary chambers of earlier designs. The head is divided into inlet and outlet chambers by a vertical divider plate extending from the apex of the channel head to the tube sheet.

The reactor coolant flow enters the inverted U-tubes, transferring heat to the secondary side fluid during its traverse, and returns to the cold leg side of the primary chamber. The flow exits the SG via two cold leg nozzles to which the RCPs are directly attached.

Steam is generated on the shell or secondary side of the SGs (which is part of SGS), flows upward, and exits through the outlet nozzle at the top of the vessel. Feedwater enters the SG at an elevation above the top of the U-tubes through a feedwater nozzle. The feedwater enters a feedring via a welded thermal sleeve connection and exits through nozzles attached to the top of the feedring. The nozzles are fabricated of nickel-chromium-iron alloy that is very resistant to erosion and corrosion with the expected secondary water chemistry and flow rate through the nozzles. The nozzles are essentially holes in the top of the feedring. They are debris-filtering in that any loose parts larger than the hole diameter are retained in the feedring. After exiting the nozzles, the feedwater flow mixes with saturated water removed by the moisture separators. The flow then enters the downcomer annulus that is between the tube wrapper and the SG shell.

The SG channel head, tube sheet, and tubes are a portion of the reactor coolant pressure boundary. The tubes transfer heat to the steam system while retaining radioactive contaminants in the primary system. The SG removes heat from the RCS during power operation and anticipated transients, and under natural circulation conditions.

The SG heat transfer function and associated secondary water and steam systems are not required to provide safe shutdown of the plant. The secondary side systems are addressed in Section 6.5.

6.4.2 Chemical and Volume Control System

The design of the Chemical and Volume Control System consists of various heat exchangers as well as demineralizers, filters, pumps, tanks, and associated valves, piping, and instrumentation. The system functions as a whole to fulfill the requirements of controlling Reactor Coolant System chemistry, purity, and inventory for normal plant operations. Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.18. The description of this system within this section is consistent with the System Specification Document (Reference 6.18).

The Class 1 safety functions provided by the CVS are limited to containment isolation of CVS lines penetrating containment; termination of inadvertent RCS boron dilution; isolation of makeup on a SG or pressuriser high-level signal; and preservation of the RCS pressure boundary, including isolation of normal CVS letdown from the RCS.

The CVS is made up of two subsystems: a purification subsystem located inside containment, which consists of regenerative and letdown HXs, mixed bed demineralisers, and filters; and a makeup subsystem, located largely outside containment and consisting of makeup pumps, miniflow HXs, chemical dosing tanks, the boric acid tank, and a letdown path to the WLS. Containment isolation valves are provided on both sides of the containment penetrations. Under normal operation, the CVS purification subsystem is connected to RCS cold leg 1B, and returns to the SG 1 outlet chamber.

6.4.2.1 Chemical Control and Chemical Shim

The CVS incorporates the following functions to support the water chemistry and chemical shim requirements of the RCS:

- Provisions to add and remove chemicals for RCS pH control at startup, during normal operation, and in support of shutdown operations

- A means of adding and removing a soluble chemical neutron absorber (boron) at concentrations and rates compatible with normal plant operation and plant shutdown.

- Provisions for adding any other chemicals to the RCS through a Chemical Mixing Tank, such as hydrogen peroxide during shutdown operations.

- A means for scavenging oxygen during startups through the addition of hydrazine via the Chemical Mixing Tank and for controlling the formation of free oxygen due to radiolysis in the core during normal operation through the addition of hydrogen.

- A means for purification, which may include the need to control RCS chemistry parameters such as chlorides, fluorides, and sulfates.

- Provisions for adding a liquid zinc acetate solution into the RCS during plant operation.

6.4.2.2 Reactor Coolant Inventory Control and Makeup

Changes in the reactor coolant volume will be accommodated by the Pressurizer Level Control Program for normal power changes, including transition from hot standby to full power operation and returning to hot standby. In addition, the pressurizer has sufficient volume, within the deadband of the level control program, to accommodate minor RCS leakage for some period of time. The CVS provides inventory control to accommodate minor leakage from the RCS, expansion during heatup from cold shutdown, and contraction during cooldown. This inventory control is provided by connections with the letdown and makeup subsystems.

6.4.2.3 Filling and Pressure-Testing the RCS

RCS filling is accomplished by using the CVS Makeup Pumps (CVS-MP-01A/B) to provide fluid at the proper boron concentration (refueling concentration). The CVS Makeup Pumps take suction from both the Boric Acid Storage Tank and the Demineralized Water Transfer and Storage System (DWS) through a three-way blend valve (CVS-PL-V115), which ensures the proper boron concentration.

The CVS Makeup Pumps produce sufficient head to pressure test the RCS after maintenance and refueling outages. However, a temporary hydrostatic test pump will be required for initial hydrotesting which will require higher operating pressures than can be achieved with the Makeup Pumps.

6.4.2.4 Borated Makeup to Auxiliary Equipment

The CVS Makeup Pumps will also be used to provide makeup at the proper boron concentration to the PXS Accumulators (PXS-MT-01A/B), Core Makeup Tanks (PXS-MT-02A/B), In-Containment Refueling Water Storage Tank (PXS-MT-03), and the SFP.

6.4.2.5 Pressurizer Auxiliary Spray

The CVS Makeup Pumps provide auxiliary spray to the pressurizer through a connection on the pressurizer main spray header. The Makeup Pumps take suction from the BAST (CVS-MT-01) and the DWS to provide borated water at a selected boron concentration. The pumps use the normal makeup path to the RCS through the shell side of the RHX and continue through the auxiliary spray isolation valve (CVS-PL-V084) to the RCS and the connection on the main spray header.

6.4.3 Normal Residual Heat Removal System

The RNS can provide closed loop heat removal from the core and the RCS during shutdown operations or mitigation of an accident.

The RNS includes two mechanical trains of decay heat removal equipment. Each train includes one RNS pump (RNS-MP-01A/B) and one RNS heat exchanger (RNS-ME-01A/B) located in the Auxiliary Building. Additional design details of this system and its constituent components are delineated in Reference 6.19 and Chapter 17. The description of this system within this section is consistent with the System Specification Document (Reference 6.19).

The Class 1 safety functions provided by the RNS are containment isolation of RNS lines penetrating containment, preventing the release of radioactive material through the boundary of RCS, and removing decay heat from the reactor during normal operation and accident conditions.

6.4.3.1 Normal Cooldown

The first phase of RCS cooldown normally consists of transferring heat from the RCS through the steam generators and the MSS to the main condensers. The RNS removes decay heat from the core and reduces the temperature of the RCS during the second phase of plant cooldown.

6.4.3.2 Refueling Heat Removal

Following cooldown, the RNS continues to remove heat from the core and the RCS during refueling operations. Once refueling of the reactor is complete, and as decay heat decreases, one subsystem of RNS equipment may be taken out of service. This occurs approximately 11 days after reactor shutdown.

6.4.3.3 Refueling Draindown

During some cooldown operations, the RCS water level is drained to a “mid-loop” level to permit steam generator draining and maintenance activities. The RCS drain path is from the CVS branch through a DVI inlet line after the RNS discharge header splits inside containment. For normal refueling operations, the RCS is drained to a level that allows air to be vented into the steam generator from the pressurizer.

6.4.3.4 Shutdown Purification

The RNS provides CVS purification flow during shutdown and refueling operations when the RCPs are not operating or are operating at reduced speeds, and whenever the CVS return line to the steam generator is unavailable for normal RCP purification flow while the RNS is aligned with the RCS.

6.4.3.5 IRWST Cooling

The RNS provides cooling for the IRWST during operation of the PRHR heat exchanger. The system is manually aligned and initiated by the operator within one to two hours of initiation of the PRHR heat exchanger, if possible. The RNS cooling limits the IRWST water temperature to less than boiling during extended operation of the PRHR heat exchangers. In the event of a single failure in the RNS, boiling of the IRWST may occur during extended operation of the PRHR.

During power operation, the RNS provides cooling for the IRWST if required and limits the IRWST to 48.9°C (120°F).

6.4.3.6 Shutdown or Post-Accident Heat Removal

Following an accident which actuates all stages of ADS, including IRWST injection, the RNS can be aligned to provide decay heat removal in order to bring the plant to cold shutdown conditions. The flow path through the RNS for this operation is the same as that used during a normal refueling shutdown.

The RNS can also be used for decay heat removal during non-LOCA scenarios after the PXS has cooled the RCS to a temperature at which the RNS can be aligned. The PRHR would provide initial cooling to bring the RCS to a temperature and pressure which the RNS could be aligned. Normal RNS cut-in temperature is 176.7°C (350°F), but for a limited number of occurrences the RNS can be aligned at 204.4°C (400°F). For this situation, it would also be assumed that the RNS was also used to cool the IRWST during PRHR operation to prevent IRWST steaming.

6.4.3.7 Low-Pressure RCS Injection

6.4.3.7.1 Injection from the Cask Loading Pit

The RNS is capable of providing low-pressure makeup from the SFS Cask Loading Pit to the RCS. The system must be manually initiated by the operator following receipt of an ADS signal. If the RNS is available, it will provide RCS makeup once the pressure in the RCS falls below the shutoff head of the RNS pumps.

Following an ADS signal in the event of a small break LOCA or a non-LOCA event, the RNS is designed to provide sufficient makeup flow so that the water level in the CMTs does not drain below the ADS Stage 4 valve actuation setpoint. In this way, successful operation of the RNS will prevent the ADS Stage 4 valves (located off the RCS hot legs) from opening, and thereby prevent substantial flooding of the containment and the need for cleanup.

6.4.3.7.2 Injection from the IRWST

The RNS is capable of providing low-pressure makeup from the IRWST to the RCS. The system must be manually initiated by the operator following receipt of an ADS signal. If the RNS is available, it can provide RCS makeup once the pressure in the RCS falls below the shutoff head of the RNS pumps.

Following an ADS signal in the event of a SBLOCA or a non-LOCA event, the RNS is designed to provide sufficient makeup flow so that the water level in the CMTs does not drain below the ADS Stage 4 valve actuation setpoint. In this way, successful operation of the RNS will prevent the ADS Stage 4 valves (located off the RCS hot legs) from opening, and thereby prevent substantial flooding of the containment and the need for clean up.

6.4.3.8 Forced Core Cooling by Containment Recirculation

After an event that results in containment flooding, the RNS can be aligned to take suction from the containment sump to provide additional core cooling. This alignment is possible after the PXS containment recirculation squib valves (PXS-PL-V118B and PXS-PL-V120B) have actuated.

If the RNS was previously used to inject water from the CLP or IRWST into the RCS to prevent the CMTs from draining, RNS containment recirculation through RNS can also be used to continually hold up the CMT level, thereby preventing actuation of ADS Stage 4.

If the RNS was not used to prevent draining of the CMTs below the ADS Stage 4 valve actuation setpoint, ADS Stage 4 will actuate and containment recirculation will still be possible. In this scenario, the RNS will take suction from the containment sump and inject through the DVI lines into a depressurized reactor vessel to provide additional core cooling.

6.4.3.9 Long-Term Post-Accident Makeup Capability from Outside Containment

After an accident which has included ADS Stage 4, long-term makeup may be required from outside containment. The flow path for this long-term supply of water is through the discharge containment penetration test connection valves (RNS-V012A/B), by administratively controlled water addition.

6.4.3.10 Low-Temperature Overpressure Protection (LTOP)

The RNS LTOP function is required to be available during shutdown, refueling, and heatup operations when the RCS cold leg temperature is ≤ 135°C (275°F).

6.4.3.11 Spent Fuel Pool Cooling

RNS can supplement or replace normal SFS cooling of the SFP during plant operation modes when the RNS is not needed for reactor core cooling.

6.4.3.12 RCS Vacuum-Refill Subcooling

The RNS provides cooling of RCS during vacuum refill operations.

6.4.3.13 Cask Loading Pit Circulation

The RNS pump suction can be aligned with the cask loading pit (CLP), by aligning valve RNS-PL-V055A/B in the MCR, and the discharge aligned to the SFP, by opening normally locked closed valve RNS-PL-V053A/B, to provide circulation of the CLP. The gate between the SFP and CLP must also be opened. This flow path allows the CLP water inventory to be recirculated to prevent stagnation and stratification and provide the required water chemistry.

6.4.4 Primary Sampling System

The primary sampling system (PSS) collects representative samples of fluids from the process streams of the reactor coolant system and associated auxiliary systems and from the containment atmosphere for analysis by the plant operating staff. This sampling process can be performed during normal plant operations or post-accident operations. Most components and equipment are common to both modes of operation. This arrangement permits the operator to gain the necessary operational experience with the PSS during normal operations, which is directly applicable to post-accident operations.

The PSS is composed of two main subsystems:

- Liquid Sampling
- Containment Atmosphere Sampling

Additional design detail of this system and its constituent components are delineated in Reference 6.36 and Chapter 21.

The Class 1 safety functions provided by the PSS are containment isolation of PSS lines penetrating containment and preventing the release of radioactive material through the boundary of RCS.

6.4.4.1 Liquid Sampling

The liquid samples have three flow paths: (1) grab sampling of the auxiliary systems and RCS pressurizer process streams (2) continuous sampling of the RCS hot legs (3) grab sampling of PXS. The paths maintain separation such that the continuous and grab sampling paths can be used simultaneously.

6.4.4.1.1 Liquid Grab Sampling

The liquid sampling portion of the PSS is used to collect and transport liquid samples from the reactor coolant system and associated auxiliary systems to a common location in a sample room located in the Auxiliary Building. Additionally there is another liquid sampling path of the PSS is used to collect and transport liquid samples from the PXS sample sources to the aforementioned sample room located in the Auxiliary Building. A radiological chemical laboratory facility is located immediately above the sampling room. Instrumentation and controls are provided to ensure safe and reliable operation of the system.

6.4.4.1.2 Continuous Liquid Sampling

The continuous liquid sampling path of the PSS is used to collect and transport liquid samples from the reactor coolant system hot leg sample sources to a common location in a sample room located in the Auxiliary Building.

The continuous flow of RCS hot leg fluid through the PSS makes it possible to (1) collect grab samples of the auxiliary systems' process streams while maintaining continuous flow of the RCS hot legs, (2) collect a representative zinc sample, (3) collect a representative corrosion product sample, and (4) collect a continuous sample of dissolved hydrogen while keeping the daily PSS effluent below the WLS design limit.

6.4.4.2 Containment Atmosphere Sampling

The containment atmosphere (CA) sampling portion of the PSS is employed to collect gaseous samples from the containment atmosphere. CA sampling is conducted in the same sampling room in the Auxiliary Building as liquid sampling. The CA sampling components, valves, and piping share the same grab sampling panel (GSP) as the liquid sampling accessories, and CA sampling control is from the same local control stations.

Similar to the liquid sampling subsystem, the valves used in the CA sampling portion of the GSP are manually operated from outside the enclosure via valve-stem extensions that penetrate the front of the GSP. To supply the motive force for CA sample collection, the CA sampling subsystem uses an ejector which employs pressurized nitrogen gas as its motive force.

Containment atmosphere samples are drawn from the inlet of each set of containment recirculation fans inside containment. Air flow inside of containment is circulated to the containment recirculation fans.

The capability to collect a containment atmosphere sample for radionuclide analysis is provided by the PSS. The PSS only collects a containment atmosphere sample; the analysis must be performed in the radiochemistry laboratory.

Containment atmosphere hydrogen monitoring is performed by the hydrogen analysers provided by the containment hydrogen control system (VLS). However, the PSS is designed to collect a representative containment sample for subsequent analysis and can therefore provide backup capability to the hydrogen control system.

6.4.4.3 Boron Concentration Monitoring System

The boron monitor will pull a sample from the RCS sample lines in order to provide semi-continuous samples.

6.4.4.4 Corrosion Product Sample Filter Package

The corrosion filter package utilizes lines which branch off of the PSS continuous sample line in order to provide .

6.5 STEAM AND POWER CONVERSION SYSTEMS

6.5.1 Summary Description

The steam and power conversion system is designed to remove heat energy from the RCS via the two SGs and to convert it to electrical power in the turbine generator. The main condenser and deaerator removes air from the condensate and transfers unusable heat in the cycle to the circulating water system (CWS). The regenerative turbine cycle heats the feedwater, and the main feedwater system (FWS) returns it to the SGs (see Chapter 17.4).

The steam generated in the two SGs is supplied to the high-pressure turbine by the main steam system. After expansion through the high-pressure turbine, the steam passes through the two moisture separator reheaters (MSRs) and is then admitted to the three low-pressure turbines. A portion of the steam is extracted from the high- and low-pressure turbines for seven stages of feedwater heating.

Exhaust steam from the low-pressure turbines is condensed and deaerated in the main condenser. The heat rejected in the main condenser is removed by the CWS. The condensate pumps take suction from the condenser hot well and deliver the condensate through four stages of low-pressure, closed, feedwater heaters to the fifth stage, the open deaerating heater. Condensate then flows to the suction of the SG feedwater booster pump and is discharged to the suction of the main feedwater pump. The SG feedwater pumps discharge the feedwater through two stages of high-pressure feedwater heating to the two SGs. Further design details of this system and its constituent components are delineated in Chapter 17, Reference 6.27, and Reference 6.28.

The turbine generator has an output of approximately 1200 MW for the Westinghouse nuclear steam supply system (NSSS) thermal output of 3415 MWt.

The following SSCs are addressed in this section:

- Main feedwater and condensate systems
- Main steam system
- Steam generator system

- Main turbine generator
- Turbine bypass feature of the MSS
- MSRs
- Condenser air removal system
- Gland seal system
- Main condenser
- Steam generator blowdown system
- Startup portion of the main feedwater system
- Circulating water system
- Auxiliary steam supply system
- Turbine island chemical feed system
- Condensate polishing system

6.5.2 Main Feedwater and Condensate Systems

The main feedwater and condensate systems provide feedwater at the required temperature, pressure, and flow rate to the SGS. The systems are located within the turbine building and are discussed further in Section 17.4). Additional design details of this system and its constituent components are delineated in Reference 6.31 and Reference 6.50.

The SGS contains the piping and valves in the auxiliary building that deliver the feedwater to the SGs.

The main portion of the feedwater flow originates from condensate pumped from the main condenser hot well by the condensate pumps. The main feed water system contains three 50% capacity main feedwater pump trains. The main condenser hot well receives makeup from the condensate storage tank, as required. The condensate passes through the condensate polishing system and/or the condensate polishing bypass, and is delivered to the deaerator tank.

During plant startup, three recirculation paths facilitate system cleanup and adjustment of water quality prior to initiating feed to the SGs. These cleanup loops are designed for approximately 33 percent of design condensate flow and include a hot well recirculation loop, a deaerator recirculation loop, and a long-cycle recirculation loop from downstream of the No. 7 feedwater heaters. Steam is provided to the deaerating feedwater heater from the auxiliary steam supply system (ASS) to preheat the feedwater to over 93.3°C (200°F) during the initial cleanup and startup recirculation operations. This preheating action, along with chemical addition, minimises the formation of iron oxides in the condensate system.

The feedwater and condensate systems supply the SGs with heated feedwater in a closed steam cycle using regenerative feedwater heating. The system comprises the CDS, the heater drain system, the main feedwater system, and portions of the SGS. The condensate system (CDS) collects condensed steam from the condenser and pumps condensate forward to the deaerator. The feedwater system takes suction from the deaerator and pumps feedwater forward to the SGS using high-pressure main feedwater pumps.

This system consists of the pipes, valves, pumps, feed heaters, and deaerator supplying feedwater from the main condenser to the two SGs via the SGS. It is required to do this during startup and operation at power, to remove the heat intentionally produced by the reactor core; and in the initial phase of shutdown operation before the RNS can be connected to the RCS, to remove the fission product decay heat from the reactor core.

The feed and condensate systems are located within the turbine building, and the SGS is located within the auxiliary building and containment.

The main feedwater and condensate systems perform the following major functions:

- Supplies main feedwater to the SGS during operation at power
- Supplies startup feedwater to the SGS during startup and during the initial phase of shutdown and RCS cooldown operation before the RNS is connectable.
- Pressurises the feedwater above the current SG pressure, and automatically controls the flow of the water into each SG to the rate required to remove the heat generated by the reactor core under the prevailing conditions, without the SG becoming overfilled.
- During operation at power, heats the feedwater to the optimum temperature for maximising the thermodynamic cycle efficiency.
- In conjunction with the condenser air removal system and the turbine island vents and drains system, removes from the feedwater those dissolved gases originating from air leaking into the sub-atmospheric parts of the CDS and from gases dissolved in the condensate in the condenser hot well.
- The heater drain system extracts some of the moisture from the steam as it expands through the turbine cylinders by draining condensate from the feedwater heaters and removing moisture from the high-pressure exhaust steam in the MSRs, thereby improving thermodynamic cycle efficiency and minimising turbine blade erosion.

Condensate is pumped out of the main condenser hot well, which is at sub-atmospheric pressure, by the condensate pumps. The water passes through the low-pressure feedwater heaters, which heat it using steam extracted from the low-pressure turbines. The last-stage low-pressure heater is incorporated into the deaerator tank, which also removes dissolved air and non-condensable gases from the feedwater and, by virtue of its substantial volume, acts as a reservoir of feedwater equivalent to 3.5 minutes supply at full-delivery flow.

The feedwater pumps (FWS-MS-01A/B/C) pressurise the water up to the high pressure required to deliver flow to the SGs. The main feedwater pumps are each preceded by a booster pump to pressurise the inlet of the main feed pump and thereby prevent cavitation. The booster pumps draw their suction from the deaerator tank. The high-pressure feed flowing out of the main feed pumps passes through the high-pressure feed heaters, which heat it up further using steam extracted from the high-pressure turbine.

Main feedwater is supplied to the SGS and then to each of the two SGs through its own main feedwater line. Each of the two lines is anchored at the interface between the auxiliary building and the turbine building, and has sufficient flexibility to provide for relative movement of the line and its associated SG resulting from thermal expansion. Each main feedwater line contains a control valve, a check valve, and an isolation valve. These valves are installed in the line before it enters the containment. The main feedwater lines are a closed system inside the reactor containment and are therefore not fitted with more valves.

The principal purpose of each main feed control valve is to maintain the level of water in its associated SG at a programmed level; its secondary purpose is to provide the capability for backup isolation. These pneumatically actuated valves are normally under automatic control but can be switched to manual.

An isolation valve (SGS-PL-V057A/B) is installed downstream of each feedwater control valve (SGS-PL-250A/B). The main functions of the isolation valve are to stop hot pressurised

feedwater from leaking into the containment (in the event of a main feedwater line break inside the containment) and to isolate the SGs in the event of a ruptured SG tube. Closure of the isolation valve uses compressed nitrogen as its energy source.

Each main feedwater line also includes a check valve (SGS-PL-V058A/B). During normal and abnormal conditions, this check valve prevents reverse flow from the SG should the feedwater pumps be tripped. In addition, the valves stop the uncontrolled blowdown from the SGs in the event of a feedwater line break outside the containment, and they stop more than one SG from blowing down in the event of feedwater line break inside the containment.

In a similar manner, the startup feedwater is supplied to the SGS and then to each of the two SGs through its own startup feedwater line and startup feedwater nozzle on each SG. The startup feedwater is provided by either of two startup feedwater pumps that take suction from the condensate storage tank. Also, the main feed system can be connected to the startup feedwater portion of the system at the feed pump outlet header. The connection has an isolation valve (SGS-PL-V067A/B) and a check valve (SGS-PL-V265A/B), allowing the main feed pumps to supply the SGs through the startup feedwater control valves.

6.5.3 Startup Portion of the Main Feedwater System

The startup portion of the main and startup feedwater system (FWS) supplies feedwater to the SGs during plant startup, hot standby, and shutdown conditions; and during transients in the event of main feedwater system unavailability. The startup feedwater flow path includes components from the FWS and the SGS. The startup flow path to the SG has an isolation valve (SGS-PL-V067A/B) and a check valve (SGS-PL-V265A/B). Further details of this subsystem and its components are given in subsection 17.4. Further design details of this system and its constituent components are delineated in Reference 6.31.

There are no Class 1 safety functions provided by the FWS. The startup feed water pumps (FWS-MP-03A/B) provide decay heat removal from the reactor during normal operation and accident conditions which is a Class 2 safety function. This decay heat removal function can prevent unnecessary actuation of the passive decay heat removal system. These events include loss of main feedwater and loss of normal alternating current (ac) power.

Startup feedwater is defined to be feedwater that passes through the startup feedwater control valves, and can be supplied from either of two sources:

1. A booster/main feedwater pump drawing from the deaerator storage tank and delivering through cross-connect piping to the startup feedwater header.

2. One or both startup feedwater pumps drawing from the condensate storage tank and delivering to the startup feedwater header.

The startup feedwater pumps are much smaller and do not require booster pumps. They draw their suction from the condensate storage tank; they supply directly to the SGs, with no feed heating at all. A cavitating venturi is installed at the discharge of each startup feedwater pump to prevent runout of the startup feedwater pump. The venturi flow elements provide a passive means of limiting the maximum achievable flow. The startup feedwater pumps start automatically on conditions that exist after a reactor trip. The pumps are automatically loaded on the standby diesel generators if offsite power is lost.

There are two startup feedwater lines, with the same disposition of valves as the two main feedwater lines. Each line supplies its own SG through an injection nozzle at the same elevation as the main feedwater nozzle but rotated circumferentially away from it. During

startup, feed is supplied through the startup feedwater control valves (SGS-PL-V255A/B) until the capacity limit of the startup pumps is approached, at which point the main feedwater pumps are placed into service and feedwater control is automatically transferred from the startup feedwater control valves to the main feedwater control valves; the startup feed isolation valves are then closed.

6.5.4 Main Steam Supply System

The main steam supply system as described in this section includes components of the steam generator system (SGS), main steam system (MSS), and main turbine system (MTS). The system is described in Section 17.4. Further design details of this system and its constituent components are delineated in Reference 6.27, 6.28, and 6.29.

The MSS supplies steam from the SGs to the high-pressure turbine over a range of flows and pressures covering the entire operating range from system warmup to maximum calculated turbine conditions. The steam generator system includes the pipes and valves that take the steam from each SG to the main steam isolation valves at the boundary of the auxiliary building and turbine building. The MSS consists of the pipes and valves that then take the steam downstream of the main steam isolation valves to the stop valves of the high-pressure turbine. It diverts a proportion of the steam to the MSR and a small amount of steam to seal the low-pressure turbine glands. A turbine bypass connection allows the steam to be dumped directly into the main condenser without passing through the turbine.

The SGS and MSS are required during operation at power to remove the heat produced by the reactor core, and also in the initial phase of shutdown operation before the RNS can be connected, to remove the fission product heat from the reactor core. The heat sinks are provided either by venting steam to atmosphere or by the turbine bypass system dumping steam to the condenser.

The system provides steam to the MSRs and the gland seal system for the main turbine. The system can dissipate heat generated by the NSSS when the turbine generator is not available by using steam dump valves to the condenser or by using the SG power-operated atmospheric relief valves or spring-loaded main steam safety valves, which discharge to the atmosphere, when the condenser is unavailable.

The main steam lines deliver a steam flow from the secondary side of the two SGs.

A portion of the main steam flow is directed to the reheaters and steam seals, with the turbine receiving the remaining steam flow. Each main steam line from the SGs is anchored at the auxiliary building wall and has sufficient flexibility to accommodate thermal expansion. The layout of the steam piping, with its proper sloping of lines and use of condensate drain pots, provides for collection and drainage of condensate to avoid water entrainment.

Turbine bypass valves are provided between the main steam isolation valves and turbine generator stop valves, as discussed in the paragraphs about the turbine bypass system in the later subsections.

Main steam piping is designed to consider the effects of erosion and corrosion. Piping containing dry, single-phase steam is constructed of carbon steel. Piping exposed to wet, two-phase steam is constructed of erosion- and corrosion-resistant low-alloy steel or carbon steel with a stainless-steel inner liner. Velocities in the main steam piping to the high-pressure turbine are limited to reduce the potential for pipe erosion. Low point drains are provided for collecting and draining moisture and to help reduce the potential for water carryover to the high- and low-pressure turbines.

Upstream of the main steam isolation valves, there are connections for the power-operated atmospheric relief valves, main steam safety valves, low point drains, high point vents, and nitrogen blanketing. Branch piping downstream of the main steam line isolation valves includes connections for the two-stage reheaters, gland seal system, turbine bypass system, auxiliary steam system, and low point drains.

Each main steam line goes from its SG and passes through the containment boundary. Each line contains a MSIV that is located outside of containment to isolate the steam lines. Upstream of the MSIV in each of the two steam lines are the six steam safety valves; each one vents to atmosphere through a discharge pipe and vent stack. Downstream of the safety valves is the power-operated atmospheric relief valve, which vents to atmosphere through a vent pipe and silencer. The operation of the power-operated atmospheric relief valves is automatically controlled by steam line pressure during plant operations; the valves automatically modulate open and exhaust to atmosphere whenever the steam line pressure exceeds a predetermined setpoint. As steam line pressure decreases, the relief valves modulate closed. Each main steam line is anchored at the point where it passes through the wall between the auxiliary building and the turbine building; the section of it from the SG to the anchor has sufficient flexibility to accommodate thermal expansion. Beyond this wall the two main steam lines are cross-connected into a common header, which itself subsequently branches into four lines to the turbine stop valves; the connections to the two MSRs, the gland sealing system, and the turbine bypass also branch from this common header.

6.5.4.1 Main Steam Safety Valves

Main steam safety valves with sufficient rated capacity are provided to prevent the steam pressure from exceeding 110 percent of the MSS design pressure following:

- A turbine trip without a reactor trip and with main feedwater flow maintained
- A turbine trip with a delayed reactor trip and the loss of main feedwater flow

At the same time, the individual safety valves are limited to the maximum allowable steam relief valve capacity (Section 17.4) to limit the potential uncontrolled blowdown flow and the ensuing reactor transient should a single safety valve inadvertently fail or stick in the open position.

Six safety valves (SGS-PL-V030A/B, V031A/B, V032A/B, V033A/B, V034A/B, and V035A/B) are provided per main steam line for the plant. The main steam supply system safety valves are located in the portion of the main steam piping upstream of the main steam isolation valves and outside the containment in the auxiliary building.

6.5.4.2 Power-Operated Atmospheric Relief Valves

A power-operated atmospheric relief valve (PORV) (SGS-PL-V233A/B) is installed on the outlet piping from each SG to provide controlled removal of reactor decay heat during normal reactor cooldown when the main steam isolation valves (SGS-PL-V040A/B) are closed or the turbine bypass system is not available. The maximum capacity of the relief valve at design pressure is limited to reduce the magnitude of a reactor transient if one valve would inadvertently open and remain open.

Each power-operated atmospheric relief valve is located outside the containment in the auxiliary building upstream of the main steam isolation valves, in the portion of the main steam line associated with each SG. This location permits valve operation following transient conditions, including those that could result in closure of the main steam isolation valves.

The operation of the power-operated atmospheric relief valves is automatically controlled by steam line pressure during plant operations. The power-operated atmospheric relief valves automatically modulate open and exhaust to atmosphere whenever the steam line pressure exceeds a predetermined setpoint. As steam line pressure decreases, the relief valves modulate closed, reseating at a pressure at least 0.7 bar (10 psi) below the opening pressure. The setpoint is selected between no-load steam pressure and the set pressure of the lowest set safety valves.

The SG power-operated atmospheric relief valves provide a means for plant cooldown by discharging steam to the atmosphere when the turbine bypass system is not available. Under such circumstances, the relief valves (in conjunction with the startup feedwater system) allow the plant to be cooled down at a controlled cooldown rate from the pressure setpoint of the lowest set of safety valves down to the point where the RNS can remove the reactor heat.

For their use during plant cooldown, the power-operated atmospheric relief valves are automatically controlled by steam line pressure, with remote manual adjustment of the pressure setpoint from the MCR or the remote shutdown room (RSR) (which contains the remote shutdown workstation (RSW)). To effect a plant cooldown, the operator manually adjusts the pressure setpoint downward in a stepwise fashion. The maximum cooldown rate achievable is limited by the flow-passing capability of the relief valves, the number of SGs (and hence the number of relief valves) in service, the available startup feedwater pumping capacity, and the desire to either maintain or recover SG water levels during the cooldown.

The PORVs also help to avoid actuation of the safety valves during certain transients and, following safety valve actuation, assist the safety valves to positively reseat by automatically reducing and regulating steam pressure to a value below the valve reseating pressure. The operation of each power-operated atmospheric relief valve is controlled in response to measurements of steam line pressure provided by four separate pressure taps on the associated steam line.

The valve operator is an air-operated modulating type, providing throttling capability over a range of steam pressures.

The atmospheric relief valves are controlled by control systems for the modulating steam relief function. The capability for remote manual valve operation is provided in the MCR and at the RSW. A solenoid is provided to vent the air from the valve operator to terminate a steam line depressurisation transient.

An isolation valve with remote controls is upstream of each power-operated relief valve, providing isolation of a leaking or stuck-open valve. The upstream location allows for maintenance on the power-operated relief valve operator at power. The motor-operated isolation valve closes automatically on low steam line pressure to terminate steam line depressurisation transients.

6.5.4.3 Main Steam Isolation Valves

The function of main steam isolation (SGS-PL-V040A/B) is to limit the following:

- Blowdown to one SG in the event of a steam line break
- The cooling effect upon the reactor coolant to within the specified fuel design limits
- Containment pressure to a value less than design pressure
- Isolate ruptured SG for SGTR.

Main steam isolation consists of one quick-acting gate valve in each main steam line and one associated globe main steam isolation bypass valve with associated actuators and instrumentation. These valves are located outside the containment, downstream of the SG safety valves and the atmospheric relief valve, in the auxiliary building. The isolation valves provide positive shutoff with minimum leakage during postulated line severance conditions either upstream or downstream of the valves.

The main steam isolation valves (MSIVs) close fully upon receipt of a manual or automatic signal and remain fully closed.

Position indication and remote manual operation of the isolation valves are provided in the main control room and remote shutdown workstation.

6.5.4.4 Steam Generator Isolation Valves

In addition to the main steam isolation valves discussed above, there are additional SGS isolation valves that are automatically actuated in order to completely isolate a SG under faulted or ruptured conditions.

Four valves (SGS-PL-V074A/B and SGS-PL-V075A/B) are associated with the steam generator blowdown system (BDS). Two series isolation valves are on each SG blowdown line as it exits the containment. These fail-closed, isolation valves receive an automatic closure signal from PMS on the following three signals:

- Low narrow-range SG level
- PRHR HX actuation
- Containment isolation signal

The drain line for each main steam line outside containment and upstream of the MSIVs contains two series, fail-closed, isolation valves that are automatically closed on receipt of a steam line isolation signal.

Each MSIV steam bypass line contains a fail-closed isolation valve that is automatically closed on receipt of a steam line isolation signal.

6.5.5 Main Turbine Generator

The main turbine receives steam from the SGs, extracts useful energy from the steam by expanding it, and then exhausts it into the main condenser. The turbine generator consists of a single double-flow, high-pressure turbine cylinder and three double-flow, low-pressure turbine cylinders. It is described fully in Section 17.4. Two MSRs are between the high- and low-pressure cylinders. Some steam is bled off at various points during the expansion of the steam as it passes through the turbine, which is used principally for heating the feedwater and reheating the steam; these processes enhance the cycle thermodynamic efficiency. A number of auxiliary systems are associated with the main turbine: the bearing lubrication oil system, a digital electrohydraulic control system, a turbine gland steam sealing system, overspeed protective devices, and barring (turning) gear. Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.29.

The main generator is on the same shaft as the turbine. Its minimum rating is approximately 1375 MVA at 0.90 power factor. Its stator is cooled by deionised water, its rotor by hydrogen

gas. The magnetisation current for the rotor comes from the rectified output of an excitation transformer, which itself is fed from the main generator; the magnetisation current is controlled through a voltage regulator. A number of auxiliary systems are associated with the main generator: the same bearing lubrication oil system as the main turbine, the stator cooling water system, the hydrogen and seal oil systems, and a carbon dioxide system for the purging of hydrogen and air during lay-up or plant outages.

The flow of main steam entering the high-pressure turbine is controlled by four control valves. The turbine control valves are adjusted automatically by electrohydraulic servo actuators. These actuators control the turbine speed when it is starting up, and for load control after the turbine generator unit is synchronised to the grid. In series with each control valve is a stop valve; its function is to shut off and isolate the steam flow to the turbine when required. The control and stop valves all close completely on a turbine trip.

Six intercept valves control steam flow to the low-pressure turbine cylinders. The intercept valves are located in the hot reheat lines at the inlet to the low-pressure turbine cylinders. There is a reheat stop valve in series with each intercept valve. The reheat stop and intercept valves all close completely on a turbine trip.

The turbine generator is supported by a spring-mounted system to isolate the dynamic behaviour of the turbine-generator equipment from the foundation structure. The support system includes a reinforced concrete deck on which the turbine generator is mounted.

6.5.6 Turbine Bypass Function

The turbine bypass pipe work and valves provide the capability to dissipate heat directly to the condenser during plant startup and during the cooldown of the RCS to the point where the RNS can be placed in service. The turbine bypass system is described in Section 17.4. The system reduces the challenges to the main steam PORVs, the main steam safety valves, the SG level control, and the pressuriser safety valves following a reactor trip, rapid load reductions during normal operation, and turbine trips without a reactor trip.

The plant is designed to accommodate a ramp load change of 5 percent per minute between 25 percent and 100 percent of full load without reactor trip or steam dump actuation. Instead, it is accommodated by the reactor power control, the pressuriser level control, the pressuriser pressure control and the SG level control systems.

For medium load rejections (greater than 10 percent but less than 50 percent, or a turbine trip from 50 percent power or less), the turbine bypass system operates in conjunction with the same control systems used for the small power reductions.

For large load rejections (greater than 50 percent power), the turbine bypass system operates in conjunction not only with the previously mentioned control systems but also with the rapid power reduction system, which is designed to rapidly reduce the reactor power to a value that can be handled by the turbine bypass system. Upon the detection of a large and rapid turbine power reduction, a pre-selected number of control rods are dropped into the reactor core, causing the reactor power to reduce to approximately 50 percent.

6.5.7 Moisture Separator Reheaters

After expanding through the high-pressure turbine, the exhaust steam is wet and at saturation temperature. It is routed through two external MSR vessels, where it is dried and superheated. The external moisture separators reduce the moisture content of the high-pressure exhaust steam. It uses multiple-vane chevron banks for moisture removal. The moisture that has been

removed drains to a moisture-separator drain tank, from where it is pumped to the deaerator, which is at similar pressure to the steam entering the low-pressure turbine.

The dried steam is then reheated in a two-stage reheater to superheated conditions: the first stage reheat uses the steam bled from partway down the high-pressure turbine, while the second-stage reheat uses a portion of the much hotter main steam supply from the SGs. Each stage of the reheater is a shell-and-tube HX, the pressure on the tube side being much higher than on the shell side. Condensed steam in the reheater (tube side) is drained to the reheater drain tank, from which it flows into the shell side of the No. 7 feedwater heater and then cascades to the No. 6 feedwater heater.

The dried and superheated steam from the reheater flows to the inlets of the three low-pressure turbines through six reheat steam lines, each with a separate stop and intercept valve.

The MSRs are required to take the wet steam emerging from the high-pressure turbine exhaust, dry it, and then superheat it. This enables the low-pressure turbine cylinders to achieve a much higher thermodynamic efficiency in their expansion of the steam, at the same time experiencing much lower rates of blade erosion from the water droplets than would otherwise be present. The heat remaining in the bled steam after its passage through the reheater is used for feed heating, further enhancing the overall thermodynamic efficiency.

6.5.8 Condenser Air Removal System

The condenser air removal system (CMS) removes non-condensable gases (mainly nitrogen, oxygen, and ammonia) from the main condenser during plant startup, cooldown, and normal operation. Without this, the condenser tubes would become blanketed by these gases and thereby lose their effectiveness in condensing the steam. The air removal system consists of four liquid ring vacuum pumps: one vacuum pump is provided for each of the three condenser shells, and one pump is provided as a standby. The non-condensable gases together with some steam are drawn from the condenser shells to the suction of the vacuum pumps, which exhaust to atmosphere through the turbine island vents drains and relief system. The standby pump package is provided since failure of the condenser air removal system for one of the main condenser shells would result in a gradually increasing backpressure in that particular condenser shell. Eventually, this would result in a turbine trip on high condenser pressure. Further design details of this system and its constituent components are delineated in Reference 6.51.

The mixture of non-condensable gases and steam is not normally radioactive; however, it is possible for the mixture to become contaminated in the event of primary-to-secondary system leakage. Therefore, the exhaust gases are monitored for radioactivity and alarmed in the MCR.

6.5.9 Gland Seal System

The annular space between the turbine shaft and the turbine casing is sealed by glands, which minimise the leakage from those turbine cylinders that are above atmospheric pressure, or the leakage into those turbine cylinders that are below atmospheric pressure. For the former, the sealing steam is the actual leakage steam through the gland; for the latter, the sealing steam is supplied from the main steam system or, during startup of the turbine, from the auxiliary steam system. At the outside ends of the glands, the leaking steam is collected in piping held just below atmospheric pressure, and then routed to the gland seal condenser. Unavoidably, there is air leakage as well into the collection pipe work because of the small gap between it

and the rotating turbine shaft. Further design details of this system and its constituent components are delineated in Reference 6.52.

The gland seal condenser is a shell-and-tube type HX where the steam-air mixture from the turbine seals is discharged into the shell side; condensate from the main condenser flows through the tube side as the cooling medium. The gland seal condenser internal pressure is maintained at a slight vacuum by motor-operated blowers. Condensate from the steam-air mixture drains to the main condenser, and the non-condensable gas (mostly air) is exhausted to the atmosphere through the turbine island vents drains and relief system through a common discharge line shared by the vapour extractor blowers.

The main condenser can be utilized for cooling down the SGs and the RCS during several design-basis initiating events. Failure of the gland seal system during such fault transients would rapidly result in the main condenser becoming unavailable. A reliable gland seal system is thus desirable but not essential.

The mixture of non-condensable gases discharged from the gland seal condenser blower is not normally radioactive, but it is possible for the mixture to become contaminated in the event of primary-to-secondary system leakage. The turbine island vent discharge radiation monitor measures the concentration of radioactive gases in the gland seal steam condenser steam as in the non-condensable gases that are discharged by the condenser vacuum pumps. This measurement provides early indication of leakage between the primary and secondary sides of the SGs.

6.5.10 Main Condenser

The main condenser is part of the AP1000 plant CDS. The main condenser provides the heat sink for the steam cycle, receiving and condensing exhaust steam from the main turbine or the turbine bypass system, accepting high-energy cycle drains, and providing partial deaeration of condensate. The main condenser is a three-shell, single-pass, multi-pressure, spring-supported unit that is hard-connected at the turbine exhaust flange. Each shell is located beneath its respective low-pressure turbine.

The cooling water passes through the tube side of each condenser shell.

The condenser is equipped with titanium tubes and has titanium-clad tube sheets. The titanium material exhibits high corrosion and erosion-resisting properties and good mechanical properties. The condenser tubes are mechanically expanded and seal-welded to the tube sheet cladding to minimise leakage at the joints.

The condenser water boxes are structurally designed as pressure vessels and constructed from reinforced steel plate. Rubber lining is applied to the water box interior surface to provide resistance to corrosion.

The main condenser is designed to receive and condense the full-load steam flow exhausted from the main turbine. It also receives discharges from auxiliary systems such as the feedwater heater vents and drains and the gland sealing steam spillover and drains. To protect the condenser shells and turbine exhaust hoods from overpressurisation, steam relief blowout diaphragms are provided in the low-pressure turbine exhaust hoods. Excessive temperature conditions are mitigated by sprays in the low-pressure turbine exhaust hoods. Two low-pressure feedwater heaters are located in the neck area of each condenser shell, adjacent to where their steam is bled from the low-pressure turbine.

The hot wells of the condenser shells are interconnected to facilitate removal of condensate by the condensate pumps. Condensate flows between the condenser shells via interconnecting piping and baffling. A single common connection is provided at the last condenser shell for the condensate pumps. Condensate flows to each condensate pump and is pumped into the feed and condensate system.

The condenser shell hot wells have a condenser storage capacity of 3 minutes of feed flow at normal full power flow rate.

The hot well level controller provides automatic makeup or extraction of condensate to maintain a normal level in the condenser hot wells. On low level, the makeup control valves open and admit condensate by vacuum-draw to the hot well from the condensate storage tank. On high-water level, the condensate reject control valves open to divert water from the condensate extraction pump discharge to the condensate storage tank. The condensate extraction or rejection stops automatically when the hot well level falls within the normal operating range.

Condensate extraction from the hot well to the storage tank can be manually overridden upon indication of high hot well conductivity to prevent transfer of contaminants into the condensate storage tank in the event of a condenser tube or tube/tube sheet joint failure.

Air in-leakage and non-condensable gases contained in the turbine exhaust steam naturally accumulate in the condenser and must be removed. This is achieved by the CMS.

A condenser tube cleaning system mechanically cleans the circulating water side of the tubes. This cleaning, along with chemical treatment of the circulating water, reduces fouling and helps to maintain the thermal performance of the condenser. Further design details of this component are delineated in Reference 6.50.

6.5.11 Steam Generator Blowdown System

The principal purpose of the BDS is to remove impurities from the feedwater within the SG, which would otherwise rise in concentration as pure water and other volatiles boil off. This is particularly necessary during the anticipated operational occurrences of in-leakage of circulating water into the main condenser and SG tube leakage, which would add contaminants. The BDS continuously extracts a small proportion of the water from each SG. The maximum purification blowdown rate is approximately 0.61 percent of the maximum steaming rate or approximately six-thousandths of the feed flow rate. This blowdown flow is cooled and depressurised before being chemically processed to remove the impurities. It completes the process by being returned into the condenser before being returned to the SGs. Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.30

The BDS also includes a recirculation-drain pump for use during operating modes when the SG pressure is low. This pump enables the BDS to fulfil the following additional functions:

- Cooling down the SG for inspection and maintenance purposes.
- Establishing and maintaining SG wet lay-up conditions during plant outages.
- Draining the secondary side of the SGs for maintenance.

The system consists of two blowdown trains, one for each SG. The blowdown water is extracted just above the tube sheet of a SG. The blowdown flow is cooled using a regenerative HX, which uses the heat to warm the condensate. Flow control valves adjust the blowdown flow rate from each SG and depressurise it. It then enters an electro deionisation demineralising unit ion-exchange purification unit, which removes impurities. Downstream of the purification unit, both trains combine into a common header, which contains a relief valve for providing overpressure protection for the low-pressure portion of the system.

It is necessary to protect the low-pressure portion of the blowdown system from the high pressure and temperature to which it could be exposed if the pressure is not reduced or the blowdown flow is not cooled. Each of the two blowdown lines has two BDS isolation valves in series (upstream there are two AOV fail closed SGS isolation valves), which are located in the auxiliary building. These BDS valves fail closed on loss of air or power. The SG blowdown lines are a closed system inside the reactor containment, and so they do not require any further valves in the line inside the containment. This is because any radioactivity within the containment atmosphere has no way of passing into a closed system. The BDS isolation valves close automatically on high blowdown system temperature or pressure, on low SG water levels, on actuation of the PRHR HX, on receipt of a containment isolation signal, or on detection of high blowdown system radiation level. The isolation of the BDS contributes to the continued availability of the SGs as a heat sink during various fault transients by not further reducing their water inventory.

The radiation monitors associated with the BDS provide a means of recognising when the secondary side becomes radioactively contaminated, an indication of a SG tube leakage or rupture. The blowdown flow and the ion exchange waste stream flow are both continuously monitored for radioactivity. If such radioactivity is detected, the blowdown flow is automatically re-aligned to the WLS in order to process the blowdown and ion-exchange waste effluent. If radioactivity exceeds a preset level, the blowdown flow control valves and the isolation valves automatically close.

6.5.12 Circulating Water System

The CWS is a site-specific system and consists of three electric-powered water pumps and the associated piping, valves, and instrumentation. The main purpose of the CWS is to supply cooling water to the main condensers to condense steam; as such, it is the principal heat sink during normal operation and during those fault conditions. Its secondary purpose is to supply cooling water to the turbine building closed cooling water system HXs and to the condenser vacuum pump seal water HXs.

The underground portions of the CWS piping are constructed of concrete pressure piping or steel (possibly with an internal coating or lining of a corrosion-resistant compound). Motor-operated butterfly valves provided in each of the circulating water lines at their inlet to and exit from the condenser shell allow isolation of portions of the condenser.

6.5.13 Auxiliary Steam Supply System

ASS provides the steam required for plant use during startup, shutdown, and normal operation. Steam is supplied from either the auxiliary boiler or the MSS. The auxiliary boiler is located in the turbine building. The system consists of steam generation equipment and distribution headers. Further design details of this system and its constituent components are delineated in Reference 6.32.

Condensate from the condensate storage tank is chemically treated and pumped to the auxiliary boiler deaerator where oxygen and non-condensables are removed using auxiliary steam. The auxiliary boiler feedwater pumps deliver condensate from the auxiliary boiler deaerator to the auxiliary boiler. A feedwater control valve, located in the feedwater piping, regulates water level in the auxiliary boiler. Feedwater flow is proportional to the auxiliary boiler steaming rate. Steam generated by the auxiliary boiler is supplied to the plant auxiliary steam distribution piping.

Boiler water quality is maintained by controlling boiler blowdown flow to an atmospheric blowdown tank and by feeding oxygen-scavenging and pH control chemicals to the boiler makeup water system. Water level in the auxiliary boiler deaerator is maintained by an automatic control valve in the condensate supply and deaerator overflow piping. The auxiliary steam boiler is an electric package boiler. It supplies the steam required during a cold start of the MSS and the turbine generator; in addition, it provides the steam for hot water heating. Main steam supplements the auxiliary steam header during startup, and it supplies the auxiliary steam during normal operation at power. The auxiliary boiler provides the steam during a plant shutdown.

The ASS provides the following services:

- Steam to the plant hot water heating system HXs for use by the heating system ventilation coils.
- Steam to the deaerator prior to returning to operation at power and after a turbine trip, to heat, pressurise, and deaerate the feedwater.
- Steam to warm the MSS and turbine SSCs during plant startup.
- Sealing steam to the glands of the main turbine prior to returning to operation at power when main steam is unavailable.
- Steam to the MSRs and to the feedwater heaters when main steam is unavailable.

6.5.14 Turbine Island Chemical Feed System

The turbine island chemical feed system (CFS) injects the required chemicals into the condensate system, the feedwater system, the ASS, the service water system (SWS), the BDS, and the DWS. It is entirely located in the turbine building. Further design details of this system and its constituent components are delineated in Reference 6.32.

6.5.15 Condensate Polishing System

The condensate polishing system (CPS) is used to remove corrosion products and ionic impurities from the condensate system during plant startup, hot standby, power operation with abnormal secondary cycle chemistry, safety shutdown, and cold shutdown operations. Further design details of this system and its constituent components are delineated in Reference 6.33.

6.5.16 Secondary Sampling System

The secondary sampling system (SSS) delivers representative samples of fluids from secondary systems to sample analyser packages. Continuous or semi-continuous online secondary chemistry monitoring detects impurity ingress and provides early diagnosis of

system chemistry excursions in the plant. Secondary sampling monitors send control signals to the CFS that automatically inject corrosion control chemicals into the condensate and feedwater systems. Additional design detail of this system and its constituent components are delineated in Reference 6.37.

6.6 PASSIVE SAFETY SYSTEMS

The AP1000 plant uses passive Class 1 safety systems and features for protecting against accidents.

The distinguishing safety enhancement of the AP1000 plant design over existing PWR technology is the adoption of passive protective safety measures, which operate during fault sequences in the event that normal duty systems have failed. These systems are regarded as passive because they rely on natural physical processes for their operation with no reliance on active components such as pumps, fans, or diesel generators; and they are designed to function without Class 1 support systems such as ac power and component cooling water.

These systems include the following:

- Passive core cooling system (PXS)
- Plant structures inside containment to promote flood-up and natural circulation cooling
- Passive containment cooling system (PCS)
- Main control room (MCR) emergency habitability system (VES)
- Passive structural heat sinks to maintain acceptable temperatures for plant personnel and required equipment
- The spent fuel pool structures and their contained water inventory

These systems and features are described briefly below.

6.6.1 Passive Core Cooling System

The PXS is designed to perform the following major Class 1safety functions:

- Emergency RCS Makeup and Boration
- Safety Injection
- Emergency Core Decay Heat Removal
- Post Accident Containment pH Control
- Nitrogen Supply Line Containment Isolation

These safety-related functions are provided by Class 1 equipment with redundancy to deal with single failures, environmental qualification, and protection from external hazards. These

functions are available during all normal modes of RCS operation including hot / cold shutdowns and refuelling. Further design details of this system and its constituent components are delineated in Reference 6.13 and Chapter 17.

The Technical Specifications (Reference 6.11) detail the requisite PXS water flows, requisite volumes, etc.

The PXS consists of a PRHR HX (PXS-ME-01), two Accumulators (PXS-MT-01A/B), two CMTs (PXS-MT-02A/B), an IRWST (PXS-MT-03), two RCS depressurization spargers (PXS-MW-01A/B), four pH adjustment baskets (MY-Y03A/B, MY-Y04A/B), Containment and IRWST screens (PXS-MY-Y02A/B, Y03A/B, Y04A/B) and associated valves, piping, and instrumentation. Two simplified sketches are included as Figures 6-3 and 6-4. These figures include the four ADS stages (RCS components) since they functionally support the PXS.

The primary function of the PXS is to bring the plant to safe shutdown conditions using only Class 1 equipment by providing the means for boration, coolant injection, and core cooling. The PXS function is performed with no reliance on ac electrical power or active cooling water support systems.

The PXS is designed to perform its Category A safety functions based on the following considerations:

- It has component redundancy to provide confidence that its Category A functions are performed even in the unlikely event of the most limiting single failure occurring coincidentally with postulated DBEs.

- Components are designed and fabricated according to industry standard quality groups commensurate with SSC Class 1.

- It is tested and inspected at appropriate intervals, as defined by standards and Technical Specifications (Tech Specs) appropriate to SSC Class 1.

- It performs its intended Category A functions following events such as fire, internal floods, internal missiles, or pipe breaks.

- It is protected from the effects of external events such as earthquakes, tornadoes, and floods.

The design is sufficiently redundant and diverse to achieve the reliabilities required to support the plant core melt frequency and significant-release frequency targets.

6.6.1.1 PXS Functions

6.6.1.1.1 Emergency RCS Makeup and Boration Function

The PXS provides RCS makeup during transients or accidents in which the normal RCS makeup supply from the chemical and volume control system (CVS) is unavailable or is insufficient. This makeup allows for transfer of heat from the core. This makeup is sufficient to accommodate significant RCS leakage and RCS cooldown without ADS actuation.

The PXS also adds negative reactivity during transients or accidents in which the normal RCS boron makeup supply from the CVS is unavailable or is insufficient. This negative

reactivity provides or recovers core shutdown margin for events which result in cooldown of the RCS, such as steam line break accidents or safe shutdown cooldowns.

During an Anticipated Transient Without Trip (ATWT), the PXS removes sufficient heat to adequately cool the core and inject sufficient boron to shut down the core.

6.6.1.1.2 Safety Injection Function

The PXS provides safety injection to the RCS to ensure adequate core cooling for the complete range of LOCAs up to and including the double-ended rupture of the largest RCS piping. In addition to mitigating the immediate effects of the LOCA, the safety injection function must provide core cooling to support long-term safe shutdown.

The ADS, which is part of the RCS, supports the PXS in performing the safety injection function by depressurizing the RCS to allow lower pressure injection supplies to inject.

6.6.1.1.3 Emergency Core Decay Heat Removal Function

The PXS provides emergency core cooling during transients, accidents, or whenever the normal heat removal paths are unavailable. The emergency core cooling prevents overheating of the core and supports the capability for the plant to meet the safety analysis acceptance criteria, including criteria for primary and secondary system pressure, departure from nucleate boiling ratio (DNBR), and pressurizer volume. During a steam generator tube rupture (SGTR) accident, the emergency core cooling removes sufficient heat to support automatic termination of the loss of reactor coolant.

6.6.1.1.4 Nitrogen Supply Line Containment Isolation

The PXS provides for containment isolation of the nitrogen supply line for the accumulators, outside of containment. It achieves this function during an event by the use of a fail-closed, air-operated valve (PXS-PL-V043) located outside of containment as well as a check valve (PXS-PL-V043) inside of containment. This will prevent additional mass and energy from entering containment during an event.

6.6.1.1.5 In Vessel Retention

The PXS provides the capability to flood the containment so that following a severe accident, the outside of the reactor vessel is flooded. This capability supports cooling of the damaged core inside the vessel.

6.6.1.1.6 RCS Cooldown Function

The PXS is able to cool the RCS to a temperature at which the Normal Residual Heat Removal System (RNS) can be put into operation if cooling with the steam generators is not possible.

6.6.1.1.7 Refueling Cavity Flooding Function

The PXS stores sufficient water to flood the refuelling cavity during normal plant refuelling operations.

6.6.1.2 PXS Subsystems

6.6.1.2.1 RCS Injection Subsystem

The RCS injection subsystem consists of CMTs (PXS-MT-02A/B), Accumulators (PXS-MT-01A/B), an IRWST (PXS-MT-03), and associated valves, piping, and instrumentation.

The safety injection from these three injection sources, as well as the containment recirculation flow paths, has a common discharge through the two DVI lines and into the reactor vessel DVI nozzles. A deflector is located in the reactor vessel downcomer at the end of each DVI nozzle to direct the PXS injection flow downward into the reactor vessel downcomer plenum in order to minimize core bypass flow and to help guide flow toward the bottom of the reactor vessel. The DVI nozzles have a venturi shape, which reduces the loss of reactor coolant in case of a break of the DVI line, and minimizes the pressure loss during PXS injection.

The CMTs provide RCS makeup and boration for LOCAs and non-LOCAs when the normal makeup system is unavailable or insufficient. There are two CMTs located inside the containment at an elevation slightly above the reactor coolant loops. During normal operation, the core makeup tanks are completely full of cold borated water. The boron concentration of this water is somewhat higher than that of the water in the Accumulators and the IRWST. The boration capability of these tanks provides adequate core shutdown margin following a steam line break and for safe shutdown events.

The CMTs are connected to the RCS through a discharge injection line and a cold leg inlet pressure balance line. The discharge line is isolated by two normally closed, parallel air-operated isolation valves that open on a loss of air pressure or electrical power.

6.6.1.2.2 Emergency Core Decay Heat Removal Subsystem

The emergency core decay heat removal subsystem consists of one PRHR HX (PXS-ME-01) and associated valves, piping, and instrumentation.

The heat exchanger is located in the IRWST, which provides the heat sink for the heat exchanger. The heat exchanger consists of a bank of C-tubes, connected at the top (inlet) and bottom (outlet) to a tubesheet and channel head mounted on the IRWST wall. The number of tubes installed provides for tube plugging margin. The PRHR HX is connected to the RCS through an inlet line from one RCS hot leg. This line contains a normally open motor operated valve (MOV). The outlet line connects to the associated steam generator cold leg plenum (reactor coolant pump suction). The outlet line contains parallel normally closed air-operated valves that open on loss of air pressure or electrical power. These valves are opened on receipt of a safeguards actuation signal.

The alignment of the PRHR HX (with a normally open inlet motor-operated valve and normally closed parallel outlet air-operated valves) maintains the heat exchanger full of reactor coolant at RCS pressure and prevents water hammer upon initiation of PRHR HX operation. The inlet line is well insulated and routed continuously upward from the top of the hot leg to a high point above the HX inlet. This arrangement ensures that the water in the line will remain hot, which will provide for natural circulation of the PRHR HX water. The water in the HX is stagnant and will be in thermal equilibrium with the water in the IRWST. This arrangement maintains a thermal driving head during normal plant standby conditions which provides for the initial PRHR HX startup operation.

The heat exchanger is elevated above the RCS loops to induce natural circulation flow

through the heat exchanger when the reactor coolant pumps are not available. The PRHR heat exchanger piping arrangement also allows actuation of the heat exchanger with reactor coolant pumps operating. When the Loop 1 reactor coolant pumps are operating, they provide forced flow in the same direction as natural circulation flow through the heat exchanger. If the pumps are operating and subsequently trip, then natural circulation provides the driving head for the heat exchanger flow.

6.6.1.2.3 Post Accident Containment pH Control Subsystem

The containment pH control subsystem consists of pH adjustment baskets (MY-Y03A/B, MY-Y04A/B). The pH adjustment baskets are located inside the containment, below the minimum post-accident floodup level.

The pH adjustment baskets provide the capability for chemical addition to the containment recirculation water in severe accident floodup conditions where core damage has occurred and core radioactivity has been released from the RCS into containment. The baskets initiate chemical addition passively when the containment flood-up level reaches the baskets. Effective mixing with the water in the containment is ensured by the use of four baskets and their location in the circulation path of water which cools the damaged core. That circulation path starts under the reactor vessel, comes up past the vessel into the loop compartments, flows into the corridor connecting the loop compartments, and flows down the stairwell to beneath the reactor vessel.

The pH adjustment baskets are filled with granulated trisodium phosphate (TSP). The baskets are located on containment floor.

The baskets are elevated about 0.3 m (1 ft) above the floor to reduce the chance that water spills in the containment will dissolve the TSP. This location minimizes the chance that spray from leaks or breaks of high-energy lines will reach them. The baskets are located along walls with adequate exposed areas enclosed with mesh.

During a LOCA, after ADS has been actuated, the TSP dissolves into the containment water as the flood-up level covers the TSP baskets. This design provides automatic pH adjustment:

- To reduce offsite doses during severe accidents (where the core has suffered damage)

- To prevent stress corrosion cracking of stainless steel during design basis accidents

6.6.1.2.4 Valve Leak Test Subsystem

A valve leak test subsystem which is used at shutdown conditions to leak-test some RCS pressure boundary isolation valves. Four PXS valves (the Accumulator isolation check valves) and eight RNS valves (two check and two stop-check valves on the RNS outlet to the DVI and four MOVs in the RNS inlet from the RCS hot leg) are provided with connections that can be used to determine their seat leakage. All of these valves are located inside the containment.

6.6.1.2.5 Automatic Depressurization Subsystem

The ADS is part of the RCS. Since it functions together with the PXS to provide core cooling in LOCA events, a brief description is provided below. Figures 6-3 and 6-4 shows the ADS.

There are four stages of ADS valves. The first three stages are connected to the pressurizer and discharge to the IRWST through spargers. The fourth stage is connected to the RCS hot legs and discharges into the containment loop compartments. Each Stage 1/2/3 has two lines and each line has two valves in series. The fourth stage has four lines with each line having two valves in series.

The valves used in the first three stages are direct current (dc) motor-operated. All of the valves are normally closed. The fourth stage valves are squib valves (see Chapter 17 for further discussion).

6.6.1.3 Operation During Plant Transients and Accidents

6.6.1.3.1 Operation During Loss of Main Feedwater Flow Events

The most severe core conditions resulting from a loss of main feedwater system flow are associated with a loss of feedwater flow at full power. The heatup transient effects of loss of feedwater flow at reduced power levels are bounded by the loss of flow at full power. This event is similar to events such as station blackout.

The AP1000 design startup feedwater (SFW) that is able to remove the core decay heat generated after the reactor trip that follows a postulated non-LOCA event. This avoids excessive heatup of the primary system and loss of subcooling and prevents water relief from the pressurizer.

Should the main feedwater (MFW) and SFW be unavailable, the PRHR HX is actuated by a Low-2 narrow range SG level and coincident Low-2 SFW flow signal. PRHR HX operation removes decay heat and begins to cool down the RCS when the PRHR HX heat transfer capability matches the core decay heat rate. The PRHR HX actuation could be insufficient to prevent pressurizer overfill, but the reactor vessel head vent valves can be used in this situation to relieve mass from the RCS and prevent pressurizer overfill. Once actuated, the PRHR HX does not require electrical power or operator actions for continued RCS cooling.

When PRHR HX cooling has sufficiently reduced the pressurizer level or RCS temperature, the CMTs are automatically actuated to provide RCS makeup and boration. The CMTs inject borated water directly into the reactor vessel downcomer. When the CMTs are actuated, the reactor coolant pumps are tripped, which results in the PRHR HX operating under natural circulation. The CMT injection maintains RCS inventory and adds negative reactivity. In this scenario, the CMTs operate in a water recirculation mode and the cold legs do not void. The CMTs remain full and ADS is not actuated.

The RCS pressure remains above the pressure of the Accumulators so they do not inject. After stabilizing plant conditions and satisfying PXS termination criteria, the operator terminates PXS operation and initiates normal plant shutdown operations.

6.6.1.3.2 Operation During Feedwater Line Break Events

For this event, the PRHR HX and the CMTs are automatically actuated. The PRHR HX removes core decay heat, and the CMTs inject borated water directly into the reactor vessel downcomer. Since the reactor coolant pumps are automatically tripped on actuation of the CMTs, the PRHR HX operates under natural circulation. In this scenario, the cold legs do not void, so the CMTs operate in the water recirculation mode to maintain RCS inventory and add negative reactivity. The CMTs remain full and ADS is not actuated. Once actuated, the PRHR HX and CMTs do not require electrical power or operator actions for continued RCS

cooling.

The RCS pressure remains above the pressure of the Accumulators, so they do not inject.

6.6.1.3.3 Operation During Steam Line Break Events and Inadvertent Opening of a SG Relief/Safety Valve Event

The main steam lines are also isolated to prevent blowdown of more than one steam generator. The CMTs operate with water recirculation to provide borated water to the reactor vessel downcomer for RCS inventory and reactivity control. The negative reactivity provided by operation of the CMTs is not fast enough to prevent the reactor from briefly returning to criticality during the transient. In the longer term, the cooldown slows down and the CMT boration is able to shut down the core. The departure from nucleate boiling design basis is met, thereby preventing fuel damage. The CMT flow also functions to increase RCS inventory so that visible pressurizer level is restored.

For this event, the CMTs operate in a water recirculation mode and the cold legs remain filled. As a result, the CMTs remain full and ADS is not actuated.

6.6.1.3.4 Operation During LOCA Events

A LOCA is a rupture of the RCS piping or branch piping that results in a decrease in RCS inventory exceeding the flow capability of the normal makeup system.

Following a postulated LOCA, the RCS pressure decreases and initiates a reactor trip and safety injection following safeguards actuation. The safeguards actuation signal trips the RCPs and opens the CMT outlet isolation air operated valves (AOVs). The CMTs provide high pressure injection and can operate via water recirculation or steam-compensated injection at full RCS pressure. For smaller LOCAs, the pressurizer level is sufficient to initially establish CMT water recirculation. For larger break sizes, the pressurizer level decreases more rapidly and steam-compensated injection occurs after the cold legs void.

As the CMTs' water level drops, level sensors in the tank actuate the ADS. The use of CMT level to actuate ADS minimizes the chance of unnecessary ADS actuations and provides reliable/timely ADS actuation when it is required during LOCAs. The ADS depressurization of the RCS is staged to limit the RCS depressurization rate and the maximum vent flow to the depressurization spargers. Limiting the RCS depressurization rate minimizes the potential for the core to uncover during ADS operation. Limiting the ADS flow to the spargers reduces the hydrodynamic loading on the IRWST.

The Accumulators begin to inject when the reactor coolant system depressurizes to about 4.8 MPa gauge (700 psig). The Accumulator injection provides for rapid reflooding of the core during large LOCAs, which prevents excessive core clad temperatures.

When the fourth stage ADS valves are actuated, the IRWST injection squib valves are also actuated. However, because the RCS pressure will be somewhat above the IRWST injection head at this time, the check valves in the IRWST injection line will not open until the RCS pressure has been further reduced by the ADS.

As the IRWST injection flow continues, the IRWST level will slowly drop and the containment water level will increase from the break flow. When the IRWST level drops to a Low-3 level setpoint, the containment recirculation lines are opened and water is drained into the PXS sump.

At this time, recirculation will begin; water in the containment will flow into the reactor to provide continued cooling of the core. Redundant flow paths from the containment to the reactor are provided.

In this long-term cooling mode, the core remains covered and decay heat is removed by steaming to the containment through the break and/or the ADS valves. The steam is condensed on the steel containment shell which is cooled by the PCS.

6.6.1.4 Description of the Passive Core Cooling Components

6.6.1.4.1 Core Makeup Tanks

The two CMTs (PXS-MT-02A/B) are vertical, cylindrical tanks with hemispherical upper and lower heads. They are made of carbon steel, clad on the internal surfaces with stainless steel. They are located inside containment on the 102.12-m (107-foot 2-inch) floor elevation. The CMTs are located above the direct vessel injection line connections to the RV, which are located at an elevation near the bottom of the hot leg.

During normal operation, the CMTs are completely filled with borated water and are maintained at RCS pressure by the cold leg pressure balance line. The temperature of the borated water in the CMTs is about the same as the containment ambient temperature since the tanks are not insulated or heated.

The inlet line from the cold leg is sized for LOCAs where the cold legs become voided and higher CMT injection flows are required. The discharge line from each CMT contains a flow-tuning orifice that provides a mechanism for the field adjustment of the injection line resistance. The orifice is used to establish the required flow rates assumed in the CMT design. The duration of CMT injection will be much longer when the CMTs operate in the water recirculation mode as compared to the steam condensation mode, and thus the time for them to drain down is dependent on the break size. An additional design function of the CMT discharge orifice is it splits flow to the DVI and to the CMT such that ADS 4 actuation is precluded by preventing the CMT level dropping to the ADS 4 actuation set point.

Connections are provided for remotely adjusting the concentration of the borated water in each CMT during normal plant operation.

Makeup water for the CMTs is provided by the CVS. Samples from the CMTs are taken periodically to check boron concentration. Each CMT has an inlet diffuser designed to reduce steam velocities entering the CMT, thereby minimising potential water hammer and reducing the amount of mixing that could occur during initial CMT draindown operation.

The CMTs are located inside the containment but outside the secondary shield wall. This facilitates maintenance and inspection of the CMT and its level and temperature sensors.

6.6.1.4.2 Accumulators

The two accumulators (PXS-MT-01A/B) are spherical tanks made of carbon steel and clad on the internal surfaces with stainless steel. They are located inside the containment on the floor just below the CMTs.

The accumulators are filled with borated water and pressurised with nitrogen gas. The temperature of the borated water in the accumulators is about the same as the containment ambient temperature since the tanks are not insulated or heated. Each accumulator is connected to one of the direct vessel injection lines. During normal operation, the

accumulator is isolated from the RCS by two check valves in series. When the RCS pressure falls below the accumulator pressure, the check valves open and borated water is forced into the RCS by the gas pressure. Mechanical operation of the check valves is the only action required to open the injection path from the accumulators to the core.

The accumulators are designed to deliver a high flow of borated water to the RV in the event of a large LOCA. This large flow rate is used to quickly establish core cooling following the large loss of RCS inventory.

The injection line from each accumulator contains a flow-tuning orifice that provides a mechanism for the field adjustment of the injection line resistance. The orifice is used to establish the required flow rates assumed in the accumulator design. The accumulator provides injection for several minutes after a large LOCA starting when the RCS pressure drops below the static accumulator pressure.

Connections are provided for remotely adjusting the level and boron concentration of the borated water in each accumulator during normal plant operation.

Accumulator water level may be adjusted either by draining or pumping borated water from the CVS to the accumulator. Samples from the accumulators are taken periodically to check the boron concentration.

Accumulator pressure is provided by a supply of nitrogen gas and can be adjusted as required during normal plant operation. However, the accumulators are normally isolated from the nitrogen supply. Gas relief valves on the accumulators protect them from overpressurisation. The system also includes the capability to remotely vent gas from the accumulator, if required.

The accumulators are located inside the containment and outside the secondary shield wall, facilitating maintenance and inspection of the accumulators and its level and temperature sensors.

6.6.1.4.3 In-Containment Refuelling Water Storage Tank

The IRWST (PXS-MT-03) is a large, stainless-steel-lined tank located underneath the operating deck inside the containment. The tank is constructed as an integral part of the containment internal structures, and is isolated from the steel containment vessel. The bottom of the IRWST is above the RCS loop elevation so that the borated refuelling water can drain by gravity into the RCS after it is sufficiently depressurised. The IRWST is connected to the RCS through both direct vessel injection lines and contains borated water at the existing temperature and pressure in containment. The IRWST does not contain material in either the tank or the recirculation path that could plug the outlet screens.

Vents installed in the roof of the IRWST are normally closed to minimise water vapour and radioactive gases leaving the tank during normal operation and to prevent debris from entering the tank from the containment operating deck. The vents open with a slight pressurisation of the IRWST to provide a path to vent steam generated by the PRHR HX, or subsequently released by the spargers, into the containment atmosphere, should the IRWST water become heated to saturated conditions. Other vents also open on small pressure differentials to allow air or steam to enter the IRWST from containment, such as during a LOCA, to prevent damage to the tank.

Overflows are provided from the IRWST to the refuelling cavity to accommodate volume and mass increases during PRHR HX or ADS operation while minimising the flooding of the containment.

The IRWST contains one PRHR HX and two depressurisation spargers. The top of the PRHR HX tubes are located underwater and extend down into the IRWST. The spargers are also submerged in the IRWST with the midarms located approximately 3 m (10 ft) below the normal water level.

The IRWST is sized to provide flooding of the refuelling cavity for normal refuelling and post-LOCA flooding of the containment for RCS long-term cooling mode; and to support the PRHR HX operation. Flow from the IRWST during the injection mode includes conservative allowances for spill flow during a direct vessel injection line break. The IRWST can provide sufficient injection until the containment sump floods up high enough to initiate recirculation flow. The injection duration varies greatly, depending upon the specific event. A direct vessel injection line break drains the IRWST more rapidly and speeds containment flooding.

Connections to the IRWST provide for transfer to and from the RCS/refuelling cavity via the RNS, purification and sampling via the SFS, and remotely adjustment of the boron concentration via the CVS. Also, the RNS can provide cooling of the IRWST. Additionally there are connections to the IRWST for sampling and instrumentation.

6.6.1.4.4 pH Adjustment Baskets

The PXS uses TSP to adjust the pH of the recirculation fluid in the containment sump. Granulated TSP is contained in stainless steel baskets (MY-Y03A/B, MY-Y04A/B) that have a mesh front that readily permits contact with water.

The TSP is provided to raise the pH of the borated water in the containment to at least 7.0 following an accident. Margin is added to the basket volume to account to long term acid formation during 30 days following a LOCA as well as for possible TSP loss and degradation during normal operation. After extended plant operation, the granular TSP may cake into a solid form as it absorbs moisture. Assuming that the TSP has caked, the dissolution time of the TSP is approximately 3 hours. Good mixing with the sump water is expected because of the baskets' construction and their placement in locations conducive to recirculation flow post-accident. The baskets are designed for easy replacement of the TSP.

6.6.1.4.5 Passive Residual Heat Removal Heat Exchanger

The PRHR HX (PXS-ME-01) consists of inlet and outlet channel heads connected together by vertical C-shaped tubes. The tubes are supported inside the IRWST. The top of the tubes is more than 1 m (3.3 ft) below the IRWST water surface.

The HX inlet piping connects to an inlet channel head located near the top of the IRWST. The inlet channel head and tube sheet are attached to the tank wall via an extension flange.

The HX is supported by a frame attached to the IRWST floor and ceiling. The extended flange is designed to accommodate thermal expansion. The HX outlet piping is connected to the outlet channel head, which is vertically below the inlet channel head near the tank bottom. The structural configuration of the outlet channel head is identical to the inlet channel head. Both channel head tube sheets are similar to the SG tube sheets and have manways for inspection and maintenance access.

The PRHR HX is designed to remove sufficient heat so that its operation in conjunction with short term heat removal by the SGs provides adequate RCS cooling and prevents water relief through the pressuriser safety valves during loss of main feedwater or main feed line break events.

The PRHR transfer of heat into the IRWST results in the water evaporating out of the IRWST. This steam is condensed on the inside of containment by the PCS and is collected by a downspout piping system and gutter arrangement. Condensation is collected by downspouts connected at the Polar Crane Girder and Internal Stiffener, and by the Gutter at the operating deck elevation, and drained back into the IRWST.

PRHR performance post a non-LOCA fault is calculated utilising either Realistic Assumptions or Conservative assumptions as delineated below.

Realistic Assumptions - In utilising realistic assumptions, the PRHR can achieve “safe shutdown” within 36 hours for approximately 14 days following such an event, with or without AC power or the RCPs. The PRHR is designed to achieve “safe shutdown” post a non-LOCA fault. It is important to note that “safe shutdown mode” (Mode 4) only applies to normal operation and does not apply to the post fault condition of “safe shutdown” as discussed in this section and Section 9C. To achieve “safe shutdown” the PRHR HX must be able to cool the RCS core average temperature to 215.6°C (420°F) (average of hot leg and cold leg temperatures). This cooldown allows the RCS pressure to be reduced, which reduces the stress in the RCS and connecting pipes to low levels, greatly reducing the chance of a subsequent LOCA.

Conservative Assumptions - In utilising conservative assumptions, the PRHR can maintain the RCS pressure and temperature below ADS set points (see Section 9C) for greater than 72 hours, with or without AC power or the RCPs. This cooldown allows the RCS pressure to be reduced, which reduces the stress in the RCS and connecting pipes to low levels, greatly reducing the chance of a subsequent LOCA.

PRHR HX flow and inlet and outlet line temperatures are monitored by indicators and alarms. The operator can take action as required to meet the Tech Spec requirements or follow emergency operating procedures to control the PRHR HX operation.

6.6.1.4.6 Depressurisation Spargers

Two reactor coolant depressurisation spargers (PXS-MW-01A/B) are provided. Each one is connected to an ADS discharge line connected to a set of ADS Stage 1, 2, and 3 valves and is submerged in the IRWST. Each sparger has four branch arms inclined downward. The connection of the sparger branch arms to the sparger hub are submerged below the normal IRWST level by approximately 3 m (10 ft). The spargers are designed to discharge steam and water into the IRWST in small directed jets, thereby promoting more effective steam condensation and IRWST water mixing and avoiding significant dynamic effects that could result in excessive structural loads on the IRWST and thereby the containment. The condensation of steam is not a safety function since the limiting mass / energy release to the containment result from large LOCAs where little if any flow passes through the IRWST spargers.

The first three stages of ADS valves discharge through the spargers and are designed to pass sufficient depressurisation venting flow with an acceptable pressure drop to support the depressurisation system performance requirements. The installation of the spargers prevents undesirable and/or excessive dynamic loads on the IRWST and other structures.

Each sparger is sized to discharge at a flow rate that supports ADS performance, which in turn allows adequate PXS injection from the IRWST and later on from the containment.

6.6.1.4.7 IRWST and Containment Recirculation Screens

The PXS has two different sets of screens that are used following a LOCA: IRWST screens and containment recirculation screens (PXS-MY-Y02A/B, Y03A/B, Y04A/B). These screens prevent debris from entering the reactor and blocking core cooling flow paths during a LOCA. These screens are seismic I Category A Class 1 equipment per Table 15A. A plan and elevation view is provided in Figures 6-20 and 6-21.

These screens are designed to pass the maximum injection flow with up to one half of their area blocked. The containment recirculation screens are located in the east loop compartment along the wall adjacent to the reactor vessel.

The approach to the screens incorporates large settling areas, deep settling pools, low velocities, and a long delay before recirculation initiation to minimize the amount of particles that reach the screens.

A debris weir high is in place in front of the screens to prevent high density debris from being swept along the floor and into the screen face. Additionally there is plate above the screen to prevent debris intrusion from above. The top of the screens is located well below the normal containment recirculation floodup level. This location makes all of their surface area available to screen particles that may be in the recirculation flow.

Each of the two containment recirculation paths is connected to an associated gravity injection line via two parallel flow paths. One path contains a squib valve backed up by a check valve. The other path contains a squib valve backed up by a normally open MOV. The squib valves provide leak-tight isolation of the IRWST and eliminate the normal back-seating differential pressure from the IRWST water column head across the check valves. They also eliminate spillage of water into the containment and potential boric acid buildup during inservice testing of the MOVs. The path with the MOV can also be opened to dump the IRWST water into the containment, which floods the outside of the reactor vessel, in case of a severe accident and complete failure to cool the core. Dumping the IRWST to the loop

compartment cools the molten core while it is located inside the reactor vessel. The PXS Containment Recirculation Screens are also discussed in Chapter 17.

6.6.1.4.8 Valves

Design features used to minimise leakage of valves in the PXS include the following:

- Hermetically-sealed globe valves are used for manual isolation valves that are 50.8 mm (2 inches) or smaller that are high pressure and contain radioactive fluid, except for some valves in the PXS test header whose stems are not normally pressurized.

- Valves that are normally open, except for check valves, and those that perform control function are provided with back seats to limit stem leakage.

Manual valves are generally used as maintenance isolation valves. When used for this function, they are under administrative control. They are located so that no single valve can isolate redundant PXS equipment or are provided with alarms in the MCR to indicate mispositioning.

The motor operators for gate valves are conservatively sized considering the frictional component of the hydraulic unbalance on the valve disc, the disc face friction, and the packing box friction. For motor-operated valves, the valve disc is guided throughout the full disc travel to prevent chattering and to provide easy gate movement. The seating surfaces are hardfaced to prevent galling and to reduce wear.

Remotely operated valves that do not receive a safeguards actuation signal have a position indicator within the MCR. When one of these valves is not in the ready position for injection during plant operation, this condition is indicated and alarmed in the MCR. These valves have various interlocks, automatic features, and position indication. Some valves have their control power locked out during normal plant operation.

The ADS consists of four different stages of valves. Two sets of ADS Stages 1, 2, and 3 are provided. Each set of ADS has three lines and each line has two valves in series, both normally closed. The Stage 4 has four lines with each line having two valves in series, one normally open and one normally closed. The four stages, therefore, include a total of 20 valves. The four ADS valve stages open sequentially.

The Stage 1, Stage 2, and Stage 3 valves have dc motor operators. The Stage 1, 2, and 3 control valves are normally closed globe valves and the isolation valves are normally closed gate valves. The Stage 4 valves are interlocked so that they cannot open until RCS pressure has been substantially reduced. The Stage 4 control valves are squib valves. There is a normally open motor-operated gate valve in series with each squib valve.

Each set of the ADS first three stages have a common inlet header connected to the top of the pressuriser. The outlet of each set of the first to third stages combine to a common discharge line to one of the spargers in the IRWST. A second, identical group of first- to third-stage valves has its own inlet and outlet lines and sparger.

Both sets of the Stage 4 valves connect directly to the top of each reactor coolant hot leg and vent directly to their associated SG compartment.

The ADS valves are designed to automatically open when actuated, and to remain open for the duration of the postulated event. Valve Stages 1 and 4 actuation sequence starts at discrete CMT levels. Valve Stages 2 and 3 actuate based upon a timed delay after actuation of the

preceding first stage. This opening sequence provides a controlled depressurisation of the RCS. The valve actuation logic is based on two-of-four level detectors in either CMT for ADS Stages 1 and 4.

The Stage 1, 2, and 3 automatic depressurisation control valves are designed to open relatively slowly. During the actuation of each stage, the isolation valve is sequenced open before the control valve, so there is some time delay between stage actuation and control valve actuation.

The operators can manually open the Stage 1 valves to a partially open position to perform a controlled degassing or depressurisation of the RCS.

Low Differential Pressure Opening Check Valves

Several applications in the PXS gravity injection piping use check valves that open with low differential pressures. These check valves are installed in the following locations:

- The IRWST gravity injection line flow paths to the reactor vessel direct vessel injection nozzles.

- The containment recirculation lines that connect to the IRWST injection lines.

The check valves selected for these applications incorporate a simple swing-check design with a stainless-steel body and hardened valve seats. The PXS check valves are Class 1, designed with their operating parts contained within the body and with a low-pressure drop across each valve. The valve internals are exposed to low-temperature reactor coolant or borated refuelling water. See section 17.5 for a more detailed description of the accumulator check valves.

Relief Valves

Relief valves are installed for PXS accumulators to protect the tanks from overpressure.

Squib Valves

Squib valves are used in several PXS lines to provide the following:

- Zero leakage during normal operation
- Reliable opening during an accident
- Reduced maintenance and associated personnel radiation exposure

Squib valves are not expected to be opened during normal operation and anticipated transients and it is not necessary that they reclose once they have opened. More details about the squib valves can be found in Chapter 17.

In the IRWST injection lines, the squib valves are in series with normally closed check valves. Inadvertent opening of these injection squib valves is prevented as a design basis event due to the design of the PMS including its diverse blocking device. More details about the blocking device can be found in Chapter 19. In the containment recirculation lines, the squib valves are in series with normally closed check valves in two lines and with normally open motor-operated valves in the other two lines. Inadvertent opening of these recirculation squib valves will not result in loss of reactor coolant or unisolable draining of the IRWST.

The type of squib valve used in these applications provides zero leakage in both directions. It also will allow flow in both directions after it has opened. A valve open-position sensor is provided for these valves.

Squib valves are also used to isolate the Stage 4 ADS lines. These squib valves are in series with normally open motor-operated gate valves. The type of squib valve used in this application provides zero leakage of reactor coolant from the RCS.

6.6.2 Passive Containment Cooling System

The Passive Containment Cooling System (PCS) is a safety-related system which is capable of transferring heat directly from the containment vessel to the environment so that the containment design pressure and temperature are not exceeded following any postulated design basis event, and so that the pressure is significantly reduced in the longer term. The heat transfer mechanism includes conduction, convection, radiation, and mass transfer (water evaporation). Figures 6-5 and 6-15 shows the basic design of PCS.

The Technical Specifications (Reference 6.11) detail the requisite PCS make up water flows and requisite volumes (e.g. Fuel Transfer Canal, Cask Loading Pit, Cask Washdown Pit) depending on the Containment and SFP decay heat balance.

The PCS performs the following Category A Class 1 functions:

- Containment vessel heat removal:
  - The PCS delivers water by gravity flow from the Passive Containment Cooling Water Storage Tank (PCCWST) to the outside, top of the containment vessel.
  - The PCS water flow wets the outside surface of the containment vessel. The process of wetting the containment facilitates the transfer of heat within the containment through the vessel wall.
  - The inside and outside of the containment vessel above the operating deck are coated with an inorganic zinc coating. The coating promotes wetability, heat conduction, inhibits corrosion.
  - The PCS provides counter-current airflow over the outside of the containment vessel driven by a natural circulation in the airflow path from the air inlets to the air discharge structure. The airflow removes the heat transferred from within containment to outside the Shield Building.
  - The PCS drains the excess water from the outside of the containment vessel through the two upper annulus drains.
  - The PCS provides a flow path to containment for long-term (post-72 hour) cooling water makeup.
- Spent fuel pool inventory makeup

- The PCS provides a flow path for long-term water makeup from the PCCWST to the spent fuel pool.

- Process monitoring

  - The PCS monitors the containment conditions that provide indications of the need to initiate various safeguards functions, including actuation of the PCS or the containment air filtration (VFS) Vacuum Relief System.

  - The PCS monitors the process parameters within the PCS required by the operators to monitor status of the system operations and to perform manual operations if necessary during safe-shutdown and accident operations.

Chapter 10 provides details of the Containment vessel functionality during a Serve Accident.

Further design details of this system and its constituent components are delineated in Reference 6.14 and Chapter 17.

6.6.2.1 PCS Functions

6.6.2.1.1 Containment Vessel Heat Removal

The heat removal function is provided following either a safe-shutdown event or a Design Basis Accident (DBA).

The PCS supports limiting the release of fission products by transferring heat from the containment atmosphere to the environment. This is accomplished by providing a volume of water that covers the containment shell to facilitate the transfer of heat to the counter-current airflow and subsequently to the environment. The removal of heat from within containment keeps the internal containment pressure within its design limits thus supporting maintenance of containment integrity. The safety Category A functions associated with heat removal are required to provide the necessary cooling in order to ensure containment integrity by preventing internal over-pressurization, thus maintain containment integrity.

PCS makes use of the steel containment shell as a heat transfer surface. Cooling air is drawn from the environment via an “always open” airflow path over the containment vessel and is returned to the environment after removing heat from the containment shell. The containment shell is wetted by passive draining of the water storage tank that is incorporated into the Shield Building structure above the containment, and is known as the PCCWST (PCS-MT-01).

Actuation of the PCS initiates water flow by gravity from the PCCWST contained in the Shield Building structure above the containment onto the containment dome outer surface, forming a water film over the structure. The water flow is automatically established by the opening of any one of three parallel, safety-related, isolation valves. Two of these isolation valves are AOV (PCS-PL-V001A/B) and the other is a MOV (PCS-PL-V001C). The AOV’s are normally closed and fail open to enhance system reliability and assure system availability. The third flow path containing the MOV is normally closed and fail-as-is. This flow path was added as a result of PSA insights to aid in mitigating common mode failure if both AOV’s were to fail closed. Opening any or all of the isolation valves will result in acceptable system performance. Upstream of each PCCWST isolation valve is a normally open, safety-related, motor-operated isolation block valve (PCS-PL-V002A/B/C) which is available to isolate

cooling water flow in the event of inadvertent actuation. These MOV's receive a confirmatory opening signal from the PMS in response to a High-2 containment pressure condition.

Valve room heating is provided to keep the room temperature above freezing. The thermal inertia of the room keeps the safety-related flow paths and required instrumentation above freezing for at least 72 hours during all design basis conditions.

As the decay heat from the core decreases with time, the water flow to the containment shell is passively decreased in a way which generally matches decay heat. The change in flowrate is attained from the decrease in storage tank level during gravity draining to containment without the need for active components. The change in flow is accomplished through the use of four standpipes installed within the PCCWST, each terminating at a different level. When the system is actuated, water is delivered via all standpipes at the full flow rate. Prior to uncovering the lowest standpipe, the operator is expected to take action to provide makeup water from the passive containment cooling ancillary water storage tank (PCCAWST) (PCS-MT-05) to the PCCWST using a PCS recirculation pump (PCS-MP01A/B), thereby continuing flow to the containment shell.

The water distribution bucket (PCS-MT-03) and water distribution weir system (PCS-MT-04) are provided to counteract the potentially adverse effects of containment vessel construction and manufacturing tolerances on flow distribution and surface wetting. The cooling water flow from the PCCWST is delivered by redundant parallel discharge lines to a water distribution bucket suspended above the centre of the containment dome.

The cooling water not evaporated from the vessel wall during heat transfer from containment flows down to the floor of the upper containment annulus. There are two sets of drains that remove water from the annulus and prevent accumulation.

Situation where PCS cooling may be employed include:

- During a safe shutdown event, the core decay heat is released to IRWST through the PRHR HX, which is contained within the PXS. The heat is subsequently released to the containment atmosphere as the IRWST attains saturation conditions. If containment pressure is increased to above the PCS setpoint, the PMS will automatically actuate PCS to begin containment cooling.

- During a DBA where large amounts of energy are released immediately from the reactor coolant pressure boundary to containment, for example a Main Steam Line Break (MSLB). These types of DBA scenarios require PCS to facilitate the transfer of heat to the outside environment to ensure containment integrity is maintained.

- During a safe shutdown or DBA scenario where energy is slowly released from within the reactor coolant pressure boundary, for example a small leak across the reactor coolant pressure boundary. PXS provides for reactor coolant makeup using the core makeup tanks and removal of decay heat to the IRWST by the PRHR HX. The IRWST eventually attains saturation conditions and begins steaming to containment. PCS is required to facilitate the transfer of heat to the outside environment to ensure containment integrity is maintained.

During a DBA involving the loss of RCS integrity, the PCS, in conjunction with the PXS, provides a continuous source of makeup to the RCS by condensing steam released to

containment, which is directed back to the IRWST to provide passive injection to the RCS

The initial inventory of PCS cooling water in the PCCWST is sufficient for 72 hours of flow without replenishment or operator action. A Class 1 flow path from a blind-flange connection to either the PCCWST or directly to the distribution bucket allows for use of offsite water supplies and provides a post-72 hour source of containment cooling water.

The PCCAWST provides this onsite supply of cooling water and is delivered to containment by the PCS recirculation pumps and flow path.

6.6.2.1.2 Process Monitoring

PCS sensors provide containment pressure signals for normal plant operations and engineered safeguards system actuation of passive containment cooling or containment vacuum relief. Alternatively the Containment Recirculation Cooling System (VCS) monitors containment temperature, which is used for automatically actuating PCS through the Diverse Actuation System (DAS). DAS is not required for design basis events, but provides a backup for multiple failure accident scenarios.

6.6.2.1.3 Spent Fuel Pool Inventory Makeup

The PCS provides a Class 1 flow path from the PCCWST to gravity drain to the spent fuel pool. In addition, a safety-related flow path from a blind-flange connection to the spent fuel pool is required for use with offsite water sources for spent fuel pool makeup.

During refuelling operations when the containment decay heat is less than or equal to 7 MWt the PCCWST is aligned to the spent fuel pool. In the event spent fuel pool cooling is lost, the PCCWST is gravity drained to the spent fuel pool to provide make up to the water inventory within the pool. The cask washdown pit, cask loading pit, and/or the PCCWST can provide the necessary makeup to the pool over time to assure the spent fuel is not uncovered.

The PCCWST provides makeup flowrate for the remainder of the initial 72 hour period after event initiation in order to prevent uncovering of the stored fuel. Following a design basis accident after a normal refueling, the reactor has returned to full power for sufficient time to build up equilibrium fission products, and assuming the worst case decay heat with 15 years of spent fuel storage, makeup is not required during the initial 72 hour period after accident initiation.

6.6.2.1.4 Other Functions

The PCS also performs the following functions:

- Containment vessel heat removal and spent fuel pool inventory makeup post 72 hours to 7 days.

  - The PCCAWST contains an inventory of cooling water sufficient for containment cooling from hour 72 through day 7. This tank is located outside near the Auxiliary Building. PCS Ancillary Pumps can provide the motive force to pump the water from the PCCAWST.

  - The PCS delivers water from the PCCAWST to containment and spent fuel pool simultaneously post 72 hours to 7 days.

- Fire protection water supply

  - The PCCWST and the PCCAWST includes a dedicated water inventory for the Fire Protection System (FPS) by either gravity draining a dedicated volume from the PCCWST or pumping from the PCCAWST.

6.6.3 Main Control Room Habitability System

The VES provides a protected environment from which operators can control the plant following an uncontrolled release of radioactivity. It is designed to operate following a design basis accident or a loss of all ac power condition or event would render the Nuclear Island Non-Radioactive Ventilation System (VBS) inoperable. If ac power is unavailable for more than 10 minutes or if "high-high" particulate or iodine radioactivity is detected in the MCR supply air duct, or low MCR differential pressure with respect to the surrounding rooms for 10 minutes, the PMS automatically isolates the MCR; operator habitability requirements are then met by the VES. The system operates passively (that is, without relying on ac power or active components) other than the one-time alignment of valves.

The MCR VES provides breathable air to the MCR and maintains the MCR at positive pressure for at least 72 hours after an accident, from a compressed air supply. Passive heat exchange to the structures surrounding the MCR together with automatic non Class 1 MCR electrical load de-energization (load de-energization provided by Class 1 IDS) provides adequate cooling of the space for at least 72 hours after a loss of all ac electrical power. Further design details of this system and its constituent components are delineated in Reference 6.16.

6.6.3.1 Ventilation and Filtration

The VES provides emergency ventilation and filtration to the MCR pressure boundary by using a bank of emergency air storage tanks which are connected to a common manifold feeding two air supply lines that route to the MCR. There are a total of 32 tanks in the VES system. The tanks contain breathable quality compressed air which is piped into the control room if the normal HVAC system is deactivated or disabled. There is one main air supply line and one alternate air supply line that connect to one main delivery line. An educator (VES-PY-N01) is attached to the end of the main air delivery line. The eductor induces a recirculation flow rate by using the energy of the compressed breathable air that is discharging from the emergency air storage tanks. The induced flow rate passes through ducting which is contained completely within the MCR pressure boundary. The ducting contains an air filtration unit (VES-MY-F01, F02, F03) that is located downstream from the discharge of the eductor.

The air filtration unit removes potentially contaminated air that could enter the MCR during ingress and egress of the boundary. The compressed air supply provided to the MCR accomplishes three purposes: 1) it provides a source of uncontaminated breathing air to the occupants in the MCR to dilute the CO_2 concentration produced by respiration of the MCR occupants; 2) it provides a constant air flow rate that is required to maintain pressurization of the MCR pressure boundary; and 3) it provides a motive air source to the eductor to passively induce a filtration and recirculation flow rate throughout the MCR pressure boundary.

In the unlikely event that power to the VBS is unavailable for more than 72 hours, then the MCR doors and air ducts may be opened up to allow for ventilation and cooling using VBS MCR Ancillary Supply Fans outside air to the MCR.

6.6.3.2 Pressurization

The VES maintains the MCR at a positive pressure with respect to the surrounding areas to minimize the ingress of airborne contaminants with a supply of compressed air. Inleakage of unfiltered and potentially contaminated air is controlled by maintaining the MCR pressure boundary at a slight positive pressure of at least 31.13 Pa (1/8-inch Water Gauge). Any leakage into and out of the MCR boundary is controlled through the use of low-leakage construction techniques. Over pressurization protection of the MCR boundary is achieved by using redundant low pressure gravity relief dampers.

Normal system makeup is provided by a connection to the breathable-quality high-pressure air compressor in the compressed and instrument air system (CAS).

6.6.3.3 Cooling

The VES limits the heatup of the Class 1 C&I equipment rooms, and the IDS equipment rooms by using the heat capacity of surrounding structures. The VES also limits the heatup of the MCR by the use of VES operation in conjunction with automatic load shedding and the heat capacity of surrounding structures.

The function of providing passive heat sinks for the MCR, C&I rooms, and IDS equipment rooms is part of the VES. The heat sinks for each room are designed to limit the temperature rise inside each room during the 72-hour period following a loss of VBS operation. The heat sinks consist primarily of the thermal mass of the concrete that makes up the ceilings and walls of these rooms.

To enhance the heat-absorbing capability of the ceilings, attached metallic plates are extended into the room and act as thermal fins to enhance the heat transfer from the room air to the concrete.

When a source of ac power is available or radiological concentrations don't trip VBS, the VBS provides normal and abnormal HVAC service to the MCR, remote shutdown workstation, control support area (CSA), C&I rooms, dc equipment rooms, battery rooms, and the nuclear island nonradioactive ventilation system equipment room.

6.6.4 C&I and Electrical Systems Supporting Passive Systems

C&I and electrical systems support the operation of Passive Systems. Table 10-29 of Chapter 10 provides a system dependency matrix that goes into greater detail for systems and the systems they depend on for operation.

6.6.4.1 Protection and Safety Monitoring System

The PMS provides detection of abnormal conditions and actuation of the appropriate Class 1 systems necessary to achieve and maintain the plant in a safe shutdown condition (Reference 6.5).

In addition, the PMS provides the equipment necessary to monitor the plant's Category A safety functions during and following an accident.

Further details about the PMS can be found in Section 6.9. Further design details of control and instrumentation systems are delineated in Chapter 19.

6.6.4.2 Diverse Actuation System

The DAS is a Class 2 system that provides diverse backup to the PMS for actuating a number of Class 1 passive systems. The DAS also provides manual actuation capability for a number of Class 1 passive systems, implemented by hardwiring the controls located in the MCR directly to the final loads in a way that completely bypasses the normal path through the PMS and the DAS automatic logic. DAS processor cabinets are located in the radiologically-controlled portion of the auxiliary building.

Further details about the DAS can be found in Section 6.9. Further design details of control and instrumentation systems are delineated in Chapter 19.

6.6.4.3 Class 1 Essential Electrical Supply System

The IDS, referred to as the essential electrical supply system in this PCSR, consists of four static battery-backed divisions.

IDS provides power for the Class 1 equipment required for the plant instrumentation, control, monitoring, and other vital functions needed for shutdown of the plant. In addition, IDS provides power to the normal and emergency lighting in the MCR and at the remote shutdown workstation.

Further details about the IDS and electrical systems are delineated in section 6.10 and Chapter 18.

6.6.4.4 Standby Electrical Supply System

The standby electrical supply system (EDS) comprises the battery-backed dc electrical power supply system and uninterruptible power supply system. EDS supports the operation of DAS.

Further details about the EDS can be found in Section 6.11. Further design details of electrical systems are delineated in Chapter 18.

6.6.5 Class 2 Systems, Structures, and Components Providing Category A Safety Functions to Preclude Operation of Passive Safety Systems

Some Class systems if available in an accident can be used to preclude the need to operate passive safety systems.

6.6.5.1 Startup Portion of the Feedwater System

The startup portion of the FWS supplies feedwater to the SG during plant startup, hot standby, and shutdown conditions. In the event of a loss of the main feedwater pumps, the startup feedwater pumps are automatically started. One operating startup feedwater pump delivers sufficient flow to the SGs to remove core decay heat and avoid actuation of the Class 1 PXS, and thus provides defence in depth for these transients. On this basis, portions of the FWS are designated as Class 2. Note that the SFW is not formally credited in Chapter 8 with the mitigation of frequent faults. The function of the startup portion of the FWS to remove core decay heat includes components from the AP1000 plant MSS and/or the SGS.

Further details about the FWS can be found in Section 6.5. Further design details of this system and its constituent components are delineated in Reference 6.31 and Chapter 17.

6.6.5.2 Chemical and Volume Control System

The CVS includes two centrifugal makeup pumps that provide makeup flow to the reactor primary circuit. One makeup pump is capable of maintaining normal RCS inventory following an RCS leak of up to a 9.5-mm (3/8-inch) inside diameter without an actuation of the PXS safety injection systems. The CVS thus provides defence in depth for these small LOCAs and, on this basis, the CVS makeup pumps are designated as Class 2. Note that the CVS is not formally credited in Chapter 8 with the mitigation of frequent faults.

The CVS also provides means of controlling boron concentrations in the primary circuit during normal operation and provides backup boration capability to the PXS in fault conditions.

Further details about the CVS can be found in Section 6.4 and Chapter 17; details about normal operation of the CVS can be found in Chapter 21. Additional design details of this system and its constituent components are delineated in Reference 6.18.

6.6.5.3 Normal Residual Heat Removal System

The RNS removes heat from the core and RCS and provides RCS low-temperature, overpressure protection at reduced RCS pressure and temperature conditions after shutdown.

The RNS cooling trains are designated as Class 2 as they provide part of the defence in depth heat removal capability. In intact circuit fault conditions, decay heat removal is provided initially by the FWS and SGs. Later in the fault when the RCS has been partially depressurized this function is provided by the RNS. When the RNS is aligned to the RCS, the RNS performs a Class 1 pressure boundary function.

Further details about the RNS can be found in Section 6.4 and Chapter 17.

6.6.5.4 Component Water Cooling System

The CCS is a closed-loop cooling system that supports the RNS, SFS, and CVS during normal operations and fault conditions. On this basis, portions of the CCS are designated as Class 2. Note that the CCS is not formally credited in Chapter 8 with the mitigation of frequent faults.

Further details about the CCS can be found in Section 6.11 and Chapter 17. Additional design details of this system and its constituent components are delineated in Reference 6.20.

6.6.5.5 Service Water System

The SWS supplies cooling water to remove heat from the CCS HXs in the turbine building. On this basis, portions of the SWS are designated as Class 2. Note that the SWS is not formally credited in Chapter 8 with the mitigation of frequent faults.

Further details about the SWS can be found in Section 6.11 and Chapter 17. Additional design details of this system and its constituent components are delineated in Reference 6.21.

6.6.5.6 Spent Fuel Cooling System

The SFS functions to remove the decay heat generated by stored spent fuel from the spent fuel pool water. On this basis, portions of the SFS are designated as Class 2 as they provide

part of the defence in depth heat removal capability. Note that the SFS is not formally credited in Chapter 8 with the mitigation of frequent faults.

Further details about the SFS can be found in Section 6.12 and Chapter 17. Additional design details of this system and its constituent components are delineated in Reference 6.17.

6.6.5.7 Nuclear Island Nonradioactive Ventilation System

When operating in supplemental air filtration mode, the VBS functions to maintain MCR habitability. On this basis, portions of the VBS are designated as Class 2 since they provide defence in depth protection for the MCR. If available it precludes the need to actuate VES.

Further details about the VBS can be found in Section 6.8 and Chapter 23.

6.7 CONTAINMENT AND SUPPORTING SYSTEMS

6.7.1 Containment

The containment system is the collection of boundaries that separate the containment atmosphere from the outside environment during design basis initiating events.

The containment building is a freestanding, cylindrical, steel vessel with elliptical upper and lower heads. It is surrounded by a seismically qualified reinforced-concrete steel-concrete sandwich shield building (see Figure 6-5 for simplified drawing of the shield building and containment vessel). The containment vessel (CNS-MV-001) provides a safety-functional interface with the ultimate heat sink, which is the surrounding atmosphere. The cylindrical section of the shield building serves as shielding and a missile barrier and is a key component of the PCS. It structurally supports the roof and is a major structural member for the entire nuclear island. Floor slabs and structural walls of the auxiliary building are structurally connected to the cylindrical section of the shield building.

The containment, shield, and auxiliary buildings are structurally integrated on a common basemat embedded below the plant grade level. The shield building is reinforced concrete and, in conjunction with the internal structures of the containment building, provides shielding for the RCS and the other radioactive systems and components housed in the containment. The shield building roof is a reinforced concrete structure containing an integral, steel-lined PCCWST. Further discussion on the containment, shield, and auxiliary buildings is provided in Chapter 16.

The HVAC systems VCS and VFS which also support containment are described in section 6.8.

6.7.2 Containment Isolation

Containment isolation is provided by containment penetrations, redundant means of isolating flowpaths through the containment shell, and the connections for verifying containment isolation leak tightness. The AP1000 plant containment system (CNS) provides the requirements the containment isolation. The SSCs that provide the isolation (penetrations, pipe, isolation valves) are part of the systems whose lines pass through the containment vessel. This includes such systems as the CAS, CVS, FPS, RNS, etc. (see Chapter 17 for the requirements of valves and components that isolate containment). Further design details of this system and its constituent components are delineated in Reference 6.15.

The CNS allows the normal or emergency operation of the plant while preserving the integrity of the containment boundary, when required. Wherever possible, the containment isolation valves are fail-closed AOVs that automatically shut when their air supply is lost or when their electrical signal is removed.

The AP1000 design has fewer mechanical containment penetrations (including hatches) than current plants. Pipe work crossing the containment boundary needs to be isolated in the event of an accident to limit the escape of fission products that may result from postulated accidents.

The function of the containment isolation valves is to allow the normal or emergency passage of fluids through the containment boundary while preserving the integrity of the containment boundary following an accident.

Each line that crosses the containment boundary is provided with containment means of isolation. The barrier inside containment is usually provided by one isolation valve, and the barrier outside containment consists of pipe work and an isolation valve. Both barriers are qualified to an appropriate level

During normal system operation, most of the piping penetrations are not isolated. The majority of these incorporate fail-closed isolation valves that close automatically with the loss of support systems, such as instrument air. Power-operated (air, motor, or pneumatic) containment isolation valves have position indication in the MCR.

Lines not in use during power operation are normally closed and remain closed under administrative control during reactor operation.

Containment isolation is achieved by closing all the isolation valves on receipt of an actuation signal from the PMS or DAS. Electrical power is provided by IDS where required.

If a change in valve position is required at any time following primary actuation, a secondary actuation signal is generated, which places the valve in an alternate position.

The containment air filtration system (VFS) is used to purge the containment atmosphere of airborne radioactivity during normal plant operation. These valves close automatically on a containment isolation signal. Chapter 17 provides further detail on the containment isolation valves by fluid system. Chapter 19 provides further detail on the PMS and DAS Control and Instrumentation systems.

6.7.3 Containment Hydrogen Control System

Hydrogen is postulated to be released following accident sequences in which the reactor overheats to the extent that the zirconium fuel cladding chemically reacts with the steam that is present. Any breach in the RCS boundary would provide a route for this hydrogen to escape into the containment atmosphere. When mixed with the air in the containment, the hydrogen may ignite and create a dynamic pressure or elevated temperature that could potentially damage containment structures and potentially create a pathway to the environment for any radioactivity released into the containment during the accident. Further design details of this system and its constituent components are delineated in Reference 6.34.

This scenario is prevented by gradually removing any hydrogen introduced into the containment by chemically combining it with the oxygen in the air in a controlled manner using the VLS. The VLS consists of three elements:

- Two passive autocatalytic recombiners (VLS-MY-E01A/B) installed above the operating deck that combine any hydrogen as it arises.

- 66 electrically powered hydrogen igniters (VLS-EH-01 through -66) distributed throughout the containment to ignite any hydrogen at their respective locations before the concentration of hydrogen can build to levels where large pressures may be generated.

- Three hydrogen sensors in the upper dome to monitor the bulk hydrogen concentration and alert the operators to the need for remedial action.

The structures within the containment are arranged to promote mixing by means of natural circulation. For a postulated break low in the containment, buoyant flows develop through the lower compartments because of density differences between the rising plume and the surrounding containment atmosphere, tending to drive mixing through the lower compartments and into the region above the operating deck. There is also a degree of mixing within the region above the operating deck, which occurs as the steam-rich leakage plume rises from the operating deck openings.

The following four general characteristics have been incorporated into the AP1000 design to promote mixing and eliminate dead-end compartments, thereby reducing the likelihood of hydrogen concentration reaching levels at which large pressures may be generated:

- The compartments below the operating deck are large, open volumes with relatively large interconnections, which promote mixing throughout the below deck region.

- All compartments below the operating deck are provided with openings through the top to eliminate the potential for a dead pocket of high hydrogen concentration.

- The operation of the PCS condenses steam and cools the non-condensable gases adjacent to the containment shell, promoting natural circulation flow in the containment.

- In addition, if forced containment air circulation is operated during post-accident recovery, the fan coolers contribute to circulation in containment.

The autocatalytic recombiners are effective for very low hydrogen concentrations (less than 1 percent) at ambient temperature, and they are not impaired by being wet or by the presence of very high steam concentrations. They begin to recombine hydrogen and oxygen almost immediately upon exposure to oxygen and hydrogen when the catalyst is not wetted. If the catalyst material is wet, then a short delay is experienced. The autocatalytic recombiners are effective over a wide range of ambient temperatures, concentrations of reactants (rich and lean oxygen/hydrogen less than 1 percent), and steam inerting (steam concentrations greater than 50 percent).

The autocatalytic recombiners are sized to accommodate the hydrogen production rate anticipated for the limited amounts of damage to the fuel and its cladding hypothetically arising from a LOCA with multiple failures in mitigation features; they have been shown to be effective at minimising the buildup of hydrogen inside the containment following LOCAs.

The hydrogen igniters can burn hydrogen at higher concentrations and prevent the concentrations from exceeding 10 percent by volume even with rapid generation of hydrogen. The hydrogen igniters are designed to accommodate the relatively fast release of hydrogen resulting from severe accident sequences.

The hydrogen ignition subsystem consists of 66 hydrogen igniters strategically distributed throughout the containment based on evaluation of hydrogen transport in the containment and hydrogen combustion characteristics. When an igniter is energised, its surface heats up to ≥926.6°C (1700°F), which is sufficient to ignite hydrogen in its vicinity once the concentration exceeds the lower flammability limit. The primary objective of installing an igniter system is to promote hydrogen-burning at a low concentration and, to the extent possible, to burn it more or less continuously so that the hydrogen concentration does not build up to high levels in the containment. To achieve this goal, the igniters are placed in the major regions of the containment where hydrogen might be released, through which it could flow or where it might accumulate. The igniter coverage, distribution, and power supply has been designed to minimise the potential loss of igniter protection globally for containment and locally for individual compartments.

A spray shield is provided to protect each igniter from falling water drops resulting from the condensation of steam on the containment shell and on nearby equipment and structures. The hydrogen sensors are designed to provide a rapid-response detection of changes in the bulk containment hydrogen concentration. The igniters are electrically powered and manually actuated. To this end, bulk containment hydrogen concentration is monitored and continuously indicated in the MCR. In addition, high hydrogen concentration alarms are provided. The sensors are powered by the EDS uninterruptible power supply system and have sufficient range to monitor concentrations up to 20 percent.

6.7.4 Containment Leak Rate Test System

The reactor containment, containment penetrations, and isolation barriers are designed to permit periodic leak rate testing. Additional design details of this system and its constituent components are delineated in Reference 6.35. The three following types of test are performed:

- Containment integrated leak rate testing (Type A) − The containment is pressurised with clean, dry air and the leak rate from the containment structure is established. Type A testing uses temporary equipment connected through the VFS exhaust penetration (C02).

- Local leak rate testing of containment penetrations with a design that incorporates features such as resilient seals, gaskets, and expansion bellows (Type B) − The leakage limiting boundary is pressurised with air or nitrogen and the pressure decay or the leak flow rate is measured. Type B testing uses permanently installed connections.

- Local leak rate testing of containment isolation valves (Type C) − The piping test volume is pressurised with air or nitrogen and pressure decay or the leak flow rate is measured. Type C testing uses features built into the tested subsystems.

6.8 HEATING, VENTILATION AND AIR CONDITIONING SYSTEMS

Nuclear containment and ventilation systems serve an important nuclear safety function in terms of supporting containment of nuclear material by ensuring that air movements and

discharges are adequately directed and filtered to reduce doses to operators and the public under both normal and accident conditions. Chapter 23 provides further discussion on the following systems.

6.8.1 Containment Recirculation Cooling System

The VCS recirculates and cools air within the containment during power operations and shutdown. This results in an energy savings and a reduction in waste generated in the form of used filters when compared to what would result from the level of a once through HVAC ventilation system. The air recirculated by this system is expected to contain some activity (mostly noble gases and some iodine), although it does not penetrate the containment boundary and thus does not give rise to any discharges to atmosphere. Therefore, Best Available Technology (BAT) for reducing discharges is not applicable to this system.

During shutdown operations in the containment, local, filtered extract systems are available for particular operations where airborne activity may be generated. This reduces the potential for airborne activity to be released into the general containment atmosphere, which the recirculation system could spread to other parts of the containment building.

The extracted air is continuously monitored for airborne activity to give an early warning of the presence of airborne activity to workers in the containment.

There is no path to discharge the VCS to the environment and so high-efficiency particulate air (HEPA) filtration is not provided.

The VCS controls containment air temperature and humidity to provide a suitable environment for equipment operability during normal operation and shutdown.

The VCS is comprised of four 50-percent-capacity fan coil units that connect to a common duct ring header and distribution system. Each fan coil unit contains a fan and associated cooling coil banks. The fan coil units are located on platforms approximately 180 degrees apart to provide a proper return air and mixing pattern through the ring header. The ring header and the fan assemblies are designed to provide uniform air and temperature distribution inside the containment. (One fan coil unit on each side of containment is normally in operation. The systems are not designed to have two fans at one side of containment operating simultaneously.) More details on VCS are provided in Section 23.4 and Reference 23.3.

6.8.2 Containment Air Filtration System

The VFS purges the containment by providing fresh air from outside and exhausting containment air into the plant vent. The air exhausted by the VFS is filtered with high-efficiency filters, charcoal filters, and postfilters. The VFS also exhausts from areas served by the VAS and health physics and hot machine shop HVAC system (VHS). The VFS is supported by diesel backup to improve its reliability.

The VFS comprises two parallel systems that may be operated individually or simultaneously as required by the operating regime with or without associated inlet air handling units. Each one is equipped with high-efficiency particulate air (HEPA) filtration and charcoal filters for removal of particulate and iodine vapour respectively. A high-efficiency filter (80 percent American Society of Heating, Refrigerating, and Air Conditioning Engineers (ASHRAE)) is installed before the HEPA filter to increase operational life and reduce the quantity of low level waste (LLW). A high-efficiency filter has a greater capacity, therefore requiring less frequent changing and potentially reducing the volumes of LLW produced.

A high-efficiency filter is also installed after the charcoal filter to ensure that discharges are as low as reasonably practicable (ALARP). Continuous monitoring of airborne discharges is provided to detect deterioration in the performance of either ventilation train. These provisions represent good industry practice for ensuring that discharges to the atmosphere and doses to members of the public are ALARP. Continuous monitoring of airborne discharges is provided to detect deterioration in the performance of either ventilation train.

The containment air filtration system consists of two 100 percent-capacity supply air handling units, a ducted supply, and an exhaust air system with containment isolation valves and piping, registers, exhaust fans, filtration units, automatic controls, and accessories. The supply air handling units are located in the south air handling equipment room of the annex building. The supply air handling units are connected to a common air intake plenum.

A gaseous radiation monitor is located downstream of the exhaust air filtration units in the common ductwork to provide an alarm if abnormal gaseous releases are detected. The plant vent exhaust flow is monitored for gaseous, particulate, and iodine releases to the environment.

During conditions of abnormal airborne radioactivity in the fuel handling area and auxiliary and/or annex buildings, the filtration units provide filtered exhaust to minimise unfiltered offsite releases.

The exhaust air containment penetrations also serve as a connection for the containment integrated leak rate test system to pressurise and depressurise the containment during integrated leak rate testing. Otherwise, the containment air filtration exhaust subsystem is not involved with the containment integrated leak rate test and is isolated from the containment during this time.

More details on VFS and its components are provided in Chapter 23 and Reference 23.5.

6.8.3 Radiologically Controlled Area Ventilation System

The VAS serves the radiologically controlled areas of the auxiliary and annex buildings. The VAS consists of two separate subsystems, the fuel handling area ventilation subsystem and the auxiliary/annex building ventilation subsystem. Both subsystems are once–through-type ventilation systems. More details on VAS and its components are provided in Chapter 23 and Reference 23.30.

During normal operations, the supply air handling units and both the exhaust fans on each of the ventilation subsystems operate continuously to ventilate the areas served on a once through basis. The supply airflow rate is modulated to maintain the areas served at a slightly negative pressure differential with respect to the outside environment.

If abnormal airborne radioactivity is detected in the duct, VFS provides filtered exhaust to mitigate unfiltered releases to the environment by maintaining the isolated zone at a slightly negative pressure differential.

The VAS serves the fuel handling area of the auxiliary building and the radiologically controlled portions of the auxiliary and annex buildings except for the VHS areas.

The VAS consists of the auxiliary/annex building ventilation subsystem and the fuel handling area ventilation subsystems.

6.8.3.1 Fuel Handling Area Ventilation Subsystem

The fuel handling area ventilation subsystem supply and exhaust ductwork is arranged to exhaust the SFP area separately from the auxiliary building. It provides directional airflow from the rail car bay/filter storage area into the spent resin equipment rooms. The exhaust fans discharge normally unfiltered exhaust air into the plant vent system for monitoring of offsite airborne gaseous and other radiological releases.

All spent fuel handling operations are performed under borated water to provide radiation protection; activity levels in the SFP are controlled by Tech Specs. In normal operation the effluent from the fuel handling area passes through HEPA filtration. Routine releases and accidental release for the fuel handling area are both low, however, if the radiation monitors detect a high level of radiation, the fuel handling extract is diverted to the VFS, which contains HEPA and charcoal filters. It can also be diverted manually if particular operations being performed could result in a release of activity.

HEPA filtration is also provided for the spent fuel pool relief panel. In the unlikely case of spent fuel pool boiling, the HEPA filters ducted to the relief panel will remove particulates from the discharged air-steam mixture. This is discussed further in Appendix 23A.

The fuel handling area ventilation subsystem serves the fuel handling area, rail car bay/filter storage area, resin transfer pump/valve room, spent resin tank room, waste disposal container area, solid waste management system (WSS) valve/piping area, and elevator machine room. The fuel handling area ventilation subsystem consists of two 50-percent-capacity supply air handling units, a ducted supply and exhaust air system, isolation dampers, diffusers, registers, exhaust fans, automatic controls, and accessories. Hot water heating coils supplied with water from the hot water heating system (VYS) and cooling coils supplied with water from the central chilled water system (VWS) are used to maintain ambient room temperatures within the normal range. The ventilation airflow capacity is designed to maintain environmental conditions that support worker efficiency during fuel handling operations. The supply air handling units are located in the air handling equipment room of the annex building. They are connected to the air intake plenum number two, located on the annex building. The units discharge into a ducted supply distribution system routed to the fuel handling and rail car bay/filter storage areas of the auxiliary building.

The supply and exhaust ducts are provided with isolation dampers that close upon detection of high airborne radioactivity in the exhaust air or high pressure differential with respect to the outside atmosphere.

The supply and exhaust ductwork is arranged to exhaust the SFP plume and to provide directional airflow from the rail car bay/filter storage area into the spent resin equipment rooms.

6.8.3.2 Auxiliary/Annex Building Ventilation Subsystem

The auxiliary/annex building ventilation subsystem serves radiologically controlled equipment, piping and valve rooms, and adjacent access and staging areas.

The radiologically controlled part of the auxiliary and annex building air ductwork is routed to minimise the spread of airborne contamination by directing the supply airflow from the low-radiation access areas into the radioactive equipment and piping rooms with a greater potential for airborne radioactivity. In addition, the exhaust air ductwork is connected to the radwaste effluent holdup tanks to prevent the potential buildup of gaseous radioactivity or

hydrogen gas within these tanks. The exhaust fans discharge the exhaust air into the plant vent system for monitoring of offsite airborne radiological releases.

The supply and exhaust ducts are configured so that two building zones may be independently isolated. The annex building staging and storage area, containment air filtration exhaust rooms, containment access corridor and adjacent auxiliary building staging, equipment areas, middle annulus, middle annulus access room, and security rooms are aligned to one zone. The other zone includes the remaining rooms and corridors, including but not limited to the radiation chemistry laboratory, primary sample room, SFP cooling water pump and HX rooms, normal residual heat removal pump and HX rooms, CVS makeup pump room, lower annulus, various radwaste equipment rooms, pipe chases, and access corridors. A radiation monitor is located in the exhaust air duct from each zone.

The auxiliary/annex building ventilation subsystem consists of two 50-percent-capacity supply air handling units, with a ducted supply and exhaust air system, isolation dampers, diffusers and registers, exhaust fans, automatic controls, and accessories. The supply air handling units are located in the air handling equipment room of the annex building. They are connected to the air intake plenum located in the extreme south end of the annex building. The units discharge into a ducted supply distribution system routed through the radiologically controlled areas of the auxiliary and annex buildings. The supply and exhaust ducts have isolation dampers that close to isolate the auxiliary and annex buildings from the outside environment when high airborne radioactivity is detected in the exhaust air duct.

The two 50-percent-capacity exhaust air fans, sized to allow the system to maintain a negative pressure, are located in the upper VAS equipment room of the auxiliary building. The exhaust air ductwork is connected to the radioactive waste drain system (WRS) sump to maintain the sump atmosphere at a negative air pressure; this prevents the exfiltration of potentially contaminated air into the surrounding area. The sump vent line is constructed of pipe work, routed upward from the sump to the interface with the HVAC system. The exhaust air ductwork is connected to the radwaste effluent holdup tanks to prevent the potential buildup of airborne radioactivity or hydrogen gas within these tanks. The vent line is constructed of pipe and is routed upward from the tank to the interface with the HVAC system. The exhaust fans discharge the exhaust air into the plant vent system for monitoring of offsite airborne radiological releases.

Unit coolers are located in the RNS and CVS pump rooms because they have significant cooling loads on an intermittent basis when large equipment is operating. Each unit cooler is sized to accommodate 100 percent of its corresponding pump cooling load. The unit coolers are provided with chilled water from redundant trains of the VWS low-capacity subsystem.

The RNS pump room unit coolers have two cooling coils per unit cooler so that chilled water supplied by either train A or train B alone can support concurrent operation of both RNS pumps. The two CVS makeup pump room unit coolers are connected to redundant trains of the chilled water system. However, operating either the train A or train B unit cooler alone maintains the common makeup pump room temperature conditions and supports operation of either makeup pump. Condensation from these cooling coils drains to the WRS.

Heating coils are located in the supply air ducts serving plant areas that require supplemental heating during periods of cold outside air temperature conditions. The heating coils are supplied with hot water from the VYS. The radiation chemistry laboratory and security room supply air ducts are provided with local electric coils and humidifiers to maintain the environmental conditions within the areas suitable for personnel comfort.

6.8.3.3 Security Room Ventilation Subsystem

The security room subsystem consists of two (2) 50% local fan coil cooling units which provide cooling via the recirculation of air. These components are provided to maintain the environmental conditions within the areas suitable for personnel comfort and special electronic equipment. Each fan coil unit includes a low efficiency-filter, chilled water cooling coil, fan and associated instrumentation and controls. The VWS is connected to the fan coil unit cooling coils.

6.8.4 Nuclear Island Nonradioactive Ventilation System

The nuclear island nonradioactive ventilation system (VBS) serves the MCR, CSA, essential power electrical spaces, the PCS valve room, RSR, and HVAC equipment rooms. The VBS is designed to perform its design functions during normal plant operations, shutdown and during and following a DBA, if VBS is operable and the supporting systems are available. See Chapter 23 and Reference 23.33 for more details pertaining to VBS.

VBS provides the following Class 1 functions;

- Provide isolation of the MCR envelope from the surrounding areas and outside environment during and following a design basis accident.
- Provide radiological monitoring of MCR supply air airborne process streams and initiation signals to the PMS for actuation of the VES.

VBS provides the following Class 2 and 3 functions;

- Provide protection of MCR and/or CSA areas from infiltration of smoke from an external source.
- Provide smoke removal capability for the MCR envelope, CSA area and Class 1E electrical equipment rooms from an internal source.
- Exhaust room air from the Class 1E battery rooms and limit the concentration of hydrogen gas to prevent a potential explosive mixture.
- Provide protection from tornado depressurization and provide security barriers.

These areas do not have sources of radioactive contamination present during normal operation or fault conditions. During a fault condition, activity could be present in the radioactive drain system that passes through (but does not serve) this area. Since the drain system has no valves or connections and operates at low pressure, the chance of leakage into this area is negligible as there would need to be a pre-existing leak coincident with a fault. Because it is not reasonably foreseeable that activity will be present in the areas served by the VBS, the exhaust systems from the VBS do not have any provisions for HEPA filtration.

The system consists of the following independent subsystems:

- MCR/control support area HVAC subsystem
- Essential power electrical room HVAC subsystem
- PCS valve room heating and ventilation subsystem

6.8.4.1 Main Control Room/Control Support Area HVAC Subsystem

MCR/control support area HVAC subsystem serves the MCR and control support area with two 100-percent-capacity supply air handling units, return/exhaust air fans, supplemental air filtration units, associated dampers, control and instrumentation, and common ductwork. The supply air handling units and return/exhaust air fans are connected to common ductwork that distributes air to the MCR and CSA areas. The MCR envelope consists of the MCR, shift manager's office, operation work area, toilet, and operations break room area. The CSA area consists of the main control support area, operations area, conference rooms, computer rooms, shift turnover room, kitchen/rest area, and restrooms. The MCR and control support area toilets have separate exhaust fans.

Outside supply air is provided to the plant areas served by the MCR/control support area HVAC subsystem through an outside air intake duct protected by an intake enclosure located on the roof of the auxiliary building. The supply, return, and toilet exhaust are the only HVAC penetrations in the MCR envelope.

Redundant radiation monitor sample line connections are located upstream of the VBS supply air isolation valves. These monitors initiate operation of the supplemental air filtration units on high gaseous radioactivity concentrations and isolate the MCR from the VBS on high-high particulate or iodine radioactivity concentrations.

The MCR/control support area HVAC subsystem is designed so that smoke, hot gases and fire suppressant will not migrate from one fire area to another and so affect safe shutdown capabilities, including operator actions. Fire or combination fire-and-smoke dampers are provided to isolate each fire area from adjacent fire areas during and following a fire. These combination fire-and-smoke dampers close in response to smoke detector signals or to the heat from a fire.

6.8.4.2 Class 1 (Essential Supply) Electrical Room HVAC Subsystem

The essential supply electrical room HVAC subsystem serves the essential supply electrical rooms, C&I rooms, electrical penetration rooms, battery rooms, spare Class 1 battery room, remote shutdown room, and reactor coolant pump trip switchgear rooms. The A and C electrical divisions, spare battery room, and reactor coolant pump trip switchgear rooms are served by one ventilation subsystem; the B and D electrical divisions and remote shutdown room are served by a second ventilation subsystem. Each subsystem consists of two 100-percent-capacity supply air handling units, return/exhaust air fans, associated dampers, C&I, and common ductwork. The supply air handling units and return/exhaust air fans are connected to a common ductwork that distributes air to the essential supply electrical rooms. The outside supply air intake enclosure for the A and C subsystem is common to the MCR/control support area intake located on the roof of the auxiliary building. The outside supply air intake for the B and D subsystem is located separately from the MCR/control support area air intake enclosure on the auxiliary building roof.

The exhaust ducts from the battery rooms are connected to the turbine building vent to remove hydrogen gas generated by the batteries.

The supply air handling unit cooling coils are provided with chilled water from the air-cooled chillers in the central chilled water system (VWS). The two air handling units for each set of electrical divisions are provided with chilled water from redundant air-cooled chillers.

Each subsystem for the Class 1 battery rooms is provided with two 100-percent-capacity exhaust fans.

The subsystem is designed so that smoke, hot gases, and fire suppressant do not migrate from one fire area to another so that they could adversely affect safe shutdown capabilities, including operator actions. Separate ventilation subsystems are provided to serve the electrical division A and C equipment rooms and the electrical division B and D equipment rooms. The use of separate HVAC distribution subsystems for the redundant trains of electrical equipment prevents smoke and hot gases from migrating from one distribution division to the other through the ventilation system ducts.

These combination fire-and-smoke dampers close in response to smoke detector signals or to the heat from a fire. During a fire, the pressure difference across the doors in the stairwells is maintained by dedicated stairwell pressurisation fans.

6.8.4.3 Passive Containment Cooling System Valve Room Heating and Ventilation Subsystem

The PCS valve room heating and ventilation subsystem serves the thermally insulated PCS valve room. The subsystem consists of one 100-percent-capacity ventilating fan, two 100-percent-capacity electric unit heaters, associated dampers, controls, and instrumentation. The PCS valve room heating and ventilation subsystem equipment is located in the PCS valve room in the containment dome area.

The exhaust fan draws outside air through an intake louver damper and exhausts it directly to the environment.

6.8.5 Annex/Auxiliary Buildings Nonradioactive Heating, Ventilation, and Air Conditioning Systems

The annex/auxiliary buildings' nonradioactive HVAC systems (VXS) serve the office areas, switchgear rooms, locker rooms, battery rooms, computer rooms, toilets, non-class 1 electrical equipment room (location of PLS cabinets), and other similar spaces. These areas do not typically have sources of radioactive contamination present during normal operation. A drain line from the BDS to the WLS passes through the areas served by the VXS. The drain line can be contaminated by the BDS system if there are fuel leaks and SG leakage, combined with a radiation monitor failure or an isolation valve failure. Since the drain system has no valves or connections within the area served by the VXS and it is gravity-drained, the chance of leakage into the VXS area is negligible because there would need to be a pre-existing leak coincident with a fault. Because the presence of activity in the areas served by the VXS is not reasonably foreseeable, the exhaust systems from the VXS have no provisions for HEPA filtration. See Chapter 23 and Reference 23.40 for more details pertaining to VXS.

The VXS serves the nonradioactive personnel and equipment areas, electrical equipment rooms, clean corridors, the ancillary diesel generator room and demineralised water deoxygenating room in the annex building, and the MSIV compartments, reactor trip switchgear rooms, and piping and electrical penetration areas in the auxiliary building.

The VXS consist of the following independent subsystems:

- General area HVAC subsystem
- Switchgear room HVAC subsystem
- Equipment room HVAC subsystem
- MSIV compartment HVAC subsystem
- Mechanical equipment areas HVAC subsystem
- Valve/piping penetration room HVAC
- Annex building offices

6.8.5.1 General Area HVAC Subsystem

The general area HVAC subsystem serves personnel areas in the annex building outside the security area. These areas include the men's and women's change rooms, the briefing room, operational support centre, offices, corridors, men's and women's toilet facilities, conference rooms, and office areas. The general area HVAC subsystem consists of two 50-percent-capacity supply air handling units and humidifiers, a ducted supply and return air system, diffusers and registers, exhaust fan, automatic controls, and accessories. The air handling units are located on the low roof of the annex building. The units discharge into ducted supply distribution systems that are routed through the building to provide air into the various rooms and areas served via registers. Electric heating coils are provided in the branch supply duct to the men's and women's change rooms and rest rooms for tempering the supply air. A humidifier is provided in the system to provide a minimum-space relative humidity of 35 percent.

6.8.5.2 Switchgear Room HVAC Subsystem

The switchgear room HVAC subsystem serves electrical switchgear rooms one and two in the annex building. The switchgear room HVAC system consists of two 100-percent-capacity air handling units, a ducted supply and return air system, and automatic controls and accessories.

The air handling units are located in the air handling equipment room in the annex building. They are connected to a common intake plenum adjacent to their air handling equipment room. This plenum also supplies air for the equipment room HVAC subsystem. The air handling units discharge into a common duct distribution system routed through the building to the rooms served. Air is returned to the air handling units from the rooms served by a return duct system.

The switchgear room HVAC subsystem is designed so that smoke can be removed after a fire by placing the system in a once-through smoke exhaust ventilation mode.

6.8.5.3 Equipment Room HVAC Subsystem

The equipment room HVAC subsystem serves electrical and mechanical equipment rooms in the annex and auxiliary buildings. These rooms include the standby power battery charger rooms one and two, the standby power battery rooms one and two, the reactor trip switchgear rooms one and two, and the standby power penetration room. This subsystem also serves the rooms and areas in the annex building, which include two rest rooms, access areas, and corridors. The equipment room HVAC system consists of two 100-percent-capacity air handling units, two battery room exhaust fans, a toilet exhaust fan, a ducted supply and return air system, and automatic controls and accessories.

The air handling units are located in the air handling equipment room in the annex building. They are connected to a common intake plenum adjacent to their air handling equipment room. This plenum also supplies air for the switchgear room HVAC subsystem. The air handling units discharge into a common duct distribution system routed through the buildings to the various areas served. Air is returned to the air handling units from the rooms served (except the battery rooms and rest rooms) by a return duct system. Electric reheat coils are provided in the ductwork to areas requiring close temperature control such as the security rooms and restrooms. Hot water unit heaters are provided in the north air handling equipment room to keep the area above 10°C (50°F).

A humidifier is provided in the branch duct to the security areas to provide a minimum space relative humidity of 35 percent.

Each standby power battery room is provided with an individual exhaust system to prevent the buildup of hydrogen gas in the room. Each exhaust system consists of an exhaust fan, an exhaust air duct, and a gravity backdraft damper located in the fan discharge. Air supplied to the battery rooms by the air handling units is exhausted to atmosphere. Air from the rest rooms is exhausted to atmosphere by a separate exhaust fan.

The portion of the equipment room HVAC subsystem servicing the auxiliary building is designed so that smoke, hot gases, and fire suppressant will not migrate from one fire area to another to the extent that they could adversely affect safe shutdown capabilities, including operator actions. Fire or combination fire-and-smoke dampers are provided to isolate each fire area from adjacent fire areas during and following a fire.

These combination fire-and-smoke dampers close in response to smoke detector signals or in response to the heat from a fire.

6.8.5.4 MSIV Compartment HVAC Subsystem

The MSIV compartment HVAC subsystem serves the two MSIV compartments in the auxiliary building that contain the main steam and feedwater lines routed between the MSIV containment and the turbine building. Each compartment is provided with separate heating and cooling equipment.

The MSIV compartment HVAC subsystem consists of two 100-percent-capacity supply air handling units per compartment with only low-efficiency filters, ducted supply air distribution directly to the space served, automatic controls, and accessories for each MSIV compartment.

The supply air handling units are located directly within the space served. One unit in each compartment normally operates to maintain the temperature of that compartment. The air handling units can be connected to the standby power system, for investment protection, in the event of loss of the plant ac electrical system.

6.8.5.5 Mechanical Equipment Areas HVAC Subsystem

The mechanical equipment areas HVAC subsystem serves the ancillary diesel generator room, demineralised water deoxygenating room, boric acid batching room, upper south air handling equipment room, and lower south air handling equipment room in the annex building.

The mechanical equipment areas HVAC subsystem consists of two 50-percent-capacity air handling units with supply fans and return/exhaust fans, a ducted supply and return air system, automatic controls, and accessories.

The air handling units are located in the air handling unit equipment room of the annex building. They are supplied from the air intake plenum number two located at the extreme end of the annex building. This plenum also supplies air for the VAS, the VHS, and the VFS.

Air from the air handling units is supplied to the ancillary diesel generator room to maintain normal design temperatures. Air supplied to the room is exhausted directly outdoors by means of a separate exhaust fan.

When the ancillary diesel generators operate, ventilation and cooling for the room are provided by manually operated dampers and opening doors to allow radiator discharge air to be exhausted directly outdoors.

6.8.5.6 Valve/Piping Penetration Room HVAC Subsystem

The valve/piping penetration room HVAC subsystem serves the valve/piping penetration room of the auxiliary building. The valve/piping penetration room HVAC subsystem consists of two 100-percent-capacity air handling units, a return air duct system, automatic controls, and accessories.

The air handling units are located directly within the space served.

6.8.6 Health Physics and Hot Machine Shop HVAC System

The VHS supply air system consists of two 100-percent-capacity air handling units, consisting of a low-efficiency filter bank and a high-efficiency filter bank, heating and cooling coils, and a supply fan with automatic inlet valves. The exhaust air system consists of two 100-percent-capacity exhaust fans sized to allow the system to maintain negative pressure. See Chapter 23 and Reference 23.45 for more details pertaining to VHS.

During normal operations, one supply air handling unit and one exhaust fan operate continuously to control air pressures in the health physics and hot machine shop areas of the annex building. The other standby supply and exhaust fans are started if the primary fans fail.

The supply airflow is automatically modulated to maintain a negative pressure in the areas served with respect to the outdoors and to surrounding areas that do not have their exhausts monitored for radioactivity. Differential pressure controllers with sensors in the general health physics area and sensors mounted outdoors modulate the automatic inlet vanes of the supply fan to maintain negative pressure. In addition, a separate differential pressure controller with a sensor in the hot machine shop modulates a damper in the supply air duct to the hot machine shop to maintain a negative pressure in the shop with respect to the outdoors and surrounding areas that do not have their exhausts monitored.

The hot machine shop provides a location within the controlled area for repair and refurbishment of equipment items from within the controlled area, i.e., they may not actually be contaminated or activated but it is easier to have a dedicated workshop rather than to undertake clearance monitoring, which may not be possible. Operations in the hot machine shop are conventional hands-on work, i.e., there is no provision for remote handling. The routine arising of airborne contamination from machining operations is not expected because equipment that can be repaired will be decontaminated beforehand. Equipment that is too active to handle manually and cannot be decontaminated will be packaged and disposed of as radioactive waste.

Airborne contamination from the remaining space extract from the hot machine shop and other areas served by this system is not expected to be significant during either normal or fault conditions.

The facility has a dedicated decontamination facility with HEPA filtration and a glove box that also has HEPA filtration. The HEPA filters on the decontamination chamber and glove box are typically ported so that a dispersed oil penetration (DOP) test can be performed.

Individual machine tools have local exhaust ventilation arrangements and HEPA filtration will be provided. The capability to perform DOP testing on the installed filters is a feature that would be included in the design as part of the local extract ventilation systems.

Filtered provision for specific areas of the hot machine shop are as follows:

- Glove boxes are red areas, and so HEPA filtration is provided.
- Individual machine tools are amber areas with significant potential for low level of activity release, so HEPA filtration is provided.
- Airborne contamination from the remaining space of the hot machine shop and other areas served by this system is not expected to be significant during either normal or fault conditions. Therefore, the remaining space is a green area with low risk, so no constant HEPA filtration is provided but the extract will be directed to the VFS if necessary. See Chapter 23 for more details pertaining to VHS.

6.8.7 Radwaste Building HVAC System

The radwaste building HVAC system (VRS) supplies and exhausts air from the radwaste building. The discharges from this ventilation system are continuously monitored for airborne activity by the VRS exhaust radiation monitor. In addition, the plant vent combined discharge is monitored and alarmed. See Chapter 23 and Reference 23.31 for more details pertaining to VRS.

The radwaste building has three potential sources of radioactive contamination, which are the following:

- Tanks for low-level liquid effluent for monitoring and sentencing − The monitor tanks contain water that has the potential for radiological contamination. The water in the monitoring tanks is not expected to contain significant contamination and will typically be below environmental discharge limits.
- An area for loading packaged solid LLW into containers for dispatch to the low level waste repository (LLWR) − Packaged solid radwaste is stored in the radwaste building. This material is bagged or loaded into storage containers at the point where it is generated or processed, so the chance of a significant release is low. All LLW will have been pre-packaged. Currently primary circuit resins are classified as intermediate-level waste (ILW). Condensate polishing resins might be LLW in the event of SG tube failures and are encapsulated at the spent resin tank. Other LLW is not encapsulated. LLW processing equipment is currently expected to be permanently installed. ILW processing equipment is mobile. If ILW and LLW are subjected to further treatment such as low- or high-force compaction in the radwaste building, then the equipment used will be self-contained with integral ventilation and HEPA filtration. The equipment may be permanently located at each site or may be transportable to undertake campaigns at more than one site. The standard radwaste equipment located in the radwaste building is portable.
- Portable or permanently installed equipment for packaging ILW and/or compacting LLW and ILW − The design has provisions for portable radwaste processing equipment. This equipment will connect to the railcar bay auxiliary building HVAC systems. Therefore, the risk of contamination from equipment and processing equipment is small. In addition, all potential sources are filtered at the component level.

The VRS general extract may contain significant airborne activity during either normal operation or fault conditions if the portable or permanently installed radwaste equipment is not properly operated.

The VRS serves the radwaste building, which includes the clean electrical/mechanical equipment room and the potentially contaminated HVAC equipment room, the packaged waste storage room, the waste accumulation room, and the mobile systems facility.

The VRS is a once-through ventilation system that consists of two integrated subsystems: the radwaste building supply air system and the radwaste building exhaust air system. These systems operate in conjunction with each other to maintain temperatures in the areas served while controlling airflow paths and building negative pressure.

The supply air system consists of two 50-percent-capacity air handling units with a ducted air distribution system, automatic controls, and accessories.

The air handling units are located in an electrical/mechanical equipment room on the side of the building. Each unit draws 100 percent outdoor air through individual louvered outdoor air intakes. The two units discharge into a common duct distribution system routed through the building. Branch connections from the main duct supply air through registers into the various areas served.

The exhaust air system consists of two 50-percent-capacity exhaust centrifugal fans sized to allow the system to maintain a negative pressure, high efficiency filtration, HEPA filtration, an exhaust air duct collection system, and automatic controls and accessories. The airflow rates are balanced to maintain a constant exhaust design airflow through the fans. The exhaust fans are located in an equipment room in the corner of the radwaste building.

The exhaust fans discharge to a common duct routed to the plant vent. A radiation monitor records activity in the discharge duct and activates an alarm in the MCR when excess activity in the effluent discharge is detected.

The exhaust air collection duct inside the radwaste building exhausts air from areas and rooms where low levels of airborne contamination may be present. Exhaust connection points are provided to allow the direct exhaust of equipment located on the mobile systems. Where there is potential for significant airborne release, mobile systems include HEPA filtration. Backdraft dampers are provided at each mobile system connection to prevent blowback through the equipment in the event of exhaust system trip. See Chapter 23 for more details pertaining to VRS.

6.8.8 Diesel Generator Building Heating and Ventilation System

The (diesel generator building heating and ventilation system) VZS supplies air to and exhausts from the diesel generator building. The diesel generator building is a physically separate building. See Chapter 23 and Reference 23.42 for more details pertaining to VZS.

The VZS serves the standby diesel generator rooms, electrical equipment service modules, stairwell, security room, diesel fuel oil day tank vaults in the diesel generator building, and the two diesel oil transfer modules located in the yard near the fuel oil storage tanks. Local area heating and ventilation equipment is used to condition the air to the stairwell and security room.

The VZS consists of the following subsystems:

- Normal heating and ventilation subsystem
- Standby exhaust ventilation subsystem
- Fuel oil day tank vault exhaust subsystem
- Diesel oil transfer module enclosures' ventilation and heating subsystem

No credible source or fault would result in a radioactive release from the diesel generator building. There is no reason to provide HEPA filtration on the VZS exhaust systems since there is no normal or fault condition in which a HEPA filter would reduce radioactive releases.

6.8.8.1 Normal Heating and Ventilation Subsystem

The normal heating and ventilation subsystem serves the diesel generator building. Each diesel generator train is provided with independent ventilation and heating equipment for the building areas serving that diesel generator train.

Each normal heating and ventilation subsystem for a diesel generator train consists of one 100-percent-capacity engine room air handling unit, which ventilates the diesel generator room; one 100-percent-capacity service module air handling unit, which ventilates the electrical equipment service module; an exhaust system for the fuel oil storage vault; and electric unit heaters in the diesel generator area. Air intake louvers for these units are located as high in the diesel generator building wall as possible.

Electric unit heaters are provided in the diesel generator room to maintain the space at a minimum temperature of 10°C (50°F) when the diesel generators are off.

Electric unit heaters are provided in the diesel generator stairwell to maintain the space at a minimum temperature.

6.8.8.2 Standby Exhaust Ventilation Subsystem

The standby exhaust ventilation subsystem for each diesel generator room consists of two 50-percent-capacity roof-mounted exhaust fans and motor-operated air intake dampers mounted in the exterior walls of the room.

6.8.8.3 Fuel Oil Day Tank Vault Exhaust Subsystem

Each fuel oil day tank vault is continuously ventilated by a centrifugal exhaust fan. The exhaust fans are mounted on the roof of the vault and ducted to draw air from near the vault floor and from above the oil containment dike to remove any oil fumes generated in the space. Air is drawn into the vault from the diesel generator room through an opening protected with a fire damper.

6.8.8.4 Diesel Oil Transfer Module Enclosures' Ventilation and Heating Subsystem

Each diesel oil transfer module enclosure is ventilated by a roof-mounted exhaust fan. Outside air is drawn into the enclosure through manually operated louvered air intakes. The louvers are closed for winter operation when heating is required. An electric unit heater is provided in each enclosure to maintain the space at a minimum temperature of 10°C (50°F). See Chapter 23 for more details pertaining to VZS.

6.8.9 Turbine Island Building Ventilation System

The turbine building ventilation system (VTS) serves all areas of the turbine building which includes the turbine hall, switchgear rooms, rectifier room, security rooms. See Chapter 23 and Reference 23.41 for more details pertaining to VTS. The general area of the turbine building is ventilated using roof ventilators.

The rooms served by VTS do not have a credible source of radioactive contamination. This part of the AP1000 plant does not have a likely source of radioactive contamination. These areas do not have HEPA filtration because it does not offer a significant protection benefit.

The first bay area of the turbine building contains the RCP variable speed drives, CCS equipment (a nonradioactive system), and the BDS. The BDS may be contaminated in the very unlikely event of concurrent fuel defects, SG leak, radiation monitor or BDS isolation failure, and a BDS leak. The VTS supply and exhaust to the BDS equipment area can be isolated to prevent radioactivity from being spread into the general turbine building areas.

The VTS operates during startup, shutdown, and normal plant operations. The system maintains acceptable air temperatures in the turbine building for equipment operation and for personnel working in the building.

The VTS consists of the following subsystems:

- General area heating and ventilation subsystem
- Local area heating and ventilation subsystem
- Electrical equipment, 1st bay equipment, and personnel work area HVAC subsystem

6.8.9.1 General Area Heating Subsystem

Most of the turbine building is supplied by the general area heating and ventilation subsystem. Air is exhausted from the turbine building to the atmosphere by roof exhaust ventilators. The roof exhaust ventilators pull in outside air through wall louvers. Wall louvers are located at the turbine generator operating deck to provide additional air during plant outage operations. The general area heating subsystem uses electric heaters to provide local heating throughout the turbine building. During heating operation, the general area ventilation system is not operated.

6.8.9.2 Electrical Equipment, 1st Bay Equipment, and Personnel Work Area HVAC Subsystems

This subsystem serves electrical equipment areas (switchgear rooms and the electrical equipment room), the 1st bay equipment (CCS pumps, BDS pumps, and RCP variable-frequency drive power converter areas), personnel work areas, secondary sampling laboratory, and office space. This subsystem is subdivided into three independent HVAC subsystems, one serving the electrical equipment areas, one the 1st bay equipment, and one the personnel work areas.

The electrical equipment HVAC system consists of two 50-percent-capacity air handling units with a supply fan and a return air fan, a ducted supply and return air system, automatic controls, and accessories. The temperature of the rooms is maintained by thermostats that control the chilled water control valves for cooling and the integral face/bypass dampers for heating. Outside air is mixed with recirculated air to maintain a positive pressure.

The 1st bay equipment area HVAC system consists of two 50-percent-capacity air handling units. The temperature of the room is maintained by thermostats that control the chilled water control valves for cooling and the integral face bypass dampers for heating. Outside air is mixed with the recirculation air to maintain a positive pressure.

The personnel work area HVAC system consists of two 50-percent-capacity air handling units, a ducted supply and return air system, automatic controls, and accessories. The temperature of the rooms is maintained by thermostats that control the chilled water control valves for cooling and the integral face/bypass dampers for heating. Electric reheat coils are provided in the ductwork to each room to maintain close temperature control. Outside air is mixed with recirculated air to maintain a positive pressure. See Section 23.13 for more details pertaining to VTS.

6.9 CONTROL AND INSTRUMENTATION

6.9.1 Control and Instrumentation

The C&I systems protect against unsafe reactor operation during steady-state and transient power operations, in addition to normal operational control. Further design details of control and instrumentation systems are delineated in Chapter 19.

The C&I architecture is shown diagrammatically in Figure 6-6. A real-time data network provides communications among the various parts of the C&I system, which include the data display and processing system (DDS), which facilitates the interaction between the plant operators and the other C&I systems; the plant protection and monitoring system (PMS); the plant control system (PLS); the in-core instrumentation system (IIS); the special monitoring system (SMS); and the DAS. Noted below are the:

- **PMS** – Provides C&I to sense fault or accident situations and to initiate the required Class 1 components and systems used to mitigate the fault and bring the plant to safe shutdown conditions.

- **DAS** – Provides a diverse backup to the PMS. This backup is included to support the aggressive risk goals for the AP1000 design by reducing the probability of a severe accident that potentially results from the unlikely coincidence of postulated transients and postulated common mode failure in the protection and control system.

The DAS and the PMS use independent and separated power sources and internal power supplies.

- **PLS –** The plant control system used for normal plant operations and control of the non-Class 1 systems and equipment.

6.9.2 Introduction

The AP1000 plant C&I systems protect against unsafe reactor operation during steady-state and transient power operations. They initiate selected protective functions to maintain the reactor within specified operating limits and respond to mitigate the consequences of DBEs.

This section covers the system descriptions, functional performance requirements, and design bases. The C&I chapter in Section 19 of this PCSR shows that the systems can be designed and built to conform to the applicable criteria, codes, and standards concerned with the safe generation of nuclear power in the UK.

6.9.3 The AP1000 Control and Instrumentation and Architecture

The AP1000 plant C&I systems comprise separate systems that perform duty plant control and monitoring, response to transients, and response to design basis accidents. Figure 6-16 illustrates the C&I architecture for the AP1000 design, which comprises the following systems (discussed in detail in this section):

- plant control system (PLS)
- diverse actuation system (DAS)
- plant protection and monitoring System (PMS)
- special monitoring system (SMS)
- Operation and control centres system (OCS)
- Data display and processing system (DDS)
- incore instrumentation system (IIS)
- main turbine control and diagnostics system (TOS)

Figure 6-16 shows two major sections separated by the real-time data network; the real-time data highway is depicted as a single network.

Figure 6-16 includes the plant protection, control, and monitoring functions. At the lower right-hand side is the PMS. It performs the reactor trip functions, the engineered safety features (ESF) actuation functions, and the qualified data processing system (QDPS) functions. The C&I equipment performing reactor trip and ESF actuation functions, their related sensors, and the reactor trip switchgear are, for the most part, four-way redundant. This redundancy permits the use of bypass logic so that a division or individual channel out of service can be accommodated by the operating portions of the protection system reverting from a two-out-of-four logic to a two-out-of-three logic.

The following control systems are used for duty operations and are not described in detail in this section:

- Meteorological and Environmental Monitoring System (MES)
- radiation monitoring system (RMS)
- Seismic Monitoring System (SJS)

6.9.4 Plant Control System

The PLS provides the functions necessary for normal operation of the plant from cold shutdown through full power. The PLS also contributes to the delivery of Category A and B safety functions (as defined in Chapter 5) in response to transients; parts of the system are therefore classified as Class 2. The PLS controls plant components that are operated from the MCR or remote shutdown workstation.

The PLS uses both discrete- (on/off) and modulating- (analogue) type actuation devices. The real-time data network (Figure 6-16) is a high-speed, redundant communications network that links systems of importance to the operator. Class 1 and 2 safety systems are connected to the network through gateways and qualified isolation devices so that the Category A and B safety functions are not compromised by failures elsewhere. Plant protection, control, and monitoring systems feed real-time data into the network for use by the control room and the DDS.

The upper portion of Figure 6-16 depicts the control rooms and data DDS. The MCR is implemented as a set of compact operator consoles featuring colour graphic displays and soft

control input devices. The graphics are supported by a set of graphics workstations that take their input from the real-time data network. An advanced alarm system, implemented in a similar technology, is also provided.

The DDS (plant computer) is implemented in a distributed architecture. The working elements of the distributed computer system are graphics workstations, although their graphics capability is secondary to their computing performance. The distributed computer system obtains its input from the real-time data network and delivers its output over the network to other users.

The diversity and defence in depth features of the AP1000 plant C&I architecture are described in WCAP-15775 (Reference 6.1) and the systems are substantiated in Chapter 19 of this PCSR.

6.9.5 Protection and Safety Monitoring System

The PMS provides detection of off-nominal conditions and actuation of Class 1 systems necessary to achieve and maintain the plant in a safe shutdown condition. The PMS controls Class 1 components in the plant that are operated from the MCR or remote shutdown workstation. Further design details of this system and its constituent components are delineated in Chapter 19.

The occurrence of a limiting fault, such as a LOCA or a secondary system break, requires a reactor trip plus actuation of one or more of the Class 1 safety systems (designated as ESFs) (Section 19). This combination of events prevents or mitigates damage to the core and RCS components, and provides containment integrity.

In addition, the PMS provides the equipment necessary to monitor the Category A safety functions during and following an accident.

6.9.5.1 Functionality of the Protection and Safety Monitoring System

The PMS consists of the equipment identified in Table 6-2. The PMS has four divisions of reactor trip and ESF actuation, and two divisions of post-accident parameter displays. The functional arrangement of the PMS is shown in Figure 6-17. The PMS is located in the auxiliary building.

The PMS performs the following Category A safety functions:

- Initiates an automatic reactor trip when plant process signals reach specified limits (Table 6-3 lists the PMS reactor trips).
- Initiates automatic actuation of ESFs when plant process signals reach specified limits (Table 6-4 lists the ESF actuations).
- Provides manual initiation of reactor trip and selected ESFs.
- Data communication between Category A and non-Category A safety systems does not inhibit the performance of the Category A safety function.
- Ensures that the automatic safety function and the Class 1 manual controls both have priority over the non-Class 1 soft controls.

The PMS performs the following non-Category A safety functions:

- Provides process signals to the PLS through isolation devices.
- Provides process signals to the DDS through isolation devices.

In conjunction with the operator workstations, the PMS performs the following functions:

- Provides the important displays, visual alerts, and fixed position controls. Instrumentation used for displaying information related to achieving Category A safety functions (information that must not be lost) is defined as Class 1. Instruments of lesser importance in determining the state of the plant do not require the same level of operational assurance and are designated as Class 2 or 3.

- Provides for the transfer of control capability from the MCR to the remote shutdown workstation (RSW) using multiple transfer switches. Each individual transfer switch is associated with only a single Class 1 safety group or with non-Class 1 control capability.

- Displays of the open/closed status of the reactor trip breakers can be retrieved in the MCR.

The PMS automatically removes blocks of reactor trip and ESF actuation when the plant approaches conditions for which the associated function is designed to provide protection. These blocks are identified in Section 19 (Table 19-1 and Table 19-4).

The PMS two-out-of-four initiation logic reverts to a two-out-of-three coincidence logic if one of the four channels is bypassed. All bypassed channels are alarmed in the MCR. The PMS does not allow simultaneous bypass of two redundant channels.

6.9.5.2 Safeguards Actuation Signal

An S-signal is used in the initiation logic of many of the ESFs described above. The variables that are monitored and used to generate an S-signal are typically those that indicate a significant plant transient requiring a response by several ESFs.

The S-signal is generated from any of the following initiating conditions:

- Low-3 pressuriser pressure
- Low-2 steam line pressure
- Low-2 cold leg temperature
- High-2 containment pressure
- Manual initiation

6.9.6 Diverse Actuation System

The DAS is a defence in depth system (Class 2 system) that provides an alternative means of initiating reactor trip, actuating selected ESFs and providing plant information to the operator.

6.9.6.1 Automatic Actuation Function

The DAS provides the following diverse automatic actuations in support of Category A safety functions (separate from the PMS):

- If RCS hot leg temperatures exceed the DAS high hot leg temperature setpoint, automatic reactor trip, turbine trip, and PRHR/IRWST signals are generated.

- If steam generators low wide range level is below the DAS low steam generator level setpoint, automatic reactor trip, turbine trip, and PRHR/IRWST and CMT/RCP signals are generated.

- If pressurizer level inputs fall below the DAS low pressurizer level setpoint, automatic reactor trip, turbine trip, and CMT/RCP signals are generated.

- If containment temperature inputs exceed the DAS high containment temperature setpoint, automatic containment isolation/PCS actuation signal is generated.

6.9.6.2 Manual Actuation Function

The manual actuation function of the DAS is implemented by hardwiring the controls located in the MCR directly to the final loads in a way that completely bypasses the normal path through the control room multiplexers, the PMS cabinets, and the DAS automatic logic.

The DAS provides the following diverse manual actuations in support of Category A safety functions (separate from the PMS):

- Reactor and turbine trip
- Passive containment cooling actuation
- CMT actuation and RCP trip
- Open Stage 1 ADS valves
- Open Stage 2 ADS valves
- Open Stage 3 ADS valves
- Open Stage 4 ADS valves
- Opening PRHR discharge isolation valves and close the IRWST gutter isolation valves
- Selected containment penetration isolation
- Containment hydrogen igniter actuation
- Initiating IRWST injection
- Initiating containment recirculation
- Initiating IRWST drain to containment

In addition to the above functions, a redundant method of actuating the following functions is provided at the DAS processor cabinets 1 and 2 (aka Remote DAS Control Panel) located in the radiological portion of the auxiliary building:

- Reactor and turbine trip
- PRHR & IRWST actuation
- CMT actuation & RCP Trip
- Containment Isolation & PCS Actuation
- ADS Stage 4 actuation
- Initiate IRWST Injection
- Initiate containment recirculation
- Initiate containment recirculation and IRWST drain

6.9.6.3 Actuation Logic Function

DAS automatic actuation functions are accomplished by channel-based subsystems. Plant parameter values from dedicated DAS sensors are compared against predetermined setpoints. If the plant parameter value exceeds the setpoint, a bistable is set in the associated channel. These signals are then voted in either a two-out-of-three or one-out-of-two twice taken basis. When two or more channels are unavailable, the automatic function is unavailable. If the voter is true, an actuation command signal is generated, which operates an interposing/interface relay with an output contact rating that is compatible with the voltage and current capacity of the final actuation devices. The manual actuation mode operates in parallel to independently actuate the final devices.

Actuation signals are output to the loads in the form of normally de-energised energise-to-actuate signals. The normally de-energised output state, along with redundant voting logic, reduces the probability of inadvertent actuation.

The DAS is designed so that, once actuated, each mitigation action goes to completion. Any subsequent return to the un-actuated state requires deliberate operator action.

Display Function

The DAS provides MCR displays of plant parameters separately from the PMS as listed in Table 19-7.

6.9.7 Radiation Monitoring System

The RMS provides plant effluent monitoring, process fluid monitoring, airborne monitoring, and continuous indication of the radiation environment in plant areas where such information is needed. The RMS is installed permanently and operates in conjunction with regular and special radiation survey programmes to help meet applicable regulatory requirements.

The RMS is divided functionally into the following two subsystems:

- Process, airborne, and effluent radiological monitoring and sampling
- Area radiation monitoring

The process and effluent radiological monitoring and sampling subsystem provides radiation monitoring for the four functions listed below. Individual monitors may provide functionality in more than one of these functions:

- Fluid process monitors determine concentrations of radioactive material in plant fluid systems.

- Airborne activity monitors provide operators with information on concentrations of radioactivity at various points in the ventilation system, providing information on airborne concentrations in the plant.

- Liquid and gaseous effluent monitors measure radioactive materials discharged to the environs.

- Post-accident monitors watch potential pathways for release of radioactive materials during accident conditions.

The area radiation monitoring subsystem provides plant personnel information on radiation at fixed locations in the plant. Post-accident monitoring functions are also performed by certain area monitors.

The RMS uses distributed radiation monitors, where each radiation monitor consists of one or more radiation detectors and a dedicated radiation processor. Each radiation processor receives averages and stores radiation data, and transmits alarms and data to the plant control system for control (as required), display, and recording. The alarms provided include low (fail), alert, and high. Selected channels have a rate-of-rise alarm. Additional design detail of this system and its constituent components are delineated in Chapter 19.

6.9.8 Special Monitoring System

The SMS consists of the digital metal impact monitoring system (DMIMS), vibration integrity monitoring system (VIMS) and feedwater vibration monitoring system (FWVMS).

The DMIMS detects the presence of metallic debris in the RCS when the debris impacts the internal parts of the RCS. The DMIMS is composed of digital circuit boards, controls, indicators, power supplies, and remotely located sensors and related signal processing devices. A minimum of two sensors are located at each natural collection region, connected to separate instrumentation channels, to maintain the impact monitoring function if a sensor fails in service.

The RCP vibration monitoring system (RCPVMS) (part of VIMS) is a continuous monitoring system that provides outputs for diagnostic tools and information to assist in evaluating the performance of the RCPs.

The FWVMS monitors the vibration of the main and booster feedwater pumps, motor, and gear unit.

The SMS does not perform any Category A, Category B, or defence in depth safety functions. The SMS consists of specialised subsystems that interface with the C&I architecture to provide diagnostic and long-term monitoring functions.

6.9.9 Operation and Control Centres System

The OCS includes the MCR, the technical support centre, the remote shutdown room, emergency operations facility, local control stations, and associated workstations for these centres (see Section 19.5.2.3 for further details). With the exception of the control console structures, the equipment in the control room is part of the other systems (for example, PMS, PLS, and DDS).

The boundaries of the OCS system for the MCR and the remote shutdown workstation are the signal interfaces with the plant components. These interfaces are via the plant protection and safety monitoring system processor and logic circuits, which interface with the reactor trip and ESF plant components; the PLS processor and logic circuits, which interface with the non-Class 1 plant components; and the plant real-time data network, which provides plant parameters, plant component status, and alarms.

6.9.10 Data Display and Processing System

The DDS provides the equipment used for processing non-Category A safety data, i.e., data that results in alarms and displays for both normal and emergency plant operations, generating these displays and alarms, providing analysis of plant data, providing plant data

logging and historical storage and retrieval, and providing operational support for plant personnel.

The DDS also contains the real-time data network, which is a redundant data highway that links the elements of the AP1000 plant C&I architecture (see Figure 6-16).

6.9.11 In-core Instrumentation System

The primary function of the IIS is to provide a three-dimensional flux map of the reactor core. This map is used to calibrate neutron detectors used by the PMS, as well as to optimise core performance. A secondary function of the IIS is to provide the PMS system with the thermocouple signals necessary for the post-accident inadequate core cooling monitor. The in-core instrument assemblies house both fixed in-core flux detectors and core exit thermocouples.

6.9.12 Main Turbine Control and Diagnostics System

The turbine generator is equipped with a digital electrohydraulic (D-EHC) system that combines the capabilities of redundant processors and high-pressure hydraulics to regulate steam flow through the turbine. The control system provides the functions of speed control, load control, overspeed protection, and automatic turbine control (ATC), which may be used for either control or supervisory purposes, at the discretion of the plant operator.

6.10 ELECTRICAL SYSTEMS

6.10.1 Electrical Power Systems

The electrical power systems comprise four main systems that provide power to various components and also include a number of other systems. Further design details of the electrical power systems and their constituent components are delineated in Chapter 18.

6.10.1.1 Essential Electrical Supply System

IDS provides reliable power for the safety-related equipment required for the plant instrumentation, control, monitoring and other vital functions needed for shutdown of the plant. In the event of a total loss of off-site and on-site ac power sources, the dc batteries constitute the sources of electrical power for operation of the required dc and ac instrument. In addition, the IDS provides power to the normal and emergency lighting in the MCR and at the remote shutdown room (RSW) (which contains the RSW).

The IDS comprises the Class 1 battery-backed dc electrical power supply system and uninterruptible power supply system. Although IDS is defined as the “Class 1E dc and uninterruptible power supply system” in design documentation, for the purposes of this PCSR, “the IDS” or “essential electrical supply system” is used for consistency.

The IDS provides power for the Class 1 equipment required for plant instrumentation, control, monitoring, and other vital functions. In addition, the IDS provides power for the emergency lighting in the MCR and at the remote shutdown workstation.

The IDS can provide power for the safe shutdown and monitoring of the plant for at least 72 hours without the support of battery chargers during a loss of all ac power sources coincident with a design basis accident (DBA). The system is designed so that no single failure will result in a condition that prevents the safe shutdown of the plant.

6.10.1.1.1 Class 1 Battery-Backed dc Supply System

The operating voltage range of the batteries is 210 to 280 Vdc. The maximum equalising charge voltage for batteries is 280 Vdc. The nominal system voltage is 250 Vdc.

The Class 1 dc subsystem is divided into four independent trains: A, B, C, and D. Each of these divisions is supplied from dedicated batteries and battery chargers.

Division A and D battery banks, and one of the battery banks in Division B and C, are designated as 24-hour battery banks and, as such, provide power to the loads required for the first 24 hours following a loss of all ac power event or a design basis accident. The second battery bank in Division B and C, designated as the 72-hour battery bank, is used for the loads requiring power for 72 hours following the same event.

6.10.1.1.2 Class 1 Uninterruptible Power Supplies

The Class 1 uninterruptible power supplies (UPS) provides power at 230 Vac to four independent divisions of Class 1 instrument and control power buses. Divisions A and D each consist of one inverter associated with an instrument and control distribution panel and a backup voltage regulating transformer with a distribution panel. The inverter is powered from the respective 24-hour battery bank switchboard. Divisions B and C each consist of two inverters, two instrument and control distribution panels, and a voltage-regulating transformer with a distribution panel. One inverter is powered by the 24-hour battery bank switchboard and the other by the 72-hour battery bank switchboard.

Under normal operation, the Class 1 inverters receive power from the associated battery bank. If an inverter is inoperable or the Class 1 250-Vdc input to the inverter is unavailable, the power is transferred automatically to the backup ac source by a static transfer switch featuring a make-before-break contact arrangement. The software utilised in the static transfer switch is diverse from the software in the inverter in order to protect against common cause failure. The backup power is received from the diesel-generator-backed, Class 2 400-Vac bus through the Class 1 voltage-regulating transformer. In addition, a manual mechanical bypass switch is provided to allow connection of a backup power source when the inverter is removed from service for maintenance.

6.10.1.2 Standby Electrical Supply System

The EDS comprises the battery-backed dc electrical power supply system and uninterruptible power supply system. Although EDS is defined as the “Non-Class 1E dc and uninterruptible power supply system” in design documentation, for the purposes of this PCSR, “EDS” or “standby electrical supply system” is used for consistency.

The EDS provides dc and uninterruptible ac power to the plant dc and ac loads needed to safely operate the plant under normal conditions and for defence in depth.

The EDS has four DC battery systems (EDS1 to EDS4) organized in two subsystems, 1 and 2 (Figure 18-5), with another dc system – EDS5 (see Figure 18-6). A spare EDS battery system is also provided and can be used in place of any of the EDS battery subsystems. See Chaper 18 and, specifically, Section 18.6 for additional details on EDS.

In addition, the EDS provides power to the hydrogen igniters located inside containment, which make up the VLS.

6.10.1.3 Main Alternating Current Power System

The main ac power system (ECS) is the power source used during plant normal operations to power all required operating equipment. The ECS receives power both from offsite and from the plant main generator should offsite power be lost without an associated reactor trip. The Class 2 standby power is included in the standby power system (ZOS). See Chapter 18 for more detail on ECS.

6.10.2 Onsite Standby Diesel Generator

The onsite ZOS is composed of two Class 2 standby diesel generator units and their separated power cabling to selected separated portions of the ECS that provide power to priority defence in depth (Class 2) loads (listed in Table 18.-6). These loads include each diesel generator subsystem's components to maintain reliability and operability of ZOS.

The onsite standby diesel generator function is to provide a backup source of ac electrical power to Category A onsite equipment needed to support decay heat removal, boration, and inventory control, as well as to minimise plant financial risks associated with the loss of the normal ac power sources.

Each generator is directly coupled to the diesel engine. Each diesel generator unit is an independent self-contained system complete with necessary support subsystems that include the following:

- Diesel engine starting subsystem
- Combustion air intake and engine exhaust subsystem
- Engine cooling subsystem
- Engine lubricating oil subsystem
- Engine speed control subsystem
- Generator, exciter, generator protection, monitoring instruments, and controls subsystems

6.10.3 Post-72-Hour Ancillary Diesel Generator Supply

To supply power during the post-72-hour period following a DBA, Class 2 ECS ancillary diesel generators are provided to supply the Class 1 voltage regulating transformers (divisions B and C only). This powers post accident monitoring systems, MCR lighting, MCR and C&I room ventilation, and pump power to refill the PCS water storage tank and the SFP, when all other sources of power are not available. Figure 18-7 shows the connections to post-72-hour loads. Note that if these diesel generators are unavailable, the plant would utilise diesel generator brought in from offsite.

6.11 AUXILIARY SYSTEMS

The plant auxiliary systems consist of non-electrical and non-HVAC defence in depth safety systems, and other water and other support systems.

6.11.1 Water Systems

6.11.1.1 Component Cooling Water System

The CCS is a closed-loop cooling system that transfers heat from various plant components to one or both SWS cooling trains, which are in turn cooled in a natural heat sink such as the ocean or a river (or cooling towers), depending on the plant operating mode. It operates during normal phases of plant operation, including power operation, normal cooldown, and refuelling. It removes heat from various components needed for plant operation and removes core decay heat and sensible heat for normal reactor shutdown and cooldown. Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.20. It provides defence in depth by providing cooling for the following:

- RNS HXs and pumps when the RCS pressure and temperature are below 31 bar (450 psi) and 176.7°C (350°F).
- Miniflow HXs of the CVS makeup pumps.
- SFP HXs for heat removal from the SFP.

The system components are arranged into two interconnected mechanical trains. Each train includes one component cooling water pump, one component cooling water HX, and one component cooling water surge tank. During normal plant operation, only one component cooling water pump, HX, and surge tank is expected to be operating, with the other component cooling water pump on standby. Should the operating component cooling water pumps stop operating; the standby pump is automatically started on low component cooling water flow rate. During normal plant cooldown and startup operations, both component cooling water pumps and HXs would be operated to handle the higher heat loads and flow rates.

The component cooling water pump discharge and suction piping for the two pumps is interconnected so that either pump can cool all the required plant components using either component cooling water HX. A bypass line around each HX containing a throttle valve prevents overcooling of the component cooling water during periods when the SWS water temperature is reduced.

During normal plant operation, one CCS mechanical train of equipment is operating. The operating train is aligned to provide component cooling for the loads identified in the list

below. The other train is aligned to automatically start in case the operating component cooling water pump fails.

The CCS transfers heat from the following plant components:

- RCPs and the RCP variable frequency drives in the RCS
- Letdown and miniflow HXs in the CVS
- Reactor coolant drain tank in the WLS
- Residual heat removal pumps and HXs in the RNS (see subsection 6.8.2)
- SFP HXs in the SFS
- Operating water-cooled chiller in the VWS
- Sample HX in the PSS
- Air compressors in the compressed air system
- Condensate pump oil coolers in the CDS

6.11.1.2 Service Water System

The SWS supplies cooling water to remove heat from the CCS HXs in the turbine building. The service water system is arranged into two trains of components and piping. Each train includes one service water pump, one strainer, and one cooling tower cell. Each train provides 100-percent-capacity cooling for normal power operation. Cross-connections between the trains upstream and downstream of the component cooling water system heat exchangers allows either service water pump to supply either heat exchanger, and allows either heat exchanger to discharge to either cooling tower cell.

The service water system operates during normal modes of plant operation, including startup, power operation (full and partial loads), cooldown, shutdown, and refuelling. The service water system is also available during loss of normal ac power conditions.

In the event of loss of normal ac power, the service water pumps and cooling tower fans, along with the associated motor operated valves, are automatically loaded onto their associated diesel bus. This includes isolation of cooling tower blowdown, which minimizes drain down of the system while both pumps are off. Both pumps and both cooling tower cells automatically start after power from the diesel generator is available. Further design details of this system and its constituent components are delineated in Chapter 17 and Reference 6.21.

6.11.1.3 Central Chilled Water System

VWS provides a source of chilled water to the cooling coils of HVAC systems in order to cool the process air. Further design details of this system and its constituent components are delineated in Reference 6.53.

The Central Chilled Water System consists of two subsystems: a high cooling capacity subsystem (HC VWS), and a low cooling capacity subsystem (LC VWS). The HC VWS provides chilled water to non-defence-in-depth HVAC systems used by the Radiologically Controlled Area Ventilation System (VAS), Containment Recirculation Cooling System (VCS), Containment Air Filtration System (VFS), Health Physics and Hot Machine Shop Ventilation System (VHS), Radwaste Building Ventilation System (VRS), Turbine Building Ventilation System (VTS), and the Annex/Aux Building Nonradioactive Ventilation System (VXS). The HC VWS also provides cooling water for the Secondary Sampling System (SSS) sample cooler, the Liquid Radwaste System (WLS) vapor condenser and gaseous radwaste system (WGS) gas cooler.

The LC VWS provides chilled water to defense-in-depth HVAC cooling coils used by the Nuclear Island Nonradioactive Ventilation System (VBS) air handling units and the VAS units coolers located in the Chemical and Volume Control System (CVS) and Normal Residual Heat Removal System (RNS) pump rooms.

The Class 1 function performed by VWS is that it maintains the integrity of the containment pressure boundary after a design basis event by isolating the chilled water supply and return pipe lines that penetrate the containment (Table 15A-1).

6.11.1.3.1 High Capacity Subsystem

The HC VWS consists of two (2) large capacity chilled water pumps, two (2) large capacity centrifugal water-cooled chillers, a chemical feed tank, an expansion tank, and associated valves, piping and instrumentation for normal operation, and two (2) small chilled water pumps and two (2) small air-cooled chillers for peaking load or low load operation. The chiller water-cooled condensers are supplied with cooling water from the CCS. The HC VWS is arranged in two sets of parallel mechanical trains with common supply and return headers, the water-cooled chiller train and the air-cooled chiller train.

6.11.1.3.2 Low Capacity Subsystem

The LC VWS consists of two (2) 100% capacity chilled water trains. Each train consists of a chilled water pump, an air-cooled chiller, an expansion tank, a chemical feed tank, and associated valves, piping, and instrumentation. The system is arranged in two independent trains with separate supply and return headers.

6.11.1.4 Fire Protection System

The FPS provides a defence in depth functions and comprises of automatic fire detection, an alarm system, and firefighting equipment in order to:

- Detect fires early
- Minimise fire spreading
- Extinguish fires quickly

Further design details of this system and its constituent components are delineated in Reference 6.54.

FPS is designed to minimise the damage to SSCs and thus the spread of radiological contamination is minimised. The AP1000 plant FPS achieves the mitigation of damage by the following:

- Detect and locate fires and provide the operator with an indication of the location.
- Provide the capability to extinguish fires in any plant area, protect site personnel, limit fire damage, and enhance safe shutdown capabilities.
- Supply fire suppression water at a flow rate and pressure sufficient to satisfy the demand of any automatic sprinkler system, plus adequate capacity for fire hoses.
- Maintain 100 percent of fire-pump design capacity, assuming failure of the largest fire pump or the loss of offsite power.
- Following a safe shutdown earthquake, provide water to hose stations for manual firefighting in areas outside of containment containing Class 1 SSCs.

- Satisfy the requirements of the PCS as an alternate source of water to wet the containment dome after a loss-of-coolant accident, if the FPS is available.
- Provide an alternate supply of cooling water to the RNS or SFS HX for decay heat removal after a loss of normal CCS function.
- Provide containment spray capability for severe accident management, if deemed necessary.

The system comprises of the following:

- Automatic fire detection and alarm system;
- Manual firefighting equipment, i.e. portable fire extinguishers and hose stations
- Automatic fire suppression systems, i.e. fixed firefighting systems such as sprinklers in specific locations outside containment.

The fixed firefighting system has seismic design requirements applied to portions of the standpipe system located in areas containing equipment required for safe shutdown following a safe shutdown earthquake so that water is available to manual hose stations. The standpipe system serving areas containing equipment required for safe shutdown following a safe shutdown earthquake is designed and supported so that it remains functional. In addition, the valves and associated penetration piping for the FPS that maintain containment isolation are Category A Class 1 (Table 15A-1).

6.11.1.5 Demineralised Water Transfer and Storage System

The DWS receives water from the demineralized water treatment system (DTS) and provides a reservoir of demineralised water to be supplied to the condensate storage tank and to be distributed throughout the plant. Demineralised water is processed in the DTS to remove dissolved oxygen. In addition to supplying water for makeup of systems that require pure water, the demineralised water is used to sluice spent radioactive resins to the WSS from the ion exchange vessels in the CVS, the SFS, and the WLS.

The DWS consists of the demineralised water storage tank, the demineralised water transfer pump, two catalytic oxygen reduction units, piping, valves, instrumentation, and a condensate storage tank. The system has one containment penetration with isolation valves on either side. Additional design detail of this system and its constituent components are delineated in Reference 6.39.

6.11.1.6 Demineralised Water Treatment System

The DTS receives water from the raw water system (RWS), processes this water to remove suspended solids and ionic impurities, and provides demineralised water to the DWS. The system includes filters, reverse osmosis units, electro deionisation units for secondary demineralisation, piping, valves, and instrumentation. Additional design detail of this system and its constituent components are delineated in Reference 6.40.

6.11.1.7 Potable Water System

The potable water system (PWS) is designed to furnish water for sanitary and domestic use and human consumption. Additional design detail of this system and its constituent components are delineated in Reference 6.41.

6.11.1.8 Turbine Building Closed Cooling Water System

The turbine building closed cooling water system (TCS) provides chemically treated demineralised cooling water for the removal of heat from HXs in the turbine building, and rejects the heat to the CWS. Additional design detail of this system and its constituent components are delineated in Reference 6.42.

6.11.1.9 Waste Water System

The waste water system WWS collects nonradioactive waste from floor and equipment drains in the sumps or tanks in the auxiliary, annex, turbine, and diesel generator buildings. Additional design detail of this system and its constituent components are delineated in Reference 6.43.

6.11.1.10 Sanitary Drainage System

The sanitary drainage system (SDS) is designed to collect the site sanitary waste for delivery to the treatment plant or an offsite facility where it is processed. Additional design detail of this system and its constituent components are delineated in Reference 6.47.

6.11.2 Process Auxiliaries

6.11.2.1 Compressed and Instrument Air System

The CAS consists of the following three subsystems:

- The instrument air subsystem supplies compressed air for air-operated valves and dampers.

- The service air subsystem supplies service air at outlets throughout the plant to power air-operated tools and is used as a motive force for air-powered pumps. The service air subsystem is also utilised as a supply source for breathing air. Individually packaged air purification equipment is used to produce breathing-quality air for protection against airborne contamination.

- The high-pressure air subsystem supplies air to the VES and fire-fighting apparatus recharge station. The high-pressure air subsystem also provides a connection for refilling the VES storage tanks from an offsite source. Major components of the CAS are located in the turbine building.

Additional design detail of this system and its constituent components are delineated in Reference 6.45.

6.11.2.2 Plant Gas System

The plant gas system (PGS) provides hydrogen, carbon dioxide, and nitrogen gas to the plant systems, as required. Other gases such as oxygen, methane, acetylene, and argon are supplied in smaller individual containers, and are not supplied by the PGS. Additional design detail of this system and its constituent components are delineated in Reference 6.46.

6.11.2.3 Standby Diesel Fuel Oil System

The standby diesel fuel oil system (DOS) consists of two standby diesel fuel storage tanks, one ancillary diesel oil storage tank, a standby diesel generator fuel oil transfer system, and an ancillary diesel generator fuel oil supply system. It consists of two independent fuel storage, transfer, and recirculation flow paths, that is, one path per diesel generator. Each path consists of a fuel oil storage tank, one fuel transfer pump, diesel fuel oil supply and fuel return piping, a day tank, and the associated specialty valves, fittings, and instrumentation. The supply lines from the transfer pumps to the day tanks include fuel oil heaters, filters, and moisture separators. The system is protected from the effects of low temperatures by the inline electric oil heater in the transfer line.

The fuel oil storage tanks are sized to provide sufficient capacity for 7 days of operation for each standby diesel generator. This provides time for additional fuel to be transported to the site, if required. The design of the tanks allows fuel to be replenished without interrupting diesel generator operation.

The ancillary diesel generator fuel oil supply portion of the DOS consists of a single tank serving both ancillary diesel generators. The tank is located inside the annex building and is served by the annex building heating and ventilation system. The tank is insulated and provided with heaters to maintain the fuel oil above the oil cloud point. Fuel oil lines from the tank to the ancillary diesel generators are insulated.

The ancillary diesel generator fuel oil storage tank is sized to provide 4 days of operation for both the ancillary diesel generators. The ancillary diesel generators are not required for the first 3 days following a loss of electrical power. Therefore, the operator has 7 days to arrange for the delivery of additional fuel. Additional design detail of this system and its constituent components are delineated in Reference 6.48.

6.11.2.4 Communication System

The communication system (EFS) provides effective intraplant communications and effective plant-to-offsite communications during normal, maintenance, transient, fire, and accident conditions, including loss of offsite power. Additional design detail of this system and its constituent components are delineated in Reference 6.44.

6.12 FUEL HANDLING, FUEL STORAGE, AND RADWASTE

6.12.1 Introduction

The fuel handling and storage and radwaste main components are described in this section for completeness; a further assessment and more specific details are contained in Chapter 26.

Fuel Handling and Storage

The fuel handling equipment is designed to handle the spent fuel assemblies underwater from the time they leave the RV until they are placed in a container for shipment to the appropriate waste facility. Underwater transfer of spent fuel assemblies provides an effective and transparent radiation shield, as well as a reliable cooling medium for removal of decay heat. The boric acid concentration in the water is sufficient to preclude criticality.

The associated fuel handling structures may be generally divided into two areas: the refuelling cavity that is flooded only during plant shutdown for refuelling, and the SFP and

transfer canal, which is kept full of water. The fuel handling and refuelling system (FHS) transfers fuel assemblies and core components during refuelling operations and stores new and spent fuel assemblies in the new and spent fuel storage racks, respectively. The refuelling machine (RM) and the fuel transfer system are operated during refuelling mode. The fuel handling machine in the fuel handling area is used during refuelling operation and during plant power operation,

New fuel is stored dry adjacent to the SFP. For refuelling, new fuel assemblies are transferred into the refuelling cavity via the SFP.

The FHS consists of the following subsystems, which are described below:

- New fuel storage
- Spent fuel storage
- Light load handling system (related to refuelling)

6.12.2 New Fuel Storage

New fuel is stored in a high-density rack that includes integral neutron-absorbing material to maintain the required degree of subcriticality. The rack is designed to store fuel of the maximum design basis enrichment. The rack in the new fuel pit consists of an array of cells interconnected to each other at several elevations and to a thick baseplate at the bottom elevation.

The new fuel rack includes storage locations for 72 fuel assemblies. The rack layout and array centre-to-centre spacing is shown in the Figures 6-12 and 6-13. This spacing provides a minimum separation between adjacent fuel assemblies, which is sufficient to maintain a subcritical array even in the event the building is flooded with unborated water or fire extinguishant aerosols, or during any DBE. The rack is designed so that a fuel assembly cannot be inserted into a location other than a one designed to receive an assembly. Surfaces that come into contact with the fuel assemblies are made from annealed austenitic stainless steel.

The new fuel storage facility is located within the seismic Category I (C-I) auxiliary building fuel handling area. The facility is protected by the external walls of the auxiliary building from the effects of natural phenomena such as earthquakes, wind, tornadoes, floods, and external missiles. The facility is designed to maintain its structural integrity following a safe shutdown earthquake and to perform its intended function following a postulated DBE such as fire, internal missiles, or pipe break. The walls surrounding the fuel handling area and new fuel storage pit protect the fuel from missiles generated inside the auxiliary building. The fuel handling area does not contain a credible source of missiles (see Chapter 11 on internal hazards and Chapter 12 on external hazards).

The dry, unlined, approximately 5.2-m (17-foot) deep reinforced concrete pit is designed to provide support for the new fuel storage rack. The rack is freestanding and sits on bearing pads supported by the pit floor. The walls of the new fuel pit are C-I. The new fuel pit is normally covered to prevent foreign objects from entering the new fuel storage rack. Since the only crane that can access the new fuel pit does not have the capacity to lift heavy objects, the new fuel pit cover is not designed to protect the fuel assemblies from the effects of dropped heavy objects. The cover also provides further protection from a fuel assembly misload. The new fuel storage pit is drained by gravity drains that are part of the WRS, draining to the waste holdup tanks that are part of the WLS.

6.12.3 Spent Fuel Storage

Spent fuel is stored in high-density racks that include integral neutron-absorbing material to maintain the required degree of subcriticality. These rack modules are freestanding, neither anchored to the pool floor nor braced to the pool wall. The spent fuel storage racks include storage locations for 612 fuel assemblies and five defective fuel assemblies. The spent fuel racks are are capable of storing fresh fuel up to 5 weight percent U-235, as well as spent fuel.

The spent fuel storage facility is located within the C-I auxiliary building fuel handling area. The walls of the SFP are an integral part of the C-I auxiliary building structure. The facility is protected from the effects of natural phenomena such as earthquakes, wind and tornadoes, floods, and external missiles. The facility is designed to maintain its structural integrity following a safe shutdown earthquake and to perform its intended function following a postulated DBE such as a fire.

The SFP provides storage space for spent fuel. The pool is approximately 13 m (42.5 ft) deep and constructed of concrete-filled structural modules. The portion of the structural modules in contact with the water in the pool is stainless steel. The normal water volume of the pool is about 721 m^3 (190,500 US gallons) of borated water (including racks without fuel at a water level 0.3 m below the operating deck) with a nominal boron concentration of 2700 ppm.

A gated opening connects the SFP and fuel transfer canal. The fuel transfer canal is connected to the in-containment refuelling cavity by a fuel transfer tube. The spent fuel transfer operation is completed underwater, and the waterways are deep enough to maintain a minimum of 2.67 m (8.75 ft) of shielding water above the active fuel height of spent fuel assemblies.

Next to the SFP and accessible by another gated, gasketed opening is a cask loading pit. It is provided for underwater loading of fuel into a shipping cask and cask draining and decontamination prior to cask shipment to the appropriate waste facility.

The fuel handling machine (FHM) traverses the SFP, the fuel transfer canal, the cask loading pit, the new fuel storage pit, and the rail car bay. It is used in the movement of both new and spent fuel assemblies. A new fuel elevator in the SFP lowers the new fuel to an elevation accessible by the FHM and its associated long handling tool.

The cask handling crane is used for operations involving the spent fuel shipping cask. The cask handling crane traverses the auxiliary building and a portion of the fuel handling area. The cask handling crane's path is designed so that the cask cannot pass over the SFP, new fuel pit, or fuel transfer canal. This precludes the cask handling crane from moving loads greater than fuel components over stored fuel.

6.12.4 Spent Fuel Pool Cooling System

The SFS is designed to remove decay heat which is generated by stored fuel assemblies from the water in the spent fuel pool. This is done by pumping the high-temperature water from within the fuel pool through a heat exchanger, and then returning the water to the pool. A secondary function of the SFS is clarification and purification of the water in the spent fuel pool, the transfer canal, and the refuelling water. The SFS is made up of two redundant mechanical trains. Further design details of this system and its constituent components are delineated in Reference 6.17 and Chapter 17.

If the Spent Fuel Pool Cooling System's normal cooling capability is lost, heat is removed from the spent fuel by heating and boiling the water in the SFP. The SFP water and other safety-related sources of makeup water (e.g. PCCWST) are sufficient to remove heat from the spent fuel via passive means for 72 hours following a design basis event including a seismic event. There is sufficient onsite water to support heat removal by boiling of the SFP for a total of 7 days.

A listing of the major functions of the spent fuel pool cooling system and the corresponding modes of operation is provided below:

- Remove heat from the water in the spent fuel pool during operation to maintain the pool water temperature within acceptable limits.
- Provide purification and clarification of the spent fuel pool water during operation.
- Provide purification of the refuelling cavity during refuelling operations.
- Transfer water between the IRWST and the refuelling cavity during refuelling operations.
- Provide purification and cooling of the IRWST during normal operation.
- The SFS is designed to perform its function in a reliable and failure-tolerant manner. This reliability is achieved with the use of rugged and redundant equipment. The SFS consists of two mechanical trains of equipment. Each train includes one spent fuel pool pump, one spent fuel pool heat exchanger, one spent fuel pool demineralizer, and one spent fuel pool filter. The two trains of equipment share common suction and discharge headers. In addition, the SFS includes the piping, valves, and instrumentation necessary for system operation.

6.12.4.1 Containment Isolation

The SFS preserves containment integrity by isolating the SFS piping lines penetrating containment using Containment Isolation valves.

6.12.4.2 Class 1 Piping Connections for Makeup to the SFP

The SFS provides Class 1 piping connections to the PCCWST, and cask washdown pit (CWP) for makeup to the SFP should normal SFS cooling be disabled following a design basis event, including a seismic event. The Cask Loading Pit (CLP) will be connected by opening the gate between the CLP and SFP. A Class 1 piping connection is provided from the CLP to the SFP and can be used if necessary.

6.12.4.3 Class 1 Drain Path from the Refueling Cavity to Containment

Redundant check valves in the drain line from the Refueling Cavity prevent out-of-sequence flooding of the Refueling Cavity during containment floodup in a design basis accident scenario. During a containment floodup event, water entering the Refueling Cavity from either a Loss of Coolant Accident (LOCA) or the In-Containment Refueling Water Storage tank (IRWST) overflow weirs will be directed through the drain path to the steam generator two (SG2) compartment. This insures proper floodup sequence by allowing this water to contribute to the initial containment floodup level, providing the driving head for containment recirculation.

6.12.4.4 Maintain Proper Refueling Cavity Level during Refueling Operations

During refueling operations, the SFS maintains the proper Refueling Cavity water level.

6.12.4.5 Maintain SFS Water Level above the Top of the Fuel Assemblies (without the RCCA)

The SFS is responsible for maintaining the SFP water level above the top of the fuel assemblies (without the RCCA) at all times during operation. During any design basis event (including a seismic event) that would cause loss of water in the pool due to boiling, makeup water is provided from PCS in order to maintain SFP water level above the top of the fuel assemblies (without the RCCA) for 72 hours.

6.12.4.6 Spent Fuel Pool Purification

The SFS purifies the SFP water during all modes of plant operation. The SFS removes radioactive corrosion products, fission products, and other impurities in order to maintain water clarity and low SFP radioactivity levels.

6.12.4.7 Refueling Cavity Purification

The SFS purifies the Refueling Cavity water during refueling operations. The SFS removes radioactive corrosion products, fission products, and other impurities in order to maintain water clarify and low Refueling Cavity water radioactivity levels.

6.12.4.8 Water Transfers

The SFS transfers water between the IRWST and the Refueling Cavity during refueling operations. The SFS can also transfer water between the IRWST, Fuel Transfer Canal (FTC), CLP, and CWP.

6.12.4.9 IRWST Cooling and Purification

The SFS can be aligned to cool the IRWST water during normal plant operation if the RNS is unavailable. The SFS removes radioactive corrosion products and fission ions to maintain low IRWST radioactivity levels during normal plant operation prior to a scheduled refueling. The SFS is designed to maintain the water in the IRWST in a way consistent with requirements to limit the radioactivity of the water in the Refueling Cavity during a refueling.

6.12.4.10 Refueling Cavity Drain

A drain line is located in the Refueling Cavity to facilitate proper draining of the Refueling Cavity to support refueling operations.

6.12.4.11 SFP Water Tritium Concentration Control

The SFS has the ability to maintain the proper concentration of tritium in the SFP. This can be accomplished by removing water from the SFP and replacing it with non-tritiated water.

6.12.4.12 Removal of Decay Heat from Spent Fuel Assemblies

The SFS removes the decay heat from the spent fuel assemblies stored in the SFP by pumping water from the pool, through a cooling heat exchanger, and back to the SFP.

6.12.4.13 Recover from SFP Boiling

If normal SFP cooling is lost, the SFP temperature will increase up to the boiling point in the pool. Once cooling is restored, the SFS can terminate boiling and reduce the SFP temperature to normal.

6.12.4.14 CLP Support of RNS

The CLP provides a defense-in-depth source of water to the RNS, which may be used to respond to an Automatic Depressurization Signal (ADS) signal after a LOCA has occurred. In this event, water from the CLP will be delivered by the RNS to the RCS to help prevent Fourth Stage ADS actuation by holding up the core makeup tanks.

6.12.4.15 SFS Support of CVS

The CVS can take suction from the SFP through the connection in the SFS pump suction to provide a defense-in-depth borated suction source.

6.12.5 Light Load Handling System

The light load handling system consists of the equipment and structures needed for the refuelling operation. This equipment comprises the following:

- Refuelling machine (RM)
- Fuel transfer system
- FHM
- New fuel elevator
- Long-handled tooling

The refuelling cavity and the fuel storage area are connected by the fuel transfer tube, which is fitted with a quick-opening hatch on the refuelling cavity end and a valve on the fuel storage area end. The hatch is in place except during refuelling to provide containment integrity. Fuel is carried through the tube on an underwater transfer car.

Fuel is moved between the RV and the fuel transfer system by the RM. The fuel transfer system is used to move a fuel assembly and its associated core component between the containment building and the auxiliary building fuel handling area. After a fuel assembly is placed in the fuel container, the lifting arm pivots the fuel assembly to the horizontal position for passage through the fuel transfer tube. After the transfer car transports the fuel assembly through the transfer tube, the lifting arm at that end of the tube pivots the assembly to a vertical position so that the assembly can be lifted out of the fuel container.

In the fuel handling area, fuel assemblies are moved about by the FHM. Initially, a short tool is used to handle new fuel assemblies, but the new fuel elevator must be used to lower the assembly to a depth at which the FHM and associated long-handled tool can place the new fuel assemblies into or remove them from the spent fuel storage racks. Additional design detail of this system and its constituent components are delineated in Reference 6.49.

6.12.6 Treatment of Radioactive Waste

The management of radioactive waste, which may be gaseous, liquid, or solid, spans all the stages in the life cycle of the AP1000 plant. Further details of the radioactive waste management arrangements can be found in Chapter 26.

Management of radwaste is being planned with the expectation that the LLW, ILW, and spent fuel waste streams will be capable of being disposed of at Nuclear Decommissioning Authority (NDA) facilities. Waste forms and treatment processes have been selected with this principle in mind and containers compliant with the Radioactive Waste Management (RWM) have been designated (Reference 6.7).

Waste will be categorised for treatment as conventional or radioactive. Radioactive material will be categorised as LLW, ILW, or high-level waste (HLW). Solid waste will be characterised and segregated using equipment discussed in the Environment Report (Reference 6.7, subsection 3.5.7) and the Westinghouse integrated waste strategy (IWS) (Chapter 26 in this PCSR).

6.12.6.1 Disposal of Spent Fuel and Intermediate-Level Waste

Spent Fuel

The spent fuel assemblies are initially stored in the spent fuel cooling pool to allow radioactive decay to occur and decay heat to be removed before they are transferred to dry cask storage (Reference 6.7). See Section 26 for further detail on spent fuel.

Rod Cluster Control Assemblies, Neutron Source Assemblies and Poison Rod Assemblies

The RCCAs, identified as “control rod clusters” in the estimates for operational wastes, include 53 assemblies assumed to be replaced once per 20 years. There are also 16 grey rod assemblies that are redundant and also assumed to be replaced once per 20 years. The control rod clusters and grey rod assemblies are disposed of within the spent fuel assemblies.

There are two primary and two secondary neutron source assemblies. The primary sources are used once during the first cycle then disposed of as waste within a spent fuel assembly. The secondary source assemblies are assumed to be replaced once every 20 years for the purpose of estimating waste. They are also disposed of within a spent fuel assembly.

The poison rod assemblies are used in the first core and only then disposed of as waste. There are 72 poison rod assemblies, to be disposed of within spent fuel assemblies.

6.12.6.2 Disposal of Low-Level Waste and Intermediate-Level Waste

The disposability of LLW raises fewer issues than that of ILW and spent fuel. Westinghouse has sought assurance from LLW Repository Limited (LLWR) that the expected LLW streams will be available.

LLW will be temporarily stored in a buffer or marshalling area within the radwaste building until required for sorting (Reference 6.7). The package waste storage room is used to store LLW for which processing has been deferred and a period of decay will provide handling benefits, e.g., dose reduction (see Chapter 26 of this PCSR).

Solid ILW will be encapsulated on a campaign basis when a sufficient volume of waste is available to complete an encapsulation run (typically coinciding with refuelling outages that occur after 18 months operation) (see Chapter 26 of this PCSR).

6.12.6.3 Treatment of Large Solid Items of Radioactive Waste: Steam Generators and Reactor Pressure Vessel Head

No large solid radioactive waste items are expected to be generated during normal operation of the AP1000 plant. Nevertheless, there may be a need to replace SGs or the RPV head during the lifetime of the plant, which will be managed in accordance with the licensee's management arrangements at the time of disposal.

6.12.7 Gaseous Radwaste System

The WGS is designed to perform the following major functions:

- Collect gaseous wastes that are radioactive or hydrogen-bearing.
- Process and discharge the waste gas, keeping offsite releases of radioactivity within acceptable limits.

The WGS is a once-through ambient-temperature-activated carbon delay system that collects and processes gaseous wastes originating from the RCS that are radioactive to prevent an uncontrolled atmospheric release. The system includes a gas cooler, a moisture separator, an activated carbon-filled guard bed, and two activated carbon-filled delay beds. The system also includes an oxygen analyser and a gas sampler.

The WGS is designed to receive radioactive gases generated during operation. The radioactive gas flowing into the WGS enters as trace contamination in a stream of hydrogen and nitrogen. The incoming gas first passes through a gas cooler. Moisture formed due to gas cooling is removed in the moisture separator. The waste gas then flows through the guard bed, where iodine and chemical (oxidising) contaminants are removed. The guard bed also removes any remaining excessive moisture from the waste gas. The waste gas then flows through the two delay beds, where xenon and krypton are delayed by a dynamic adsorption process. Additional design detail of this system and its constituent components are delineated in Reference 6.25.

Inputs to the WGS are the following:

- **WLS degasifier** − The degasifier extracts both hydrogen and fission gases from the CVS letdown flow or from the reactor coolant drain tank discharge. The liquid from the degasifier is routed to the WLS.
- **Reactor coolant drain tank** − Hydrogen dissolved in the influent to the reactor coolant drain tank enters the WGS via either the reactor coolant drain tank (RCDT) vent or the WLS degasifier discharge as noted above.

6.12.8 Liquid Radwaste System

The WLS is designed to collect, process, store, and dispose of liquid radioactive waste generated as the result of normal operation, including anticipated operational occurrences such as RCS-level reduction for refuelling. Nonradioactive secondary system waste water is not processed by the WLS. However, if significant radioactivity is detected in secondary-side systems, the SG blowdown or a portion of the blowdown may be diverted to the WLS for processing and disposal. Additional design detail of this system and its constituent components are delineated in Reference 6.24.

The WLS includes tanks, pumps, ion exchangers, and filters. The WLS is designed to either process radioactively contaminated liquid waste or to store it for processing by mobile equipment. The liquid waste is divided into four major categories:

- Borated reactor-grade waste water collected from the RCS effluents received through the CVS, the PSS sink drains, and equipment leakoffs and drains.

- Floor drains and other wastes with potentially high suspended solids content, collected from various building floor drains and sumps.

- Detergent wastes collected from the plant hot sinks and showers and some cleanup and decontamination processes. Such waste generally has low concentrations of radioactivity.

- Chemical waste collected from the laboratory and other relatively small volume sources. This could be a mixture of hazardous and radioactive wastes, or other radioactive wastes with high dissolved solids content.

The liquid waste streams are summarised in this section.

The WLS has effluent holdup tanks that contain the liquid waste prior to processing. They primarily receive borated and hydrogen-bearing liquid from two sources: the reactor coolant drain tank and the CVS letdown. The reactor coolant drain tank collects leakage and drainage from various primary systems and components inside the containment. Effluent from the CVS (letdown) is produced mainly as a result of RCS heatup, boron concentration changes, and RCS-level reduction for refuelling. Input collected by the effluent system normally contains hydrogen and dissolved radioactive gases. Therefore, it is routed through the WLS vacuum degasifier before being stored in the effluent holdup tanks. The contents of these tanks may be recirculated and sampled, recycled through the degasifier for further gas stripping, returned to the RCS by way of the CVS makeup pumps, processed through the WLS ion exchangers and directed to the monitor tanks for discharge, or discharged to the mobile treatment facility,.

The WLS in the AP1000 plant first filters the incoming liquid, which then enters four ion exchange resin vessels in series. Any of these vessels can be manually bypassed, and the order of the last two can be interchanged so as to provide complete usage of the ion exchange resin. The top of the first vessel is normally charged with activated carbon to act as a deep-bed filter and to remove oil from floor drain wastes. Moderate amounts of other wastes can also be routed through this vessel. It can be bypassed for processing relatively clean waste streams. This vessel is somewhat larger than the other three, with an extra sluice connection to allow removal of the top bed of activated carbon. This feature is associated with the deep-bed filter function of the vessel; the top layer of activated carbon collects organic material, and the ability to remove it without disturbing the underlying zeolite bed

minimises solid waste production. The second, third, and fourth beds are in identical ion exchange vessels, which are selectively loaded with resin, depending on prevailing plant conditions.

After deionisation, the water passes through an after-filter, where any remaining radioactive particulates and resin fines are removed. The processed water then enters one of the monitor tanks. When a monitor tank is full, the system automatically realigns to route the processed water to another monitor tank.

6.12.9 Solid Waste Management System

The solid waste management system (WSS) is designed to collect and accumulate spent ion exchange resins and deep-bed filtration media, spent filter cartridges, dry active wastes, and mixed wastes generated as a result of normal plant operation, including anticipated operational occurrences. The system is located in the auxiliary building and the radwaste building. Additional design detail of this system and its constituent components are delineated in Reference 6.23.

6.12.10 Radioactive Waste Drain System

The WRS collects radioactive liquid wastes from equipment and floor drainage of the radioactive portions of the auxiliary building, annex building, and radwaste building, and directs these wastes to a centrally located sump located in the auxiliary building. The contents of the sump are pumped to the WLS tanks. Additional design detail of this system and its constituent components are delineated in Reference 6.38.

6.12.11 Waste Storage

In addition to the nuclear island and non-nuclear island buildings, there are facilities for the storage of solid LLW, ILW, and HLW generated during AP1000 plant operation. These facilities are described in the sections below.

The solid waste management facilities allow an operator to manage waste according to the waste management hierarchy. Much of the GDA information in the UK AP1000 Environment Report (Reference 6.7) provides a licensee with the basis to begin developing waste avoidance, minimisation, and reuse/recycle plans and procedures.

6.12.11.1 Low-Level Waste Storage

The LLW store is located within the boundary of the licensed site (Reference 6.7). The radwaste building holds monitoring tanks containing processed effluent awaiting clearance for release to the environment or further processing if necessary.

LLW is bagged, collected manually, and transported to areas of the waste accumulation room. The waste is packaged in suitable licensed containers, transported to the buffer store, and finally sent offsite for final disposal (Reference 6.7). The transportation of the waste will take into consideration safety procedures, which are discussed in more detail in Reference 6.7.

Design Structure

The radwaste building is a non-nuclear seismic building with lockable doors to minimise unauthorised entry and inadvertent exposure. It is categorised as a non-nuclear seismic (NNS) structure and contains no Class 1 equipment but is designed for wind and seismic loads.

The LLW buffer store is a covered area comprising a concrete hard-standing area with a steel-framed canopy (see Chapter 26 of this PCSR).

Transfer, Inspection, Maintenance and Periodic Testing of Waste packages

The Environment Report (Reference 6.7) describes briefly how the waste packages are handled in the LLW store, giving consideration to the radiation protection, environment, and safety aspects. One example of the safety procedures is that LLW will be sorted under controlled conditions through the use of glove boxes.

Instruments monitor and control the process variables associated with LLW processing. This includes radiometric measurements within LLW handling equipment and general area monitoring. This is discussed in Chapter 26 of this PCSR.

Chapter 26 of this PCSR presents the analytical techniques available and related sample requirements for the LLW wastes to ensure that compliance with the site discharge criteria can be demonstrated. The same report refers to the use of the low-resolution gamma spectroscopy (LRGS) assay when the LLW is drummed in the radwaste building. Once drums have completed quality assurance (QA), they are placed in a suitable licensed container within the radwaste building.

Package Type

The waste package used for LLW is one currently accepted by the LLWR. As such, it has been designed to comply with the current requirements for handling, retrieval, transport, storage, and disposal. More information may be found in Chapter 26 and Reference 6.7.

6.12.11.2 Intermediate-Level Waste Storage

ILW is stored within suitable contamination-zoned and shielded areas of the auxiliary building prior to treatment in the mobile encapsulation plant (MEU). The MEU is described in Chapter 26 and other sections of this PCSR where maintenance, control console, shielding, ventilation, safety, seismic qualification, and waste tracking system are discussed. Once the ILW is encapsulated in RWM waste packages, the boxes and drums will be transported to an onsite ILW store where they will be stored until a national ILW repository becomes available. The transportation of the waste will consider safety procedures that are discussed in more detail in Reference 6.7 and Chapter 26.

The first phase of construction will provide an ILW store suitable for 20 years of ILW production. The ILW store will be designed with a reserve-storage capacity for a total inventory of 60 years of operational waste arisings from one AP1000 plant unit. The ILW store has a 100-year design life and could be used to retain ILW after the AP1000 plant is decommissioned and until the national ILW repository becomes available (Reference 6.7 and Chapter 26).

Design Structure

The ILW store is a reinforced concrete structure (Reference 6.7), consisting of a waste package reception area and a shielded vault serviced by a certified nuclear crane. A seismic assessment for the ILW store has been carried out and the results are summarised in Chapter 26. The seismic assessment has determined that the AP1000 plant ILW store does not need to be seismically qualified from a radiological consequence perspective (Chapter 26).

In-store and encapsulation equipment will be modular and components will be regularly or routinely replaced rather than being designed for the full 100-year storage period. All components subject to wear are located in a way that will allow easy access, removal, and replacement with minimum disturbance to adjacent components (Chapter 26).

Control System

The implementation requirements for the standard security systems for the ILW store will be determined during the detailed design associated with the specific site (Chapter 26).

The ILW store will have a dedicated control console. More details on the operating modes (normal and manual modes; and recovery mode, intended to be used following equipment failure) can be found in the Radioactive Waste Arisings, Management and Disposal report (Chapter 26). The primary control positions for controlling process operations will typically be local to the process and will be provided (where possible) with a direct view of the main operations, supported by closed circuit television (CCTV) where appropriate. The CCTV cameras are described in Chapter 26.

The operators in the control room will be suitably shielded from both packages in the vault and the import/export area (Chapter 26).

Environmental Conditions

The Radioactive Waste Arisings, Management and Disposal report (Chapter 26) shows the intention and the importance of controlling the store environment conditions. The operational limits and conditions, such as surface chloride contamination values, are presented in this section, while temperature is covered in Chapter 26.

Transfer, Inspection, Maintenance, and Periodic Testing of Waste Packages

The ILW store is a reinforced concrete structure (Reference 6.7), consisting of a waste package reception area and a shielded vault serviced by a certified nuclear crane. The ILW storage requirements and procedures to ensure safety, radiation protection, transportability, stock control, and ability to retrieve waste packages are discussed in the Environment Report (Reference 6.7). Some of these topics are also covered in the Radioactive Waste Arisings, Management and Disposal report (Chapter 26). The proposed operation tasks for the encapsulation plant, considering all these concepts, are in Chapter 26.

Instruments monitor and control the process variables associated with ILW processing. These include radiometric measurements within the ILW import/export equipment and general area monitoring. This is discussed in Chapter 26, which presents the analytical technique available and related sample requirements for the ILW wastes to ensure that compliance with the site discharge criteria can be demonstrated.

Reference 6.7 discusses how the design and proposed operation of the ILW store will enable retrieval and visual examination of individual packages. This report states that activity level of ILW waste packages will be monitored before they are transferred to the ILW store vault and before they are sent to the repository. It also describes the remedial action strategy for ILW packages when defects or external damage are found (further described in the Waste Arisings, Management and Disposal report (Chapter 26)).

Package Type

ILW packages will comply with the requirements for handling, retrieval, transport, storage, and disposal. The in-store and encapsulation equipment, such as MEU, 4-drum stillages, and the nuclear crane, will be suitable to engage and handle these RWM waste packages (Chapter 26).

6.12.11.3 HLW storage

After spent fuel is removed from the reactor, it will be stored in the fuel storage pool. Details about the fuel storage pool can be found in subsection 6.12.3.

Because spent fuel is not expected to be reprocessed, HI-STORM 100U system has been proposed to be used to dry-store the spent fuel once it has been removed from the storage pool for the operational period of the plant and beyond. In Reference 6.7, subsection 3.5.8.3 and Figure 3.5-17, the dry-storage features of the HI-STORM 100U System and its components is shown in more detail. Once the spent fuel assemblies have reached the acceptable limits for heat generation (typically 100 years), they will be transported from their dry cask storage to the national geological disposal facility (GDF) when it is available.

The NDA has completed a disposability assessment of AP1000 plant spent fuel to satisfy the GDA requirements. This assessment concluded that the characteristics of spent fuel from an AP1000 plant (with 65-MWd/tonne U burnup) are consistent with those from the Sizewell B PWR and that compared with legacy wastes, no new issues arise that challenge the fundamental disposability of the wastes expected to arise from operation of such a reactor. This assessment has also assumed that spent fuel would be overpacked for disposal. The exact long-term disposal canister material and design remains to be confirmed (Reference 6.7).

Uncertainties remain surrounding the treatment of spent fuel, which is discussed in more detail in subsection 26.7.5.3.

Design Structure

The dry spent fuel storage is a seismically qualified below-ground dry-storage facility (Reference 6.7). The Environment Report (Reference 6.7) indicates the design features that are considered to minimise unauthorised intrusion and to provide radiation shielding for the spent fuel cooling pool and dry spent fuel storage.

Transfer, Inspection, Maintenance, and Periodic Testing of Waste Packages

Spent fuel handling and storage are described in the Environment Report (Reference 6.7). The handling equipment, which takes into account radiation protection aspects, ease of maintenance, and minimisation of the probability and consequences of associated incidents and accidents, is an example of how human intervention and maintenance could be minimised.

Package Type

The decision on how to package spent fuel for storage will be made by a future licensee. Available information at this time is discussed in Chapter 26.

6.12.12 Radwaste Management Strategy

The strategy for managing radioactive waste onsite is described in detail in Chapter 26. It includes an IWS based on the expected waste and spent fuel generation and management practices throughout the AP1000 plant life cycle.

Aspects of waste minimisation, continued safe storage, acceptance criteria, and record keeping are presented in detail in Chapter 26.

6.13 CIVIL STRUCTURES

6.13.1 Introduction

The AP1000 plant consists of the following five principal structures. Each building is constructed on an individual basemat:

- Nuclear island
- Turbine building
- Annex building
- Diesel generator building
- Radwaste building

The structures that make up the nuclear island are as follows:

- Containment vessel
- Shield building
- Auxiliary building

These nuclear island buildings are depicted on the site plan. The Class 1 equipment designed to deliver Category A functions is located in the nuclear island.

6.13.2 Site Layout and Civil Structures

A site plan will be defined in the site-specific licensing process by the licencee. A generic proposed plan has been provided for site interface purposes and is shown in this section with a generic description of the plant arrangement. Site-specific features of the overall site layout are those features outside the standard plant arrangement. Specific details of the site plan will be covered in the utility site application.

6.13.2.1 Plant Arrangement

The standard plant arrangement consists of the following five principal building structures:

- Nuclear island which includes the following structures:
  - Containment Vessel
  - Shield Building
  - Auxiliary Building

- Turbine building
- Annex building
- Diesel generator building
- Radwaste building

The turbine, annex, diesel generator, and radwaste buildings contain no equipment that is essential to nuclear safety, therefore their hazard-withstand requirement is less rigorous than that for the nuclear island.

These building structures are laid out so that the turbine building and the other principal buildings are adjacent to the nuclear island to meet their functional requirement. Figure 6-7 provides a functional representation of the principal systems and components located in each of the key AP1000 plant buildings. This figure identifies major systems and components that are contained in these structures.

The circulating water system (CWS) is site-specific and circulates cooling water to the main condenser and back to the heat sink through supply and return pipes that are below ground. Supply to the CWS will depend on the specific site requirements. Cooling for the CWS can be from either seawater cooling or cooling towers. The preferred design for the UK is to use seawater cooling as described in the Environmental Report. However, the supporting secondary systems design reflected in the PCSR assume the use of CWS cooling towers.

The transformer area is located immediately adjacent to the turbine building. The unit auxiliary transformers, the reserve auxiliary transformers, and the main step-up transformers are located in the transformer area. The main switchyard area and the rail and road access to the site are site-specific. Figure 6-8 shows the typical plant layout.

6.13.2.2 Plant Arrangement Considerations

Radioactive equipment and piping in all buildings are arranged and shielded to minimise radiation exposure. The overall plant arrangement utilises building configurations and structural designs to minimise the building volumes and quantities of bulk materials (concrete, structural steel, and rebar) consistent with safety, operational, maintenance, and structural needs.

SSCs essential to maintaining nuclear safety are contained in the nuclear island. Separation between redundant essential Class 1 equipment and systems ensures that the safety functions can be performed. In general, this separation is provided by partitioning areas with concrete walls. The auxiliary building arrangement provides separation for radioactive and nonradioactive equipment and provides separate pathways to these areas for personnel access. Pathways through the plant are designed to accommodate equipment maintenance and removal from within the plant. Adequate space is provided for equipment maintenance, laydown, removal, and inspection. Hatches, monorails, hoists, and removable shield walls are provided to facilitate maintenance.

6.13.2.3 Nuclear Island

The nuclear island structures are designed to withstand the effects of natural phenomena such as earthquakes and extreme weather, and internal events such as fires and flooding, without losing the capability to perform their safety functions.

The nuclear island structures include the containment (the steel containment vessel and the containment internal structures) and the shield and auxiliary buildings. The containment and the shield and auxiliary buildings are structurally integrated on a common base mat.

Containment Building

The containment building comprises the containment vessel and the structures contained within it. The containment building is designed to house the reactor vessel and core, and the following other related major systems and equipment:

- Reactor coolant system
  - Loop piping
  - Two steam generators
  - Four reactor coolant pumps
  - Pressuriser
  - Automatic depressurisation system
- Passive core cooling system
  - IRWST
  - Passive residual heat removal heat exchanger
  - Two core makeup tanks
  - Two accumulators
- Pipes and valves between the RCS and the RNS
- Purification portion of the CVS
- Inside containment isolation valves
- Polar crane

Shield Building

The shield building surrounds the containment building and supports the PCS storage tank and its associated piping and valves and its own dedicated HVAC system. Additionally the shield building provides missile protection for containment and the PCS air flow path.

Auxiliary Building

The auxiliary building consists of two separated portions: the radiological portion and the non-radiological portion.

The radiological portion of the auxiliary building houses SSCs associated with auxiliary functions involved with radioactive material; it has been designed to meet the nuclear safety functions associated with handling these materials and with the contained systems and functions. In addition, this portion contains DAS processor cabinets. The SSCs within this building are as follows:

- RNS pumps and its HXs
- CVS makeup pump
- Containment isolation valves (outside)
- Spent fuel storage pool and its cooling system, the fuel transfer canal, the cask washdown pit, and the cask-loading pit
- New fuel storage pit and the rail car bay/filter storage area

- Liquid radwaste system (except for monitor tanks in the radwaste building, and discharge piping)
- Gaseous radwaste system
- Solid radwaste system (wet process waste handling equipment)
- MCR emergency habitability system air storage cylinders (although these air cylinders are housed in the radiological auxiliary building, they are included in the containment/shield building fire area)
- DAS processor cabinets

The non-radiological portion of the Auxiliary Building houses SSCs associated with the plant MCR, C&I, the passive DC electrical supplies, and auxiliary functions that do not directly involve radioactive material. The SSCs within this building are as follows:

- Feed and steam mains, the steam isolation valves, the feed isolation valves, the steam generator blowdown lines and isolation valves, and the SG power-operated relief valves and steam safety valves
- Four divisions of the IDS batteries and associated equipment; e.g., chargers; and switchgear
- Four divisions of the PMS, four electrical equipment rooms, and four C&I rooms. Divisions A, B, C, and D of the PMS are segregated between these rooms and compartments.
- MCR
- RCP trip switchgear
- Reactor trip switchgear
- Remote shutdown room
- VBS components
- VWS (chillers outside on building roof)

6.13.2.4 Turbine Building

The Turbine Building houses the Main Turbine, Generator, and associated fluid and electrical systems. It provides weather protection for the laydown and maintenance of major turbine/ generator components. The principal systems and equipment are as follows:

- Two CCS pumps and heat exchangers
- BDS piping, valves, and equipment
- Turbine generator and its auxiliaries
- Main Condenser
- MSS piping and valves
- Moisture separator reheaters
- Low-pressure feed heaters, deaerator, and high-pressure feed heaters

- Three condensate pumps
- Three main feedwater pumps
- Two startup feedwater pumps
- Switchgear rooms
- Electrical equipment room
- Lube oil storage tanks
- Motor-driven fire pump
- Air compressors
- Backup batteries and battery-charging equipment
- Condensate chemical dosing equipment
- Various tanks for storing chemicals
- Component cooling water pumps, HXs, and associated piping, valves
- SWS strainers and piping and valves
- Four RCP variable-speed drives
- VTS
- SSS
- VWS chillers
- CWS piping and valves
- TCS pump, HXs, piping and valves

6.13.2.5 Annex Building

The annex building provides the main personnel entrance to the power generation complex. It includes access ways for personnel and equipment to the clean areas of the nuclear island in the auxiliary building and to the radiologically controlled area. The building includes the health physics facilities for the control of entry to and exit from the radiologically controlled area, as well as personnel support facilities such as locker rooms. The building also contains the non-Class 1 ac and dc electrical power systems, other electrical equipment, the control support area and various HVAC systems. In addition, the annex building contains the ancillary diesel generators and their fuel supply.

The annex building also contains the following equipment:

- Demineralised water deoxygenating equipment
- Boric acid batching equipment
- Air intake plenum for the radiologically controlled area ventilation system and the containment air filtration system
- Exhaust air filtration units from the containment air filtration system
- Ancillary diesel generators and day tank
- EDS batteries and switchgear
- Machine shops
- Control support area (CSA)

6.13.2.6 Diesel Generator Building

The diesel generator building houses two, segregated, standby diesel generators and their associated electrical, HVAC, and limited fuel oil supply equipment. The two standby diesel generators supply power to priority defence in depth (Class 2) loads in the event of loss-of-normal power from the offsite and onsite ac power sources. Only one operating ZOS standby diesel generator is needed to fulfil this defence in depth duty (further details on this requirement can be found in Chapter 18).

The standby diesel generators are supplied from individual day tanks that are in turn supplied from two, segregated, above-ground bulk fuel oil storage tanks, one for each diesel generator. Each tank has sufficient fuel to supply its diesel generator for 7 days of operation at the maximum continuous rating. These bulk tanks are remote from the diesel generator and any other AP1000 plant buildings.

6.13.2.7 Radwaste Building

The radwaste building includes facilities for segregated storage of various relatively low-level categories of waste prior to processing, and for storing processed waste in shipping and disposal containers.

The liquid radwaste processing areas are designed to contain any liquid spills, including a raised perimeter and floor drains that lead to the liquid radwaste system waste holdup tanks in the auxiliary building.

The radwaste building consists of the following:

- Various radwaste processing and packaging operations
- A waste accumulation room
- A packaged waste storage room
- Two liquid radwaste system monitor tank rooms
- A truck staging area
- An HVAC equipment room
- An electrical and mechanical equipment room

6.13.3 Containment

6.13.3.1 Building Function

The containment building is the containment vessel and the structures contained within it. The containment building is an integral part of the overall containment system with the functions of containing the release of airborne radioactivity following postulated DBAs and providing shielding for the reactor core and the RCS during normal operations.

The containment vessel is an integral part of the PCS. The containment vessel, shield building structures, and the PCS are designed to remove sufficient energy from the containment to prevent the containment from exceeding its design pressure following postulated DBAs.

The containment building is designed to house the RCS and other related systems and provides a low leakage barrier.

6.13.3.2 Civil/Structural Features

The containment vessel, a C-I structure (see Chapter 16, Table 16.1), is a freestanding cylindrical steel containment vessel with elliptical upper and lower heads. It is surrounded by a C-I shield building.

There are three floor elevations (grade access, maintenance floor, and operating deck) and four lower equipment compartments within the containment building. Removable hatches are provided for access to equipment at other elevations.

The IRWST is located below the operating deck. Its capacity exceeds the quantity of water required to accomplish safety functions or to fill the refuelling cavity during refuelling operations. The refuelling cavity has several floor elevations. The upper and lower reactor internals storage area and the fuel transfer tube are at the lower elevation. See Appendix 20K for more detail on the structural integrity of the containment vessel.

6.13.4 Shield Building

6.13.4.1 Building Function

The shield building is the structure that surrounds the containment vessel. During normal operations, a primary function of the shield building is to provide shielding for the containment vessel and the radioactive systems and components located in the containment building. The shield building, in conjunction with the internal structures of the containment building, provides the required shielding for the RCS and the other radioactive systems and components housed in the containment.

The shield building protects containment from external events. The shield building protects the containment vessel and the RCS from the effects of tornadoes and tornado-produced missiles.

During accident conditions, the shield building provides the required shielding for radioactive airborne materials that may be dispersed in the containment as well as radioactive particles in the water distributed throughout the containment.

The shield building is an integral part of the PCS.

6.13.4.2 Civil/Structural Features

The shield building is a C-I structure (Chapter 16, Table 16.1). It shares a common basemat with the containment building and the auxiliary building.

Figure 20D-1, provides a sectional view of the shield building. The view show the basic configuration of the shield building and the annulus area between the containment vessel and the shield building.

The following items represent the main features of the shield building and the annulus area:

- Shield building cylindrical structure
- Shield building roof structure
- Lower annulus area
- Middle annulus area
- Upper annulus area

- PCS air inlet
- PCS air inlet plenum
- PCS water storage tank
- PCS air exhaust
- PCS air baffle

The cylindrical section of the shield building serves as shielding and a missile barrier and is a key component of the PCS. It structurally supports the roof and is a major structural member for the entire nuclear island.

A watertight seal is provided between the upper and middle annulus areas to provide an environmental barrier. The middle annulus area contains the majority of containment penetrations and radioactive piping. This environmental barrier is provided to protect against the following:

- Since the upper annulus is open to the environment, the barrier protects the middle annulus from precipitation and environmental temperatures.

- In the event of an accident or spurious actuation, water from the PCS water storage tank drains by gravity onto the containment vessel outer surface. The water, which runs down the outside of the containment vessel, is prevented from draining into the middle annulus area by the watertight seal. Drains are provided to direct the PCS runoff water out of the shield building.

- The PCS is designed to perform with the upper annulus permanently open to the environment to permit sufficient airflow through the shield building in the event of an accident. The watertight seal protects the middle annulus area from ambient environmental conditions.

The shield building roof is a reinforced concrete conical shell supporting the PCS water storage tank and air exhaust. Air intakes are located at the top of the cylindrical portion of the shield building. The conical roof supports the PCS water storage tank, which is constructed with a stainless-steel liner attached to reinforced concrete walls. The PCS air exhaust in the centre of the roof discharges containment cooling air directly upwards.

The PCS air baffle is located in the upper annulus area. It is attached to the cylindrical section of the containment vessel. The function of the PCS air baffle is to provide a pathway for natural circulation of cooling air in the event that a DBA results in a large release of energy into the containment. In this event, the outer surface of the containment vessel transfers heat and mass (water vapour) to the air between the baffle and the containment shell. This heated and higher humidity and thus lower-density air flows up through the air baffle to the air exhaust, and cooler and higher-density air is drawn into the shield building through the air inlets at the top cylindrical portion of the shield building.

6.13.5 Auxiliary Building

6.13.5.1 Building Function

The primary function of the auxiliary building is to provide protection and separation for the C-I mechanical and electrical equipment located outside the containment building.

The auxiliary building provides protection for the Class 1 safety equipment against the consequences of either a postulated internal or external event. The auxiliary building also provides shielding for the radioactive equipment and piping housed within the building.

The most significant equipment, systems, and functions contained within the auxiliary building are the following:

- Main Control Room (MCR)
- Class 1 control and instrumentation systems
- Class 1 electrical system
- Fuel handling area
- Mechanical equipment areas
- Containment penetration areas
- Main steam and feedwater isolation valve compartment

6.13.5.2 Civil/Structural Features

The auxiliary building is a C-I, reinforced concrete structure (Chapter 16, Table 16-1). It shares a common basemat with the shield building.

The auxiliary building wraps around approximately 70 percent of the circumference of the shield building. Floor slabs and the structural walls of the auxiliary building are structurally connected to the cylindrical section of the shield building.

6.13.6 Annex Building

6.13.6.1 Building Function

The annex building, shown in Figure 16-2, provides the main personnel entrance to the power generation complex. The building includes the health physics facilities for the control of entry to and exit from the radiological control area as well as personnel support facilities such as locker rooms. The building also contains the standby power supply system, the ECS ancillary diesel generators and their fuel supply, other electrical equipment, the control support area, and various HVAC systems. No Class 1 safety equipment is located in the annex building.

The annex building includes the health physics facilities and provides personnel and equipment accessways to and from the containment building and the rest of the radiological control area via the auxiliary building. Large, direct accessways are provided to the upper and lower equipment hatches of the containment building for personnel access during outages and for the entry and exit of large equipment. The building includes a hot machine shop for servicing radiological control area equipment. The hot machine shop has decontamination facilities including a portable decontamination system that may be used for decontamination operations throughout the nuclear island. The portion of the annex building which is Category II (C-II) is delineated in Figure 6-7.

6.13.6.2 Civil/Structural Features

The seismic designation of the annex building is shown in Chapter 16, Table 16.1. Certain areas of the building, such as the hot machine shop and the control support area, are provided with shielding for protection against low-level radiation from internal or external sources under accident conditions. This is accomplished by either reinforced concrete walls or reinforced masonry walls. The control support area (CSA) is designed so that it may be used as a technical support centre (TSC) if desired.

The annex building is a combination reinforced concrete and steel-framed structure with insulated metal siding. Floor and roof slabs are reinforced concrete supported by metal decking. Floors are designed to act as diaphragms to transmit horizontal loads to sidewall bracing and to concrete shear walls. The building foundation is a reinforced concrete mat.

6.13.7 Diesel Generator Building

6.13.7.1 Building Function

The diesel generator building. shown in Figure 16-2, houses two identical slide-along diesel generators separated by a 3-hour firewall. These generators provide backup power for plant operation in the event of a disruption of normal power sources. No Class 1 equipment is located in the diesel generator building.

6.13.7.2 Civil/Structural Features

The diesel generator building houses the two diesel generators and their associated HVAC equipment, none of which are required for the safe plant shutdown. The seismic designation of the diesel generator building is shown in Chapter 16, Table 16-1. The building is designed in accordance with the Codes specified in Chapter 16.

The building is a single-story, steel-framed structure with insulated metal siding. The roof is composed of a metal deck supporting a concrete slab; it serves as a horizontal diaphragm to transmit lateral loads to sidewall bracing and thereby to the foundation.

The foundation consists of a reinforced concrete mat. The diesel generators are skid-mounted and rest on vibration isolators supported directly from the mat.

6.13.8 Radwaste Building

6.13.8.1 Building Function

The radwaste building includes facilities for segregated storage of various categories of waste prior to processing, for processing by mobile systems and storing processed waste in shipping and disposal containers. No Class 1 equipment is located in the radwaste building.

Dedicated floor areas and trailer parking space for mobile processing systems are provided for the following:

- Contaminated laundry shipping for offsite processing
- Dry-waste processing and packaging
- Hazardous/mixed waste shipping for offsite processing
- Chemical waste treatment
- Empty waste container receiving and storage
- Storage and loading packaged wastes for shipment

The radwaste building also provides temporary storage of other categories of plant wastes. Three liquid waste monitor tanks are located within the radwaste building. These tanks contain processed effluents that are ready for further treatment and/or disposal.

6.13.8.2 Civil/Structural Features

The radwaste building is shown in Figure 16-2. The seismic designation of the radwaste building is shown in Chapter 16, Table 16.1. The liquid radwaste processing areas are designed to contain any liquid spills. These provisions include a raised perimeter and floor drains that lead to the WLS waste holdup tanks. The foundation for the entire building is a reinforced concrete mat on grade.

6.13.9 Turbine Building

6.13.9.1 Building Function

The turbine building houses the main turbine, generator, and associated fluid and electrical systems. It provides weather protection and space for the laydown and maintenance of major turbine, generator, and other components. The turbine building also houses the CCS pumps and HXs, the startup portion of the FWS, and the condensate tank water purification system. There is no Class 1 safety equipment located in the turbine building.

6.13.9.2 Civil/Structure Features

The turbine building (Figures 16-2) consists of two sections: the first bay and the main area, which houses the turbine. The first bay is immediately adjacent to the auxiliary building and consists of reinforced concrete walls and steel framing with reinforced concrete and steel-grated floors. The main area is a steel-framed building with reinforced concrete and steel-grated floors. The first bay and the main area are seismically separated. The turbine building ground floor (structural mat) is a reinforced concrete slab shared by the first bay and main area structure. The seismic designation of the turbine building and first bay is shown in Chapter 16, Table 16-1.

APPENDIX 6A
REVIEW OF MAJOR AP1000 DESIGN DECISIONS

6A.1 INTRODUCTION

Westinghouse has developed the AP1000 design to have an electric power production capability comparable with existing nuclear power stations, but with a level of risk that is more than an order of magnitude lower than the best reactors currently operating. Current nuclear power stations have achieved an acceptable level of risk by evolving ever-increasing complexity with respect to their ESFs but this complexity is subject to the law of diminishing returns. If taken too far in developing a new design, very low levels of risk might be achievable but at a price so high that it would be uneconomical to build the nuclear power station. Westinghouse has taken an alternative approach in designing the AP1000 plant: it has reduced complexity by making the ESFs passive rather than active to the maximum degree feasible, thereby achieving a very high level of safety and a simplified design.

The essence of this review of design decisions is to categorise the plant improvements presented as follows as risk reduction measures that contribute to achieving an overall plant risk that will be ALARP:

- The Westinghouse process has achieved an AP1000 plant design that is in accordance with relevant good nuclear engineering practice through the use of relevant international codes and standards and the use of engineering good practice and operating experience in the design process.

- The designers have followed some key principles – the use of proven technology, the use of passive safety measures for all Category A functions, the pursuit of fault tolerance, and the provision of defence in depth SSCs – that combined, result in very low overall levels of risk throughout the life cycle of the power station.

- The basic design was enhanced by using PSA to identify worthwhile improvements. Thus, each principal design decision contributed to an overall plant risk that is ALARP in its own right.

- No other worthwhile design feature has been overlooked or needs to be incorporated in the design because the resultant further reduction in risk would be achieved at a cost disproportionate to the benefit realised.

6A.2 KEY DESIGN PRINCIPLES

6A.2.1 Proven Technology

In essence, the first engineering key principle is to avoid the hazard by means of good design. The driving design philosophy of the AP1000 plant was to keep it safe by using proven engineering and a simple feasible design arrangement; that is to say, risk can be reduced by using well-established technologies and proven engineering techniques, and the productive path to safety is through the reducing the likelihood of failure modes rather than adding more ESFs.

Design decisions were made in favour of the safer solution, even if it was more expensive. Risks were made ALARP by making the safety systems simple, automatic, driven by natural forces, and diverse from the systems that make power.

Wherever possible, the designers of the AP1000 plant designed out potentially unsafe conditions rather than designing in a complicated recovery strategy. Likewise, the operator response was designed out for the limiting design basis initiating events, thereby eliminating operator reliability from the accident sequence.

6A.2.2 Fault Tolerance

The second engineering key principle requires the design to be fault-tolerant. This involves identifying those faults that might challenge the design and then showing that the design's inherent characteristics are such that most of the fault sequences do not develop to the point where they could challenge a safety function. Section 8.3 describes the fault identification process for the AP1000 design. The AP1000 list of faults is broadly similar to those of current generation PWRs. What is different is that many of the required safety measures are passive, whereas they would be active systems for current-generation plants. This leads to significant improvements in fault tolerance.

6A.2.3 Passive Safety Measures

Chapter 6 provides a list of the safety measures incorporated into the AP1000 design. All the Class 1 safety systems required for design basis initiating events in the reactor are passive in that they only require a valve or circuit breaker to make a one-time change to its state to actuate, and power, if required, coming from a highly reliable battery-backed dc electrical supply.

6A.2.4 Defense in Depth

Typically design basis initiating events can be responded to using active Class 2 components if available. These are identified as defence in depth provisions in addition to the Class 1 passive systems, which satisfy design basis requirements. These systems are described in Chapter 6 and, where supported by further operator action, identified in Chapter 13.

6A.3 REVIEW OF PRINCIPAL DESIGN DECISIONS

6A.3.1 Introduction

This section describes the principal design decisions made for the AP600 and AP1000 plants. Because none of the design decisions described for the AP600 plant were reversed for the AP1000 plant, the entire section ultimately applies to the latter. These decisions occurred over the design life of the AP600 and AP1000 plants, a period of some 15 years, and many occurred concurrently. The selection of these example decisions was such that they are mostly independent of each other. They are included in this report to demonstrate the thorough nature of the AP600 and AP1000 design process; the process reinforced a rigorous, disciplined approach to achieving safety through simplicity and developing a design that improves the risk reduction measures that contribute to achieving a plant judged to be ALARP.

Only a sample of the design decisions made for the AP600 and AP1000 plants are discussed. Many more decisions were made. The following sections address the design decisions made during the evolution of the AP1000 plant, as grouped into the following categories:

- Residual heat removal
- Containment design
- Control room systems
- Primary system design
- Fuel route
- Duty systems

6A.3.2 Residual Heat Removal

6A.3.2.1 Reactor Coolant Post-LOCA Injection, Boration, and Cooling

Following a LOCA, the safety systems must provide borated makeup for the water lost so as to maintain the reactor core reactivity subcritical and immersed in water. Many PWRs today rely on pumped systems and large sources of borated water from outside the containment to provide this makeup and cooling. These types of systems require Class 1 and C-I sources of ac power and water. In the case of the AP1000 design, this is done without reliance on ac power.

Note that a significant simplification of the design has been achieved by the use of the PCS which makes the containment shell the ultimate heat sink heat transfer surface. This avoids the need to have an engineered cooling chain with support systems to transfer heat from the core/containment to the environment. The elements of the design used for core injection, boration, and cooling include:

- The passive core cooling system (PXS)
  - A PRHR HX actuated by opening one of two fail-open AOVs.
  - Two CMT gravity injection flow paths, each actuated by opening one of two fail-open AOVs.
  - Two sets of ADS depressurisation Stages 1, 2, and 3,where each stage is actuated by opening two of two MOVs
  - Four ADS Stage 4 flow paths each actuated by opening one squib valve
  - Two accumulators, which inject when RCS pressure decreases below compressed motive gas
  - Two IRWST injection paths each actuated by opening of one of two squib valves
  - Two passive core cooling long-term recirculation paths each actuated by opening one of two squib valves.
- The passive containment cooling system (PCS)
  - Three PCS flow paths; two paths actuated by opening one of one fail-open AOV and one path actuated by opening one of one MOV.

The only requirement of the above SSCs for dc power, after an accident starts, is to trigger the ESF actuation signals and provide power for one-time realignment of various valves. Heat and fluids then move by natural forces. Of these eight functions, one function requires no valve re-alignment, three functions are accomplished by opening one of two fail-open AOVs (PRHR HX, CMTs, PCS), two functions are accomplished by opening one of four squib valves (IRWST, RECIRC), and one function is accomplished by opening three of four squib valves (ADS Stage 4). Only the six ADS Stages 1, 2, and 3 require opening two of two MOVs in any two of the six flow paths for success

Advantages and Disadvantages

The following detailed advantages result from the chosen design option:

- AOV actuations are fail-open and are actuated on removal or loss of power.
- No reliance on ac power
- No reliance on external sources of water
- No reliance on pumps
- No reliance on HXs cooled by other cooling systems (e.g., CCS, SWS)
- No penetrations through the containment required
- No reliance on operator action during the first 72 hours after the most limiting accidents
- No liquid radioactive effluent
- No risk for accidental loss of coolant outside the containment

The main uncertainty with this design option was that there was little large-scale experience with a total pressure balance and natural-circulation LOCA response systems. However, as part of the AP600 plant development programme, extensive rig testing was performed to validate system functionality and the analysis capability for candidate total pressure balance and natural-circulation LOCA response systems. This testing carries through to the AP1000 design.

One shortcoming of the PCS is that after 72 hours, the PCCWST on top of the containment shield building empties and flow to the top of the containment needs to be supplied using active pumping. The PCS recirculation pumps in the auxiliary building are utilised and they take suction from a hurricane missile-protected, seismic C-II tank: the PCCAWST. Additionally an offsite pump can be brought in to provide flow through the Class 1 External Makeup Flange. The pumps can be powered by normal ac power supply, ancillary diesel generators located in the seismic Class II portion of the annex building, or an offsite portable generator. The PCCAWST has an adequate water supply for an additional 4 days of PCS post-accident cooling of the containment (see subsection 6A.3.3.9 for more details).

6A.3.2.2 Selection of Squib Valves in Preference to Conventional Valve Types

Squib valves are self-contained valves actuated by an explosive charge on receipt of a firing signal. They are widely used on boiling water reactors and in the aerospace industry for one-off emergency operation. Squib valves are used for the following three applications within the safety systems of the AP1000 plant:

- Stage 4 ADS valves
- IRWST injection line isolation valves
- Containment recirculation line isolation valves

Squib valve operation needs to be very reliable. Experience has shown that squib valves are more reliable than other types of valve because of the reliability of their actuating propellants

and the simplicity of their mechanical design. For comparison purposes, the following probabilities for the failure to open on demand of each type are assumed by the AP1000 PSA (Ref. 6A.1) as follows:

- AOVs, 8.76E-3 failures per demand
- Motor-operated valves (MOVs), 1.41E-2 failures per demand
- Squib valves, 5.80E-4 failures per demand

The in-service testing for each squib valve includes both a test of the remote position indication and a test-firing of the igniter and propellant. The squib valve charge assembly is removed and then test-fired outside of the valve in a test rig that can monitor explosive charge performance. Any failures would result in the removal of the charges from the same production lot and replacement with new charges from a different lot. ASME code requires that 20 percent of the charges be tested every 2 years. The plant maintenance schedule defines the performance of these tests during refuelling outages, when the squib valves can be accessed for propellant charge removal.

The nature of a squib valve body design makes it virtually leak–free, that is, the valve is not subject to internal leakage, as with standard valve designs such as globe, butterfly, gate, and nonreturn valves. This is an important safety function because any such leakage would require valve replacement.

Advantages and Disadvantages

Squib valves offer the following advantages over other valve types:

- Greater reliability by at least an order of magnitude. This is because of their simple design and non-reliance on any external power other than for the actuation signal.

- Leak-free design.

- Easily tested and maintained.

The following disadvantages result from choosing squib valves over other valve types:

- The explosive charge and igniter used within a squib valve have limited shelf and service lives. However, the required maintenance and testing can easily be accommodated within the AP1000 plant refuelling outages.

- Functional end-to-end testing is not possible.

6A.3.2.3 Diversity in Squib Valve Design

Squib valves are used for the following three applications within the AP1000 safety systems:

- Stage 4 ADS valves
- IRWST injection line isolation
- Containment recirculation line isolation

Common mode failure within and between the applications of the three systems is minimised by using a different valve design for each of the three applications: one for the Stage 4 ADS squib valves, a second high-pressure valve design for the IRWST injection lines, and a third low-pressure recirculation line squib valves.

Design diversity is achieved through differences in the design details of the key valve actuation components, which requires differences in their physical configurations (and design tolerances) for the following:

- Valve body (inside surface forms shearing piston walls)
- Valve bonnet and retaining hardware (cylinder head that also houses the propellant cartridge)
- Propellant cartridges (volume/arrangement excluding propellant material/igniters)
- Actuation plug (shearing piston)
- Actuation plug piston tensioning (and shearing) bolt
- Shear caps (shearing wall thickness that is pressure-dependent)
- Valve latching mechanism (hold shearing piston in place after actuation)
- Metal foam (compression dampening upon actuation)
- Metal foam retainer plate and retaining hardware
- Various valve body bolts and compression chamber metal O-rings.

In summary, design variations and design tolerances between the various designs provide adequate design diversity to protect against squib valve common failure modes.

Advantages and Disadvantages

Having a diverse valve design for each of the three squib valve applications in the AP1000 design minimises the simultaneous common mode failure of the three applications.

6A.3.2.4 Passive Core Cooling System Pipe Size Increases

The primary function of the PXS is to provide emergency core cooling following postulated design basis initiating events. The PXS is designed to perform the following functions:

- Emergency core decay heat removal
- RCS emergency makeup and boration
- Safety injection
- Containment pH control

The PXS is designed to operate without the use of active equipment such as pumps and ac power sources. Once actuated, the PXS functions depend on natural circulation and processes such as gravity injection and the expansion of compressed gases.

For the AP600 design, the analysis was finished for system performance, pipe size, routing and stresses, and building structural response. The AP1000 design challenge was to increase the capacity of the PXS while changing as little of the AP600 plant physical design as possible. Alternatives included adding Class 1 pumps, increasing the thermal head differences from the core to the heat sinks, rerouting pipe to reduce the pressure drop, or increasing pipe sizes.

Adding Class 1 pumps would have defeated the passive nature of the AP600/1000 concept and was rejected at the outset. Increasing the thermal head differences would have required a redesign of structures inside the containment; this type of redesign affects finished layouts, pipe routings, building structural calculations, building seismic responses, component seismic responses, system flow calculations, accident response calculations, containment free volume, containment flood-up volumes, and more. Rerouting piping for pressure reduction would yield very little because the piping was already routed for minimum resistance while maintaining structural adequacy. The remaining alternative of increasing the size of the pipes was selected because it had the least impact on the finished design.

Scoping calculations were performed to determine the required pipe size. Then the next larger standard pipe size was selected and placed on the same centrelines as those of the AP600 design. This approach created pipe routings that had margin in the pressure drop due to using pipe that was slightly larger than required and that could probably pass structural evaluations because the smaller pipe sizes had already passed. These assumptions proved valid and the PXS design was resized for the AP1000 design with as little extra impact on the fully certified AP600 design as was reasonably practicable.

Advantages and Disadvantages

The following advantages resulted from increasing the pipe sizes within the PXS to accommodate the increased duty required by the AP1000 design:

- Slightly increased margin in the pressure drop ensured achieving the higher natural circulation flow rates required.
- No need for a redesign of any structures inside the containment.
- No need to reroute the PXS pipe work.
- No need to repeat the building structural calculations.
- No need to repeat the building seismic responses and component seismic responses.
- No change in the containment free volume and containment flood-up volumes.

The only disadvantage resulting from increasing the pipe sizes within the PXS to accommodate the increased duty required by the AP1000 design is the minimal extra cost of the larger pipes and valves.

6A.3.2.5 Core Makeup Tanks Size Increase

The CMTs are part of the PXS. They hold cold borated water stored RCS pressure for RCS makeup and boration and for safety injection to the RCS in the event of a LOCA. The amount of water required for the latter duty on an AP1000 plant is more than that required by the AP600 plant, suggesting the need for larger tanks.

Given that design analysis had been completed for the AP600 design with respect to system performance, tank size, stresses, and building structural response, the AP1000 design challenge was to increase the capacity of the CMTs while changing as little of the AP600 physical design as possible.

The CMTs were resized for the AP1000 design by ascertaining the largest tank size that could fit into the rooms assigned to the CMTs and placing them on the same centrelines as in the AP600 design. The PXS performance was then reanalysed.

This showed that the CMT volumes still had margin for small-break LOCAs, while maintaining the in-containment structural, flood-up, and high pressure injection capability.

Advantages and Disadvantages

The following advantages result from resizing the CMT but keeping the other aspects the same:

- No diminution in the flood-up and high pressure injection capability of the resized tanks.
- The ability to carry across the stress analysis and the building structural response analysis because there is no change to the in-containment structural layout.

The only disadvantage resulting from resizing the CMT but keeping the other aspects the same is the reduced but still adequate margin for small-break LOCAs.

6A.3.2.6 Increasing the Capacity of the In-Containment Refuelling Water Storage Tank

It is desirable to increase the post-LOCA containment flood-up level for the AP1000 design to maintain and increase the long-term core cooling safety margins. One of the changes made to the AP1000 design to accomplish this was to increase the water level in the IRWST during normal operation, but without changing any of the structures within the containment, that is, without adding a bigger tank. The option chosen was to fill the tank more fully.

To do this, it is important to be able to measure IRWST level accurately during normal operating conditions. The instrumentation used previously was a wide-range differential pressure-level sensor. This sensor was prone to relatively large errors when the tank was full. Whilst this was adequate for the AP600 design, the AP1000 design needed a better measurement if the tank were to be filled to a higher level.

To maintain the operating margin in the tank, a more accurate narrow-range ultrasonic sensor was added. It is permissible to use this type of sensor for monitoring the water level during normal operation because it does not have to function in the post-accident environment. For the actuation of the ESF signal, lower narrow range IRWST level instruments are installed. In the post-accident environment, the wide-range level sensors are sufficient to monitor the draindown of the IRWST.

In summary, the ultrasonic level sensor is a simple device that is wall-mounted inside the IRWST above the maximum water level. By adding this narrow range instrumentation, much of the error is eliminated, allowing the normal water level in the IRWST to be raised while maintaining the previous operating margin. This allows for a more reliable water volume capacity and thus the ability to increased flood-up level post-LOCA.

Advantages and Disadvantages

The following advantages result from incorporating a more accurate measurement of the IRWST level:

- Increased ability to measure the post-LOCA containment flood-up level, thereby maintaining and increasing the long-term core cooling safety margins.

- Avoiding the cost of making the IRWST larger.
- No change to the in-containment structural layout.
- No reanalysis of the stresses and the building structural response.

The only disadvantage resulting from incorporating a more accurate measurement of the IRWST level is the slight risk of damage to a more sensitive ultrasonic level sensor.

6A.3.2.7 Passive Residual Heat Removal Heat Exchanger

The PRHR HX is part of the PXS. It is located in the IRWST, which provides the heat sink for the HX. The HX is elevated above the RCS loops to induce natural circulation flow through the HX when the RCPs are not available. The PRHR HX piping arrangement also allows actuation of the HX with RCPs operating. When the RCPs are operating, they provide forced flow in the same direction as natural circulation flow through the HX. If the pumps are operating and subsequently trip, then natural circulation continues to provide the driving head for HX flow.

For postulated non-LOCA events, where a loss of capability to remove core decay heat via the SGs occurs, the PRHR HX can automatically remove core decay heat and transfer it to the IRWST water. If or when the IRWST water becomes heated to its saturation temperature, the PRHR HX continues to remove heat from the RCS by boiling the IRWST water. The steam generated in the IRWST is vented into the containment, condensed on the containment vessel, and returned by gravity via the IRWST condensate return gutter.

Thus, the PRHR HX can remove core decay heat and cool the RCS with or without AC power and the RCPs operating for greater than 72 hours days. This PRHR performance is substantiated using either realistic or conservative design basis assumptions.

In utilising conservative design basis assumptions, the PRHR can maintain RCS conditions for greater than 72 hours before degradation of heat removal may occur, which would lead to the eventual actuation of ADS (See Appendix 9C) in order to transition to open loop cooling, assuming no restoration of power.

In utilizing more realistic assumptions, the PRHR has been shown to be able to cool the RCS to 215.6°C (420°F) within 36 hours, and to maintain RCS conditions for greater than 14 days prior to transition to open loop cooling, assuming no restoration of power.

This allows the RCS to be depressurised and the stress in the RCS and connecting pipe to be reduced to low levels. This also allows plant conditions to be established for initiation of RNS operation. During a SG tube rupture event, the PRHR HX removes core decay heat and reduces RCS temperature and pressure, equalising with SG pressure and terminating break flow without overfilling the SG.

Given that design analysis had been completed for the AP600 plant with respect to PRHR HX performance, HX size, stresses, and building structural response, the AP1000 design challenge was to increase the capacity of the CMTs while changing as little of the AP600 physical design as possible.

The principal design change was to add enough extra tubes to the PRHR HX to satisfy the requirements on cooldown time for AP1000 design basis initiating events. There was also a requirement to alter the attachment to the IRWST without changing the in-containment

structural layout. The PRHR HX was placed on the same centrelines as in the AP600 design. The IRWST water volume increase provided by raising the normal water level did not need to be increased for the AP1000 PRHR HX function.

Advantages and Disadvantages

The following advantages result from resizing the PRHR HX but keeping the other aspects the same:

- Adding extra tubes to the PRHR HX results in no diminution in its capability for cooling down the reactor for AP1000 design basis initiating events.

- The stress analysis and the building structural response analysis were carried across because there is no change to the in-containment structural layout.

The only disadvantage resulting from resizing the PRHR HX but keeping the other aspects the same is that it is necessary to alter the HX's attachment to the IRWST.

6A.3.2.8 Increase in the Automatic Depressurisation System Stage 4 Pipe Size

Opening the ADS valves is required for PXS IRWST injection and long-term recirculation to function as required to provide emergency core cooling following postulated accident conditions. Twenty valves are divided into four depressurisation stages. These stages connect to the RCS at three different locations. The ADS Stages 1, 2, and 3 valves are included as part of the pressuriser safety and relief valve module, and are connected to nozzles on top of the pressuriser. The Stage 4 valves connect to the hot leg of each reactor coolant loop. The Stage 1 valves may also be used, as required following an accident, to remove non-condensable gases from the steam space of the pressuriser.

The Stage 1 ADS valves are dc-powered, motor-operated, 10-cm DN (4 inch) valves. The Stage 2 and 3 ADS valves are dc-powered, motor-operated, 20-cm DN (8 inch) valves. The Stage 4 ADS valves are 35-cm DN (14 inch) squib valves arranged in series with normally open, dc-powered, motor-operated valves. The control system for opening the ADS valves has an appropriate level of diverse and redundant features to minimise inadvertent opening of the valves. For each discharge path, a pair of valves is placed in series to minimise the potential for an inadvertent discharge of the ADS valves. The Stage 4 valves are interlocked so that they cannot be opened until RCS pressure has been substantially reduced.

An analysis was carried out to ascertain whether, and by how much, the various ADS pipes and associated valves had to increase in size to accommodate the higher power and reactor coolant volume of the AP1000 design as compared with the AP600 design. PSA conducted for the AP1000 design showed that no additional size increase over the AP600 ADS Stage 1, 2, and 3 pipes valves was required. Calculations indicated the requirement for a larger size for ADS Stage 4 piping and valves; because the required size fell between standard pipe sizes, however, the next larger pipe size, 36 cm, was chosen. The pipe centrelines were kept the same to simplify incorporation of the larger pipe into the layout. This resulted in an ADS Stage 4 capability of slightly more than was required to accommodate the increase in power. The ADS Stage 4 piping size was increased from 25 cm DN (10 inch) to 35 cm DN (14 inch). The only other required ADS change was to revise the CMT level setpoints used for ADS actuation based on the larger AP1000 plant CMT capacity to ensure sufficient RCS pressure decrease in order to ensure timely IRWST gravity draindown initiation.

Advantages and Disadvantages

The following advantages result from using a commercially available standard size for the ADS Stage 4 piping and valves:

- Additional capability for dealing with design basis initiating events
- No change to the in-containment structural layout
- No reanalysis of the stresses and the building structural response

The only disadvantages resulting from using a commercially available standard size for the ADS Stage 4 piping and valves are the slightly more severe consequences from inadvertent operation of the Stage 4 valves.

6A.3.2.9 In-Vessel Retention

Certain beyond design basis accident sequences could lead to a core melt; whilst this is extremely unlikely, it is not incredible. This possibility required some form of mitigation. The AP600 plant designers addressed this challenge by developing the capability for IVR.

The alternative to having IVR capability would be to incorporate some form of "core catcher" outside the RV. A core catcher would have to have features that precluded re-criticality of the mixtures of core structural materials and building structures (known as corium), and to cool it to prevent or slow its reaction with the core catcher materials around the RV. This could have been the design solution for the AP1000 plant reactor.

The AP600 plant achieved IVR capability by taking advantage of the large amounts of water into the lower portions of the containment. The expected level of water in the containment after an accident is above the nozzles of the RV and, hence, above the top of the fuel. It was recognised that a possible design solution for the core melt scenario would be to take credit for this water and use it to cool the corium. The water would flow into the RV insulation structure, and come into contact with the RV where it would then boil and cool the RV. The steam would rise within the insulation structure and be vented into the upper containment, carrying core heat with it. This steam would condense on the inner surface of the containment vessel and then return to the lower portion of the containment, where it could repeat the cycle. This bulk boiling heat transfer from the RV was shown by prototype testing to remove sufficient heat to prevent failure of a depressurised RV. This testing also demonstrated that there was significant margin to the critical boiling heat flux and that steam blanketing of the RV surface would not occur. To realise this solution, the design team had to demonstrate two things: first, prototype testing had to be performed to duplicate bulk boiling heat removal and steam venting, measure the critical heat flux limits, and demonstrate sufficient margin to these limits given the heat fluxes expected during a core melt; second, a mechanical design of the RV insulation had to be developed that allowed water to get next to the RV in a severe accident, while not allowing air to flow next to the RV during normal operation. All of these objectives were achieved. Testing was performed at the University of California, Santa Barbara, to establish the design parameters for cooling the vessel during a core melt. A unique design of the lower portion of the RV insulation was developed that used buoyancy to allow water in, when present, but not to allow air flow into the insulation/vessel annulus during normal plant operation. This design solution for enabling IVR at the AP600 power level was selected and implemented in the design.

Advantages and Disadvantages

The following advantages result from choosing the IVR option:

- The RV remains intact, thereby providing a robust barrier to the release of core material into the containment following a postulated severe accident. This prevents the occurrence of ex-core phenomena such steam explosion or corium concrete interactions that would threaten containment integrity.

- This greatly reduces the calculated frequency of large radioactivity releases to the public.

- Eliminating the RV melt-through failure mechanism obviates the need for a mitigating feature such as a core catcher, thereby avoiding the substantial cost of a core catcher.

6A.3.2.10 Improvements to the Design of the In-Vessel Retention

The additional power capability of the AP1000 design over the AP600 design has increased the severe accident (core melt) demands on the IVR design solution. To maintain the passive response to severe accidents, the design of the AP1000 IVR required some modification. The result of the testing performed for the AP600 design to establish the thermal hydraulic parameters associated with core melt did not provide sufficient margin to the calculated parameters for the AP1000 design.

To achieve the removal of the AP1000's higher decay heat and to maintain significant margin to the critical heat flux, the IVR heat transfer mode could not be by bulk boiling. The design team redesigned the reactor insulation such that the steam generated during the vessel cooling was not vented to the containment atmosphere but was instead re-introduced into the flooded portion of the containment at the RV nozzle level. The purpose of this design change was to create two-phase natural circulation within the RV insulation package; with the containment single phase flood-up water providing water into the bottom inlet of the insulation, and two-phase steam and water exiting the insulation at the nozzle gallery. This two-phase circulation flow path was expected to create significant cooling water velocities along the vessel wall that would significantly increase the critical heat flux and allow greater heat removal rates without failing the RV wall.

To realise this solution, the design team had to demonstrate two things: first, prototype testing had to be performed to duplicate the two-phase natural circulation flow path and establish the cooling fluid flow velocities, measure the critical heat flux limits, and demonstrate sufficient margin to these limits given the heat fluxes expected during a core melt; second, a mechanical design of the RV insulation had to be optimised to maximise the RV heat removal in a severe accident. All of these objectives were achieved. Testing was performed at the University of California, Santa Barbara, to establish the two-phase flow rate capability, determine the heat removal capability, show substantial margin to critical heat flux, and establish the design parameters for the vessel insulation. A unique design of the lower portion of the RV insulation was developed that used buoyancy to allow water in, when present, but not to allow air flow into the insulation/vessel annulus during normal plant operation. This design solution for enabling IVR at the AP1000 plant power level was selected and implemented in the design.

In addition, the RV insulation design was modified to increase the flow areas of the water inlet devices and steam outlet devices, make their operation by natural forces simpler and more reliable, provide additional shielding during normal operations, and make the design easier to fabricate and erect.

This solution was chosen using a process that promoted satisfying design requirements with the least change to the current design, high reliance on proven technology (natural forces), and lowest risk for public or operator radiation exposure.

Advantages and Disadvantages

The following advantages result from improving the design of the IVR:

- Minimum changes from the AP600 design and hence read through of the AP600 design test results.
- Improved reliability of the natural circulation capability.
- Additional shielding provided, thereby reducing operational dose.
- Easier to fabricate and erect, thereby reducing cost.

The only disadvantage resulting from improving the design of the IVR is that it required additional structure and a shaped internal boundary for the RV insulation design, which incurred a development cost.

6A.3.2.11 Alternative Source of Cooling for the Normal Residual Heat Removal System Heat Exchangers

The RNS cools the core when it is shut down at low pressure by reducing the temperature of the RCS during the second phase of plant cooldown, the first (high-pressure) phase of the cooldown being the transfer of heat from the RCS to the MSS through the SGs. The RNS draws reactor coolant from the RCS hot leg and then cools it in two HXs outside the containment before returning it to the RV through the direct vessel injection lines. Its HXs are cooled by the CCS.

An alternative heat sink would be desirable in the unlikely event that component cooling water flow to the RNS HXs should be lost. The FPS provides this additional method for cooling. What the AP1000 design requires is to include a fire hose connection point at the input side of the HXs and a drain at the HX outlet. The cooling water would go through the system once, its supply coming either from one of the two firewater storage tanks or from any external source such as a fire engine.

This simple use of a fire protection connection in a once-through cooling mode provides additional defence in depth capability for cooling the RNS. This solution was chosen using a process that promoted satisfying design requirements with the least change to the current design, high reliance on proven technology, and lowest risk for public or operator radiation exposure.

Advantages and Disadvantages

The advantage of using a fire protection connection in a once-through cooling mode is increased reliability of the RNS.

The only disadvantage is that less firefighting water would be available in the event of a fire simultaneously with the loss of the component cooling water.

6A.3.2.12 High-Pressure Normal Residual Heat Removal System

The core damage frequency from interfacing system LOCA (ISLOCAs) for currently operating PWRs is now known to be substantially greater than the PSA estimates made when they were designed. An ISLOCA is an event in which a break occurs outside the containment in a system connected to the RCS. Early PSAs were typically limited to modelling ISLOCA sequences that included only the catastrophic failures of the check valves that isolate the RCS from the low-pressure systems. Also, the PSAs included little consideration of human errors leading to an ISLOCA and the subsequent effects of the accident-caused harsh environment or flooding on plant equipment and recovery activities. Because of this concern, the AP1000 plant designers have re-evaluated the design pressure of the RNS.

The RNS is a duty system that provides shutdown cooling for the RCS. During normal shutdown operations, the RCS is cooled and depressurised to the RNS's cut-in temperature and pressure.

Once RCS pressure has been reduced, the RNS suction line isolation valves are opened and the RNS pumps are started to provide the shutdown cooling. The RNS takes suction from the RCS hot leg and discharges to the RV through the direct vessel injection lines. The RNS suction lines (one to each RNS pump) contain three normally closed isolation valves in series; with a design pressure equal to RCS design pressure.

The valves are interlocked so that they cannot be opened unless the RCS pressure is reduced to 3 MPa (450 psig), which is within the design pressure of the low-pressure portion of the RNS. The normally closed isolation valves, including the valves that are containment isolation valves, are designed for full RCS pressure.

Overpressurisation would only occur if the three motor-operated isolation valves leaked excessively, or if the valves were inadvertently opened with the RCS pressure above the design pressure of the RNS.

The second potential over pressurisation pathway for the RNS is by way of the discharge lines, which each connect to a direct vessel injection line. Each line contains two normally closed check valves, which, as reactor coolant pressure boundary valves, are designed for the RCS design pressure. The RNS discharge lines penetrate the containment and have two containment isolation valves that are again designed for full RCS pressure.

Overpressurisation would occur only if the three check valves and the motor-operated gate isolation valves leaked excessively. The portions of the RNS from the RCS to the outside containment isolation valves are designed for the design pressure and temperature of the RCS. Traditionally, the portion of the RNS outside containment was designed to 4 MPa (600 psig). In operating plants today, ISLOCAs are discounted, based on the suction valves' interlock with RCS pressure and the power lock-out of these valves at the valve motor control centres. Such a design provides multiple redundant system isolation and a system design pressure that is 27 percent of RCS design pressure and 1 Mpa (145 psig) higher than the operating pressure of the RNS.

Guidance from the Nuclear Regulatory Commission (NRC) has suggested that a design pressure of 40 percent of the normal operating pressure of the RNS and a minimum wall thickness would enhance the survivability of the piping to more than 90 percent when pressurised to full RCS pressure. As a result of this suggestion, the design pressure of the AP1000 RNS outside containment has been increased to 6.1 Mpa (900 psig), to decrease the likelihood of ISLOCAs in the RNS.

Advantages and Disadvantages

The following advantages result from increasing the design pressure of the low-pressure portion of the RNS:

- Significant reduction in the likelihood of an ISLOCA
- Lower risk of public or operator radiation exposure
- Fairly simple to engineer

6A.3.3 Containment Design

6A.3.3.1 Low-Leakage Steel Containment

Containment is the last boundary preventing an uncontrolled release of radioactive fission products or coolant to the environment. It is a design requirement for the containment to retain its contents during any design basis initiating event such as a steam line break or a LOCA, and certain beyond design basis initiating events such as a LOCA. Thus, the containment design must be able to withstand the maximum expected pressure during any design basis accident and following a large-break LOCA.

The containment buildings of currently operating PWRs are typically steel lined, concrete and steel structures that can become relatively porous in time due to small cracks resulting from thermal expansion and contraction and due to periodic pressurisations (leakage tests) during the plant operating life. For this reason these structures are constructed with a thin, steel liner that forms the main barrier to leakage. These containments typically rely on internal sprays and/or water cooled fan coolers to limit containment pressure and reduce pressure following a postulated accident. The sprays are supplied by active pumping systems, and require supporting cooling water, electrical power, and HVAC systems. The same is true of fan cooler type cooling designs. Given the assessed reliability of such arrangements, some regulators require provisions for venting of the containment before it became overpressurised or its concrete weakened by the high temperature to provide defence in depth. These venting systems then require the addition of large filtration equipment or structures to prevent the direct release of radioactivity to the public. The use of containment venting to provide defence in depth for ensuring containment integrity creates specific problems in that, when core steaming is terminated or when containment cooling system function is restored, it is possible that the pressure within the containment is reduced significantly below atmospheric pressure. This results in damage to the thin containment steel liner that forms the leak-tight barrier to the release of radiation such that the design basis leakage may be exceeded. These plants then rely on the containment missile barrier (sometimes referred to as the secondary containment) and large HVAC equipment and filters to remove sufficient radioactivity to minimise releases to the public and operating personnel.

The AP1000 design achieves a containment that can reliably withstand any design basis accident including a large-break LOCA without leaking. It does this by adopting a steel containment structure cooled by water draining by gravity over its outer surface, which evaporates into a naturally flowing current of air. The containment structure is a freestanding steel pressure vessel, designed and built in accordance with the requirements of the ASME Code. This vessel has a high enough design pressure, a large enough free volume, and a large enough heat transfer area to accommodate the worst pressure challenge resulting from any design basis accident or a large-break LOCA without any requirement to vent. Unlike concrete, it is not unduly susceptible to high temperatures. The pressure vessel design requirements extend to its penetrations and attachments.

Advantages and Disadvantages

The following advantages result from using a steel containment structure:

- The gravity-fed arrangement for the distribution of water over the exterior of the steel containment vessel is far more reliable than the traditional pumped containment spray and/or fan coolers and their associated support systems, thereby providing a passive means of removing heat and reducing containment pressure.

- The only real leak paths though the steel containment are through the containment penetrations, which are periodically tested. Leakage though the 44.45-mm (1.75-inch) thick steel or the fully radiographed welds is incredible. This allows the AP1000 plant steel containment to have a greatly reduced design leak rate compared to concrete containments. This alleviates the need to have a double containment with HVAC and filtered exhaust to meet the required onsite and offsite dose limits.

- The steel containment will not exceed its ultimate failure pressure for an extended time following a large-break LOCA, even if no water is applied to the outside surface and there is only air cooling of the containment. This provides the plant operators with a significant time to establish water application to the shell without the need to vent the containment post accident.

The only disadvantage resulting from using a steel containment structure is that it is does not have as high a resistance to external pressure as a concrete and steel reinforce containment.

6A.3.3.2 Containment Height Increase

The increase in electrical power output in moving from the AP600 design to the AP1000 design required increasing the size of some of the principal components within the containment: RV, SGs, and pressuriser. This necessitated some increase in the size of the containment to accommodate them, albeit retaining the same layout as the AP600 design. However, a more important consideration was the internal pressure following a fault sequence.

The increased power of the AP1000 design inherently increases the steam mass and energy released into the containment building as a result of a LOCA or main steam line break. An essential requirement for the containment is to provide sufficient free volume to accommodate the mass and energy release from such an event without challenging the containment design limits. Not only were the mass and energy releases for AP1000 design greater than those for AP600 design, but the limiting event changed from a LOCA to a main steam line break.

The options were to increase the free volume of the containment or to make it stronger, or some combination of the two. Making the containment larger by increasing its diameter was not an attractive option because this would involve extensive redesign. Additionally, increasing the diameter would require a pro-rata increase in steel thickness for a given post-accident pressure, which would contravene the design constraint of containment vessel plate being sufficiently thin that post-welding heat treatment during installation in the field would not be required; this consideration also limits the option of increasing the containment strength whilst keeping its original size (the option of massively strengthening the containment is reviewed in subsection 6A.5.1).

The design decision was to make the containment vessel taller but by as little as possible. Once the diameter is fixed, the strength of the containment vessel is determined by the material type and by maximising the plate thickness to 44.45 mm (1.75-inch) from the AP600 thickness of 39.8 mm (1.66 inches). The selection process was first to investigate alternate plate material to maximise vessel strength. This would minimise height by minimising the volume increase required for the increased mass and energy release.

Once plate material and thickness had been selected, the height was changed by integral increments of commercially available plate width to maximise simplicity of fabrication. As the volume increases for each plate width, the resultant peak accident pressure decreases. The least number of additional plate widths was chosen consistent with the requirement to be within the maximum allowable containment vessel pressures. The design outcome was a slightly increased margin to plate allowable stresses compared with the AP600 design.

In summary, the containment vessel plate material and additional vessel height were chosen in a process that promoted satisfying its design requirements with the lowest risk of a containment breach during an accident sequence, high reliance on proven technology (natural forces), and lowest cost.

Advantages and Disadvantages

The following advantages result from increasing the height of the containment rather than its diameter:

- The existing plant layouts, pipe routings, building structural calculations, building seismic responses, component seismic responses, system flow calculations, accident response calculations, and containment flood-up volumes are largely unaffected, thereby avoiding the substantial costs of redoing them.

- The need for post-welding heat treatment during installation is avoided for the containment vessel plate.

- The containment design basis external pressure limit is not reduced.

Disadvantages resulting from increasing the height of the containment rather than its diameter are as follows:

- A taller shield building is required.
- A taller shield building results in the PCCWST being higher off the ground. A higher PCCWST makes the justification of the seismic withstand of the auxiliary building more challenging.
- The taller containment requires one more heavy lift structural module than the AP600 (this would most likely be true for the increased diameter containment due to the increased plate area vs. height).

Shield Building Air Inlets

The PCS transfers heat directly from the steel containment vessel to cooling air drawn from the external environment, thereby with water evaporation from the shell outer surface, preventing the containment vessel from exceeding its design pressure and temperature following an accident. The PCS has inlets for the cooling air located near the top of the cylindrical section of the shield building.

The air inlets must be structurally robust because they are part of the shield building, which protects the steel containment structure from various external hazards, one of which is the crashing aeroplane. The design of AP600 plant air inlets consists of 15 large discrete openings in the top of the shield building, which penetrate the 914-mm- (3-foot-) thick reinforced concrete shield building. The air inlets are sized to allow containment cooling at a level sufficient to ensure that the peak containment pressure does not surpass the containment design pressure following any design basis initiating event. Air inlets of this type and size are also sufficient to support containment cooling for the AP1000 plant, and were incorporated into its original design.

However, it has since been questioned whether this design is sufficiently robust to withstand the impact of a large commercial aircraft. An additional concern is that the large openings provide a pathway for debris or fuel from a crashing aircraft to reach the steel containment vessel. It has been decided that the shield building must incorporate design features that provide inherent protection against the effects of such aircraft impact, which are regarded as beyond design basis (BDB). Therefore, alternative designs were explored for the AP1000 plant with the goal to maintain the original cooling airflow rate capability but strengthened the shield building at the elevation of the air inlets so as to withstand a BDB impact of a large commercial aircraft.

One solution would have been to greatly increase the thickness of concrete of the shield building at the elevation of the air inlets. However, impact testing has shown that containing high-strength concrete within steel liner plates on both faces significantly increases its impact resistance, so a more modest increase in concrete thickness could provide the required strength. Analysis demonstrated that modifying that portion of the shield building containing the air inlets to a 1.37-m (4.5 feet) thickness of high-strength concrete contained within steel liners on both faces was sufficient for that portion of the shield building to withstand a BDB aircraft impact.

Reducing the size of the air inlets to restrict debris or fuel from entering the building further enhanced the air inlet portion of the shield building. Containment cooling requires a minimum inlet area to provide adequate air cooling for the steel containment vessel. However, each air inlet does not have to be as large as the 15 air inlets of the original design, provided that a significant flow area was maintained. This could be achieved by dividing the flow area into many smaller air inlets. The optimum design was found to be for 236 small inlet ducts to replace the original 15 large openings. The smaller inlets consist of 457-mm (18-inch) diameter circular steel tubes inclined upward from outside face to inside face. The new air inlets present no significant change to the design basis pressure response; for cases when the PCS operates; and does not significantly reduce the time for operator actions to maintain the containment below failure pressure for the BDB, air-only cooling situations assumed by PSA. The redesigned air inlets also provide a significant increase in the shield building's ability to restrict debris and fuel from entering it because of their small size and orientation. This design provides an additional safety benefit by further reducing radiation sky shine.

Advantages and Disadvantages

The following advantages result from strengthening that portion of the shield building containing the air inlets, and replacing the 15 large air inlets with 236 small inlet ducts:

- Strengthening of the upper portion of the shield building provides protection against the impact of a large commercial aircraft.
- Redesign of the air inlets significantly reduces the risk of damage to the steel containment structure from burning fuel and debris from a crashing aircraft.
- Redesign reduces the radiation sky shine.

The disadvantages resulting from strengthening that portion of the shield building containing the air inlets and replacing the 15 large air inlets with 236 small inlet ducts are:

- The BDB air-only PCS cooling capability of the PCS is reduced.

6A.3.3.3 Post-accident Isotope Control

Radioactive isotopes accumulate in the reactor coolant during operation. Some of these isotopes are gaseous or volatile; most are soluble or suspended in reactor coolant water. During a LOCA, these accumulated isotopes are released into the upper containment, thereby creating a radiation source. This source can be strong enough to be a hazard to those outside the containment.

The currently operating PWR plants use a containment spray system to cool the containment atmosphere; however, this spray also washes these soluble and suspended isotopes out of the containment atmosphere and off the containment walls. These containment spray systems include a water source outside the containment, containment penetrations, pumps, valves, nozzles, and other equipment that must be redundant, qualified, controlled, tested, maintained, and repaired.

The AP1000 plant does not need a containment spray system to cool the containment atmosphere because this function is performed by the PCS. The principal means of post-accident isotope control for the AP1000 design relies on natural forces like natural convection, condensation, and conduction to transfer decay heat from the atmosphere of the

containment to the containment walls, which are cooled (there is also a containment spray utilising the FPS (see subsection 6A.3.3.10) as a backup for this function). The resulting steam condenses onto the containment wall and then returns to IRWST or to the containment sump by gravity. Through analysis and testing, it has been shown that the soluble and suspended isotopes move with the water and thus finish up in the water in the IRWST or the lower portions of the containment.

Advantages and Disadvantages

The following advantages result from using the natural convection and condensation of the steam on the containment walls to remove radioactive isotopes from the containment atmosphere:

- The mechanism for isotope removal is entirely passive, with no risk of active failure.
- No risk of containment bypass due to a failed containment spray penetration.
- Reduction in complexity and cost in not having to install a Class 1 safety-grade containment spray system.

The only disadvantage is that it creates a slightly higher general accident dose rate outside the containment, but one still within allowable limits.

6A.3.3.4 Fire Protection Function for the Passive Containment Cooling Water Tank

The regulations for nuclear power plants in the United States (US) require that the fire protection water delivery system for fires affecting Class 1 equipment must be classified as Seismic Category 1. The AP1000 design has the additional requirement that safety functions must be performed without ac power.

Other than the containment building, the AP1000 plant only has one building that houses such Class 1 equipment: the auxiliary building, which is divided at each level by a concrete wall without any doors. On one side are systems with potentially radioactive fluids; on the other, the clean side, are the plant control and protection equipment and control room operators. The lowest level of the auxiliary building is below grade, so there can be no drainage of firewater without ac power. Consequently, there is a restriction of how much water can be put into the nonradiological clean side of the auxiliary building.

The AP1000 design process was directed at creating a FPS that requires no safety claims to be made on fire fighting fluids at all. This was attempted by careful design of the plant layout into fire areas and zones, such that the equipment in a given fire area could be lost to the fire without loss of overall plant safety functions. Within the containment building, additional spatial separation requirements were enforced for redundant equipment to make sure safety functions could be maintained in the event of a fire in the containment. This eliminated the requirement for a pumped FPS for internal fire hazards except for BDB fire events in the clean side of the auxiliary building.

Thus, the only required firewater delivery system is to the clean side of the auxiliary building, and preferably one in which the water to the fire hose stations is delivered by gravity rather than by pumps. The solution adopted by the AP1000 plant designers is to dedicate a specific amount of water within the PCCWST to this particular duty. This tank is seismic Category 1. The firewater delivery system can deliver two hose streams of 17 m^3/hr (75 US gallons per minute) for 2 hours.

A standpipe within the PCCWST limits the amount of PCCWST water that can be drained for fire fighting to less than amount of water that would threaten (flood) the Class 1 safety equipment in the nonradiological portion of the auxiliary building.

Advantages and Disadvantages

The following advantages result from using the PCCWST as the source of fire fighting water to the clean side of the auxiliary building:

- The supply to the firewater delivery system is already seismically qualified because of its primary safety duty, thereby avoiding the substantial cost of a new dedicated, seismic Category 1 tank.
- It does not require safety-related ac power or diesel-powered fire pumps.
- The amount of firefighting water that can be delivered is restricted to less than the amount that could flood Class 1 equipment by the simple expedient of using a standpipe within the PCCWST.

The only disadvantage of using the PCCWST as the source of fire fighting water to the nonradiological side of the auxiliary building is that the PCCWST capacity was slightly increased to include the required firewater volume.

6A.3.3.5 Catalytic Hydrogen Recombiner

A variety of PWR accident sequences can generate free hydrogen gas in the containment atmosphere. Most of these generate very small amounts, but some BDB accidents can generate large amounts. Regardless of the source, accumulations of hydrogen could rise to a potentially explosive level following such accidents.

To provide continuous, hydrogen removal capability that does not rely on ac power, catalytic hydrogen recombiners were chosen for in-containment hydrogen control in addition to the hydrogen igniters placed throughout containment. The passive autocatalytic recombiners are simple and passive in nature, without moving parts and no requirement for electrical power or any other support system. They are self-actuated in the presence of the reactants: hydrogen and oxygen. Passive autocatalytic recombiners are effective over a wide range of ambient temperatures, concentrations of reactants (rich and lean, oxygen/hydrogen less than 1 percent), and steam inerting (steam concentrations greater than 50 percent).

The catalytic hydrogen recombiner capacity is sufficient to reduce the hydrogen released following all design basis events.

A hydrogen ignition system is provided to address the possibility of a BDB event that results in a rapid production of large amounts of hydrogen, such that the rate of production exceeds the capacity of the recombiners. The primary objective of installing the catalytic hydrogen recombiners is to remove hydrogen at low concentrations and, to the extent possible, to remove hydrogen from the containment atmosphere more or less continuously so that the hydrogen concentration does not build up in the containment.

Advantages and Disadvantages

The following advantages result from incorporating catalytic hydrogen recombiners:

- They function at low hydrogen concentrations and operate passively, with no reliance on electrical power.
- They result in the lowest risk for hydrogen detonation, which might possibly result in a release of radioactivity from the containment.
- Proven technology.

Disadvantages resulting from incorporating catalytic hydrogen recombiners are as follows:

- Their capacity is limited to moderate hydrogen production levels and would be inadequate for certain severe accidents that are BDB.

6A.3.3.6 Trisodium Phosphate Baskets

Following a LOCA, it is necessary that the flood-up water inside the containment be treated to make its pH at or above 7.0. This is done to enhance radionuclide retention within the water inside the containment (in particular, prevent the formation of elemental iodine in the containment sump), and to prevent stress corrosion cracking of containment components during long-term containment flood-up. In many operating plants, this pH control is established by the chemistry of the containment recirculation water brought in from tanks outside containment. However, the response of an AP1000 plant to a LOCA without ac power does not involve any water entering or leaving the containment.

The possibilities for pH control inside the containment during a LOCA were investigated and analysed. This included consideration of tanks with buffer solution and baskets with solid TSP placed in containment. TSP is safe, stable, readily soluble in water and easy to inspect. The chosen option was to install baskets containing TSP at a low elevation in the containment, well below the containment flood-up level for continuous recirculation. In the event of a LOCA, the water accumulating in the lower region of the containment would self-buffer by dissolving the TSP. The pH adjustment is capable of maintaining containment pH within a range of 7.0 to 9.5.

Advantages and Disadvantages

The following advantages result from incorporating TSP baskets low in the containment:

- Buffers the containment recirculation water passively with no reliance on operator action or automatic initiation.
- Eliminates the possibility of inadvertent discharge of chemical solutions inside containment.
- Thoroughly tested and practicable

- Lowest initial cost
- Easy to inspect and does not degrade
- Relatively harmless to people

There are no disadvantages identified from incorporating TSP baskets.

6A.3.3.7 Provision for Post-72 Hour Continuation of Class 1 Equipment Functions

It was suggested that 72 hours of operation of Category A functions by Class 1 equipment (i.e., containment cooling, dc electrical power supply, control room habitability, SFP water makeup, and post-accident monitoring) could be insufficient to allow external resources to arrive onsite, based upon the experiences with hurricanes in the US. It was also suggested that potential onsite resources might not be available unless they were qualified. For example, the site firefighting water supply should be assumed to be unavailable for supplying water to continue containment cooling. Hence, there is a requirement that an onsite, qualified capability to continue containment cooling must be available for the period up to 7 days, assuming a total loss of offsite power.

Installing a much larger tank on the top of the shield building, or providing additional batteries to allow continued operation for 7 days would have required a total re-evaluation of the AP1000 design, with major changes in the AP1000 structures and passive safety concept. Given the costs involved, the ensuing time delays, feasibility issues, and limited improvement in actual plant safety; this was not considered to be a practical option.

One option for satisfying this requirement would be to seismically qualify and missile protect the site FPS. Another possibility would be to add a new qualified system for providing water to the PCCWST. After due consideration, the AP1000 plant designers decided that the latter option was their preference. A C-II ancillary water tank (PCCAWST) that is designed for site meteorological conditions and wind-generated missiles was added to provide sufficient water for post-72 hour PCS cooling and SFP water makeup. The existing PCS recirculation pumps equipment anchorage and associated piping inside the auxiliary building were upgraded to seismic class II, and two ancillary diesel generators and their fuel supply were added into the seismic II portion of the Annex building to provide power for the PCS recirculation pumps, MCR ventilation, and for recharging the Class 1 batteries.

Because the FPS and DWS already have piping connections to the PCCWST from the auxiliary building, the designers chose to use it as an additional method for replenishing the water inventory. This can be achieved by supplying it either from the fire protection or demineralised water tanks, or from any external source using a fire pump truck connecting onto the existing fire supply hose connection point on the outside of the auxiliary building. This simple use of using the existing fire protection and DWS connections provides defence in depth capability to replenish the PCCWST.

Advantages and Disadvantages

The following advantages result from adding a new qualified tank, pumps, and diesel generators to continue the required Class 1 SSC operations beyond 72 hours:

- Much lower cost and avoidance of a huge delay in the AP1000 plant programme from making the PCCWST substantially bigger.
- Lower cost than making the entire FPS a qualified system.
- High reliance on simple proven technology, that is, pumps used during normal operations and two small, local diesel generators.
- Ease of connecting a mobile fire-pumping engine to the new qualified PCCAWST water tank to further extend PCS and SFP cooling should the other sources of onsite water remain unavailable after 1 week.

The only disadvantage is that the reliability of the active post-72 hour SSCs is intrinsically lower than the Class 1 SSCs that they support.

6A.3.3.8 Containment Spray from the Fire System

As demonstrated in subsection 6A.3.3.5, the AP1000 design does not rely on containment spray for post-accident isotope control. However, the US NRC requires that the AP1000 design include a manually initiated containment spray for certain BDB initiating events, not only for isotope control but also as an alternate means for flooding the RV (IVR), for debris quenching should vessel failure occur, and to control containment pressure should the PCS fail.

One design solution to this requirement that was considered was to include a dedicated containment spray system with its own pumps, valves, water source, and containment penetrations. An alternative, simpler solution was to feed the containment spray headers and nozzles from an existing system within the containment. The selected system was that portion of the FPS that is within the containment. This provides the containment spray function without the need for the additional equipment of a dedicated spray system.

Advantages and Disadvantages

The following advantages result from providing the water supply to the containment spray headers and nozzles from the existing FPS:

- Substantial reduction in complexity and cost in not having to install an additional spray water supply to the containment spray headers and nozzles.
- The in-containment fire system already achieves the required reliability for a backup system that is only required for BDB fault initiating events.
- There is no increase in the testing and maintenance burden.

The only disadvantage resulting from incorporating the existing FPS in the containment spray system is that there is less water available for fire fighting should there be a fire simultaneous with the BDB sequence where the use of sprays is required.

6A.3.3.9 Minimisation of the Number of Containment Penetrations

The penetrations through the containment are designed to be leak tight and allow pipes and cables to pass through the containment vessel boundary with no loss of the containment atmosphere, which might be pressurised and radioactive after an accident, and escape to the outside environment. Very often, however, they do constitute sites of small leakage pathways. The penetrations and their associated piping up to the first isolation valves are Class 1 and must be periodically inspected and tested. Minimising the number of penetrations reduces the possibility of containment leakage during a fault sequence, and reduces the inspection and maintenance burdens.

The use of passive safety systems and the placement of all PXS components and water supplies inside containment has eliminated many of the containment penetrations that are required for Class 1 systems in evolutionary plant designs. In addition, the AP1000 plant designers have reduced the number of penetrations by using a variety of innovative techniques as follows:

- Service systems within the containment, such as component cooling water or compressed air, are configured inside the containment so as to require only one supply or return penetration for each service.

- Some intermittent services with common fluids share common penetrations. For example, both the chilled water and the hot water heating services to HVAC within the containment share common penetrations, since they will not be used at the same time.

- The fire fighting water and the containment spray supply systems also share a common penetration.

- C&I penetrations are reduced by taking advantage of digital data highway technology. Multiplexing cabinets are located so that C&I signals share a common highway penetration in lieu of multiple individual signal penetrations.

Advantages and Disadvantages

The following advantages result from minimising the number of containment penetrations:

- Reduces the possibility of containment leakage during a fault sequence.
- Reduces the cost of providing penetrations.
- Reduces the inspection and maintenance burden.

There are no significant disadvantages resulting from minimising the number of containment penetrations.

6A.3.4 Control Room Systems

6A.3.4.1 Use of Digital Control and Instrumentation Systems

The digital C&I systems within the AP1000 plant control, protect, and monitor the reactor and plant. They consist of the following systems linked by real-time data highway:

- Protection and Safety Monitoring System (PMS)
- Special Monitoring System (SMS)
- Plant Control System (PLS)

- Incore Instrumentation System (IIS)

The Diverse Actuation System (DAS) does not link to the data highway.

The above systems have been subjected to safety evaluations that show that they can be designed and built to conform to the applicable criteria, codes, and standards concerned with the safe generation of nuclear power.

The real-time data highway is a high-speed, redundant communications network that links systems of importance to the control room and the DDS. Class 1 systems are connected to the network through gateways and qualified isolation devices so that the Category A safety functions are not compromised by failures elsewhere. Plant protection, control, and monitoring systems feed real-time data into the network for use by the control room and the DDS.

Protection and Safety Monitoring System

The PMS detects off-nominal conditions, and then actuates the appropriate Class 1 systems necessary to achieve and maintain the plant in a safe condition. It also controls the Class 1 components in the plant that are operated from the MCR or the remote shutdown workstation. In addition, the PMS provides the equipment necessary to monitor the plant Class 1 functions during and following an accident.

The adequacy of the hardware and software within the PMS has been demonstrated through a verification and validation process so that, in particular, the software development process is consistent with appropriate industry standards.

Special Monitoring System

The SMS does not perform any Category A or defence in depth safety functions. The SMS consists of specialised subsystems that interface with the C&I architecture to provide diagnostic and long-term monitoring functions.

Plant Control System

The PLS provides the functions necessary for normal operation of the plant, from cold shutdown to full power. This system controls the duty systems in the plant, which are operated from the MCR or remote shutdown workstation. The PLS contains the C&I needed to change reactor power, control pressuriser pressure and level, control feedwater flow, turbine control, and perform other plant functions associated with power generation.

Diverse Actuation System

The DAS provides an alternate means of initiating reactor trip and actuating selected ESFs; it also provides plant information to the operator.

In-Core Instrumentation System

The primary function of the IIS is to provide a three-dimensional flux map of the reactor core. This map is used to calibrate neutron detectors used by the PMS, as well as to optimise core performance. A secondary function of the IIS is to provide the PMS with the thermocouple signals necessary for the post-accident inadequate core cooling monitor. The in-core instrument assemblies house both fixed in-core flux detectors and core exit thermocouples.

Advantages and Disadvantages

The following advantages result from adopting digital C&I instead of an analogue system:

- Opportunity to incorporate more advanced control system concepts, thereby allowing better and more refined control.
- Enhanced human-machine interface features to reduce operator burden.
- Online component testing at full power and in less time.
- Improved C&I system availability, achieved through redundancy and advanced diagnostics.
- Significantly reduced costs of initial installation and through-life maintenance.
- Relatively easy to carry out through-life updates of the hardware, as its functionality depends only on the software, which is also relatively easy to update.
- Reduced likelihood of plant trips caused by C&I system problems.
- Use of a data highway eliminates large quantities of C&I system hardware, cabling, cable trays, cable spreading areas, containment penetrations, and other equipment.

The only disadvantage resulting from adopting digital C&I instead of an analogue system is that it is more difficult and expensive to verify the integrity of a programmable electronic system of such complexity.

6A.3.4.2 Use of a Digital Control Room

The control room provides the facilities that the operations personnel need to safely operate the plant, deal with any abnormal conditions, and produce electricity. Over the past few decades there have been many substantial advances in the technology of the operator-machine interfaces in modern control rooms. The success of modern control rooms has been proven in other comparable industries. The AP600 design and the subsequent enhancements in the AP1000 design have taken advantage of this new operator-interface technology, and the resultant MCR represents a move away from the traditional “control board” control room design:

- The number of fixed controls and displays has been minimised to the extent practical.
- The main operator-machine interface is by means of computer-based colour monitors, mice, and keyboards.
- The graphics are supported by a set of graphics workstations, which take their input from the real-time data network.
- An advanced alarm system, implemented in a similar technology, is also provided.

The data display and processing (plant computer) system is implemented in a distributed architecture. The working elements of the distributed computer system are graphics workstations, although their graphics capability is secondary to their computing performance.

The distributed computer system obtains its input from the real-time data network and delivers its output over the network to other users.

Advantages and Disadvantages

The following advantages result from new operator-interface technology in the MCR:

- The advanced control room technology has been proven to improve operator performance, increase productivity, and reduce the likelihood of human errors.
- The visual display units (VDU) -based operator-interface integrates a number of systems into one flexible interface technology. This includes the use of large screen displays that enable plant overview and alarm status information to be visible from any likely operator location in the MCR, thus facilitating crew group plant status awareness and decision-making.
- The number of operations personnel required to be located in the control room may be decreased, thereby reducing electric generation costs.
- Increased ease in modifying the display formats.
- Increased ease in updating the control room hardware.

The only disadvantage resulting from new operator-interface technology in the MCR is that the software driving the displays is difficult and expensive to verify.

6A.3.4.3 Inclusion of a Diverse Actuation System

The DAS provides an alternate means of initiating a reactor trip and actuating specific ESFs in the event of a common mode failure within the PMS; that is, it provides diverse backup to the main protection system. The DAS has three functions: diverse automatic actuation, diverse manual actuation, and diverse indication of the plant information needed by the operator for a manual actuation of critical safety measures.

The DAS is included within the C&I architecture to support the risk goals in the AP1000 plant PSA for analysed events (Chapter 10). The DAS reduces the probability of a severe accident resulting from the unlikely coincidence of a postulated initiating event (PIE) and postulated common-mode failures in the protection and control systems. Common-mode failure between the PMS and the DAS is unlikely because each runs on a different operating system from the other, and there are no sensors shared between the two systems.

The DAS is not claimed as a safety measure by the fault schedule. However, it does provide defence in depth, and as such it possesses either two-out-of-three or a one-out-of two taken twice logic to prevent spurious actuation, and is designed to higher quality standards than normal duty systems.

Advantages and Disadvantages

The following advantages result from the inclusion of the design:

- Diverse initiation of specific safety measures in the event of a common-mode failure within the PMS.

- Diverse indication to the operators in the event of a common-mode failure within the PMS.

Disadvantages resulting from the inclusion of the DAS in the AP1000 design are the following:

- It might cause some spurious reactor trips.
- Initial cost and through-life maintenance cost.

6A.3.4.4 Human Factors Enhanced Control Room

The AP1000 MCR is an evolution of the AP600 design. It takes full advantage of the latest control room operator-interface technology. A detailed human factors engineering programme has supported the development of the AP1000 MCR and its operator-interface design. This programme included task analysis, operating experience reviews, engineering tests, the application of human factors' design guidelines, and verification and validation assessments.

The overall purpose of the MCR is to provide a comfortable environment in which the operators and supervisors can safely, efficiently, and reliably monitor and control plant process during normal, abnormal, and accident conditions. Displays are provided to enable the operators to determine the plant status, and control facilities are provided to allow the operators to execute control actions. Alarms are provided to draw the operators' attention to key indications that may require operator action. It must remain habitable during abnormal or emergency conditions, including earthquakes.

The MCR provides an area that enables the operations personnel to focus their attention on the safe and efficient operation of the plant. It supports good operator performance by supplying the facilities for the operators to interact with other plant personnel, while preventing distractions from nonoperations personnel. It supports the operations personnel in the effective and timely execution of their assigned tasks and responsibilities.

The MCR accommodates an operator console, a supervisor's console, safety consoles, the wall panel information system, large screen displays, and the DAS panel. The operator console provides the displays and controls to start up, manoeuvre, and shut down the plant; it is designed to be staffed by one to six operators. The operator interfaces are the duty system control displays, soft controls, alarm presentation system displays, computerised procedures displays, as well as the VDU monitors, keyboards, and mice. The supervisor's console is a smaller version of the operators' console and is designed to be staffed by one or two personnel. The primary dedicated safety panel and VDU-based safety system workstations are located at the centre of the operator console, with a secondary safety panel located in close proximity to the supervisor's console. The DAS panel is located at a sidewall in the MCR. The MCR also includes communication devices; document laydown areas, printers, and storage space. A meeting table is provided and equipped with a VDU-based workstation to allow access to the duty control system by, for example, a technical advisor or shift manager, without disrupting control room operations. In close proximity to the MCR are

the shift supervisor's office, the operations staff area, an operations work area, restrooms, and kitchen facilities.

Advantages and Disadvantages

Incorporating the improvements from the detailed human factors engineering programme into the design of the AP1000 plant and its operator interfaces results in the following advantages:

- Enhances the performance of the operators during normal, abnormal, and fault conditions, with increased likelihood of success.
- Reduces the possibility of operator distraction, whilst allowing the necessary interaction with other plant personnel.
- Allows access to the duty control system by, for example, a technical advisor or shift manager, without disrupting control room operations.
- Simplifies initial construction of the MCR, resulting in substantial cost savings.
- Simplifies maintenance of the MCR, resulting in cost savings.

The only disadvantage resulting from incorporating the improvements resulting from the detailed human factors engineering programme into the design of the AP1000 plant MCR and its operator interfaces is significant development cost, but this is spread over the entire AP1000 fleet.

6A.3.4.5 Elimination of the Internal Flooding Threat from the Nonradiological Portion of the Auxiliary Building

The AP1000 auxiliary building is designed so that on each floor there is a solid concrete wall separating the spaces that are potentially radioactive and those that are not. The nonradiological side of the auxiliary building (the clean auxiliary building) accommodates the MCR and the rooms housing the plant control and protection hardware and their battery rooms.

Some of these would be under threat from flooding should there be any substantial leak of water within the clean auxiliary building. The potential sources of water in the clean auxiliary building are the potable water for the manned MCR spaces, the fire protection water for the safety-significant equipment within the clean auxiliary building, and the pipes carrying water from the containment building through the clean auxiliary building to the turbine building.

The lowest level within the clean auxiliary building is two floors below ground level, thereby requiring some means of preventing any water that might accumulate from becoming a threat to the safety-significant equipment housed there. This might be achieved either by establishing a large sump or by providing an active means for clearing any accumulating water (without using ac power), or by limiting the amount of potential flooding water to a volume that would not threaten any safety-significant equipment. The latter option was selected.

The potable water day tank is above the MCR area. It is filled as required but is otherwise isolated from external sources; thus any leakage is limited to the day tank volume.

The potable water piping from the tank is sized such that even in the event of a pipe rupture the leak rate would be modest. The pipes are routed within the manned spaces so that any leakage would be detected quickly. The potable water is thus not a flooding hazard to the Class 1 equipment within the clean auxiliary building.

The volume of fire protection water available to the auxiliary building is limited by the design solution discussed in subsection 6A.3.3.6. Even in the event that this fire protection water should flood the lowest level of the clean auxiliary building, the water level would be below that of the Class 1 battery electrical connections, the lowest Class 1 equipment in the clean auxiliary building. The maximum potential volume of water from the fire fighting water supply would thus not be a threat to any of the Class 1 equipment housed there.

The piping carrying water from the containment to the turbine building is routed through two rooms within the clean auxiliary building. Both of these rooms are enclosed in concrete, with the only routes for water to escape from them, including through the doors, being to drains within the turbine building. Thus, any leakage of water from the piping carrying water from the containment to the turbine building would not accumulate within the clean auxiliary building but instead would drain out of it by gravity.

Advantages and Disadvantages

The following advantages result from limiting the maximum potential volume of water that could flood the lowest level of the clean auxiliary building:

- Limiting the volume of the potable water tank costs nothing, and might even be slightly cheaper than a larger tank.

- The volume of fire protection water is restricted to below the amount where flooding could be a problem by the simple expedient of using standpipes within the PCCWST (see subsection 6.A3.3.).

Disadvantages resulting from limiting the maximum potential volume of water that could flood the lowest level of the clean auxiliary building are the following:

- The filling of the potable water tank needs to be manually initiated and performed on a regular basis.

- Reinforcing the two rooms containing the transfer piping from the containment building to the turbine building and installing drain paths to turbine building does incur a cost.

6A.3.5 Primary System Design

6A.3.5.1 Selection of the Reactor Coolant Pump Type

The type of RCP adopted for many currently operating plants is a shaft seal pump, A weakness of the shaft seal-type RCP is the potential for seal degradation and coolant leakage from the seal unless high-pressure, cold, seal injection water is provided, or cooling water flow is maintained to the RCP thermal barrier to cool any reactor coolant leakage through the seal. The AP600 designers felt that other types of RCPs should be considered since a basic design premise of the AP600 plant design was to maintain safety and respond to accident situations without reliance on ac power. Providing seal injection or thermal barrier cooling to the shaft seal RCPs for an extended time following the postulated loss of all ac power would be difficult to accomplish using only passive, natural forces.

A potential design option for the AP600 plant was the use of sealless motor pumps. It is noted that the AP600 required forced RCS circulation for normal operation at power, as natural circulation would be inadequate.

Sealless RCPs have been used in non-commercial nuclear applications. Sealless pumps used in these applications have been demonstrated to be highly reliable and represented a RCP solution with no possibility of coolant leakage since they have no seals to leak. The selection was made to use a sealless motor type pump for the AP600 design, based on simplicity, reliability, and experience with similarly sized motors. The pump is not claimed to function post-accident, and its pressure boundary is continuous, without any leakage during normal or fault conditions. The larger power rating of the AP1000 design required a significant upscaling of the pump/motors.

Advantages and Disadvantages

The following advantages result from choosing sealless pumps:

- No risk of a RCP seal LOCA through failure of the shaft seals or shaft damage following a loss of all ac power event, thereby significantly enhancing safety.

- Because the motor and the pump bearings are within the coolant boundary, the canned-motor pump also allows the designer to eliminate the shaft seal pump support systems, such as seal injection, seal leakoff, and lubricating oil system. In addition, the FPS can be simplified since no provisions for mitigating a lubricating oil fire are required. This avoids complexity and results in lower overall cost.

- Higher intrinsic reliability than shaft seal pumps.

- Reduced fire risk, because there is no lubricating oil system.

- Reduced radioactive effluent, because there is no shaft seal leak-off flow to collect and process.

- The decision to attach the pumps directly to their SG, eliminates the crossover leg required for shaft seal pumps. This also eliminates the high/low stagnation portion of the crossover, thus promoting natural circulation for post-accident cooling, and there is no depression of the water level in the reactor vessel caused by the loop seal clearing following postulated cold leg LOCAs.

- Reduced pump maintenance.

- Lower maintenance dose due to the avoidance of maintenance time in the vicinity of the SGs resulting from the need to remove the entire pump and motor.

The following disadvantages result from choosing sealless motor pumps:

- They are not as efficient as shaft seal pumps.

- Unlike shaft seal pumps, sealless pumps cannot be repaired in situ, requiring the plant design to accommodate the ability for quick removal and replacement of an entire RCP(s).

- Unlike shaft seal pumps, canned-motor pumps of the size required for the AP1000 design had not been built before. This required that large sealless pump designs be developed and that an extensive test programme be conducted as part of the design verification.

- Sealless RCPs slow down quickly when electrical power is removed as compared to shaft seal RCPs, which employ a large flywheel outside the RCS pressure boundary. The sealless RCPs solution to this challenge was the addition of rotating inertia to the pump in the form of a heavy flywheel inside the motor housing.

6A.3.5.2 Use of Grey Rods for Load-Following

Most nuclear power plants today are operated as base load plants but with some ability to load-follow. In typical operating PWRs, this load-following capability is achieved by means of systems that increase and decrease the boron concentration of the reactor coolant water by adding borated or unborated water while removing reactor coolant. In order to avoid releasing very large quantities of borated water, these plants often evaporate water and recycle the water and recovered boric acid, on a short time scale. This requires elaborate and complicated boron and water handling systems outside the containment, and results in restrictions on the rate of load-follow available.

The AP1000 designers recognised that there is an alternative to short-term reactivity control other than changing boron concentration in the reactor coolant, "grey" control rods. These are control rods with low-density neutron absorber, which can be moved to provide modest reactivity adjustments. The materials for grey rods are well known, and their effectiveness for partial reactivity control is easily analysed. It should be noted that grey rods are used in addition to the "black" safety rods, and are not needed for shutting the reactor down. The use of grey rods for load follow minimises the radioactive effluent from the RCS since the reactor coolant boron concentration is only slowly reduced during a plant fuel cycle to account for fuel reactivity decrease as the fuel is used. This effluent can be more easily processed and released after dilution while meeting typical environmental release regulations. Also, due to the small amount of effluent produced, the need to process and recycle water and boric acid is eliminated.

Advantages and Disadvantages

The following advantages result from choosing grey control rods as the means for providing a load-following capability:

- Results in a significant reduction in the amount of liquid radioactive effluent that must be processed during plant load follow operation and a significant simplification of the WLS.

- Potentially eliminates the need for boron recycling, because relatively little boric acid is used during power operation as load-follow is accomplished with grey rods and without changes in the RCS boron concentration.

- Reduced operator dose because the water and boric acid used for plant reactivity control has not been recycled and contains no residual radioactivity. Also, operator dose is reduced since there is no boron and water recycle equipment to operate and maintain.

- Improved operational flexibility, especially towards the end of a fuel cycle, the most difficult situation for a boron control system.

- Greater ability to load-follow than would be achievable with continual boron recycling in and out of the primary coolant.

- Reduced possibility for a reactivity excursion caused by inadvertent dilution of the reactor coolant.

The following disadvantages are apparent:

- The addition of grey rods results in additional control rod drive line penetrations through the RV head and additional RCCAs, guides, and control rod drive mechanisms.

- Potential reactivity faults caused by inadvertent grey rod withdrawal

- Operator dose resulting from maintenance of the added control rod drive mechanisms.

6A.3.5.3 Locating the Chemical and Volume Control System Purification Loop within the Containment

One of the major functions of the CVS is to remove impurities and minimise the radioactivity of the reactor coolant by demineralising and filtering the coolant during all normal operating modes.

In typical operating PWR plants today, this function is performed by a variety of CVS components, most of which are outside the containment, by taking reactor coolant out of the containment (letdown flow). The letdown flow temperature and pressure are reduced, it is demineralised and filtered, dissolved hydrogen is replenished, and it is then pumped back into the containment and the RCS (makeup flow). This process results in the contamination of the equipment and introduces potential reactor coolant leak sites outside the containment.

In the AP1000 plant, the CVS components used to continuously demineralise and filter the reactor coolant are located entirely within the containment. These components include the CVS regenerative HX, letdown HX, demineralisers, filters, and their associated valves, piping, and instrumentation; all of which are designed to operate at RCS pressure. The flow through this in-containment purification loop is driven without the need of continuously operating charging pumps, making use of the reactor coolant pump developed head to provide the motive force.

Advantages and Disadvantages

The following advantages result from locating the CVS within the containment:

- The AP1000 CVS is greatly simplified compared to other PWR designs; eliminating the need for continuously operating makeup pumps, eliminating the need for a volume control tank (VCT), eliminating control of the VCT hydrogen cover gas and fission gas removal, and greatly reducing the quantity of CVS piping and valves.

- The operation of the CVS is greatly simplified and the dose to operator and maintenance personnel is reduced by the elimination of CVS components and the amount of radioactive piping, valves, and instrumentation.

- The potential for leaks of radioactive water outside containment is greatly reduced since the need for reactor coolant letdown during power operation is virtually eliminated.

There are no disadvantages to locating the CVS within the containment.

6A.3.5.4 Zinc Addition to the Primary Coolant

The buildup of crud (typically oxides of activated metal) on component surfaces in the RCS has the potential to cause stress corrosion cracking and crud-induced power shift due to boron concentration in the crud on fuel rods. Also, this crud often becomes solubilised during reactor cooldown operations and results in increased radiation doses during reactor disassembly and refuelling operations. Operation with chemical zinc in the coolant has been demonstrated to change the oxide film on the primary system component surfaces in such a way as to significantly reduce the potential for stress corrosion cracking and crud-induced power shift. Also, zinc addition results in a significant reduction in crud related release into the reactor coolant and has resulted in occupational radiation exposure reductions of as much as 50 percent when incorporated as early as the hot functional testing. Zinc addition to the RCS has been implemented at numerous PWRs to date, with zinc concentrations ranging from 5 to 40 parts per billion (ppb).

The design of the AP1000 CVS incorporates a zinc addition subsystem. The reactor coolant water chemistry specifications for the AP1000 design specify a maximum zinc concentration of 40 ppb to maximise the benefits associated with zinc addition.

Advantages and Disadvantages

The following advantages result from adding zinc to the primary coolant:

- Reduced likelihood of stress corrosion cracking in reactor coolant system components.
- Crud-induced power shift is minimised.
- Reduces occupational radiation exposure to the operators and maintenance personnel.
- Zinc addition is based on operating plant experience and is a proven technology

There are no disadvantages to adding zinc to the primary coolant except for the slight increase in operations and cost of the required equipment.

6A.3.6 Duty Systems

6A.3.6.1 Startup Feedwater Cavitating Venturi

The startup feedwater pumps and their associated pipes and valves comprise the duty system for normal decay heat removal from the RCS at high pressure. If the system operates correctly, it obviates the need for the Class 1 safety measure, the PRHR HX. During a transient with the loss of the main feedwater supply, at least one of the two startup feedwater pumps takes suction from the condensate storage tank and delivers feedwater to the SGs.

The potential exists for excessive startup feedwater flow should the SG pressure be low. The AP1000 design employs a cavitating venturi at the discharge of each of the two startup feedwater pumps to limit the flow. The venturi is designed to cavitate at a point near pump runout; the choked flow in the throat of the venturi under such conditions prevents further flow increase. Thus, the venturi prevents a startup feedwater pump from running out past its designed maximum flow rate. Pump runout protection is important during conditions when the steam generators are at low or atmospheric pressure or following a line break downstream of the pumps. The venturis limit the pump runout such that the required NPSH does not exceed the available NPSH at maximum flow conditions. The venturis also ensure that the total flow rate from both pumps is limited so the maximum flow to the SGs is not exceeded. Thus the venturi flow elements provide a passive mean of limiting the flow. The cavitating venturi also provides the secondary function of a flow measurement signal at normal flow rates.

Advantages and Disadvantages

The following advantages result from incorporating a cavitating venturi at the outlet of the startup feedwater pumps:

- Reduced likelihood of exceeding the startup feedwater pump runout flow limit and ensures the pump NPSH requirement is always met
- Reduced likelihood of excessive cooldown of the primary circuit, thereby causing a reactivity injection
- Proven technology

The only disadvantage of incorporating a cavitating venturi is cost. However, because it also enables flow to be measured, a function that would have to be provided anyway, its net cost is negligible.

6A.3.6.2 Use of Air Diaphragm Pumps for Waste Water Duty

Wastewater needs to be transferred within the plant, from tank to tank or for processing, and ultimately it must be discharged out of the plant. This wastewater can be contaminated and nonradioactive, radioactive, or contaminated and radioactive; the contamination might be oily. In currently operating nuclear power plants, such transfers are brought about by a wide variety of pump types: centrifugal, positive displacement, air-operated, and others. Those pump types that require seals, especially rotating seals, are prone to leakage with the potential for consequent radioactive or oily effluent and accidental loss of radioactive fluid outside the containment.

It was decided to pick a pump type with no seals for wastewater pumping duty. In this type of pump, the working fluid remains fully contained inside the pump's pressure boundary, thereby eliminating any chance of seal leakage. After consideration of the available pump types, the air diaphragm pump was chosen.

Advantages and Disadvantages

The following advantages result from using all air diaphragm pumps for wastewater pumping duty:

- Less expensive than other pump types of the same capacity.
- Diaphragm pumps are simple and easy to maintain, and standardisation reduces the number and types of spare parts that must be maintained.
- As a fully contained pump, eliminates the possibility of accidental loss of radioactive fluid due to seal leakage, thereby minimising the risk of public or operator radiation exposure from wastewater leakage.

There are no disadvantages resulting from using air diaphragm pumps for wastewater pumping duty.

6A.3.6.3 ac Power Fast Bus Transfer

The onsite ac power system comprises a normal power supply, a preferred power supply, a maintenance power supply, and a standby power supply. The normal, preferred, and maintenance power supplies are included in the main ac power system. The standby power supply is included in the onsite standby power system. These power supplies provide ac at 11 kV.

During normal power generation mode, the main turbine generator supplies electric power to the plant auxiliary loads through the unit auxiliary transformers. This is the normal power supply.

When the plant is shut down or starting up, the generator breaker is open and ac power is provided from the preferred power supply. This comes from the high-voltage substation by way of the main step-up transformers (main generator transformers, in UK parlance) and the unit auxiliary transformers.

During maintenance on the main step-up transformers, power comes from the high-voltage substation by way of the two reserve auxiliary transformers (station transformers, in UK parlance). Each reserve auxiliary transformer can be used in place of a unit auxiliary transformer; that is, its output rating is the same. Bus transfer to the maintenance power supply is manual or automatic, through a fast bus transfer scheme.

Two onsite standby diesel generators power the onsite standby power system. This supplies power to selected loads in the event of the loss of the normal or the preferred ac power supplies. These loads provide defence in depth functionality. The diesel generators are automatically started and connected to their respective buses. In the event of a fast bus transfer, the diesel connection to the bus is delayed such that the fast bus and residual transfer is allowed to initiate.

The original AP1000 design had only one reserve auxiliary transformer and was vulnerable to losing ac power due to the failure any of the following:

- Any one of five large oil-filled transformers
- The 26-kV isophase bus duct
- The associated malfunction of the protective relay for the above electrical equipment

The ac power cut would last for up to approximately 2 minutes, until such time as the onsite standby diesel generators started, warmed up, and loaded; or the plant operators transferred selected loads to the single reserve auxiliary transformer. This condition would result in a reactor trip because of the loss of the four RCPs, which are powered from the unit auxiliary transformer buses.

To prevent such a reactor trip from the electrical faults mentioned above, a fast bus transfer capability was incorporated into the AP1000 design. Automating the bus transfer from the unit auxiliary transformers to the single reserve auxiliary transformer would have required shedding sufficient unnecessary loads so as to be within the rating of the reserve auxiliary transformer; this would have required a complex automatic system. Instead, it was decided to go for a simple automatic capability and second reserve auxiliary transformer to allow the transfer of loads from the unit auxiliary transformers to the reserve auxiliary transformers.

In summary, the addition of another reserve auxiliary transformer was chosen to allow for the bus transfer from the unit auxiliary transformers to the reserve auxiliary transformers.

Advantages and Disadvantages

The following advantages result from incorporating a fast bus transfer capability and a second reserve auxiliary transformer:

- Prevents a reactor trip in case of any of various electrical faults, and thereby minimises challenges to the plant shutdown cooling or safety related systems, minimises plant transients, and avoids the cost of lost electrical production.

- Results in a much simpler and more reliable automatic system than the option of a single reserve auxiliary transformer.

- Two reserve auxiliary transformers allow functionally redundant pumps or groups of loads to be supplied from separate buses.

- Two reserve auxiliary transformers allow increased operational flexibility.

The only disadvantages resulting from incorporating a fast bus transfer capability and a second reserve auxiliary transformer are an increased initial cost and ongoing maintenance costs over not installing the system at all.

7 LIFE CYCLE ENGINEERING AND SAFETY

7.1 Introduction

This section provides an overview of the engineering and safety arrangements throughout the life cycle of the AP1000 pressurised water reactor (PWR) plant. It focuses on specific aspects of the management arrangements associated with the achievement of nuclear safety throughout the design life cycle of the plant considering the design, change control, construction, commissioning, maintenance, ageing, and degradation and decommissioning.

This chapter summarises the general arrangements for the overall project including the expectations of the engineering and safety principles and processes to be applied and implemented during the lifetime of the AP1000 plant. Design, build, test, and maintenance activities influence the safety of the AP1000 plant throughout its life. Many of these activities occur after generic design acceptance. These later activities cannot be addressed at this time since they are the responsibility of the licensee. It shall be noted that this chapter describes anticipated actions from a licensee in accordance with UK regulatory guidance. It will be the prerogative of the future utility to decide on its own processes and programmes for these topics and others.

This chapter focuses specifically on the nuclear safety aspects of the United Kingdom (UK) AP1000 plant submitted for generic design assessment (GDA). However, where there is an impact on the nuclear safety of the plant from other aspects of the UK AP1000 plant design, these are also included.

Plant ageing mechanisms need to be understood and managed to ensure the design and constructed plant remain safe and that the risks remain as low as reasonably practicable (ALARP) for the duration of the plant life cycle. As modifications are introduced into the plant design and facilities, the safety case must be revisited to ensure the modifications keep the plant operating within its safety envelope. The scope and purpose of how the safety case is developed throughout the plant life is provided in Chapter 2. As the safety case develops and the responsibility for it is handed over to the site licensee, appropriate management arrangements will need to identify how information is transferred to the licensee, who must ensure they understand the technical arguments contained in the document(s). These aspects of knowledge transfer, intelligent customer (IC), and the role of the design authority (DA) are summarised in Section 7.2. The overall management of safety is discussed in Chapter 3.

Periodic safety reviews ensure the safety case remains valid throughout the plant life, as the behaviour or nature of the plant changes over time. During the operational phase, periodic safety reviews also demonstrate that ageing and other time-related phenomena will not compromise safety, particularly before the next periodic review. There is normally a maximum time limit of 10 years before each periodic review.

The safety of pre-power operation, power operation, and post-power operation activities for the AP1000 plant (see Figure 7-1) will be based on risk reduction, dose minimisation, the ALARP principle, waste minimisation, and passive safe storage. This is ensured through the following:

- **Design** – The systems, structures, and components (SSCs) that comprise the AP1000 plant are designed to keep risk ALARP.

- **Construction Commissioning** – The AP1000 plant SSCs are built in accordance with the design and will be systematically and rigorously commissioned to demonstrate the

required functionality in accordance with the safety case and design intent. Plant facilities that provide a safety function will be appropriately configured and the required functionality will be demonstrated during commissioning.

- **Operation Maintenance** – The AP1000 reactor and any plant facilities that provide a safety function will be operated and maintained in accordance with the safety case. Activities will be controlled in a safe manner and risks demonstrated to be ALARP.

- **Decommissioning** – The AP1000 reactor and associated facilities are designed to have minimal impact on the environment at the end of its operating life. The AP1000 reactor and its facilities will be capable of being safely decommissioned in accordance with government policy for which a safety case will be prepared.

Westinghouse has developed a number of safety programmes to be used in support of the potential licensee throughout the design, construction, and operation of the AP1000 plant, a brief description of which is provided in the Plant Life Cycle Safety Report (Reference 7.1). The Plant Life Cycle Safety Report outlines the information required to demonstrate that the construction and installation activities will result in a plant of appropriate quality and that the constructed plant will be capable of being operated within safe limits. The Plant Life Cycle Safety Report also describes the process by which the knowledge within the AP1000 plant safety case can be most comprehensively transferred to the potential licensee and outlines Westinghouse's expectations for any operator management system.

7.2 Design Implementation

The Westinghouse safety management framework is discussed in Chapter 3 and notes the safety philosophy policy statement. In support of this policy, Westinghouse, as the plant designer, is committed to the following:

- Providing safe working conditions to protect the health and safety of employees and contractors

- Reducing waste, preventing pollution, conserving resources, and using energy efficiently in its operations

- Complying with the applicable environment, health, and safety (EHS) legislation and regulations, as well as any other requirements, including fire regulations

- Continually improving EHS management systems and performance by establishing and maintaining meaningful objectives and targets, taking into consideration significant EHS aspects; technological options; and legal, operational, business, and other requirements

- Establishing and maintaining procedures to identify the potential for and response to accidents and emergency situations, and to prevent and mitigate the impacts associated with them

- Training employees to work in a safe and environmentally responsible manner

- Effectively managing and promptly resolving impacts from historical operations in a manner that minimises risks and liabilities while accommodating current operations

- Periodically monitoring, auditing, and evaluating EHS performance as it relates to applicable design requirements and established objectives and targets

The way in which this policy is implemented through the design is discussed further in the Plant Life Cycle Safety Report (Reference 7.1, Section 3).

7.2.1 Knowledge Transfer

As mentioned in Chapter 3, to ensure that the knowledge transfer process is comprehensive, there must be strong interfaces with potential site licensees during the GDA process and following licence acceptance. Westinghouse has worked with potential utility licensees during the GDA process concerning submissions to the UK regulators with the purpose of ensuring that an acceptable safety case has been made for the AP1000 design. Although the utility involvement has evolved throughout the GDA there has been a high level of interactions and utilities have been invited to Level 1-4 regulatory meetings throughout GDA. This arena forms the basis for ensuring that the interested utilities are engaged in the production of the GDA safety submission and will include an understanding of the following:

- The design
- Procedures to be used during the procurement and construction phases
- Procedures for normal operation, and emergency and accident management
- Procedures required during the installation and commissioning phases
- The safe operating envelope and the operating regime required to maintain the integrity of that envelope
- Technical Specifications
- Operating instructions (OIs), including the commissioning schedules
- Maintenance schedules
- Training requirements
- Emergency preparedness
- Radiological protection arrangements
- Safety case used as the basis for the GDA submission

The aim of the knowledge transfer process is to ensure that potential licensees have the capability to secure and maintain the safety of the facility and that, where necessary, the licensee has the means to perform as an IC. Whilst it is appreciated that potential licensees are required to demonstrate their arrangements for compliance to the requirements of the site licence, sufficient information will be made available by Westinghouse to enable those organisations to enact their arrangements as per appropriate contract arrangements. The definition of an IC is defined in Reference 7.2 as follows:

> *As an IC, in the context of nuclear safety, the management of the facility should know what is required, should fully understand the need for a contractor's services, should*

specify requirements, should supervise the work and should technically review the output before, during and after implementation. The concept of IC relates to the attributes of the organisation rather than the capabilities of the individual post holders.

These aspects of demonstrating that the licensee has suitable IC capability are discussed further in the Plant Life Cycle Safety Report (Reference 7.1).

Westinghouse expects to be fully integrated into the potential licensee's management arrangements and Westinghouse's arrangements will meet and will be aligned with those of the licensee. This in itself will aid the knowledge transfer during the licensing process and later in the various plant phases.

Westinghouse will support the licensee to ensure that the knowledge of the aspects of the design, construction, commissioning, and future operability of the plant is transmitted in an effective and appropriate manner and provide visible assurance that this has been achieved. Thus, any contract between Westinghouse and a licensee is expected to define the tasks and interrelationship between the organisations. The management arrangements and the related communication processes between the licensee and Westinghouse have to be agreed within this framework.

The principles on the use and management of contractors given in Reference 7.2 have been applied by Westinghouse in the production of safety submission for the GDA process. The broad principles are as follows:

- The overall responsibility for, and the control of, the nuclear and radiological safety and security of all its business, including work carried out on its behalf by contractors, is maintained by the IC.

- The choices between sourcing work in-house or from contractors should be informed by a clear policy that takes due account of the nuclear safety implications of those choices.

- It is ensured that an IC capability is maintained for all work carried out on its behalf by contractors that may impact upon nuclear safety.

- It is ensured that the IC only lets contracts for work with nuclear safety significance to contractors with suitable competence, safety standards and resources.

- It is ensured that all contractor organisations are familiar with the nuclear safety implications of their work and interact in a well coordinated manner with their own staff.

- It is ensured in practice that the contractor's work is carried out to the required level of safety and quality.

These principles of the suitability to act as an IC will be applied to the licensee to determine if they themselves have the knowledge and depth of understanding of the overall safety of the AP1000 plant. In addition to being able to act as an IC, the licensee will have to demonstrate that they have suitable safety management arrangements in place, demonstrate compliance to those arrangements, and demonstrate that they adequately control and supervise all activities where safety may be affected, including being capable of exerting proper controls of the activities of contractors.

The arrangements for knowledge transfer will be defined and discussed in detail with the licensees and the process developed throughout the various project phases leading up to and

beyond the start of operations. These aspects are covered further in the Plant Life Cycle Safety Report (Reference 7.1).

Westinghouse has assumed the position of IC for the purposes of the GDA submission.

As discussed in the Plant Life Cycle Safety Report (Reference 7.1), one area where it will be demonstrated that suitable and sufficient information has been made available, transferred, and understood is the appointment of duly authorised persons (DAPs) and suitably qualified and experienced persons (SQEPs). These appointments are made by the licensee and are a requirement of the site licence conditions (SLCs), specifically those relating to commissioning, control, and supervision of all operations that may affect safety, including the examination, maintenance, inspection, and testing (EMIT) of safety equipment.

It must also be ensured that the potential licensees are aware of and learn from any information gained from the construction, commissioning, and operation of other AP1000 plants worldwide. To facilitate this, it is essential that Westinghouse has good processes for the management and preservation of knowledge relating to the design development of the AP1000 plant and, where appropriate, these aspects of knowledge management are transferred to the licensees. These processes and procedures are discussed further in Chapter 3.

7.2.2 Design Authority

The concept of knowledge transfer is fundamental in defining who the DA is for the AP1000 plant throughout the plant life cycle. Westinghouse will be the DA until at a suitable point this role will be transitioned over to the licensee and Westinghouse will become the responsible designer (Reference 7.3), defined as follows:

> *The organisation which has a formal responsibility for maintaining detailed, specialised knowledge of all the systems and components important to safety, and a core competence in the detailed design process.*

Design changes made by the licensee during the plant life must be made with the full knowledge and understanding of the design and safety functions that need to be provided. This knowledge is to be retained and made available by the licensee over the lifetime of the plant until it has been decommissioned.

The licensee is also responsible for maintaining the design integrity and the overall basis for safety over the plant life. Thus, the role of DA is defined in Reference 7.3 as follows:

> *The defined function of a licensee's organisation with the responsibility for, and the requisite knowledge to maintain, the design integrity and the overall basis for safety of its nuclear facilities throughout the full lifecycle of those facilities. Design Authority relates to the attributes of an organisation rather than the capabilities of individual post holders.*

Prior to a licensee being designated as the DA, the licensee must demonstrate sufficient knowledge to understand the safety case requirements for the plant and be able to assess the impact of proposed design changes on the functionality, reliability, and availability claims made in the safety case. The licensee will also need to demonstrate an understanding of any specific constraints that impact the practical use of the plant, such as restrictions on space, availability of services, and environmental considerations.

The Westinghouse design safety case for the AP1000 plant will be evaluated throughout the plant life. In this context, Westinghouse has processes in place to do the following:

- Review relevant plant modifications
- Perform design substantiation for modifications proposed
- Record and learn from operational experience across all AP1000 plants
- Communicate the need for essential plant upgrades and changes to operating constraints across all AP1000 plants

The licensee and Westinghouse will have arrangements in place to enable delivery of Westinghouse service as the responsible designer during the plant construction and commissioning, recognising that some elements may be assigned to other responsible designers. The DA is expected to demonstrate certain capability principles and, during the transfer of this role from Westinghouse to the licensee, any contractual arrangements will be in accordance with these principles, which include the following:

- Be a defined function within the licensee's organisation.
- Have the authority and responsibility to propose, approve, or reject design changes.
- Have the capability to understand the totality of the design and nuclear safety case in the context of each stage of the full plant life cycle.
- Have the resources, capability, and management processes to assess the changes to the plant's conditions, limits, and performance characteristics, and have the authority to recommend modification to or suspension of operation.
- Have appropriate and up-to-date knowledge, skills, experience, and resources.
- Regularly assess and determine the continued adequacy of the plant's design and safety case, and have the authority and responsibility to respond to the issues identified.

Where the DA does not have the detailed knowledge required of all the systems and components important to safety, it may choose to assign those responsibilities to responsible designers using the supply chain.

While Westinghouse remains the DA, design changes will be in accordance with Westinghouse's own procedures, as discussed in Chapter 3. However, the licensee will be required to have suitable arrangements in place to maintain design integrity and, throughout the licensing process, any changes will have to be made in accordance with the licensee's arrangements for making modifications to the design under construction, SLC 20 (Reference 7.4). Thus, Westinghouse's processes will align with and be integrated into the licensee's arrangements, where applicable.

7.3 Design Change Control

7.3.1 Introduction

The management of safety is outlined in Chapter 3 and discussed further in the Plant Life Cycle Safety Report (Reference 7.1).

The evolution of the design of the AP1000 plant is described in detail in the Genesis and Process of the AP1000 design document (Reference 7.5) and has been built on the design

philosophy that emphasises “safe and simple”, while recognising the benefits of a standard design to be deployed on multiple sites.

Westinghouse has considered, and continues to consider, safety in the early design of equipment and facilities, and the design review (Section 7.3.2) is one of the primary tools to capture plant lifetime nuclear and personnel safety aspects.

To ensure design change control up to and including commissioning the AP1000 plant and supporting facilities, Westinghouse operates a Quality Management System (QMS) that contains the management processes outlined below. During the licensing process and after a site licence has been granted, Westinghouse’s procedures will be aligned with the licensee’s arrangements for SLC 20 (Reference 7.4) and SLC 22 (Reference 7.6), as appropriate.

Design modifications throughout the life cycle of the plant:

- Once the design documentation for the plant has been agreed, any subsequent design changes will be subject to design change management control. The reviews, which form part of the design change process, are used to verify the completeness and adequacy of the design change to meet the design intent.

- Any proposed changes to the plant baseline design must be assessed to ensure the safety case is not undermined and the effects on adjacent systems have been considered. This process is applicable throughout the construction, commissioning, and operational phases.

Design control for facilities:

- When modifications are made to the facility reference design, a safety design change committee, or equivalent, will review the changes, in accordance with the licensee’s site licence arrangements. Where applicable, an appropriate Nuclear Site Safety Committee subcommittee, set up in accordance with the site licensee management arrangements, will review operational procedures in accordance with their safety category/classification and endorse or authorise the documents. The relationship between Westinghouse and the licensee may require Westinghouse to provide any information and support to the licensee to enable them to make informed decisions and to be able to present the case for change knowledgeably to the regulators.

- Following the granting of a site licence, the licensee will have the option to assess the impact of any changes to be carried out by Westinghouse, another third party, or the licensee’s own in-house design team. Consideration must be given to the roles and responsibilities held by Westinghouse and the licensee as responsible designer and DA and the need to demonstrate suitable IC capability where applicable.

- Records of all plant design change control will be kept in accordance with SLC 6 (Reference 7.8).

- The regulatory authorities may request visibility of any modification (Reference 7.4) and impose hold points before allowing that modification to proceed. The licensee will manage any such hold points in accordance with its management arrangements.

These processes will interface with the site licence holder’s arrangements for meeting SLC 14, SLC 19, SLC 20, SLC 21, and SLC 22 (References 7.9, 7.10, 7.4, 7.11, and 7.6, respectively) and any others deemed appropriate.

Safety of the AP1000 plant design through the life cycle of the plant will be managed in accordance with appropriate legislative requirements by Westinghouse and then the site licence holder, with their priority being to design, construct, commission, and operate the plant safely and ensure any risks to workers or the public remain ALARP and within legislative requirements.

7.3.2 Safety through Design Review

Westinghouse considers safety from the early stages in the design of equipment and facilities and throughout any modifications during the construction and commissioning stages.

The design review process (see Figure 7-2) is one of the primary tools used to ensure that plant lifetime nuclear and personnel safety considerations are properly considered when products, processes, analytical tools, systems, equipment, or servicing tools are introduced or undergo major change. This is an important aspect of the Westinghouse design verification process before or during manufacturing, construction, commissioning, and operation.

Design reviews are conducted at appropriate stages of the design development through manufacture, construction, commissioning, and operation to provide an objective overview of design adequacy, safety, performance, and cost.

Design reviews are performed when:

- A system or plant failure could result in significant risk to public safety, the environment, worker health, company finances, or customer satisfaction.
- The design is a significant departure or extrapolation from a past proven design or analytical methodology.
- The physical configuration is similar to proven designs, but there are potentially significant changes in application or acceptance criteria.
- The design involves significant changes to power plant operations, processes, or systems.
- A customer or regulatory agency stipulates a requirement (for Class 1 items, independent reviews are performed by individuals or multidisciplined review teams).

Sufficient time must be provided in the design plan to ensure that adequate reviews are performed and action items are resolved satisfactorily before the design or design change is released. Design reviews address the following as applicable:

- Correct selection of design input
- Correct incorporation of design inputs into the design
- Specification of design input and verification requirements for interfacing organisations
- Adequate identification, description, and reasonableness of assumptions
- Appropriateness of design methods
- Reasonableness of design output compared to design input

- Adequacy of critical fits and clearances and, when applicable, plant construction and equipment installation
- Plant installation
- Impact to supply base/supplier, manufacturability, and cost effectiveness

7.3.3 Maintenance

Maintainability is to be "designed in" by extensive layout reviews by the AP1000 design team. From the beginning of AP1000 development, the layout was generated in 3-D computer-aided engineering (CAE) software. As items (structure, equipment, pipeline, duct, and tray) are added to the design, it may be checked for interferences, inspection access, and maintenance access. These evaluations may be performed with site licensee involvement. Design decisions will be made to minimise maintenance time, the need to work from heights, accessibility, and other risks that occur while routine and breakdown maintenance activities are performed.

The design change control process will ensure that maintenance activities are considered when design reviews are undertaken, especially during modifications made onsite in accordance with SLC 20 (Reference 7.4). This will involve interfacing arrangements between Westinghouse and the site licence holder for EMIT and other maintenance arrangements in accordance with SLC 28 (Reference 7.12).

7.4 Construction

7.4.1 Introduction

Civil engineering construction is a major component of the Westinghouse AP1000 nuclear power plant (NPP). The plant, including the civil engineering aspects, has been designed with the intention of being capable of being sited at any reasonable location in the world without modification.

The Westinghouse AP1000 design employs construction methods and a plant layout that are conducive to safe construction. Much of the design is modular, which allows the build and test of subassemblies to be undertaken in a factory environment. The size of the plant and the number of components is also significantly less than previous generations of PWRs. These approaches will reduce site construction work and hence the risks from those activities. Modular construction in a factory environment is expected to have a positive effect on product quality and safety and can contribute to reduced maintenance requirements during the lifetime operation of the plant.

During the construction phase, responsibility for safety, health, and the environment will rest with the licensee. The licensee's arrangements will ensure that they will be compliant with Construction (Design and Management) (CDM) regulations (Reference 7.13). The licensee will determine the extent of work responsibility that they wish to hand over to Westinghouse and other contractors. As a minimum, the licensee will ensure that both Westinghouse's and the licensee's management arrangements permit access to the relevant Westinghouse knowledge and support necessary to ensure health and safety of people, and environmental protection onsite during construction and subsequent commissioning and operation of the plant. Throughout the construction phase, Westinghouse will work closely with the licensee to provide the necessary technical information to enable the development of the appropriate safety case documentation. Westinghouse's construction arrangements will align with and be delivered under the licensee's arrangements. These will need to be confirmed as acceptable

by the licensee, i.e., that they meet the expectations of the UK regulators. These aspects are discussed further in the Plant Life Cycle Safety Report (Reference 7.1).

For justification of the civil engineering structures, supporting information can be found in Chapter 16, based on the structure's relevant categorisation and classification identified in Appendix 15A.

The use of a steel-concrete composite construction method for some structures where concrete is placed between two steel plates that provide the reinforcement, instead of conventional internal reinforcement bars, is unconventional in the UK for nuclear power station construction. Therefore, the justification for SC structures has been considered in particular detail by Westinghouse, and Chapter 16 refers to this detailed information.

The adequacy of construction, installation, and preliminary operation of components and systems is verified during construction and installation commissioning. Development of the construction and installation tests is based on the engineering information for the equipment and systems installed.

The construction verification process is the means to demonstrate that the AP1000 plant is constructed to the design intent. This process provides assurance that a plant that receives a design acceptance is manufactured and the equipment installed in conformance with the accepted design.

An equivalence study has been carried out to ensure that any codes and standards used in the above construction verification programme have been demonstrated to be acceptable for use in the UK. This is provided in the AP1000 Equivalence/Maturity Study of U.S. Codes and Standards (Reference 7.15).

7.4.2 Overview of Construction Verification Process

During the design process, systems are designed and optimised to provide the highest degree of nuclear safety to ensure worker and public protection and compliance with all appropriate standards.

Principal design criteria establish the necessary design, fabrication, construction, testing, and performance requirements for SSCs important to safety; that is, SSCs that provide plant protection such that the power plant can be operated throughout its life cycle with minimised risk to the health and safety of the public and workers.

The safety of the nuclear plant is governed by the necessity to reduce risks to be ALARP and to ensure worker and public protection. This is achieved by conservative design to meet regulatory criteria and established industry codes and standards. The design process then proceeds following approved engineering practices and procedures using verified computer codes and test information. From the design activities, items required for verification of the design are logged and records kept.

7.4.3 Construction Objectives

The construction verification process follows the hierarchical objectives (shown in Figure 7-3) with verification of these objectives ensuring that the construction of the plant is in accordance with the design.

The licensee will ensure that prior to construction and installation adequate safety arrangements will be made and implemented, including the following:

- Procedures will be in place to ensure that, insofar as safety can be affected, the construction and installation of the plant is controlled, supervised, and carried out by an SQEP in accordance with written procedures.

- Roles and responsibilities relevant to the construction and installation of the plant will be defined.

- Relevant safety-related CDM regulations (Reference 7.13) appointments will be identified and adequate arrangements will be made and implemented.

- Where other contractors are employed on the construction and installation activities, adequate arrangements will be made to cover the work; for example, quality assurance (QA) programmes on the interaction between Westinghouse, the contractor, and the licensee.

- Records of the construction, installation, and testing undertaken will be retained by the licensee and, where appropriate, by Westinghouse in accordance with the licensee's arrangements.

Any construction activities undertaken on the licensed site will be in accordance with the licensee's arrangements. The licensee will assess the contractor's arrangements, including those of Westinghouse. Where necessary, modifications may be made to Westinghouse's arrangements to demonstrate acceptance by the licensee. Part of this process will involve the production of a construction and installation schedule in accordance with the arrangements outlined above.

7.5 Commissioning

7.5.1 Introduction

During commissioning, responsibility for the safety of the plant and the environment will rest with the licensee. Commissioning of the AP1000 PWR NPP follows the construction and installation phase. Commissioning verifies that the construction, installation, and operation of the plant behave according to their design intent and the assumptions made in the safety case.

Westinghouse will ensure that prior to commissioning adequate arrangements are made, implemented, and aligned with the licensee's arrangements. Westinghouse's arrangements will include the following:

- Procedures are in place to ensure that, insofar as safety can be affected, the commissioning of the plant is controlled, supervised, and carried out by an SQEP in accordance with written procedures.

- Roles and responsibilities relevant to the commissioning of the plant will be identified.

- Relevant safety-related CDM regulations (Reference 7.13) appointments will be made and implemented.

- Where other contractors are employed on commissioning activities, adequate arrangements will be made to cover the work.

- Records of commissioning undertaken will be retained by Westinghouse and provided to the licensee.

- Suitable safety-related hold points will be introduced.

In addition, documents to describe the commissioning tests (for example, method statements) will be prepared, authorised, and issued as appropriate. Local procedures to cover commissioning requirements, including any handover processes (for example, from construction to commissioning), will be made. These arrangements need to be confirmed as acceptable by the licensee.

Upon successful commissioning, the following claims made within the safety case can be justified:

- The plant has been designed so that all risks are ALARP.
- The plant has been built in accordance with the design.
- The plant has been fully commissioned to allow validation of the safety case assumptions.
- The plant can be safely operated and maintained in accordance with the safety case throughout its life cycle.

The main purpose of commissioning tests is to ensure that the assumptions made in the Pre-Construction Safety Report (PCSR) and other safety documentation are proven, such that the plant can operate safely. Commissioning tests serve as a progressive transition between the construction, equipment installation and the start of normal operation of the various plant systems. These tests may take place in-factory (as the AP1000 reactor is a modular design), on specific test facilities, or onsite. The choice depends on the type of equipment, the level of a system's integration that can be simulated offsite (e.g., control and instrumentation (C&I) systems), and the ability to obtain specific conditions onsite (e.g., for qualification tests or accident transients).

The method for defining commissioning tests is chosen to ensure that all operational aspects of system functions are tested, including safety-classified functions, taking into account offsite tests, where relevant.

As noted above a comprehensive commissioning programme will be prepared for implementation on the licensed site. This programme will be structured to include hold points at key milestones, at which the acceptability of the commissioning tests results will be verified (with particular focus on demonstrating that the plant will meet the appropriate design safety requirements) before entering into the next phase of commissioning.

7.5.2 Overview of Construction Testing Process

Equipment and construction specifications are developed to describe construction details such as welding methods and the necessary inspections and tests to ensure the quality of the welding. Principal design criteria establish the necessary design, fabrication, construction, testing, and performance requirements for SSCs important to safety, i.e., SSCs that provide assurance that the power plant can be operated such that the risk to the health and safety of the public and workforce can be shown to be ALARP.

7.5.3 Commissioning Phases

Commissioning follows the verification phase in a progressive test programme similar to that shown in Figure 7-4. This figure shows a typical PWR commissioning high-level test

programme profile broken down into manageable stages. The following subsections provide a brief overview of each stage. Note that due to the modular and staged construction schedule for the AP1000, the phases of Figure 7-4 will overlap by plant area. Each area of the plant will follow the progression of Figure 7-4.

The AP1000 test programme refers to the testing phases as "construction and installation tests" (typically, Phases 1 and 2, Figure 7-4), "pre-operational tests" (typically, Phases 3 and 4), and "startup tests" (typically, Phase 5 and onwards).

7.5.3.1 Safety Commissioning and Safety Commissioning Schedule

The site licensee and Westinghouse will produce the AP1000 plant safety commissioning schedule. This is a definitive record of requirements and evidence of the tests conducted in order to substantiate the claims and assumptions made within the plant safety case. The test results will demonstrate that the as-built plant is acceptable for safe operation.

The AP1000 commissioning strategy will be based on the following key objectives that will ensure the safe conduct of commissioning:

- Identify processes, systems, and equipment to be commissioned, as well as their interfaces, safety functions, and performance requirements.
- Identify processes, systems, and equipment that cannot be safely commission tested, and ensure that an appropriate justification for not undertaking commissioning tests and inspections is provided.
- Describe commissioning tests, including statements that the tests will demonstrate the required performance of the plant and meet their safety justifications in accordance with the safety category and classifications.
- Identify the limits and conditions of plant operation so that operating rules can be established in accordance with SLC 23 (Reference 7.16).
- Make reference to the operating conditions and limits and OIs that will apply to the commissioning stage in accordance with SLC 24 (Reference 7.17).
- Make reference to the stages into which the commissioning will be split (e.g., phase permissioning hold points) (see Figure 7-4 as an example).
- Align with the site licensee safety management arrangements for commissioning.
- Define the following aspects, with respect to safety management during commissioning:
  - Linkages to and interfaces with relevant safety documentation, e.g., fault schedules, probabilistic safety assessment design justification reports, and PCSR.
  - Interfaces between organisations participating in the commissioning programme.
  - Ownership and responsibility (e.g., from the site owner, site licensee, construction organisation, and commissioning organisation), whilst at all times ensuring that the site licensee retains overall responsibility for safety and the environment.

  - Discharge of responsibility for safety as a result of completed tests.
  - Handover arrangements for the transfer of responsibilities between the construction organisation and the commissioning organisation.

- Demonstrate that sufficient and appropriate commissioning tests have been undertaken to confirm the assumptions made in the safety case.
- Provide verification that the plant has been constructed in accordance with the design intent.

7.5.4 Phase 1: Initial Plant Testing

Phase 1 commissioning starts with the inspection, setting to work of support systems, and component-level activities such as instrument calibration, setting to work motorised valves, motors, and pumps.

The intent is to define activities that will be undertaken to verify that the as-built system conforms to the design features and characteristics defined in the design description of the plant. Construction and installation tests are performed to verify the adequacy of construction, installation, and preliminary operation of components and systems. Various electrical and mechanical tests are performed, including cleaning and flushing, hydrostatic testing, electrical checks, operability checks, and instrumentation calibration. The completion of the construction and installation test programme demonstrates that the system is ready for pre-operational testing.

7.5.5 Phase 2: Cold Functional Testing

During Phase 2 testing, whole systems are run for the first time (for example, the flushing of pipework systems). Typically the integrity of the containment system is proven and an integrated leak test is performed to demonstrate the leakage integrity of the primary containment to withstand the calculated design basis accident (DBA) peak pressure. Another example is that the cold pressure testing also takes place for the rest of the reactor primary circuit.

7.5.6 Phase 3: Hot Functional Testing

This involves the plant being run as a totally integrated system for the first time with the whole of the nuclear steam supply system (NSSS) intact, and with all the necessary supporting nuclear and conventional plant systems commissioned but without fuel in the core. The reactor coolant system (RCS) will be progressively run up to full operating conditions from energy input from the reactor coolant pumps (RCPs).

The main purpose of the pre-operational testing is to operate the primary circuit at temperature in order to pre-condition the internal surfaces of the reactor vessel and primary circuit. During the test conditions all reactor protection functions are gradually introduced. For example, during the gradual heat up and subsequent cool-down, thermal expansion and vibration of pipework is measured to confirm compliance with the plant design and demonstrate that systems operate within design limits. Additionally, integrated operation of plant systems under pre-core hot functional conditions is demonstrated

This phase can prove useful for the staff of the licensee in helping to gain operating experience alongside Westinghouse personnel with the plant under hot conditions. This is

part of the knowledge transfer process and helps to demonstrate compliance with the licensee's arrangements for SLC 10 and SLC 12 (References 7.18).

7.5.7 Phase 4: Preparations for Fuel Load

This is the final commissioning of the systems that support fuel loading. Before the receipt of fuel; construction, preoperational testing, flushing and room turnover are sufficiently completed to successfully receive and store the fuel assemblies needed for initial core load. Conditions in the auxiliary building fuel handling area are made ready to prevent damage to the fuel assemblies. There is a turnover of the fuel handling machine, rail car bay crane and cask crane, as well as complete preoperational testing.

Component testing, flushing and preoperational flow testing on systems that interface with the spent fuel pool prior to fuel receipt are a necessity. Once these are complete, necessary controls are put into place to ensure the spent fuel pool remains dry until initial core load. The spent fuel pool could serve as a storage function before fuel load. The use of the spent fuel pool in this function depends on the number of fuel assemblies that the new fuel storage vault holds.

Due to the introduction of nuclear fuel on site, zones will be established and maintained for security, access, administrative controls and Foreign Material Exclusion (FME).

Prior to fuel receipt, the operators are trained to receive, inspect, and place nuclear fuel. Phases 3 and 4 are the pre-operational testing of the plant, some of which only apply to the first AP1000 plant tests (see Table 7-1). It is anticipated that first plant tests will have been performed outside the UK.

7.5.8 Phase 5: Fuel Load

Fuel assemblies together with inserted components (control rods, burnable poison assemblies, and primary and secondary neutron sources) are placed in the reactor vessel, according to an established and approved sequence.

During and following the insertion of each fuel assembly, until the last fuel assembly has been loaded, the response of the neutron detectors is observed and compared with previous fuel loading data or calculations to verify that the observed changes in core reactivity are as expected. Specific instructions are provided if unexpected changes in reactivity are observed.

Because of the unique conditions that exist during initial fuel loading, temporary neutron detectors may be used in the reactor vessel to provide additional reactivity monitoring. Credit for the use of temporary detectors may be taken in meeting Technical Specification requirements on the number of operable source range channels.

Once fuel loading is complete, the upper reactor internals are loaded and the integrated head package moved into position. Once all the head closure bolts are tightened, the reactor is in Mode 5.

7.5.9 Phase 6: Pre-Critical and Low-Power Physics Tests

During this phase the fully assembled core is exposed to the full RCS conditions taking the plant from Mode 5 (cold shutdown, ambient conditions) to Mode 2 (startup).

Surveillance test procedures are demonstrated at this time and further analysis of pipework thermal growth and vibration is performed.

The reactor power is gradually increased but remains under 5 percent, and physics tests are undertaken.

Following criticality and prior to operation at power levels greater than 5 percent of rated power, physics tests are performed to verify that the operating characteristics of the reactor core are consistent with design predictions. During these tests, values are obtained for the reactivity worth of control and shutdown rod banks, isothermal temperature coefficients, and critical boron concentration for selected rod bank configurations.

Other tests at low power include verification of the response of the nuclear instrumentation system and radiation surveys.

For each test, the test procedure presents a general description for the test objective, test prerequisites, test description, and test performance criteria, where applicable. In describing a test, the operating and safety significant characteristics of the plant to be tested and evaluated are identified.

Following successful completion of the initial criticality tests, low-power tests are conducted, typically at power levels less than 5 percent, to measure physical characteristics of the reactor system, and to verify the operability of the plant systems at low-power levels.

7.5.10 Phase 7: Raise Power

The overall objective of the raise power phase is to demonstrate the safe and reliable operation and performance of the plant under both steady-state and transient conditions. It is also designed to verify the adequacy of the operating procedures for normal and abnormal operating conditions.

Major transient tests such as reactor trips and load rejections are carried out during this phase with a variety of procedures being carried out on the conventional plant and systems.

After low-power testing is completed, testing is performed at specified elevated power levels to demonstrate that the plant operates in accordance with design during normal steady-state operations.

During power ascension, tests are performed to obtain operational data and to demonstrate the operational capabilities of the plant.

7.5.11 First-Time-Only Tests and the First Three Plant Tests

The AP1000 plant as a standard design will undergo the same test programmes for the same SSCs in some key areas with only the local environment changing between sites. It is anticipated that first-time-only and the first three plant tests will be performed on plants outside the UK and will not be performed on the UK AP1000 plants. These tests are shown in Table 7-1.

7.6 Examination, Maintenance, Inspection, and Testing

7.6.1 Introduction

The purpose of the AP1000 UK Safety Categorisation and Classification Methodology (Reference 7.20) is to categorise safety functions required to maintain safety in the event of specific fault sequences, identifying which SSCs deliver these safety functions, and classifying them accordingly.

The classification scheme helps to define the quality management requirements placed on SSCs during the design, manufacture, commissioning and through-life operations, including EMIT, as part of a comprehensive preventative maintenance programme. In particular, the safety class of a given SSC can be used to determine what maintenance considerations are appropriate to that SSC to ensure it operates on demand.

The AP1000 UK Safety Categorisation and Classification of Systems, Structures and Components (see Appendix 15A) forms the basis of the engineering schedule for the AP1000 plant, providing the classification of the SSCs based on their safety function category. Information identifying how the safety category and safety class are determined is presented in Chapter 5.

Class 1 passive systems are the principal means of providing Category A safety functions and must have the highest levels of integrity, performance, and availability. The EMIT provisions identified in the engineering schedule for such SSCs will be commensurate with this safety importance. The same applies to the Class 1 systems that provide supporting functionality, such as Class 1 power supplies and C&I.

The active systems that are claimed to provide backup or alternative means to the passive systems are not Class 1 systems; they are appropriately classified within the EMIT programme. This will ensure these systems operate on demand and underpin the deterministic and probabilistic claims identified within the safety case.

7.6.2 Examination, Maintenance, Inspection, and Testing Process

It is a requirement that the licensee must provide EMIT schedules in accordance with SLC 28 (Reference 7.12) to ensure that appropriate maintenance is provided to ensure nuclear safety functions are met on demand.

The EMIT process will be part of the site licensee management arrangements supported by the licensee quality programme that will interface with the Westinghouse QMS.

This will ensure that appropriate instructions and methods have been followed in support of the EMIT programme and that these instructions and methods remain valid during any changes or modifications throughout the plant life cycle.

The instructions and methods for carrying out EMIT will describe the criteria for identifying the safety significance of all plant items and systems, and identify the safety significance of all examination, inspection, maintenance, and test activities.

The EMIT schedule may comprise a single document, but most likely will contain several parts. If this is the case, the schedule should be produced in a tiered format, with a hierarchy indicating the specific nuclear safety significance of the maintenance activities. The engineering schedule in Appendix 15A will be further developed during site-specific licensing to form the basis of the EMIT schedule.

Some activities specified in the EMIT schedule will only be able to be carried out during shutdown periods. On this basis, the maximum operating period between shutdowns will need to be identified and any tolerances for the EMIT activity to be included in the schedule. All EMIT activities will be undertaken by a SQEP.

Intervals in the EMIT schedule of work should be carried out in accordance with the specified time interval, to ensure reliability of the SSCs demanded within the safety case.

If any Class 1 SSC is determined not to have operated on demand or identified as faulty during maintenance activities then this occurrence must be reported and investigated by the licensee under their arrangements made to satisfy SLC 7 (Reference 7.21). In addition if this occurs during the commissioning phase, Westinghouse will also be required to be involved in the investigation process.

Records of any EMIT will be made and kept by the licensees in accordance with their arrangements. Any such EMIT undertaken by Westinghouse will be recorded, and the information will be provided to the licensees.

7.6.3 Examination, Maintenance, Inspection, and Testing Schedules

EMIT schedules are to be prepared by the site licensee on the premise that the plant and equipment in use will retain the reliability claimed in the safety case, thus ensuring that the risk of failure associated with the process is kept ALARP. The reliability of the AP1000 plant will be maintained by a process of planned maintenance procedures, including replacement, based upon a sound understanding of the plant and equipment's ageing mechanisms supported by the programme of EMIT.

The EMIT programme should be implemented in accordance with the requirements of the maintenance schedule and related procedures and instructions produced by the site licensee.

EMIT activities undertaken on SSCs with nuclear or radiological implications will be identified in the plant maintenance programme and classified according to the methodology described earlier. Each task in the schedule will be classified according to its nuclear safety significance using the classification scheme. This is necessary to ensure that such equipment is maintained to appropriate standards, thereby providing confidence that the SSC will fulfil its safety functional requirements if called upon, and the plant remains within its operating limits and conditions.

EMIT schedules will be written by the site licensee, with guidance from the design engineers (Westinghouse and other suppliers). At a system level, the items that need to be included in the EMIT schedule are those on which the nuclear safety case imposes performance and/or availability requirements.

It is a requirement that the EMIT schedules should take into account the requirement that the redundancy or diversity assumed in the safety case remains consistent with its nuclear safety significance based on the classification scheme, even whilst the corresponding system is being maintained or tested, in some cases during plant operation.

Generically the EMIT schedules will be developed from the testing undertaken during plant startup and commissioning. They will be maintained throughout the operational phases of the plant remaining a "live" document. This in turn being updated as changes and modifications are made to the plant.

7.7 Operational Phase

The safety management during the operation of the plant will be the responsibility of the licensee within the operating organisation. The primary safety management responsibility of the licensee is the protection of the public and the operators from harm arising from ionising radiation or other causes. The licensee will operate and maintain the plant in accordance with the licence granted by the Office for Nuclear Regulation (ONR) and will comply with relevant UK legislation.

However, in moving into the operational phase, Westinghouse will be involved with the licensee in providing guidance and information on what may be included in their arrangements and procedures. Further discussion is provided in the Plant Life Cycle Safety Report (Reference 7.1, Section 9), which is summarised in the following sections.

7.7.1 Operating Instructions

Where appropriate, written OIs will be provided to the licensee for operations that may affect safety during all phases of the plant life. These will be written, validated, and approved by an SQEP. Such information will aid the knowledge transfer process. Specifically these will include the OIs necessary to ensure that the limits and conditions identified in the safety case remain valid. These instructions are expected to be vast and very comprehensive.

Any records of training or demonstration that the OIs have been followed will be in accordance with the licensee's arrangements and where appropriate integrated into Westinghouse's processes.

7.7.2 Manning Levels

Westinghouse will provide recommended information relating to the preparation and plans for the operation of the AP1000 plant to the licensee. The purpose is to provide reasonable assurance that the licensee will establish and maintain manning levels and technical competences that reasonable assurance of adequate protection of public health and safety is provided. The licensee will demonstrate to the ONR that suitable arrangements are in place for compliance to the requirements of SLC 36 (Reference 7.22).

Such manning levels will also include those levels needed to respond to an onsite and offsite emergency.

Where there is reliance upon the services of Westinghouse contracted personnel, the structure of that part of Westinghouse, the authorities, responsibilities, and interfaces with the licensees will be provided, and suitable instructions and procedures will be established.

7.7.3 Training

Personnel who have responsibility for an action that may affect safety have to be adequately trained for that purpose. This is a requirement not only of the site licence, but also other UK legislation, including The Ionising Radiations Regulations (IRRs) (Reference 7.23) and Management of Health and Safety at Work Regulations (Reference 7.24).

Westinghouse identifies the need to ensure that all people employed on behalf of Westinghouse are suitably qualified (for example, trained) and experienced for the tasks they are to perform. The appropriate Westinghouse procedures relating to training will also be applied, as discussed in Chapter 3.

In addition, Westinghouse will align their training requirements with the arrangements of the licensee and align the procedure for maintaining appropriate training records with those of the licensee. Implementation of the above arrangements will ensure that all personnel associated with the construction, installation, and commissioning of the AP1000 plant will be SQEPs.

Where appropriate, Westinghouse will provide training to licensee personnel in the safe operation and maintenance of the AP1000 plant to assist the licensee in accordance with its requirements to ensure that only SQEPs perform any duties that may affect safety. This is also an essential part of the knowledge transfer process and ensures that the licensee can demonstrate its ability to act as an IC and as a DA.

In addition, the licensee will be expected to identify DAPs to either carry out or directly supervise operations of the highest safety significance. If required, Westinghouse will assist in the training of DAPs.

7.7.4 Emergency Procedures and Services

Westinghouse states that all facilities must be operated within their safe operating parameters so that they do not present a hazard to employees, the public, or the environment. In addition, all plants and facilities require an appropriate emergency plan to control and mitigate the impact of unforeseen circumstances. Procedures will be developed to establish an integrated emergency response and crisis management at the project level. The licensee is responsible for making and implementing emergency arrangements and will ensure that Westinghouse's procedures align. The procedures will ensure suitable consideration has been given to compliance with the Radiation (Emergency Preparedness and Public Information) Regulations (REPPIR) 2001 (Reference 7.25) and Control of Major Accident Hazards (COMAH) Regulations (Reference 7.26).

These procedures address the implementation of an effective response to any minor onsite incident ranging through to a major offsite incident. Where appropriate, external bodies whose assistance, cooperation, or services are required to fulfil those arrangements will be consulted during the preparation.

Further information regarding emergency preparedness is provided in Chapter 25 and refers to the need for both an onsite and an offsite emergency plan and the emergency response facilities.

7.7.5 Radiological Protection

The AP1000 design incorporates radiation exposure reduction principles to keep the worker and public doses ALARP. Chapter 24 discusses the normal operational radiological aspects of the design and operation of the AP1000 plant.

7.7.6 Nuclear Material Arrangements

Prior to any active commissioning, as part of the licensing requirements, the licensee must have adequate arrangements in place to ensure that the introduction and storage of any nuclear materials is controlled (Reference 7.27). If specified by the ONR, consent must be obtained prior to any nuclear matter being brought on to the site. Such arrangements must be in place for the operations with new and spent fuel and radioactive waste. Such arrangements will include ensuring that there is an adequate safety case, suitable records of the nature of the material, and its storage location on plant. Such facilities are required to have appropriate criticality safety controls in place. This is normally achieved using criticality certificates that detail the safety measures in place to prevent an accidental criticality outside of the reactor

core. Where appropriate, the European Atomic Energy Community (EURATOM) will be informed of any imports/exports, and arrangements will be expected to be in place for EURATOM verification. While this is clearly a requirement of the licensee, Westinghouse will support the licensee as necessary to ensure compliance to these requirements during commissioning activities.

7.8 Ageing and Degradation

7.8.1 Introduction

Ageing management is defined as engineering, operations, and maintenance actions to control ageing degradation of SSCs within acceptable limits.

To provide for the timely detection and mitigation of ageing degradation of SSCs important to safety, NPP owners/operators should have in place a systematic ageing management programme, which takes account of regulatory policy and guidance.

Ageing management, as a part of its input to life cycle management, should consider the benefits to the plant of maintaining SSCs in good working order.

The AP1000 plant has been designed to operate for 60 years; this claim is to be justified within the safety case or relevant SSCs within the plant footprint will be identified that can be easily repaired in situ or replaced if they become obsolete. Consideration is given to the ageing process affecting the following:

- The SSCs that make up the primary and secondary circuits, for example, electrical and mechanical systems.

- The SSCs that make up the nuclear island (NI) facilities and supporting auxiliary buildings, for example, the civil structures.

All the SSCs with a nuclear safety function are maintained within the EMIT programme, and any other supporting SSCs will be maintained via the licensed site maintenance plan. The EMIT programme will ensure the required reliability of those SSCs with a safety function to operate on demand, but eventually there will be a time when an SSC can no longer be maintained or repaired, i.e., it is beyond its operable life. This is also applicable to those systems that do not have a direct nuclear safety function but would impact nuclear safety if they failed.

The site licensee should consider within its management arrangements how stores will be procured to avoid obsolescence and how modifications to replace failed or faulty parts will be undertaken. This impacts the stores' policy and whether like-for-like parts will continue to be available over the plant's 60-year life cycle.

Consideration will also be required of the safety implications of new parts and modifications, along with how they will be assessed to confirm safe operation within the existing plant.

This section of the PCSR identifies how the ageing process is justified within the safety case and the Westinghouse approach to justifying the claim for a 60-year design life of the plant.

7.8.2 Background

Westinghouse has designed, developed, and manufactured nuclear facilities since the 1950s. Beginning with the world's first large central station nuclear plant (Shippingport), which produced power from 1957 until 1982, Westinghouse has designed and delivered more than 100 commercial NPPs worldwide, including the design of Sizewell B, with a combined electrical generating capacity in excess of 90,000 MW. The design of the AP1000 plant is therefore supported by decades of successful plant operating experience that have accumulated many operating years without significant issue. Westinghouse has substantial proven experience, knowledge, and capability to design, manufacture, and furnish technical assistance for the installation, startup, and service of NPPs.

The AP1000 plant is of similar design to that of the earlier Westinghouse designs that use similar proven materials and manufacturing processes in the construction and commissioning of the plant.

Records of safe operating experience are insufficient to directly support reliability claims for a new build project in the UK, but they provide confidence that similar materials, standards, and codes have been successfully operating in existing plants. Materials in existing plants will experience similar behaviour when exposed to ageing and degradation mechanisms in the AP1000 plant. Understanding the in-service performance of these materials has aided design, manufacture, and the management and mitigation of through-life ageing and degradation issues in the AP1000 plant.

7.8.3 Methodology

A structured safety argument to demonstrate that the plant is fit for purpose for the required design lifetime of 60 years is presented in Volume 4 of the PCSR.

The structural integrity of large vessels and components is substantiated in Chapter 20. A four-legged approach is used to justify the incredibility of failure argument composed of the following:

- Leg 1 Interpolation/Extrapolation of Experience – Good Design and Manufacture
- Leg 2 Functional Testing
- Leg 3 Failure Analysis
- Leg 4 Forewarning of Failure

Compliance with the appropriate American Society of Mechanical Engineers (ASME) standards for Class 1 components provides the basic demonstration of fitness for purpose and is generally inferred as providing substantiation for a component frequency of failure of 10^{-5}/yr.

Additional qualitative arguments are presented in the component safety reports in Chapter 20 to demonstrate evidence of defence in depth and to substantiate component reliability commensurate with the classification for the lifetime of the SSCs.

This approach is used for other items, namely the electrical and mechanical systems. Additional high-integrity SSCs requiring further justification have further supplementary measures to ensure high quality.

7.8.4 Codes and Standards

The plant is designed, fabricated, and installed in accordance with the codes, standards, and regulations identified in Volume 4 of the PCSR. Complying with such proven and established codes, standards, and regulations minimises the level of design and manufacturing uncertainty. For example, compliance with the ASME Boiler and Pressure Vessel Code provides assurance over a wide range of issues from material procurement, component design, selection of manufacturing consumables, qualification of welders, specification of heat treatment, manufacturing quality checks and nondestructive examination, testing, installation, pre-service inspection (PSI), and in-service inspection (ISI) requirements (see Chapter 20). The extensive body of experience that is embodied within the ASME Code and the successful operation of a significant number of pressure vessels (both nuclear and non-nuclear) means that compliance with the code provides assurance that the vessel reliability will remain high for the design life of the component.

Similarly this level of assurance is claimed for both the primary and secondary SSCs within Volume 4 of the PCSR.

7.8.5 Component Manufacture

The quality of the component manufacture makes a significant contribution in ensuring that the AP1000 plant materials maintain proven service performance. The materials are selected to meet or exceed ASME or equivalent specifications based on the following:

- Tight control on chemical composition is enforced to minimise the effects of irradiation embrittlement or thermal ageing to ensure that materials remain ductile when stressed.

- Materials are compatible with each other and with the environment and are resistant to environmental degradation over the life of the plant. Degradation characteristics are known and understood.

- Material testing is sufficient to demonstrate that the material properties are compliant with the relevant specifications.

The materials selected for use in the plant will be compatible with the full range of internal and external environmental conditions that may be encountered over the plant life and are predicted not to degrade to an unacceptable degree in that time. These environmental conditions include temperature, humidity, radiation, chemistry of fluid or materials in contact, and other external conditions that may affect the performance of a material.

To ensure the selected materials support the design life of the plant, the AP1000 equipment qualification programme is in place that relies on the Institute of Electrical and Electronics Engineers (IEEE) 323 (Reference 7.32) definition for design life.

7.8.6 Ageing Evaluation Programme for Safety-Related Electrical and Mechanical Equipment

The Ageing Evaluation Program describes methods for addressing potential age-related, common-mode failure mechanisms used in AP1000 plant equipment qualification programmes. These programmes make use of guidance from IEEE 323 and IEEE 344 (Reference 7.32 and 7.33). The approach conforms to current industry positions and makes maximum use of available data and experience in the evaluation, test, and analysis of ageing mechanisms. Specific treatment of seismic qualification, part of the qualification test sequence recommended in IEEE 323, is addressed in IEEE 344.

As stated in IEEE 323, ageing of Class 1 equipment during normal service is considered an integral part of the qualification programme. The objective is not to address random age-induced failures that occur in-service and are detected by periodic testing and maintenance programmes. The objective is to address the concern that some ageing mechanisms, when considered in conjunction with the specified design basis events (DBE), may have the potential for common-mode failure.

The approach places primary emphasis on common-mode failures due to enveloping DBEs. For example, reasonable assurance against common-mode failures being induced because of a loss of heating, ventilation, and air conditioning (HVAC) is provided by adequate design, normal maintenance, and calibration procedures. The objectives of the ageing evaluation programme are:

- To establish, where possible, the effects of the degradation due to ageing mechanisms that occur before the occurrence of an accident, when equipment are called upon to function.

- To provide increased confidence that equipment perform their safety function under the specified service condition.

The general approach to addressing ageing allocates equipment to one of two subprogrammes (A or B).

- **Subprogramme A** – Includes electrical equipment required to perform a safety function in a high-energy line break (HELB) environment. For this equipment an ageing simulation is included as part of the equipment qualification test sequence. The equipment is energised during the ageing simulation.

- **Subprogramme B** – Includes equipment required to mitigate HELBs but that, due to its location, is isolated from any adverse external environment resulting from the accident. For equipment in Subprogramme B the single DBE capable of producing an adverse environment at the equipment location is the seismic event. Ageing, for Subprogramme B, is not included in the equipment qualification test sequence. Significant ageing mechanisms are determined by evaluation of available test data. Generally, this data is from separate programmes conducted to demonstrate that aged components continue to meet manufacturer's performance specifications under applicable seismic DBE conditions and that seismic testing of unaged equipment is not invalidated by anticipated ageing mechanisms.

IEEE 627 (Reference 7.34) describes the methodology that has been adopted to qualify equipment. The two standards primarily used to demonstrate compliance with this standard are IEEE 323 and IEEE 344.

7.8.7 In-Service Inspection and Testing

In order to provide assurance the electrical and mechanical systems remain operable within the design life and to ensure that defects will be detected prior to becoming a threat to the life cycle of the plant, an extensive programme of ISI and in-service testing (IST) will help to identify degradation long before failure.

Pre-service inspection data and ISI data from other sites enables judgement of in-service defects and helps plan maintenance to extend the lifetime of the plant.

ISI and IST is the preferred method of forewarning possible failure of plant SSCs. The role of ISI and IST is to detect defects before it becomes problematic and enable the operator to take remedial action.

7.8.8 Civil Engineering Structures

The NI structures house SSCs that provide the principal means of delivering Category A safety functions. These functions must be delivered to achieve and maintain a nonhazardous, stable state for at least 72 hours of the initiating event for a DBA throughout the design life of the plant. Failure of these SSCs has the potential to lead to core damage or activity release to the environment outside design basis limits. Thus, the civil engineering structures composing the NI are all designated as A1 (Category A safety function and Class 1 contribution to this safety function.). They are also seismic Category I (see Section 5.8). Based on this classification the civil engineering structures are constructed to the highest quality standards to ensure the AP1000 plant maintains proven service performance. The materials are selected to meet or exceed specifications, and designed, fabricated, and installed in accordance with the codes, standards, and regulations identified in Volume 4 of this PCSR. Complying with such proven and established codes, standards, and regulations minimises the level of design, construction, and manufacturing uncertainty.

Selected materials are compatible with each other and with the environment and are resistant to environmental degradation over the life of the plant. Degradation characteristics are known and understood and will be suitable to meet decommissioning requirements at the end of plant life.

Materials testing based on existing Westinghouse operating plants can be used to demonstrate that the construction material properties are compliant with the relevant specifications identified in Volume 4 of this PCSR.

7.9 Decommissioning

7.9.1 Introduction

The objective of this section is to summarise the aspects of the AP1000 plant that will facilitate safe decommissioning at the end of the plant operational life and identify that the claims made regarding decommissioning within the safety case can be adequately achieved.

The fundamental objective of decommissioning is to reduce the risks associated with the plant to an acceptable level. In order to achieve this end state, radioactive and conventional wastes must be removed from the site as far as reasonably practicable and/or to achieve the criteria agreed for delicensing in accordance with government policy. This objective includes the requirements to demonstrate that the doses to workers and the public will be ALARP, and that legislation under the Environmental Protection Act will be met using best available technique (BAT) to establish acceptable methods of decommissioning.

Although decommissioning is the last stage in the overall life cycle of a facility, decommissioning must be considered at the planning and design stages and also considered during any modifications to the plant.

SLC 35 (Reference 7.28) requires the licensee to make adequate arrangements for the safe decommissioning of the site, and these will need to accord with any relevant government policy. As part of this, a decommissioning programme to implement the decommissioning strategy will be required along with the decommissioning safety case.

Further decommissioning details and evidence to support the decommissioning strategy and end-of-life aspects of the plant are identified within Chapter 27. The main claims justified within the safety case regarding the decommissioning of the plant are the following:

- That the environmental impact of the plant during decommissioning will be minimised and will be within authorised limits and operational targets.
- That the plant design will allow for the proper management of radioactive waste and spent fuel.
- That the plant can be decommissioned safely.

These assumptions will be managed by the site licence holder in accordance with its own processes and procedures, and in accordance with relevant legislation and licence conditions. The site licence holders will have the responsibility for the final decommissioning plan.

7.9.2 Assumptions

With regard to decommissioning on the site, the following assumptions are made within the safety case:

- Irradiated fuel from the plant is stored on the originating site in an appropriate facility for the operating life of the plant. At the end of the operating life, a decision will be made whether to continue to store irradiated fuel onsite or to dispatch it to an appropriate final disposal repository.
- Operational intermediate-level waste (ILW) is conditioned into suitable final disposal packages. The ILW will be transported to an onsite ILW store, where it will be held in a passively safe condition until a national ILW repository becomes available. This is discussed further in Chapter 27.
- The generation of low-level waste (LLW) from site operations is managed using standard waste minimisation techniques. As required, LLW packages will be dispatched from the originating site to an appropriate final disposal repository.
- Three options exist for the decommissioning of the NPP: immediate decommissioning, delayed or safe store, and entombment.

7.9.3 Decommissioning Stages

Three stages of decommissioning are identified in Chapter 27. The three stages are based on International Atomic Energy Agency (IAEA) safety standards, and briefly described in Table 7-2.

7.9.3.1 Stage 1 Decommissioning

During Stage 1 decommissioning the first contamination barrier is kept as it was during operation, but the mechanical opening systems and penetrations are permanently blocked and sealed (valves, plugs). The containment building is kept in a state appropriate to the remaining hazard, and the atmosphere inside the building is subject to appropriate control. Access to the building is subject to monitoring and surveillance procedures. The unit is under surveillance and the equipment necessary for monitoring radioactivity, both inside and outside the plant, is kept in good condition. Inspections are carried out to check that the plant remains in good condition. If necessary, checks are carried out to see that there are no leaks in the first contamination barrier and the containment building.

During this period, the work described in Chapter 27 will be implemented. The principal activities to be accomplished during Stage 1 are the following:

- Removal of fuel from the reactor to the spent fuel pool.
- Removal of radioactive inventory from the reactor system and non-decommissioning service systems
- Contamination mapping of all radioactive and potentially radioactive systems to ensure that health and safety risks associated with maintenance and dismantling of the radioactive systems are understood and the decontamination and radioactive waste treatment options can be assessed
- Post-operational clean out and in-situ decontamination (e.g., chemical decontamination of active circuits) of non-decommissioning service systems and reactor system
- Establishment of new radiation control areas based on the above actions as work progresses
- Review configuration of existing service systems and plan for their use/modification in decommissioning activities
- Removal of fuel from the spent fuel pool to the spent fuel store.

7.9.3.2 Stage 2 Decommissioning

During Stage 2 decommissioning, the first activities associated with dismantling and removal of systems and components are carried out. The contamination barrier is reduced to minimum size and all easily dismantled parts are removed. The sealing of the barrier is reinforced by physical means and the biological shield is extended if necessary so that it completely surrounds the barrier.

Depending on the extent to which other equipment is removed or decontaminated, access to the former containment building can be permitted. The non-radioactive buildings or equipment in the plant may be converted for new purposes. Surveillance around the barrier

can be relaxed, but it is desirable for periodic spot checks to be continued as appropriate, together with surveillance of the environment. External inspection of the sealed parts should also be performed.

During this period, the work described in Chapter 27 will be implemented. The principal activities to be accomplished during Stage 2 are:

- Modification of existing service systems and installation of temporary service systems to meet decommissioning requirements (e.g., shielding, monitoring, ventilation systems)
- Removal of radioactive inventory, post-operational clean out and in-situ decontamination of spent fuel pool system and fuel handling system
- Dismantling of non-radioactive systems and non-decommissioning service systems
- Conversion of fuel handling building into an interim waste storage, decontamination, waste reduction, packaging, and processing area for ILW
- Contamination mapping, dismantling, decontamination and disposal of non-decommissioning service systems
- Contamination mapping of residual radioactive and potentially radioactive systems
- Radiation and security controls

7.9.3.3 Stage 3 Decommissioning

During Stage 3 decommissioning, all materials, equipment, and parts of the plant in which activity remains significant despite decontamination will be removed as active waste.

During this period, the work described in Chapter 27 will be implemented. The principal activities to be accomplished during Stage 3 are:

- Removal, dismantling, decontamination and disposal of the reactor pressure vessel (RPV) and internals
- Removal of radioactive inventory, post-operational clean out, decontamination, and dismantling and disposal of residual radioactive systems
- Contamination mapping of residual radioactive and potentially radioactive decommissioning service systems, the containment building and shield building
- Cutting, processing, and removal of active concrete in the containment building and fuel handling building
- Dismantling, decontamination, and disposal of the containment building, shield building, and turbine building
- Removal of radioactive inventory, post-operational clean out, decontamination, dismantling and disposal of radioactive decommissioning service systems (temporary service systems will be supplied as required)

- Dismantling and disposal of non-radioactive decommissioning service systems (temporary service systems will be supplied as required)
- Dismantling, decontamination and disposal of the auxiliary building
- Dismantling, decontamination and disposal of the radwaste building
- Dismantling, decontamination and disposal of the temporary decommissioning service systems, waste water system, diesel generator building and annex building
- Dismantling, decontamination and disposal of the temporary decommissioning facility

The stages may be carried out by rapidly progressing from one stage to the next one, or may be carried out over a prolonged period. It is recognised that spent fuel requires considerable time to cool and that long-term storage will be required with additional time required for decommissioning the spent fuel storage facilities.

The plant and site are cleared for unrestricted use. From the point of view of radiological protection, no further surveillance, inspection, or tests will be necessary. In some cases, the whole plant, including inactive components, may be dismantled to make room for a replacement facility or other usage.

Decommissioning of Waste Stores

The ILW store design life is substantially longer than the power generation facility and as such will be a standalone structure supported by its own services and utilities. If the national ILW repository is available before end of AP1000 operations, ILW decommissioning waste could be shipped direct to the repository without interim storage onsite. Having the national ILW repository available before the end of AP1000 operations will also allow the decommissioning and dismantlement of the onsite ILW store using the decommissioning facilities created for the AP1000 plant. Once all the stored waste packages have been removed from the ILW store to offsite storage (national ILW repository or other appropriate storage facility) the building can be decommissioned.

The onsite spent fuel store will be decommissioned following the transfer of stored spent fuel to the national HLW repository (once available). On site storage up to 160 years after plant start up may be required to allow all the fuel to decay before shipment to the national HLW repository.

7.9.4 Site End Point

It is expected that the intended site end point and the subsequent management of contaminated land, if appropriate, will be addressed by the site licensee as part of their update of the decommissioning strategy. One decommissioning objective should always be to remove hazards so that the site does not present an unacceptable level of risk to human health or the wider environment. The final site end point will depend on the potential future use of the site.

The following is an example of one desirable site end point:

- Active materials will be decontaminated and removed.
- Structures, if present, will be deplanted and demolished during final site clearance.

- Buildings will be removed down to a depth of 1 m below ground level.
- Roads, car parks, and underground services will be removed.
- Active drains and outfalls will be removed. Foul and surface water drains will be removed if less than 1 m below ground level.
- Basements, if present, will be demolished to 1 m below ground level, and any remaining subsurface structures punctured to assist drainage.
- Land requiring remediation will be identified and treated appropriately.
- Surveying and sampling will be performed to demonstrate that the land is:
  - Suitable for delicensing in accordance with current regulatory guidance (Reference 7.29).
  - Not considered contaminated land as per the current regulations.
- Ground will be appropriately landscaped and land drains installed, if required.

7.9.5 Differing Approaches to Decommissioning

The IAEA have recognised the following three primary decommissioning strategies in developing safety standards:

- **Immediate Dismantling** – Dismantling commences soon after shutdown of the plant (typically within 5 years) with radioactive material above a specific level being removed. This strategy does not allow for any significant decay of radionuclides.
- **Deferred Dismantling or Safe Enclosure (Safe Store)** – Those parts of the facility containing radioactivity are processed or brought into a condition such that they can be stored and maintained in a safe manner (e.g., liquids are drained from the system and irradiated fuel and operational waste materials removed). The facility is placed in long-term storage (e.g., 50 years) prior to later dismantling. This option allows for decay of radionuclides.
- **Entombment** – As with the deferred dismantling option, liquids and waste are removed. The remaining radioactive material is encased onsite (normally in concrete). Essentially, the site becomes a near-surface waste repository.

The nature of the AP1000 design is amenable to all three options due to the fact that it is based on a modular build strategy that naturally lends itself to the immediate dismantling option. This makes decommissioning easier as these modules can be removed (and contained if necessary) to the waste processing area for further dismantlement, decontamination, packaging, and disposal.

7.9.6 Decommissioning Concept

The UK AP1000 NPP Decommissioning Plan (Reference 7.31) provides an outline decommissioning plan that demonstrates the technical and practical feasibility of one method by which the AP1000 plant can be safely decommissioned. The outline plan provides assurance that decommissioning can be safely accomplished within the currently acceptable

limits of personnel exposure to radiation and will not result in any pollution impact on the decommissioned site or wider environment. Further evidence that the safety case can be justified is given in Chapter 27.

The outline plan is based on an immediate dismantling option and adopts a staged approach, which can be seen in Table 7-2.

This outline strategy assumes that, prior to Stage 1 works commencing, temporary buildings will be provided for processing and storage of ILW and LLW generated by dismantling large-scale components.

The outline plan forms the basis for a detailed decommissioning strategy to be produced in parallel with the decommissioning safety case by the licensee and developed throughout the life cycle of the facility. As the end of the operational lifetime of the facility is approached, a detailed decommissioning plan will be produced along with the safety case. This detailed plan will expand and improve upon the outline plan and will reflect the BAT.

7.10 Health and Safety Arrangements for Project Execution

This chapter focuses on the nuclear safety aspects of the project. However, there are many other aspects of safety that can have impact on the nuclear safety of the facility. Thus, it is considered prudent to provide a brief explanation of the expectations and standards on other safety aspects that Westinghouse expects to be implemented during the construction phase. These topics are considered in more detail in the Plant Life Cycle Safety Report (Reference 7.1).

The construction scope for the AP1000 plant will typically be performed by a Westinghouse partner that is a competent and experienced architect-engineer (AE)/contractor. The AE will be expected to demonstrate its safety performance record on similar job sites and the content and application of its EHS Manual.

It is expected that the AE will develop a site-specific EHS programme to govern all aspects of protecting the environment and the health and safety of project/site employees during construction. The arrangements will have to be acceptable to the licensee and reflect their requirements.

The areas expected to be covered will include, but are not exclusive to, the following:

- Onsite medical services
- Construction fire prevention programme
- Appropriate site and material security programme
- Accident reporting and investigation to input into the continual improvement programme
- Work planning, including risk assessments, permit to work systems, safe systems of work, and method statements
- Recognition and rewards programme to provide positive reinforcement for behaviours and activities that support a strong, effective health and safety programme
- Accountability on an individual and project level

- Worker participation to ensure that both management and safety representatives encourage participation by the workforce in all aspects of programme implementation
- Audits and assessments
- Environmental safety

The UK AP1000 Environment Report (Reference 7.30) has been prepared to consolidate and summarise the environmental information presented. Other environmental aspects are covered in Chapter 26.

Table 7-1. First-Time-Only Test and the First Three Plant Tests(1)

First-Time-Only Plant Tests
In-containment refuelling water storage tank heatup test
Pressuriser surge line stratification evaluation
Reactor vessel internals vibration testing
Natural circulation tests
Rod cluster control assembly out of bank measurements
Load follow demonstration
First Three Plant Tests
Core makeup tank heated recirculation tests
Automatic depressurisation system blowdown test

Note (1) All of these tests will be performed on AP1000 plants before the UK AP1000 plants startup and as a result will not have to be performed on the UK AP1000 plants.

Table 7-2. Decommissioning Stages and Estimated Timeline

Stage 1	Stage 2	Stage 3
Approx. 10 years	**Approx. 6 years**	**Approx. 6 years**
Removal of fuel from the reactor to the spent fuel pool	Modification of existing service systems and installation of temporary service systems to meet decommissioning requirements	Removal, dismantling, decontamination and disposal of the RPV and internals
Removal of radioactive inventory from the reactor system and non-decommissioning service systems	Removal of radioactive inventory, post-operational clean out and in-situ decontamination of spent fuel pool system and fuel handling system	Removal of radioactive inventory, post-operational clean out, decontamination, dismantling and disposal of residual radioactive systems
Contamination mapping of all radioactive and potentially radioactive systems	Dismantling of non-radioactive systems and non-decommissioning service systems	Dismantling and removal of remaining non-radioactive systems
Post-operational clean out and in-situ decontamination of non-decommissioning service systems and reactor system	Conversion of the fuel handling building into an interim waste storage, decontamination, waste reduction, packaging, and processing area for ILW	Contamination mapping of residual radioactive and potentially radioactive decommissioning service systems, the containment vessel (CV) and shield building
Establishment of new radiation control areas based on the above actions as work progresses	Contamination mapping, dismantling, decontamination and disposal of non-decommissioning service systems	Cutting, processing, and removal of active and clean concrete in the CV and fuel handling building
Review configuration of existing service systems and plan for their use/modification in decommissioning activities	Contamination mapping of residual radioactive and potentially radioactive systems	Dismantling, decontamination and disposal of the CV, shield building and turbine building
Removal of fuel from the spent fuel pool to the spent fuel store	Radiation and security controls	Removal of radioactive inventory, post-operational clean out, decontamination, dismantling and disposal of radioactive decommissioning service systems
		Dismantling, decontamination and disposal of the auxiliary building
		Dismantling, decontamination and disposal of the radwaste building

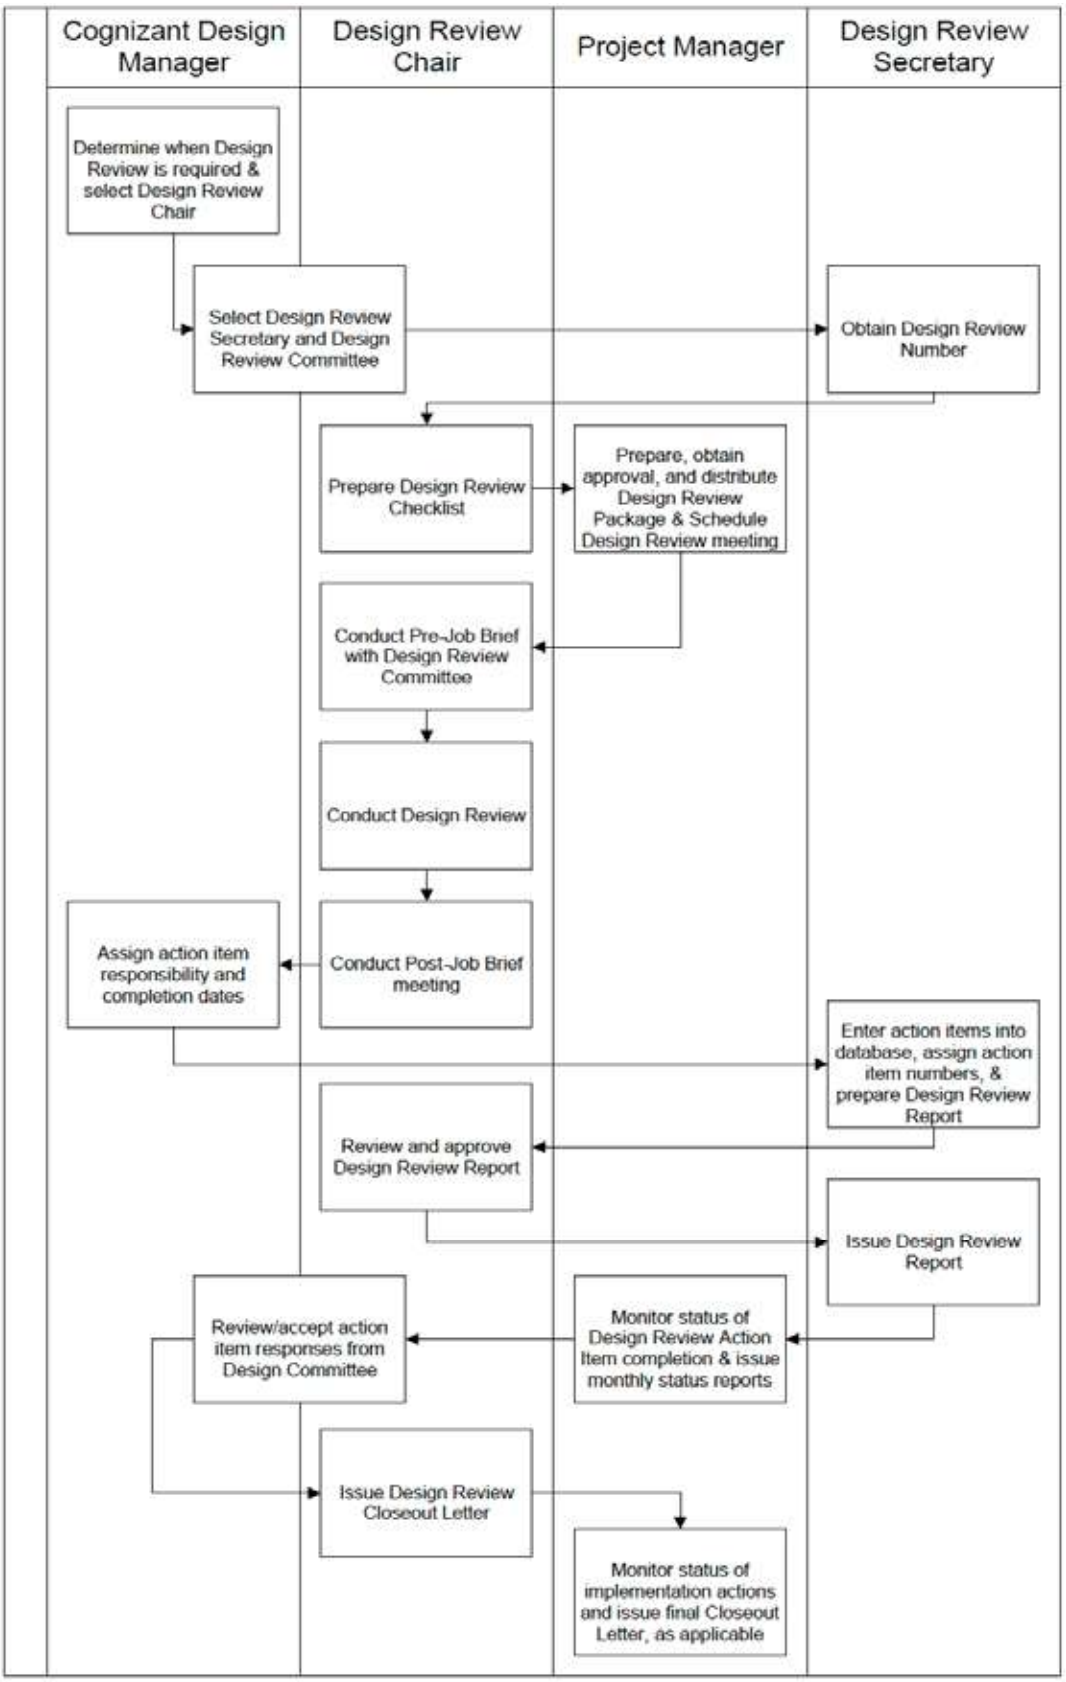

Figure 7-2. Design Review Process

Level 1	Level 2	Level 3
		Construction facilities shall be subject to production readiness inspection. This shall include assessment of facilities, processes and any hazards that the facilities present to the AP1000 plant.
		Information provided for construction shall have been subject to review.
	Construction process inputs are defined and controlled	All construction processes, including storage, handling, and manufacture shall be compatible with the achievement of design intent.
		There shall be a process in place whereby the construction team can query the design.
		Construction procedures shall be subject to an appropriate level of review and approval. This shall involve adequate arrangements for suitable training and audit of training records.
		Adequate review point arrangements shall be in place, based on the stages of construction, to gain the necessary assurance of construction quality.
The AP 1000 plant is constructed in accordance with the design intent.	Construction process is carried out in a controlled manner	It is required that defence in depth is applied to the construction assurance in a manner that is proportional to safety significance. This will involve, where appropriate, separation of ensurance and assurance functions.
		Quality oversight of construction is required.
		Construction plant and facilities shall be maintained and inspected such that they are fit for purpose in the construction of the AP1000.
		At all stages of construction the AP1000 shall be maintained in accordance with design intent.
	Construction process produces adequate evidence of design intent achievement	There shall be adequate evidence of design intent achievement for construction. This shall include required procedures, processes, process records, inspection and audit records.
	Construction non conformity of output with input is controlled	It is required that processes are in place for either concession or non conforming construction product.

8 FAULT AND ACCIDENT ANALYSIS

8.1 Introduction

Volume 3 of the Pre-Construction Safety Report (PCSR) presents the faults and accident assessment for the AP1000 design. This volume of the AP1000 design safety case aims to demonstrate that the AP1000 design and operation are tolerant to faults; that United Kingdom (UK) safety targets are met; and that the risks from AP1000 plant operation to the public, workforce, and environment are as low as reasonably practicable (ALARP). The safety case developed in these chapters is based on the demonstration that provision of Category A safety functions is sufficient to meet regulatory targets and ALARP requirements for at least the first 72 hours following any abnormal event and Category B safety functions post 72 hours.

The purpose of this chapter is to provide an overview of the faults, their class, and the key safety features credited in mitigating the faults. References are made to the accident analysis methodology and results that are presented in the following chapters of the PCSR. It is recognised that fault and accident studies underpin the entire safety case, and the methodology presented here is consistent with UK safety assessment principles (SAPs) (Reference 8.1) and best practices.

This chapter describes the fault and accident analysis process, which is based on the design reference point (DRP) defined in Reference 8.3 and expanded upon in Chapter 9 and the systems, structures, or components (SSCs) described in Chapter 6. Chapter 8 describes the methodology for fault and hazard identification. The information collected is used as input to the design basis assessment (Chapter 9), probabilistic safety assessment (PSA) (Chapter 10), internal and external hazards assessments (Chapters 11 and 12), human factors assessment (Chapter 13), and the overall ALARP assessment (Chapter 14). Engineering substantiation is given in Volume 4.

The chapter describes the identification of faults and hazards and groups them according to their evaluation in other Chapters (9 to 13). The complete fault list is given in Appendix 8A.

Chapters 9 through 13 demonstrate that the appropriate safety criteria are met and that the AP1000 design meets the regulatory targets and is ALARP. Chapter 14 of this PCSR brings together the results of Chapters 9 to 13 of this volume and demonstrates that the AP1000 design is robust with respect to all types of faults.

8.2 Overview of Fault and Accident Analysis Methodology

The methodology used in this PCSR is based on UK best practices. An overview is given in Figure 8-1. The application of the methodology ensures that the targets given in the UK SAPs (Reference 8.1) are accommodated in the design.

The elements of the methodology are summarised in the remainder of this section and shown in Figure 8-1.

8.2.1 Reference Design

The safety case begins with the definition of a reference design. For this PCSR, the reference design is contained in the PCSR, as described in the Design Reference Point document (Reference 8.3). The reference design also includes a definition of normal operations. The reference design is described in Chapter 6 of this PCSR. As part of the AP1000 design development and licensing process, a number of design alternatives have been incorporated.

This process and the design changes considered and/or made as alternatives are discussed within the ALARP assessment in Section 14.6.

The reference design documentation also includes Technical Specifications (Tech Specs) that define design limits and conditions on plant operations. These limits and conditions are inputs to the fault analysis and may also be informed by the analysis. See Section 5.6.

As described in Chapter 2, the PCSR is included in the configuration management process for the AP1000 design so that the effects of any subsequent design changes on the safety case will be assessed (see Figure 8-1).

8.2.2 Systematic Fault and Hazard Identification

The next stage of the process is a systematic, auditable, and comprehensive identification of faults. This includes internally initiated faults, internal hazards, external hazards, and human errors. It also includes all modes of normal operation of the reactor and radioactive inventories in other areas (the spent fuel in the auxiliary building and waste routes, in particular). These faults are listed in the fault schedule given in Appendix 8A and in Reference 8.4.

Some of the faults include minor variations that do not impact the SSCs used to mitigate them or their classification. In addition, there are faults that are different enough in their mitigating SSCs, event classification, or consequences that they need to be listed as separate faults.

The identification process is described in Section 8.3.1 for internally initiated faults, and Sections 8.3.2 and 8.3.3 for internal and external hazards. The identification of human errors is described in Chapter 13.

8.2.3 Design Basis Assessment

Once the faults have been identified, each is allocated to a design basis (DB) class. This allocation depends on the initiating event frequency (IEF) of the fault.

The DB classes are derived from SAP Target 4 and from the frequency limits given in the SAPs for DB faults and frequent faults (Reference 8.1) with some additional interpretations. The resulting mitigated consequences are required to be below the dose targets associated with the DB classes, as follows:

DB1 – Infrequent DB faults with an initiating event frequency between 10^{-3}/yr and 10^{-5}/yr. Consequences are limited to:

- Public dose < 10 mSv or worker dose < 200 mSv for events between 10^{-3} and 10^{-4} /yr
- Public dose < 100 mSv or worker dose < 500 mSv for events between 10^{-4} and 10^{-5} /yr

DB2 – Frequent DB faults with an initiating event frequency >10^{-3}/yr. Consequences are limited to public dose < 1 mSv or worker dose < 20 mSv.

DBL – Low probability design basis faults with an IEF between 10^{-5} and 10^{-6}/yr with consequences limited to public dose < 200 mSv or worker dose < 1000 mSv.

BDB – Beyond design basis (BDB) faults with an IEF <10^{-6}/yr, e.g., below the frequency for DBL faults. The consequences would be higher than for DBL events.

HFLC – High-frequency, low-consequence (HFLC) faults with IE frequencies $>10^{-3}$/yr with consequence limits between DB limits and normal operating limits.

DB0 – All other faults; no radiological consequences expected.

The HFLC class is formally outside the DB but it is UK best practice to consider it, since it covers frequent faults with consequences above those associated with normal operations.

The DB class, together with the categorisation and classification scheme given in Section 5.2 of this PCSR, normally defines the requirements for safety measures as follows:

DB2 – Two diverse mitigation capabilities are required for each Category A safety function. At least one capability must be Class 1. The other may be Class 2. Analysis of the plant with consideration for a common cause failure may be performed with less conservative methods and/or inputs and may apply relaxed acceptance criteria.

DB1 – One Class 1 mitigation capability is required for each Category A safety function.

DBL – One Class 1 mitigation capability is required for each Category A safety function. Analysis of the plant may be performed with less conservative methods and/or inputs and may apply relaxed acceptance criteria.

HFLC – No formal requirement, but best practice is to identify one Class 2 system for each Category B safety function.

BDB – No formal requirement except for demonstrating event considerations are ALARP.

DB0 – No formal requirement except for demonstrating event considerations are ALARP.

The AP1000 plant has been designed with consideration for the effects of fluid system pressure part failure. As such, supplemental design requirements have been applied to piping systems where improved reliability (reduction in the associated IEF) are beneficial to plant safety; worker and public radiation exposure; and plant examination, maintenance, inspection, and testing (EMIT) obligations. Refer to Section 11.4 for additional discussion of these supplemental design requirements.

The AP1000 plant has applied these supplemental requirements, combined with additional measures, to significantly reduce the probability of pressure part failures in risk important piping systems. These measures include:

- Reduced piping stresses, more restrictive than American Society of Mechanical Engineers (ASME) requirements
- Increased understanding of material stress-strain behaviour (mechanistic applications only)
- Improved piping pre-service and in-service inspections
- Reduced length of piping through the use of passive safety systems, sealless reactor coolant pumps (RCPs) and other plant simplifications
- Reduced number of welds through the use of bent piping instead of elbows

- Use of improved piping and weld materials based on industry operating experience to reduce chance of corrosion mechanisms (e.g., erosion-corrosion, galvanic corrosion, stress-cracking corrosion)
- Arrangement of piping systems to avoid thermal stripping
- Design of piping systems to avoid significant dynamic effects
- Improved sensitivity and reliability of leak detection capabilities

The result of the application of these design requirements and characteristics is a significant reduction in the likelihood of pressure part failure. Based on this reduction, such events are classified as low probability design basis events (DBL Class events). This is a reasonable approach as both the mechanistic and deterministic principles apply requirements to the design, fabrication, construction, operation, and EMIT functions for the full extent of plant life.

Because of the low probability of DBL faults, the analysis of such faults can have reduced margins (although still conservative) and the consequences can be greater (i.e., higher dose limits), compared with what is used for more probable design basis events (DB1, DB2).

For internally initiated faults (faults originating within the reactor, safety systems, or balance of plant) the DB analysis consists of a deterministic assessment of the initiating fault and the corresponding safety measures (i.e., SSCs) provided by the design. Transient or other calculations using conservative initial conditions, assumptions, and methods demonstrate that the consequences of the DB faults are below the limits listed at the beginning of this section for the corresponding DB class. Conservative assumptions include the assumption of failure of all non-claimed systems and a single failure, as well as conservative initial conditions. In addition, for frequent faults (DB2 class), a single common cause failure is assumed instead of a single failure. Generally only limited DB analysis is undertaken for HFLC events and none for DB0 or BDB events, although they are all considered in the PSA.

The DB analysis may depend explicitly or implicitly on a number of limits and conditions. Generally for the AP1000 plant, the limits and conditions do not allow for Class 1 SSCs to be removed from service for planned maintenance when the reactor is at power or at hot standby conditions, such that SSC unavailability due to maintenance need not be considered. During shutdown, the same situation is true for SSCs required to be operable; however, as the plant is brought to lower operating Modes, some SSCs are permitted to be removed from service for planned maintenance and inservice testing / inspection. These limits and conditions fall into three main groups: limits and conditions that identify the initial conditions for transient analysis, limits and conditions that are assumed for the operation of SSCs important for safety, and limits and conditions imposed by the analysis to limit effective doses either to the public or to the workforce. The limits and conditions that are assumed for the operation of SSCs include such things as water inventory, water temperature, or boron concentration. They also include the availability of SSCs such as valves. These limits and conditions are listed as being important to the safety case. Most will be associated with Tech Specs applied to Class 1 SSCs or with short-term availability controls applied to Class 2 SSCs; some may be candidates for operating rules or to have operating rules associated with them (see Chapter 5). The link between the DB analysis and the Tech Specs is shown in Figure 8-1.

The SSCs identified in the DB assessment and their safety classifications are listed in Appendix 15A “engineering schedule”. The role of each SSC in the DB assessment leads to its classification as described in Chapter 5.

In addition to the above, any operator actions identified in the assessment are also listed. These operator actions fall into two groups: those required to actuate or realign SSCs as part of the response to the fault, and those identified to reduce operator dose such as the requirement to evacuate on the activation of a gamma alarm. Such operator actions are classified in a similar manner to SSCs, as described in Chapter 5 and are consolidated in Chapter 13.

The DB assessment of internally initiated faults is provided in Chapter 9.

8.2.4 Design Basis Assessment of Internal and External Hazards

For internal hazards, the DB1 hazards are the most severe accidents within the normal design basis of the plant that could occur on site, taking such things as fire loading or water inventories into account. An SSC not designed or evaluated to survive a DB hazard is assumed to fail and then it is demonstrated that there are sufficient remaining SSCs to provide all Category A safety functions. Demonstration of the capability of achieving safe shutdown is required following a hazard that directly causes a plant trip or that disables SSCs that are required to be operable by Technical Specifications that require the plant to shutdown if the SSCs are in-operable beyond the specified time period. Failure of an SSC as a result of an internal hazard initiating event where the hazard does not also initiate a reactor fault would simply require the reactor to be manually shut down using the duty systems.

Required diverse mitigation of frequent internal hazards varies based on the initiating hazard. Section 4.0 of Table 8A-2 provides only a primary mitigation capability for most hazard faults, as most of the faults with a "frequent" intensity level would not be onerous enough to induce a reactor trip or controlled shutdown. If they would require such mitigation, they are assumed to already be tagged to the appropriate frequent faults via the individual hazard schedules presented in Chapter 11. Internal frequent fires pose the most onerous impact to diverse mitigation, and as such are discussed in detail in Section 8.2.4.1. In nearly all cases, diverse actuation of passive Class 1 SSCs is available via Class 2 Control & Instrumentation (C&I) diverse actuation system (DAS). All other internal hazard categories are briefly covered in the list below.

- Pressure Part Failure events are categorised based on their likelihood of pipe gross failure, and as such, frequent fault events are already captured within the line break scenarios presented in Sections 1-3 of Table 8A-2. For example, fault 1.4.2, a small break loss-of-coolant accident (LOCA) 2" or smaller is considered a cliff edge frequent fault, and is analysed as such.

- Internal frequent flooding events either identify frequent fault pressure part failure scenarios, or a generic internal flooding scenario that would not compromise the ability of DAS to provide diverse mitigation.

- Internal explosions are generally limited to compartments, and as such, frequent fault internal explosions are already bounded by frequent internal fire events; however, explosions are not postulated at locations that could compromise DAS. Therefore, diverse mitigation of DAS for a reactor trip is possible for all scenarios.

- Dropped load events are evaluated similarly to pressure part failure events, where bounding line break faults are identified and diversity is demonstrated as applicable. For a "frequent" dropped load event, the size of the dropped load, the impact zone of influence, and the mitigation capability of the structures and interacting components can be given more credit such that there is no frequent fault dropped load event that

would be expected to compromise the ability of DAS to provide diverse mitigation to a generic reactor trip event.

- Biological agent frequent faults would not pose any unique impact compared to a more onerous infrequent fault event. This fault would not compromise the DAS automatic functionality, and as such, diverse mitiation is available.

- Onsite transport frequent faults can only occur at specific locations on the grounds of the plant. Based on the separate locations of the primary DAS panel in the main control room and the redundant location in the security room, there is no infrequent limiting event, let alone frequent event, that could damage both locations and preclude diverse mitigation of SSCs.

- A release of toxic, corrosive, or flammable material frequent fault is already covered by one of the other internal hazard events (e.g., biological agent, internal fire, or onsite transport), as the consequences would be the same.

- Electromagnetic interference frequent faults are not considered to have any additional compromise to diverse mitigation equipment due to the electromagnetic interference requirements for the diverse C&I system (DAS); See Chapter 19.

The DB analysis for internal hazards is given in Chapter 11.

For external hazards, DB1 hazards are those with an IE frequency $>10^{-4}$/yr. Any SSC not specifically designed to survive a DB hazard is assumed to fail. The DB analysis consists of demonstrating that sufficient SSCs are available to provide all Category A safety functions after the event. In some cases, more frequent, less severe DB hazards are also listed (DB2). For these frequent internal hazard faults, two diverse mitigation capabilities are required as is discussed for internal events in Section 8.2.3.

Finally, in some cases there is a risk that the maximum DB1 hazard may be exceeded. For these DBL external hazards, analyses and/or evaluations are performed to demonstrate that there is a reasonable likelihood that sufficient SSCs will be available to mitigate the event. For these DBL hazards, the analysis may be performed with relaxed acceptance criteria and with less conservative methods/inputs.

The DB analysis for external hazards is given in Chapter 12.

8.2.4.1 Internal Fire

The initiation of an internal fire is considered a frequent fault. In accordance with Section 8.2.3, two diverse mitigation capabilities should be provided. Note that an internal fire fault is similar to a frequent intact circuit fault with respect to the SSCs that are credited to provide both primary and diverse mitigation. All of the credited SSCs are Class 1 except for the DAS C&I. All of the Class 1 SSCs have fire separation, and as a result can still meet their safety functions after a fire. Also, all of the mechanical SSCs that provide the primary mitigation of an intact circuit fault are fail safe, which reduces the probability of being disabled by a fire. As a result, for an internal fire plus a common cause failure (CCF), the AP1000 design would generally provide diverse Class 1 mitigation.

However, there is a limited exception to the AP1000 diverse capability for fires; that is a specific fire could completely disable the DAS since it is a Class 2 system and does not have

fire separation. This exception is considered acceptable because of the following AP1000 design features:

- DAS is a small system with only a few sensors, cables and cabinets. As a result the probability of a fire that might disable DAS is low since there are a limited number of challenging fire initiation locations.

- Fire induced hot shorts causing spurious automatic depressurisation system (ADS) component actuations are considered beyond design basis events; such a fire needs to start in a DAS cabinet, propagate to second DAS cabinet, cause spurious signals in at least two specific controllers before operators respond to fire alarms and de-energize DAS.

- Spurious plant trip caused by fire in DAS actuation cabinets that might cause a spurious reactor trip is considered an infrequent fault; such a fire needs to start and propagate to short wires or to cause processors to malfunction and cause spurious signals. DAS is an energize-to-actuate design that requires two spurious signals to generate an automatic actuation.

- A fire could disable DAS without causing spurious reactor trip; such a fire is considered a frequent fault (DB2). The availability controls on DAS do not require plant to be shutdown if DAS is unavailable. Therefore in case a fire disabled DAS, the plant should be assumed to continue to operate and would not have to transition to safe shutdown.

Furthermore, the PSA shows that the AP1000 design has a low core damage frequency for internal fire initiators. The PSA considers the potential for fires to propagate beyond the fire area of inception and thus affect more than one division of Class 1 SSCs delivering a Category A safety function, coincident with failures in the unaffected SSCs. The assessment shows that, under such conditions, the core damage frequency is below the Target 8 BSO.

Based on this discussion, Fault 4.1.1 of Table 8A-2 lists fires as frequent faults, and provides diverse mitigation capabilities; however, it notes that the diverse cases do not apply to fires located at limited locations that could disable DAS.

8.2.5 Human Factors

Human factors play a significant role in fault analysis. Since the methodology for human error analysis is specific for that purpose, operator actions or errors identified in the fault analysis elsewhere are considered in Chapter 13 along with specific human error identification and assessment.

In the DB assessments, any operator action identified as necessary for the provision of a Category A safety function (or the provision of a Category B safety function in some cases) is identified. Failure of the operators to perform these actions is then assessed in Chapter 13.

8.2.6 Probabilistic Safety Assessment

The PSA for the AP1000 design is discussed in Chapter 10. The PSA consists of a complete Level 1 and Level 2 PSA and an indicative Level 3 PSA for internally initiated faults with a discussion of seismic margins. The existing PSA addresses internal hazards, including fire and internal floods, in a simplified manner.

The Level 1 PSA uses best-estimate assumptions to consider the DB initiating events as well as other initiating events. It also considers combinations of failures of SSCs based on their probabilities. The SSCs credited in the PSA include those identified in the DB analysis as principal and defence in depth means of providing Category A safety functions for the reactor. Additional SSCs beyond these are also credited. These combinations of failures are represented as a series of event trees (ETs) with "nodes" corresponding to the failure of a particular SSC. The probability of failure of each of these systems is justified in Chapters 17, 18, and 19 of this PCSR. The end points of the Level 1 PSA fall into two groups: those that do not result in damage to the core, and those that result in core damage states. One of the major outputs of the study is the core damage frequency (CDF). Another major output is the relative importance of different SSCs. The Level 1 PSA is used in the fault and accident analysis to assess the adequacy of the reliability claims made for the SSCs identified in the DB analysis.

The SAPs (Reference 8.1) give targets for the individual risk of death of 10^{-4}/yr basic safety level (BSL) and 10^{-6}/yr basic safety objective (BSO) in Targets 5 and 7 for workers and members of the public, respectively. Individual risk of death cannot be directly obtained from the PSA.

An overview of the PSA is shown in Figure 8-2.

8.2.7 Severe Accident Assessment

Severe accidents are defined as fault sequences that lead to major core damage and containment releases (exceeding the DB dose levels given in Target 4) resulting from an initiating event and a sequence of failures of mitigating measures (including principal and defence in depth features). The analysis of severe accidents for the AP1000 plant is part of the Level 2 and 3 PSA in this PCSR and is presented in Chapter 10.

The Level 2 PSA takes each of the core damage states from the Level 1 PSA and performs a best-estimate analysis of these severe accident sequences to follow the progression of the core damage. The analysis uses best-estimate techniques to assess the contribution of various severe accident phenomena to failure of the containment function to assess the possible characteristics of any release of radioactivity. The following phenomena are assessed:

- Core heatup, melting, and relocation
- In-core zirconium-water reaction
- In-vessel retention of molten core debris in the lower plenum
- Fission product release and transport and offsite doses
- In-vessel steam explosion
- High pressure core melt phenomena
- Ex-vessel steam explosion
- Molten core concrete interaction
- Long-term containment pressurisation with failure of passive containment cooling system (PCS) cooling and alternative sources of water cooling

- Hydrogen combustion
- Equipment survivability

The possible releases from core damage events are grouped into different damage states based on:

- the size of the release from the core/RCS,
- the radioactive inventory in the containment,
- the height/energy/rate and magnitude of the release from the containment,
- the timing of the release.

The sum of the frequencies of all these major releases is the large release frequency (LRF). The use of this severe accident assessment to identify risk-reduction measures is described in Section 14.6.3.

The source terms coming from the Level 2 PSA are further analysed in the indicative Level 3 PSA, which considers pathways back to the human population surrounding the site and emergency counter-measures to estimate societal risk. The Level 3 PSA is only indicative, since a full Level 3 PSA can only be done once a specific site is in view, since population densities, prevailing weather, probabilistic weather variations, and planned emergency countermeasures are all site specific. A more detailed Level 3 PSA would form part of a site-specific PCSR. In the absence of a detailed Level 3 PSA, the LRF is used as a surrogate for the risk of 100 deaths or more in the comparison with the societal risk target in SAP Target 9.

An overview of the PSA is shown in Figure 8-2.

8.2.8 Assessment that Risks are As Low As Reasonably Practicable

The DB assessment and PSA provide insights for use in the design of the safety measures used to provide the Category A safety functions (Category B for HFLC events) to meet DB and probabilistic targets.

It is an additional requirement in the UK that the risks from faults to the public, workforce, and environment should be ALARP. As part of the assessment of each fault, an assessment is made of other measures that might be claimed to decrease the risk from the fault. Whether or not these measures are claimed is based on whether to do so would be ALARP.

Chapter 14 provides a summary of the full ALARP assessment for the AP1000 plant. Each chapter in volume 3 (9 – 13) provides specific ALARP assessments for individual faults.

8.2.9 Engineering Substantiation

Appendix 15A “Engineering Schedule” provides a detailed picture of the requirements placed on engineered systems to provide safety functions during fault and accident conditions.

The safety case is dependent upon these engineered systems meeting their designated requirements. Engineering substantiation provides the evidence that each system can meet these requirements (with a suitable level of confidence) and provides details of the maintenance and testing regime that is required to ensure that they remain able to do so

throughout the life of the plant. The evidence and maintenance and testing requirements are added to the engineering schedule shown in Figure 8-1.

Engineering substantiation is discussed in Volume 4.

8.3 Fault and Hazard Identification

Fault and hazard identification, together with the corresponding fault schedule, form an important part of the safety assessment, as they are the basis of demonstrating the tolerance of the design to faults and hazards.

The main requirement for fault and hazard identification is that it should be systematic, auditable, and comprehensive. In particular, the fault and hazard identification must cover all normal operating conditions and all inventories of radioactivity, whether they are in the reactor, fuel route, waste routes or other parts of the plant.

Faults and hazards fall into one of the following types:

- Internally initiated faults
- Internal hazards
- External hazards
- Human errors

The methodology for identifying all of the faults and hazards in these groups is slightly different, and the methodology adopted in this PCSR is described below for each group. These faults are listed in the fault schedule given in Appendix 8A which also includes other data arising from subsequent stages of the process.

8.3.1 Internally Initiated Faults

The approach to fault identification is to start with the faults identified in the standard AP1000 design. This has been supplemented by separate systematic studies to demonstrate completeness of the AP1000 standard design for reactor faults and to include faults in systems and operations outside the reactor.

In the first instance, internally initiated faults have been identified by application of the checklist of categorised initiating faults specified in American National Standards Institute (ANSI) N18.2 (Reference 8.7). This document presents a checklist of categorised hazards that have been drawn from assessment of United States (US) nuclear plant SSC failure Modes and from many years of operating experience.

The application of the ANSI N18.2 checklist has been reviewed against the AP1000 design and PSA and has been appropriately updated to reflect the plant-specific design features. In particular, the fault list was augmented by design-specific faults, such as spurious actuation of the passive residual heat removal (PRHR) system.

This identification of initiating faults is also supported by a review of operating experience documented in Nuclear Regulatory Commission technical report designation/contractor report (NUREG/CR)-2300 (Reference 8.8, Section 5-4.1) and NUREG/CR-5750 (Reference 8.9), as well as the Institute of Nuclear Power Operations (INPO) and Westinghouse databases. A more recent review using NUREG/CR-6928 (Reference 8.6) has identified no additional hazards that need to be addressed.

The application of the ANSI N18.2 checklist has also been reviewed against relevant good practice in hazard identification. As a result of this, bounding initiating faults relating to shutdown states are identified, as are bounding initiating faults relating to spent fuel handling and storage.

It is recognised, however, that the above approach is not completely systematic and therefore does not fully meet UK requirements for fault identification. Further, the ANSI N18.2 checklist only considers single events as initiators of a fault sequence and does not consider combinations of events that might contribute at a frequency greater than 10^{-5}/yr.

The ANSI N18.2 checklist does not include faults or hazards in parts of the plant other than the reactor itself. There is a need to identify faults and hazards as they may apply to the fuel route, waste routes, and any other part of the plant where there are inventories of radioactive material.

The ANSI N18.2 checklist does include anticipated transient without trip (ATWT) faults. If these are considered as initiating events, their frequency puts them outside the DB for the AP1000 design, and therefore they would not be considered. However, it is UK practice to consider potential ATWT events for all frequent fault initiating events or transients followed by a common cause failure in a principal safety function. On this basis, ATWT events are not identified as initiating events but are included as part of the assessment of frequent faults.

A top-down assessment was undertaken to demonstrate that the list of faults and hazards for the reactor is comprehensive and to provide a list of faults for systems outside the reactor. This top-down assessment relied on the observation that all initiating events correspond to the loss or degradation of one of the following principle safety functions:

- Control of nuclear criticality
- Removal of heat from nuclear fuel
- Confinement (containment) of radioactive material
- Shielding of personnel from direct radiation

Each of these safety functions was applied in turn to the primary and secondary side of the reactor, to all parts of the fuel route, to the radwaste routes, and to any other part of the plant where there is radioactive material. In each case, all normal operating conditions were reviewed.

The application of this methodology did not reveal any significant omissions from the list of reactor faults already identified but did supplement the list with faults in areas other than the reactor.

8.3.2 Internal Hazards

Internal hazards are those hazards to plant and structures that originate within the site boundary but that are external to the nuclear or active systems. The licensee has control over the initiating events to some extent.

The internal hazards identified in Chapter 11 are as follows:

- Fire
- Internal flooding
- Pressure part failure, including:
  - Water spray

  - Jets
  - Steam leakage
  - Pipe whip effects
- Explosions
- Missiles
- Releases of toxic, corrosive and flammable material
- Collapsing, falling or mishandling loads
- Biological agents
- Onsite transport accidents
- Electromagnetic interference (EMI)

Combinations of the hazards and the potential for consequential failures are assessed in Chapter 11 of this PCSR.

8.3.3 External Hazards

External hazards are those hazards to a site and facilities that originate externally to both the site and its processes, i.e., the licensee may have very little or no control over the initiating event. External hazards fall into two main groups: naturally occurring events such as extreme weather or earthquakes, and man-made events such as explosions or aircraft crash. The identification and analysis of external hazards is given in Chapter 12.

Through structured technical review, the following list of external hazards has been identified as applicable for assessment:

- Seismic events
- External flooding
- Aircraft impact
- External explosions
- Extreme temperature
- Drought
- Extreme wind
- External fire
- External missiles
- Biological fouling
- EMI and lightning

8.3.4 Human Errors

The AP1000 design is designed to minimise the impact that operator errors can have on plant safety. However, three types of human errors are identified and classified consistent with those defined in the International Atomic Energy Agency (IAEA) guidance, “Human Reliability Analysis in Probabilistic Safety Assessment for Nuclear Power Plants: A Safety Practice” (Reference 8.2).

- **Type A** – Unrevealed maintenance errors that might compromise the performance of a safety system when it is demanded.

- **Type B** – Maintenance or operator errors that could cause an initiating fault.

- **Type C** – Operator errors that affect the course of an accident in a detrimental way.

A systematic study has been undertaken to identify all such errors that might have a significant effect on the safety of the AP1000 design. A number of initiating faults identified as internally initiated faults have a contribution from Type B errors. Similarly, the progression of a number of internally initiated faults may be affected by Type C errors. These are covered further in Chapter 13.

Human error contributions to internally initiated faults (Type B errors) are included in the relevant fault in the fault list in Appendix 8A. Where operator actions are required in the DB analysis, they are identified and the failure of operators to properly execute them is included in the list of Type C errors addressed in Chapter 13.

The identification of human errors and the screening and assessment of these errors is summarised in Chapter 13 of this PCSR.

8.4 Fault Schedule

The faults and hazards identified by the various processes described above are listed in the fault schedule given in Table 8A-2. However, there are numerous individual faults, and many of them are similar to one another. The usual practice is to group variations of similar faults so that the results of any variation of a given fault describe the limiting consequences. Each fault identified has a limiting transient analysed in the DB assessment. The radiological consequences presented are meant to bound the most limiting case for a particular fault.

From the DB point of view, several of the PSA events can be grouped together since the only difference is the point of release, which leads to different consequences but not to differences in the requirements for the provision of safety functions. Alternatively, some PSA events need to be split as the provision of safety functions is different, although, from a PSA point of view, the release points and timescales are the same. Table 8A-2 breaks down the faults for both DB and PSA use.

Table 8A-2 also includes faults for non-power operation conditions (shutdown and refuelling operating conditions). In the PSA, most of these events are assumed to be bounded by the corresponding power operation event where applicable. In some cases, separate calculations are presented. Table 8A-2 also includes faults outside the reactor, which are not included in the PSA.

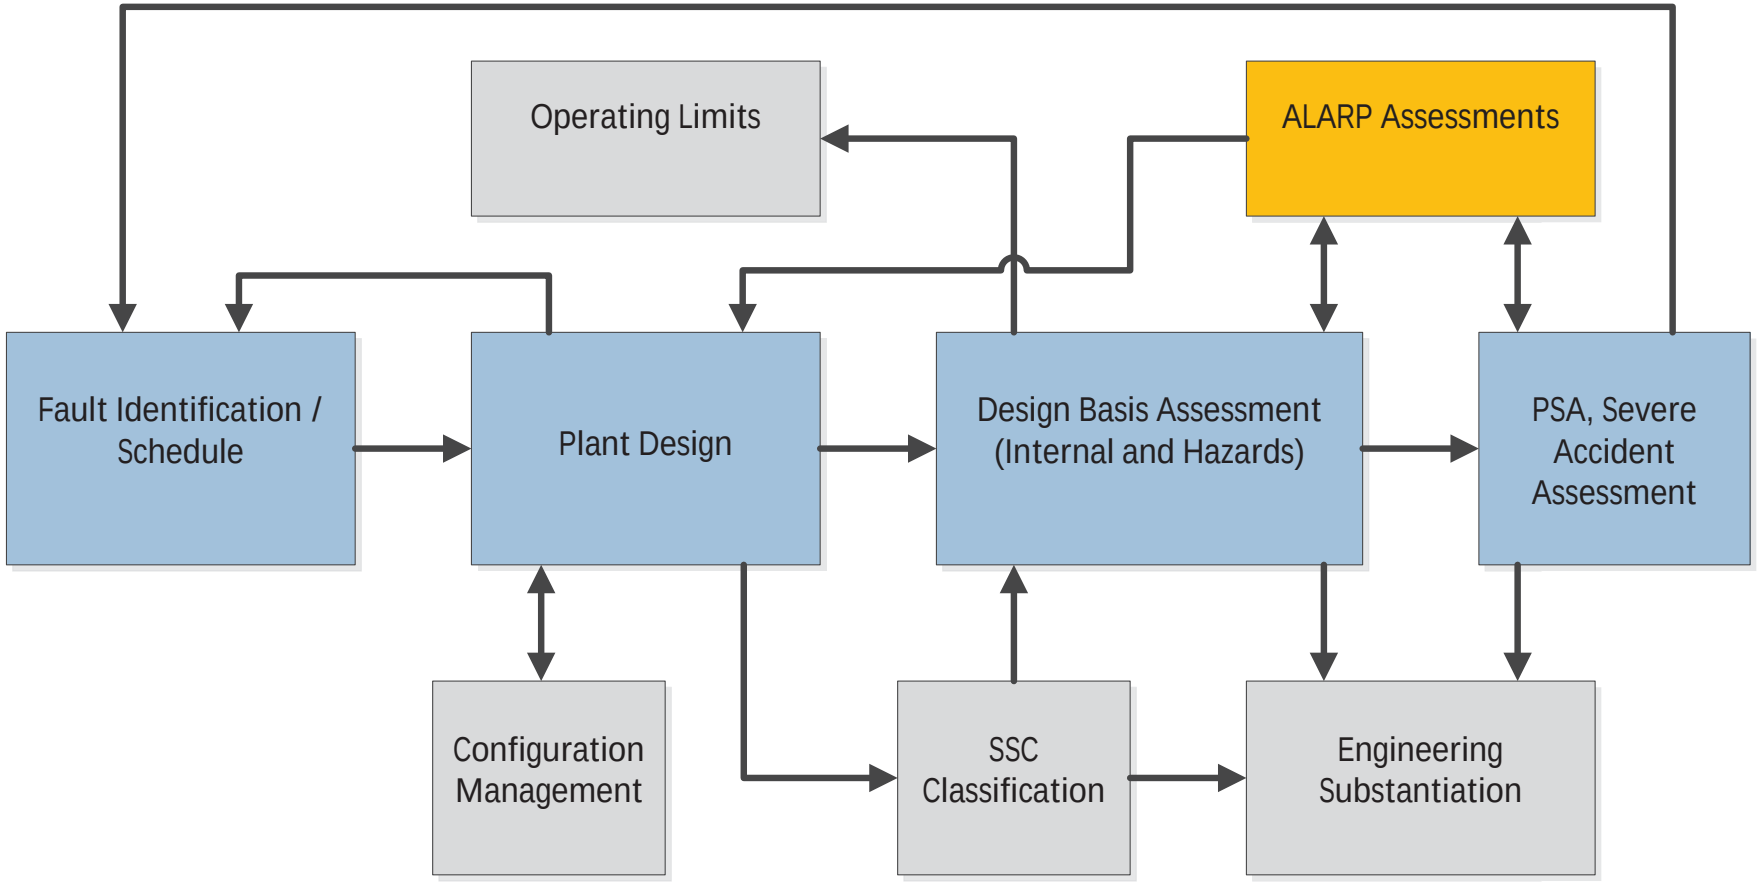

Figure 8-1 Fault and Accident Analysis Overview

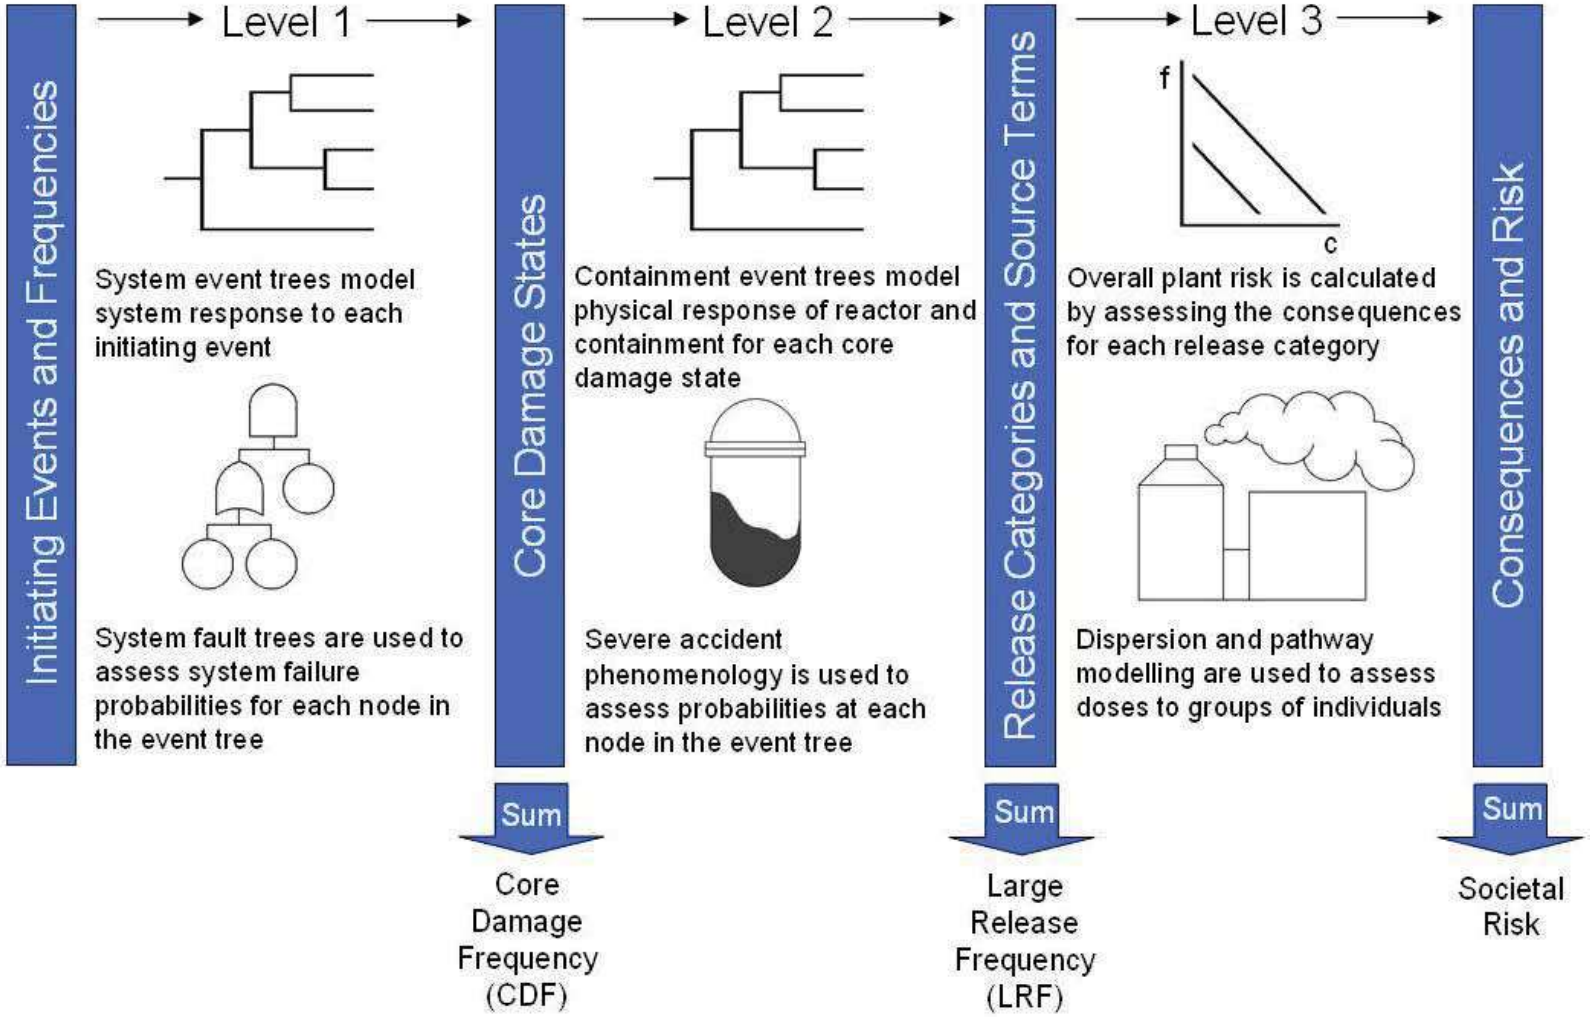

Figure 8-2 Probabilistic Safety Assessment Overview

APPENDIX 8A
FAULT AND ACCIDENT ANALYSIS
AP1000 COMPOSITE FAULT LIST

8A.1 Background

The fault list, presented as Tables 8A-2 and 8A-3 in this appendix, covers the full set of initiating faults that are addressed throughout the safety justification provided within this Pre-Construction Safety Report (PCSR). This fault list is based on a systematic fault identification study, undertaken using the methodology described earlier in this chapter, particularly those associated with reactor operations outside of the reactor coolant system (RCS) boundary.

The fault list for reactor internal faults in Table 8A-2 has been structured in a manner which demonstrates that the list of design basis faults can be reconciled with equivalent faults identified in the probabilistic safety assessment (PSA) and that all the faults identified in the PSA, which fall within the design basis, are covered by the design basis assessment (DBA). To this end, the fault list itself has been prepared by organising and consolidating the faults identified from all document sources under the appropriate initiating event category defined in the PSA. Section 1.0 is titled "Reactor Internal Events," and contains all design basis initiating events that originate at-power (i.e., Modes 1-2), and have a direct consequence on the reactor system. Section 1.0 also evaluates the design basis events initiating at-power for all modes of operation. Section 2.0 "Additional Reactor Internal Faults" contains design basis initiating events that originate only at lower operational power modes, but have direct consequences on the reactor system. Section 3.0 "Non-Reactor Faults" are design basis initiating events that may originate at any time, but do not have direct consequences on the reactor system; rather, they result in radiological consequences due to some malfunction during a maintenance activity or impact the ability of the spent fuel pool (SFP) to provide adequate protection of spent fuel.

Hazard schedules exist as identified in Chapters 11 and 12, and an appropriate linkage to the fault schedule entries in Table 8A-2 are provided therein. If the consequences of a particular internal or external hazard results in an already identified fault, reference is provided to fault IDs within Sections 1-3, and the appropriate mitigation claims are provided in Table 8A-2 in addition to the hazard protection claims provided in the referencing hazard schedule entry. If the hazard fault is not already contained within Sections 1-3, a unique entry is provided in Section 4.0 of Table 8A-2 for internal hazards and in Section 5.0 of Table 8A-2 for external hazards. These sections address all major hazard categories as discussed in Chapters 11 and 12, and provide appropriate linkage to the detailed hazard evaluations presented in those chapters, which cover the safety justification for the plant in the context of these hazards. The approach to demonstrating safety for external and internal hazards is based on justifying the resilience of the essential structures, systems and components to defend against fault sequences initiated by external or internal events. The demonstration of resilience is based on arguments relating to withstand, diversity, and segregation. The PSA also focuses on the impact of internal and external hazards on the availability of safety features in event trees.

Information on the document source(s) for each fault and identification reference(s) used within the source(s) for each fault are documented in Reference 8.4. This allows full traceability of each fault back to its relevant source(s), including the human factors (HF) assessment topic report for those faults which involve HF initiators.

8A.2 Fault Schedule Structure

- Fault Identification (ID) – A discrete identification number is provided for each fault entry. Separate faults may be identified for the same initiating event occurring during different operating mode(s), or in different locations within the plant where unique consequences may result.

- Initiating Event (Fault and Consequences) - A brief description of each initiating fault and the unmitigated consequences of the fault progression are given. The fault consequence column provides a description of the state of the plant following the initiating fault. The information in this column does not provide details of how the fault is mitigated, which is provided in following columns.

- Initiating Event Frequency (IEF) / Design Basis (DB) Class - This column provides the initiating event frequency information for the fault and the event classification (refer to Section 8.2.3). The IEFs are in most cases obtained directly from the PSA (See Chapter 10); however, if generated independently because the discrete fault is not contained in the same manner within the PSA, clarification is given in the "comments" column. General Notes regarding IEFs:

  1. The probabilities used in this table are based on the AP1000 plant PSA (see Chapter 10). These event probabilities are only one of the tools to identify an appropriate accident class for the event. Other factors are considered as discussed in section 8.2.3. In several cases, these IEFs are conservatively high, especially for events that are not a significant contributor to the overall PSA safety metrics (e.g., CDF). In other cases, the probabilities would put events into the beyond design basis class since their IEF is under 1E-06/yr, as discussed in Section 8.2.3. In some cases, these events are included in the design basis as DBL events because of uncertainties in the IEF. An example is a postulated large break loss-of-coolant accident (LBLOCA); as indicated in the fault schedule, this fault has an IEF of ~8E-07 per year, which would lead to it being classified in the BDB class. However, in the AP1000 design fault schedule it is classified as a DBL event and analysed to DBL assumptions, methods and consequences.

  2. Since most of the faults in shutdown mode are significantly less limiting then at power, the PSA does not provide the probability for all of shutdown events[1]. For these analysed in the PSA, associated probabilities will be used in the fault schedule. For the faults in shutdown Modes not defined in the PSA, the following logic is applied when the reactor is shut down; the probability of any event in shutdown Modes is significantly smaller that the conservative probabilities estimated for at power modes. This is due to both the limited time at risk (for all of the shutdown Modes combined [3-6]), and the lower pressure and temperature in these modes. The time at risk is on the order of 5% of the cycle time. For the sake of this fault schedule, probabilities are estimated to be 1/20th of the frequency estimated for at power faults. This is considered extremely conservative, as it does not take credit for the effect of the reduced pressure and temperature conditions. Also, this probability is cumulative to all shutdown Modes combined, and is used herein as bounding.

[1] A more detailed low power and shutdown PSA is expected to be performed during site licensing; at that time, these IEFs would be reassessed.

- Possible Modes Affected - The fifth column indicates the reactor operational Modes where the fault is applicable. The six operational Modes are identified in Table 8A-1 below, and discussed in more detail in Section 6.2. Different Modes of operation may be pertinent to different faults, and as such, the fault list in Table 8A-2 includes faults that are specific to shutdown Modes as a separate group.

- Engineered Safety Functions (ESFs) – This set of columns is intended to provide the claimed protection and/or mitigation functions and the associated actuation systems and signals, as applicable. This section is intended to be in alignment with sections titled "…SSCs credited" for primary DBA and diversity analyses presented throughout Chapter 9. Additional details on the format and content of this section is provided in the "Systems, Structures, or Components" section below.

    - Actuation/Indication Signals – The AP1000 plant C&I logic is designed such that multiple actuation signals could lead to a single ESF actuation. All of the potential ESFs for a DBA analysis and their associated signals are identified in Table 9.0-10. The typical approach in Table 8A-2 is to present the SSCs and actuation/indication signals identified in the limiting design basis analysis referenced in Chapter 9. A C&I system may be identified without a specific signal for manual ESF actuations, which are assumed to occur at a specific conservative point in time rather than immediately after the first indication is provided to the operator or after a number of indications are provided to the operator.

    - Short term reactivity control – This set of columns is intended to identify rapid reactivity control protection, which in almost all cases is provided by the rod breakers or the rod motor-generator (MG) set field breakers. Long term reactivity control is discussed either in the comments section or within the referenced detailed evaluation of the fault. For some faults, additional clarification is provided in the comments column due to a limiting analysis covering both at-power and shutdown conditions although the different operational modes may have different initial positioning of the control rods.

    - Safe Shutdown - Note that the SSCs listed are sufficient to mitigate the faults as well as to bring the plant to a safe shutdown. Refer to Appendix 9C for additional details on the operation of these SSCs as well as their performance capabilities in the long term.

- Comments – Clarifications, nuances, exceptions, and any additional detail not contained within the other columns is included in this column.

- Further Assessment of Fault –The last column in the table serves to provide traceability of the fault to its subsequent assessment description elsewhere in Volume 3 where the fault is discussed in more detail. These references are provided for deterministic and PSA analysis, as applicable. Note that the PSA analysis usually considers a range of similar initiating faults as well as more failures and fewer mitigating SSCs than considered in deterministic analyses.

8A.3 Systems, Structures, or Components

Methodology

The central columns in Table 8A-2 provide information on the front line SSCs that are claimed in order to maintain the engineered safety functions of reactivity control, heat removal, and containment of radioactive material within each fault progression. Each fault may contain one or more of the following:

- White (no shade) rows contain the primary design basis safety case engineered safety functions credited. As discussed in section 8.2.3, the primary mitigation of all faults only credits Class 1 SSCs.

- Grey shaded rows present diverse core cooling engineered safety functions for DB2 frequent faults. As discussed in section 8.2.3, the mitigation of these faults relies mainly on Class 2 C&I actuation of Class 1 passive SSCs. Class 2 mitigation SSCs are also credited on a limited exception basis.

- Blue shaded rows present diverse anticipated transient without trip (ATWT) engineered safety functions for DB2 frequent faults. As discussed in section 8.2.3, the mitigation of these faults relies mainly on Class 2 C&I actuation of Class 1 passive SSCs. Class 2 mitigation SSCs are also credited on a limited exception basis.

Additional discussion is provided below on unique mitigating safety functions, and how they may be presented in the "engineered safety functions" section of Table 8A-2:

- Support SSCs
- Pressure Control
- Containment Cooling
- Containment Isolation

Support SSCs

The AP1000 plant Class 1 SSCs require few support systems to allow them to provide their safety functions. Table 8A-4 lists the front line SSCs listed in Table 8A-2 and their necessary support systems. For example, the Class 1 equipment is supported by the essential electrical supply system (Class 1 direct current (dc) and UPS system [IDS]). The IDS provides reliable power for the Class 1 equipment required for the plant instrumentation, control, monitoring, and other vital functions needed to shut down the plant. In addition, the IDS provides power to the normal and emergency lighting in the main control room (MCR) and at the remote shutdown workstation. The IDS is capable of providing reliable power for the safe shutdown of the plant without the support of battery chargers during a loss of all alternating current (ac) power sources coincident with a design basis accident. The system is designed so that no single failure will result in a condition that will prevent the safe shutdown of the plant.

The front line SSCs listed in the central columns in Table 8A-2 are mostly Class 1 passive SSCs and are capable of providing for at least 72 hours of operation. After this time, a few additional SSCs are required to continue their operation. This long-term support of the passive SSCs can be provided by installed "ancillary" equipment or by offsite SSCs which can be transported to the plant and installed within the 72 hours available. Table 8A-5 lists these SSCs.

Heating, ventilation, and air conditioning (HVAC) SSCs are noted when their operation is necessary to provide cooling to support SSC operation. The HVAC transfers heat to the chilled water system (VWS) for this cooling. Although both the PMS and DAS are supported by an HVAC system during normal plant operation, neither require HVAC cooling post accident. The PMS relies upon passive heat sinks (room walls and ceilings) to limit the temperature rise for the first 72 hours. Afterwards, fans are credited to circulate outside air. The fans can either be the installed ancillary fans powered by the installed ancillary diesel generators (DGs) or they can be fans and DGs from offsite. The DAS has a limited operational time post accident and the temperature rise during that time (without HVAC) is acceptable. The DAS room may contain backup plant security equipment. If this option is used then there would be additional heat input to the room, however in this case the room would be continuously manned and that person would have procedures to take actions to prevent excessive heat rise (open doors, turn off the backup security equipment).

Pressure Control

For all of the faults discussed in Table 8A-2, the primary safety case RCS pressure control is provided by the spring-operated passive pressuriser safety valves or is not applicable (i.e., depressurisation events such LOCAs); as such, it is not listed for any fault. The diverse cases require no pressure relief or valve actuation. The AP1000 plant pressuriser size is large enough that frequent faults do not require the opening of the pressuriser safety valves to prevent over-pressurising the RCS. There are no pressuriser power operated relief valves in the AP1000 design. In addition, normal operations rely on pressuriser (PZR) sprays, turbine bypass system, and rapid power reduction system to control RCS pressure.

Containment Cooling

As indicated above, diversity is required in the safety functions credited in mitigating frequent faults. Table 8A-4 lists the features that provide this diversity. Note that the ultimate heat sink is provided by the PCS for both the primary and diverse cases. This is acceptable because there is no CCF that can cause the PCS to fail to meet its diversity requirements. The following outlines the reasons for this (a more detailed discussion is provided in Appendix A of Reference 8.5):

- The drain of water from the PCS water storage tank is diverse:
  - The water drain from the PCS water storage tank uses three 100 percent capacity paths and the valves that initiate water flow are diverse; there are two air-operated valves (AOVs) and one motor-operated valve (MOV) as shown on Figure 8A-1.
  - The actuation of the PCS valves uses diverse power supplies; the AOVs are self-powered (springs) and the MOV uses Class 1 dc power. The AOVs open on loss of instrument air pressure or loss of power to the air control solenoids.
  - The control of these valves uses diverse C&I systems; all three actuation valves are actuated by both the protection and safety monitoring system (PMS) and the DAS.
- If water fails to drain from the PCS water storage tank, then air-only cooling of the outside of the containment is sufficient for at least 24 hours. During this time the operators will be able to manually align another water supply; both the fire protection system and the demineralised water system (DWS) have installed connections to provide water to the outside of the containment shell. Chapter 10 provides analysis of PCS air-only cooling. Figure 8A-1 shows these alternate water supplies.

- Other postulated failure mechanisms are not credited. These mechanisms include:
  - Blockage of the air flow path. This is not credited because the total area is enormous, the inlets are located in a 360 degree radius at the top of the shield building cylinder and blockage of significant portion of the inlets would not cause the passive cooling process to fail. In addition, even if the inlets were greatly blocked and the air flow path reduced, water drain from the PCS without any air flow would adequately cool the containment.
  - Inadequate heat transfer through the containment shell. Extensive testing has been performed to support the design of the PCS. Three different facilities/scales were used. The PCS performance has been confirmed by independent analysis. In addition, for frequent faults the demands on the PCS heat transfer are less than they are for the limiting DBAs (large-break loss of coolant accident (LOCA) and double-ended guillotine steam line break).

Containment Isolation

Containment isolation (CI) valves form part of the containment pressure boundary and provide a means for fluid penetrations not serving accident consequence limiting systems to be provided with two isolation barriers. These isolation devices are either passive or active (automatic). Manual valves, de-activated automatic valves secured in their closed position (including check valves with flow through the valve secured), blind flanges, and closed systems are considered passive devices. Check valves, or other automatic valves designed to close without operator action following an accident, are considered active devices. Two barriers in series are provided for each penetration so that no single credible failure or malfunction of an active component can result in a loss of isolation or leakage that exceeds limits assumed in the fault studies. One of these barriers may be a closed system. Faults which require CI are indicated by the inclusion of CI as a safety function device.

The primary means of providing CI is by automatic closure Class 1 valves actuated by the Class 1 PMS. This capability applies to both LOCA and non-LOCA faults. These features are single failure tolerant and automatically actuated. The Class 2 DAS provides a diverse capability to actuate the risk important CI valves (Class 1). The risk important CIs include lines that connect to the RCS or the containment atmosphere and are greater than 2.54 cm (1 inch) in diameter.

In addition to diverse actuation of CI valves, diversity is provided for a common cause failure (CCF) of CI valves, where the same design is used for the inside and outside valves. Some containment penetration lines have diverse valves (such as an air operated valve outside and a check valve inside); such lines would not be subject to a CCF. For lines that use the same valve type inside and outside, a diverse containment isolation capability is provided to deal with a CCF that could fail both valves. The largest containment line that could be subject to a CCF is a containment air filtration system (VFS) line which is 40.6 cm (16 inch). If this line remained open due to a CCF, some containment atmospheric inventory (steam and air) would be lost out through the un-isolated path. Over a few hours, the loss of containment inventory would decrease and then stop as the air concentration in the containment atmosphere decreased. This behaviour is the result of the PCS heat transfer improving as the concentration of air decreases in the containment until all of the decay heat can be removed by the PCS with the containment pressure at atmospheric pressure. The amount of containment atmosphere lost is limited such that, on a best estimate basis (appropriate for sequences with a CCF), long term passive residual heat removal or small LOCA containment recirculation operation can continue for an extended time. Chapter 9 provides additional information. Note that in the fault schedule shown in Table 8A-2, CI is always shown as

being provided by valve closure, either by PMS or DAS actuation. The diverse means (without valve closure) discussed in this paragraph is a variation that applies to the diverse core cooling cases shown in Table 8A-2 for DB2 frequent faults.

8A.4 Conclusions

The information presented in Table 8A-2 is intended to address the requirement raised by the Office for Nuclear Regulation at Step 3 of the GDA process that *"There is a need to demonstrate that the list of design basis initiating events is complete and can be reconciled with the list of faults in the PSA"*.

Future decommissioning and spent fuel management arrangements are considered later in the PCSR. In regards to spent fuel management, Westinghouse proposes using dry fuel storage system for longer term storage of spent fuel. After cooling in the pool, fuel would be retrieved and dried before being transferred into dry storage. Subsequently the fuel would be consigned for disposal into the planned geological disposal facility. Although Westinghouse expects that operators may wish to follow a different strategy, it is presently considered as the reference design. Given the longer term nature of decommissioning operations and the uncertainty regarding the preferred option for spent fuel management, a more generic list of faults has been identified and is presented in Table 8A-3.

The fault schedule provided in Table 8A-2 along with this introductory text shows that the AP1000 design provides sufficient SSCs with appropriate classification to meet regulatory targets and demonstrate an ALARP design.

Table 8A-1 Definition of Operational Modes

Mode	Title	Reactivity Condition (K_{eff})	% Rated Thermal Power (1)	Average Reactor Coolant Temperature °C (°F)
1	Power Operation	≥ 0.99	> 5	N/A
2	Start-up	≥ 0.99	≤ 5	N/A
3	Hot Standby	< 0.99	N/A	> 216 (420)
4	Safe Shutdown(2)	< 0.99	N/A	216 (420) ≥ T_{avg}(4) > 93 (200)
5	Cold Shutdown(2)	< 0.99	N/A	≤ 93 (≤ 200)
6	Refuelling(3)	N/A	N/A	N/A

Notes:

1. Excluding decay heat
2. All reactor vessel head closure bolts fully tensioned
3. One or more reactor vessel head closure bolts less than fully tensioned
4. Average Temperature

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards[1]

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions[2]				Comments	Further Assessment of Fault
					Reactivity Control (short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1. Reactor Internal Events										
1.1 Reactor Pressure Vessel Rupture										
1.1.1	Rupture of RPV due to random failure event	Excessive loss of RCS inventory beyond makeup capabilities. Core damage and large fission product release.	3.2E-08 per reactor year BDB	1-6	N/A	Voids(C1)	N/A	Emergency cooling assumed to be inadequate due to severity of event	Limiting scenario assumes break below core level. Not assumed to be a credible event when the RCS is open in Modes 5-6 with the RCS open due to lack of pressurisation.	BDB Fault. Included in PSA (Chapter 10).
1.2 Large LOCA										
1.2.1	Large break loss of coolant accident (LBLOCA)	Rapid loss of coolant, with concurrent de-pressurisation of the RCS.	8.4E-07 per reactor year DBL	1-2	N/A	Voids(C1)	PMS(A,C1) – Low-2 Pressuriser Pressure	CMT(C1) (Core makeup tank) CI(C1)	Note that Rod Breakers are tripped on the PMS Low-2 pressuriser pressure signal. Break is >9" (22.9cm) in RCS primary circuit pipe due to random failure event. Break size range for LBLOCA is as adopted in the PSA. Large break in a pipe is assumed to bound other faults identified involving a major rupture in individual items of primary circuit plant (i.e. PZR shell, SG bottom head, Pump failure (bowl or motor casing). ASTRUM methodology used in DB analysis. Break area is treated as a statistical parameter.	Modes 1 and 2 are discussed in Section 9.6.4, "Large Break Loss of Coolant Accident". This fault is also discussed in Section 10.4.

							PMS (A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.2.2	Large break loss of coolant accident (LBLOCA)	Rapid loss of coolant, with concurrent de-pressurisation of the RCS.	4.2E-08 per reactor year (See Note 1 in 8A.1) DBL/BDB	3,4 and 5 with RCS intact	N/A	Rods already inserted	PMS(A,C1) – High-2 Containment Pressure	CMT(C1) CI(C1) PCS(C1)	Mode 3 analysis performed in Section 9.8.4.6.4, assuming accumulators out of service confirms that fault in shutdown mode is significantly less limiting then at power, even when equipment availability in different modes is considered. A LBLOCA is increasingly unlikely as the plant transitions to lower modes, and is not credible in Mode 5 due to lower pressures and temperatures.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.4, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		

[1] Table 8A-2 is a summary of internal and external faults and hazards presented throughout the PCSR. As such, abbreviations and acronyms are not defined throughout the table.

[2] For information regarding RCS pressure control, see Section 8A-3, "Pressure Control".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
1.2.3	Large break loss of coolant accident (LBLOCA)	N/A	BDB	5 with RCS open, 6	N/A	Rods already inserted	See Comments		Mode 5 and 6 with RCS open, CMTs are not required to be available, RCS makeup function is provided by in-containment refuelling water storage tank (IRWST). No analysis is required since a LBLOCA in Mode 5 with the RCS open and in Mode 6 is not considered credible. In the event of a line break due a dropped load, the consequences are bounded by Faults 2.3.2 and 2.3.3, but there is no loss of inventory outside of containment.	Modes 5 and 6 are discussed in Section 9.8.4.6.4, "Loss-of-Coolant Accident Events in Shutdown Modes".
1.3 Interfacing System LOCA										
1.3.1	Interfacing system LOCA due to random failures of the low/high pressure boundaries between low pressure (LP) systems and the RCS	May lead to an un-isolable loss of coolant outside the containment. Similar to LBLOCA.	<1E-06 per reactor year BDB	1-6	N/A	Voids(C1)	N/A	Emergency cooling assumed to be inadequate due to large loss of primary coolant outside containment	In lower modes, this event would not overpressurise the interfacing system, and therefore would not result in an uncontrolled loss of coolant.	BDB Fault. Included in PSA, see Section 10.4.8.9.
1.4 Medium LOCA										
1.4.1	Medium break loss-of-coolant accident	Loss of coolant with a concurrent de-pressurisation of the RCS.	6.8E-06 per reactor year DBL	1-2	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod breakers (C1)	PMS(A,C1) – Low-2 Pressuriser Pressure	PRHR(C1) CMT(C1) CI(C1)	Bounding case models a 10-inch (25.4 cm) break in the bottom of a cold leg, connected to the balance line of CMT-1. Probability is calculated for a break range between 4” (10.2 cm) and 9” (22.9 cm) in the RCS primary circuit due to random failure event.	Modes 1 and 2 are discussed in Section 9.6.5.3.6, "MBLOCA - 254 mm (10-inch) Cold Leg Break Results". This fault is also discussed in Section 10.4.
							N/A	ACCUM(C1)		
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.4.2	Medium break loss-of-coolant accident	Loss of coolant with a concurrent de-pressurisation of the RCS.	3.4E-07 per reactor year (See Note 1 in 8A.1) DBL/BDB	3,4,5 with RCS intact	N/A	Rods already inserted	PMS(A,C1) – High-2 Containment Pressure	PRHR(C1) CMT(C1) CI(C1) PCS(C1)	A medium-break loss-of-coolant accident (MBLOCA) is increasingly unlikely as the plant transitions to lower modes, and is not credible in Mode 5 due to lower pressures and temperatures.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.4, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
1.4.3	Medium break loss-of-coolant accident	N/A	3.4E-07 per reactor year (See Note 1 in 8A.1) BDB	5 with RCS open, 6	N/A				A MBLOCA is not credible when RCS is open. In the event of a line break due a dropped load, the consequences are bounded by Faults 2.3.2 and 2.3.3, but there is no loss of inventory outside of containment.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.4, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
1.5 Spurious Actuation of ADS										
1.5.1	Failures (false signals, human errors or mechanical ruptures) that result in inadvertent operation of ADS 4	Rapid loss of coolant, with concurrent de-pressurisation of the RCS. Less limiting than large LOCAs in fault 1.2 Challenges structural design of ADS stage 4 pipes and supports.	<1E-07 per reactor year BDB	1-6	See Comments				The potential for a failure to initiate spurious ADS stage 4 flow is so low it is a BDB event. All failures are considered including mechanical ruptures and inadvertent actuation signals. Note that spurious failures not due to software are assumed to be less than 1E-05 events per year. Failures that could cause spurious squib valve opening are discussed in PCSR Chapters 10.4, 17.5 and 19.2. Additional information is available in the Squib Valve Safety Case, UKP-GW-GL-200. Consequences acceptable in Modes 4-6.	This beyond design basis fault is discussed in Section 10.4.
1.5.2	Failures (false signals, human errors or mechanical ruptures) that result in inadvertent operation of ADS 1-3 Inadvertent Opening of a Pressuriser Safety Valve	Inadvertent depressurisation of the reactor coolant system which results in a rapidly decreasing reactor coolant system pressure and a decrease in moderator density feedback.	<1E-07 per reactor year DB1/BDB	1-5 with RCS Intact	PMS(A,C1) – Low-2 Pressuriser Pressure or PMS(A,C1) – OTΔT	Rod breakers (C1)	PMS(A,C1) – Low-2 Steam Generator (SG) narrow range (NR) level coincident with Low-2 startup feedwater (SFW) flow	PRHR(C1)	The potential for a failure to initiate spurious ADS stage 1-3 flow is so low it is a BDB event. Note that spurious failures not due to software are assumed to be less than 1E-05 events per year. Inadvertent pressuriser safety opening has an IEF of 3.9E-04 events per reactor year, and is therefore categorized as a DB1. Therefore, this fault is analysed as a DB1 event and covers both the spurious ADS 1-3 as well as inadvertent pressuriser safety valve opening. This event is also considered in PSA. Failures that could cause spurious are discussed in PCSR Sections 10.4, 17.5 and 19.2. Additional information is available in the Squib Valve Safety Case, UKP-GW-GL-200. These events are not credible in Modes 5 and 6 with the RCS open.	Modes 1 and 2 are discussed in Section 9.6.1, "Inadvertent Opening of a Pressuriser Safety Valve or Inadvertent Operation of the ADS". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.1, "Inadvertent Opening of a Pressuriser Safety Valve or Inadvertent Operation of the Automatic Depressurisation System". This fault is also discussed in Section 10.4.

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
1.6 CMT Line Break										
1.6.1	Core Makeup Tank Inlet Line Break	Similar to a MBLOCA (Fault 1.4.1), loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the pressuriser.	5.4E-07 per reactor year DBL	1-2	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod breakers (C1)	PMS(A,C1) – Low 2 Pressuriser Pressure	PRHR(C1) CMT(C1) CI(C1)	Fault is considered to bound possible failures of the Core Makeup Tank itself. Fault assessed as a separate group because of non-availability of CMT as a consequence. Section 9.6.5.3.8 argues that fault is bounded by the limiting DVI line and the MBLOCA breaks. For Modes 3-6, CMT line break is bounded by MBLOCA (see Fault 1.4.2-1.4.3).	Modes 1 and 2 are discussed in Section 9.6.5.3.8, "Core Makeup Tank Line Break Results". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
							N/A	ACCUM(C1)

1.7 Direct Vessel Injection Line Break										
1.7.1	Direct vessel injection (DVI) line break	Similar to a MBLOCA (Fault 1.4.1), loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the Pressuriser.	1.4E-06 per reactor year DBL	1-2	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod breakers (C1)	PMS(A,C1) – Low 2 Pressuriser Pressure	PRHR(C1) CMT(C1) CI(C1)	Fault includes any rupture occurring in one of the safety injection lines including the DVI line and lines that connect the CMT, accumulator, or IRWST to DVI. Fault differs from MBLOCA because one CMT, one accumulator, one injection line, and one recirculation line spill to containment without injecting to the RCS. For Modes 3-6, DVI line break is bounded by MBLOCA (see Fault 1.4.2-1.4.3).	Modes 1 and 2 are discussed in Section 9.6.5.3.5, "Direct Vessel Injection Line Break Results". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.

							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.8 Small LOCA										
1.8.1	Small break loss-of-coolant accident	Loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the Pressuriser.	>1E-04 per reactor year DB1	1-2	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod breakers (C1)	PMS(A,C1) – Low 2 Pressuriser Pressure	PRHR(C1) CMT(C1) CI(C1)	Frequency determination is presented in UKP-GW-GL-797. This fault is applicable to larger small break LOCAs, greater than cliff edge small LOCAs (2 inch/ 5.1 cm) and less than medium LOCAs (4 inch / 10.2 cm).	Modes 1 and 2 are discussed in Section 9.6.5.3.4, "SBLOCA - 50.8 mm (2-inch) Cold Leg Break Results". This fault is also discussed in Section 10.4.
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.8.2	Small break loss-of-coolant accident	Loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the pressuriser.	1E-04 per reactor year DB2 Cliff Edge	1, 2	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod breakers (C1)	PMS(A,C1) – Low 2 Pressuriser Pressure	PRHR(C1) CMT(C1) CI(C1)	Frequency determination is presented in UKP-GW-GL-797. This fault is applicable to LOCAs greater than RCS leaks (0.95 cm [3/8 inch]) and less than infrequent fault small LOCAs (5.1 cm [2 inches]). Small-break loss-of-coolant accident (SBLOCA) fault is also considered to bound break in chemical and volume control system (CVS) make-up or let down line. Note that five sets of mitigating SSCs are listed for this event. The first one contains all of the C1 equipment that would normally actuate to mitigate the event. The next three sets of equipment demonstrate the capability of the AP1000 plant to tolerate a CCF and still provide adequate core cooling. For the third diverse core cooling case, the use of the ADS stages 1-3 is credited although it may not be necessary depending on the magnitude of the impact of nitrogen discharge from the accumulators. The RCS pressure is calculated to remain at the accumulator empty pressure such that a limited amount of nitrogen is expected to discharge from the accumulators. In this situation the PRHR heat exchanger (HX) is expected to work well enough to keep the RCS pressure low enough to allow for normal residual heat removal system (RNS) injection. However, crediting operation of ADS stages 1-3 removes any such uncertainty. The last set of equipment demonstrates the capability of the plant to tolerate a PMS CCF ATWT event and still shutdown the reactor. Note that a mechanical CCF of the rods is bounded by this this C&I CCF (See Supporting Analysis).	Modes 1 and 2 are discussed in Section 9.6.5.3.4, "SBLOCA - 50.8 mm (2-inch) Cold Leg Break Results". This fault is also discussed in Section 10.4.

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.8.3	Small break loss-of-coolant accident	Loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the pressuriser.	1.4E-04 per reactor year (See Note 1 in 8A.1) DB1	3,4 and 5 with RCS Intact	N/A	Rods already inserted	PMS(A,C1) – Low 2 Pressuriser Level	PRHR(C1) CMT(C1) CI(C1)	In shutdown modes, both accumulators are isolated at 6.895 MPa. (1000 psia) or less. In MODE 5 one CMT can be isolated. Since the probability of being in these MODEs is less than at power, the max LOCA size would be reduced (ignored in this assessment). There is no need to consider ATWT event in shutdown, since rods already inserted.	Modes 3, 4, and 5 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.8.4	Small break loss-of-coolant accident	N/A	N/A	5 with RCS Open, 6	N/A				In these MODEs the RCS is at atmospheric pressure such that a LOCA is no longer considered a credible fault. In the event of a line break due a dropped load in this Mode, the consequences are bounded by Faults 2.3.2 and 2.3.3, but there is no loss of inventory outside of containment.	Modes 5 and 6 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
1.9 Reactor Coolant Leakage										
1.9.1	Reactor coolant leakage	Loss of coolant, smaller than limiting SBLOCA (Fault 1.8.1).	1.4E-03 per reactor year HFLC	1-6	N/A (See Comments)				Under normal operating conditions the plant will "ride the transient out" without generating a reactor trip. If fault progresses, the mitigation SSCs would be consistent with frequent fault SBLOCA (Fault 1.8.2) In MODEs 3-6 the rods are already inserted. The description in this row considers a scenario where the safety class 2 CVS does not perform its intended function, thus loss of CVS is initiating event. Very low rate of coolant loss from RCS (up to 22.71m^3/hr [100 gpm]), eventually leading to low-2 pressuriser level indication. For Modes 4-6, the IEF is 7.0 E-05, making it an infrequent fault (See Note 1 in 8A.1), with low consequences. Regardless, the consequences are bounded by a SBLOCA (Faults 1.8.3-1.8.4).	Modes 1 and 2 are discussed in Section 9.6.5.3.10, "Reactor Coolant Leakage Results". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
1.9.2	Failure of small lines carrying primary coolant outside containment	Activity release outside of containment to the environment. The loss of coolant reduces pressuriser level and creates a demand for makeup.	>1E-03 per reactor year DB2	1-6	N/A (See Comments)				The mitigation SSCs are consistent with frequent fault SBLOCA (Fault 1.8.2) This leakage event is assumed to be detected and isolated within 30 minutes of event initiation based on availability of Class 1 Radiation Monitoring System (RMS) alarm and plant emergency operating procedures. For Modes 4-6, the IEF is 5.0 E-05, making it a DB1 infrequent fault (See Note 1 in 8A.1). Thus, the consequences are bounded by a SBLOCA (Faults 1.8.3-1.8.4).	Mode 1 is discussed in Section 9.6.2, "Failure of Small Lines Carrying Primary Coolant Outside Containment" and Modes 2, 3, 4, and 5 are discussed in Section 9.8.4.6.2, "Failure of Small Lines Carrying Primary Coolant Outside Containment"

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
1.9.3	Failures (false signals, human errors or mechanical ruptures) that result in inadvertent operation of the IRWST injection squib valves	Opening of these squib valves would result in leakage through upstream check valve pressure balance holes. In addition, these check valves are assumed to be in-operable (stuck closed) following this fault because of the large load applied.	<1E-07 BDB	1-6	See Comments				The potential for a failure to spuriously open IRWST injection squib valves is so low it is a BDB event. All failure modes are considered including mechanical ruptures and inadvertent actuation signals. Note that spurious failures not due to software are assumed to be less than 1E-05 events per year. Failures that could cause spurious squib valve opening are discussed in PCSR Sections 10.4, 17.5 and 19.2. Additional information is available in the Squib Valve Safety Case, UKP-GW-GL-200. Consequences acceptable in MODEs 4, 5, 6.	This beyond design basis fault is discussed in Section 10.4.
1.10 PRHR Tube Rupture										
1.10.1	Passive residual heat removal tube rupture	Loss of coolant, smaller than limiting SBLOCA (Fault 1.8.1).	1.1E-04 per reactor year DB1	1-5 with RCS Intact	N/A (See Comments)				If CVS operation or PRHR isolation fail, fault progression and mitigation SSCs is similar to SBLOCA (depending on the size of the break). PRHR system performance would be degraded by a break in PRHR tube(s); however, sufficient functionality to support fault mitigation would still be available. Event is not a credible initiator in Modes 5 and 6 with the RCS open, as there is no pressure on the PRHR tubing.	Modes 1 and 2 are discussed in Section 9.6.5.3.9, "Passive Residual Heat Removal Tube Rupture Results". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.1, "Loss-of-Coolant Accident Events in Shutdown Modes". This fault is also discussed in Section 10.4.
1.11 SGTR										
1.11.1	Steam Generator Tube Rupture (SGTR)	Increase in contamination of the secondary system due to leakage of radioactive coolant from the RCS and a subsequent release of activity to the atmosphere.	3.3E-03 per reactor year DB2	1, 2	PMS(A,C1) – Low-2 Pressuriser Level	Rod breakers (C1)	PMS(A,C1) – Low 2 Pressuriser Level	PRHR(C1) CMT(C1)	The IEF for this fault is based on historical data, and the SG tubes for the AP1000 plant are manufactured in accordance with relevant good practice, which incorporates improved materials and processes. No ruptures have been experienced since these major improvements were made. As such, the initiating event frequency is realistically expected to be below 1E-03 events per reactor year, but is still evaluated as a frequent fault event. Fault due to random failure event. Limiting case is a single tube rupture compared to multiple tube ruptures. The analysis presented in Section 9.6.3.2.3 assumes a loss of offsite power at the start of the event resulting in rod insertion. For diverse core cooling scenario, loss of normal feedwater fault is bounding (Fault 1.16.1).	Modes 1 and 2 are discussed in Section 9.6.3, "Steam Generator Tube Rupture". This fault is also discussed in Section 10.4. Note that the diversity case has not been explicitly analysed, and will be addressed during site licensing. It is explained in Section 9.6.3.3.1 why the scenario is expected to be mitigated adequately.
							PMS(A,C1) – Low-2 Steamline Pressure	CI(C1)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.11.2	Steam Generator Tube Rupture (SGTR)	Increase in contamination of the secondary system due to leakage of radioactive coolant from the RCS and a subsequent release of activity to the atmosphere.	1.7E-04 per reactor year (See Note 1 in 8A.1) DB1	3-5 with RCS Intact	N/A	Rods already inserted	PMS(A,C1) – Low 2 Pressuriser Level	CMT(C1) PRHR(C1)	Fault due to random failure event. There is no need to consider ATWT event in shutdown, since rods already inserted.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.3, “Steam Generator Tube Rupture in Lower Modes". Also discussed in Chapter 10.4.
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1) CI(C1)		
1.11.3	Steam Generator Tube Rupture (SGTR)	N/A	N/A	5 with RCS Open, 6	N/A	Rods already inserted	N/A		In Modes 5 and 6, the RCS pressure and temperature are reduced, thus, a SGTR event is not credible.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.6.3, “Steam Generator Tube Rupture in Lower Modes". Also discussed in Chapter 10.4.
1.12 Transient with Main Feed water										
1.12.1	Inadvertent operation of the core makeup tanks	Significant core makeup tank injection flow leading to a boration of the RCS.	>1E-03 per reactor year DB2	1-2	PMS(A,C1) – High 3 Pressuriser Level	Rod breakers (C1)	PMS (M,C1) - High-2 Pressuriser Level	Head Vent(C1)	Fault is caused by operator error, false electrical signal or a valve malfunction. Fault is assessed individually in ‘Transient With Main Feed-water Available’ Section in Chapter 9 because of assumed difference regarding availability of one CMT post fault. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control. For ATWT, this event is bounded by Fault 1.13.1a “Complete loss of forced reactor coolant flow”	Modes 1 and 2 are discussed in Section 9.5.1, "Inadvertent Operation of the Core Makeup Tanks during Power Operation".
							PMS(A,C1) – High 3 Pressuriser Level	PRHR(C1)		
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(M,C2)	Rod MG Set breakers (C2)	DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							N/A	ACCUM(C1)		
							DAS(A,C2) – High Containment Temperature	PCS(C1) CI(C1)		
1.12.2	Inadvertent operation of the core makeup tanks	Significant core makeup tank injection flow leading to a boration of the RCS.	>1E-03 per reactor year DB2	3-5 with RCS Intact	N/A	Rods already inserted	PMS (M,C1) - High-2 Pressuriser Level	Head Vent (C1)	The limiting case is initiated from shutdown with rods already inserted, which produces minimum initial shutdown margin. Fault is caused by operator error, false electrical signal or a valve malfunction. In shutdown modes, assume both accumulators isolated at 6.895 MPa. After RNS cut in, RNS relief valves may provide relief in lieu of head vent valves. There is no need to consider ATWT event in shutdown, since rods already inserted.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.5, "Increase in Reactor Coolant Inventory".
							PMS(A,C1) – High 3 Pressuriser Level	PRHR(C1)		
							PMS(A,C1) – Low Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					N/A	Rods already inserted	DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) – High Containment Temperature	PCS(C1) CI(C1)		
1.12.3	Inadvertent operation of the core makeup tanks	N/A	N/A	5 with RCS Open, 6	N/A				Fault is not credible in Mode 5 with RCS pressure boundary open and in Mode 6 due to the CMTs being isolated.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.5, "Increase in Reactor Coolant Inventory".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.12.4	Chemical and volume control system malfunction that increase reactor coolant inventory	Injection of highly borated water into the RCS from one or both of the CCS pumps.	>1.0x10-3 per reactor year DB2	1-4 prior to RNS alignment	PMS(A,C1) – Low-2 Cold Leg Temperature	Rod breakers (C1)	PMS (M,C1) - High-2 Pressuriser Level	Head Vent (C1)	Note that in the PSA, CVS malfunction is part of the core power excursion, not transient with main feedwater. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control. For ATWT, this event is bounded by Fault 1.12.8 .	Modes 1 and 2 are discussed in Section 9.5.2, "Chemical and volume control system malfunction that increase reactor coolant inventory". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.5, "Increase in Reactor Coolant Inventory".
							PMS(A,C1) – High 3 Pressuriser Level	PRHR(C1)		
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(M,C2)	Rod MG Set breakers (C2)	Same Mitigation SSCs as Fault 1.12.8			
1.12.4a	Chemical and volume control system malfunction that increase reactor coolant inventory	Injection of highly borated water into the RCS from one or both of the CCS pumps. Overpressurisation could result in RCS coolant being relieved via RNS relief valves.	>5E-05 per reactor year (See Note 1 in 8A.1) DB1	4 after RNS alignment, 5 with RCS Intact	N/A	Rods already inserted	PMS(M,C1)	PRHR(C1)	Frequency of occurrence at lower modes reduced to DB1 fault. Operators would be expected to be monitoring RNS conditions continuously during these MODEs. Further analysis to substantiate these claims will be performed during site licensing. Should RCS inventory swell beyond the volume of the RCS/RNS, the RNS spring-operated relief valves would provide pressure relief. Radiological consequences are bounded by RNS line break, see Fault 2.3.1. Expected to be lower releases due to no break.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.5, "Increase in Reactor Coolant Inventory".
							PMS(M,C1)	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.12.5	Chemical and volume control system malfunction that increase reactor coolant inventory	None, RCS pressure boundary open, no potential for over pressurisation.	N/A	5 with RCS Open, 6	N/A				This event is not credible when the RCS pressure boundary is open.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.5, "Increase in Reactor Coolant Inventory".

	Fault	Consequences			Signals	Devices	Signals	Devices		
1.12.6	Inadvertent operation of pressuriser heaters	Potential to cause over-pressurisation of the reactor coolant system (RCS).	>1E-03 per reactor year DB2	1-5 RCS Pressure Boundary Intact	PMS(A,C1) – High-2 Pressuriser Pressure or Overtemperature ΔT or Low-2 RCP speed	Rod breakers (C1)	PMS(A,C1) - Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	This fault is bounded by the loss of load/turbine trip fault (Fault 1.12.8). For this transient, the sole concern would be over-pressurising the RCS. [ ] Based on this comparison, it can be concluded that the inadvertent operation of the pressuriser heaters would not challenge RCS pressure limits or PSV pressure relief capacity. For the primary safety case, eventually the reactor would be tripped on high RCS pressure and the PSVs are available to limit the RCS pressure transient caused by the heat load from the pressuriser heaters.	See Loss of Load / Turbine Trip discussion presented in Section 9.2.3 “Turbine Trip”. This fault will be examined in more detail to confirm claims and arguments presented during site licensing.

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.12.8	Turbine trip Loss of external electrical load	Loss of steam flow from SGs and decrease in heat removal. Loss of major load on the plan where the AC power remains available to operate major plant components.	>1E-03 per reactor year DB2	1-2	PMS(A,C1) – High-2 Pressuriser Pressure or Overtemperature ΔT or Low-2 RCP speed	Rod breakers (C1)	PMS(A,C1) - Low-2 SG NR level coincident with Low-2 SFW flow	PRHR(C1)	Turbine bypass accommodates up to 40% of rated steam flow during normal (power) operation. With Rapid Power Reduction System, this event is not expected to result in Reactor Trip or Safety Valve Actuation. PZR spray limits increase in coolant pressure. If automatic turbine bypass fails (or if condenser unavailable) the PZR and SG safety valves are sized to protect RCS and SG. Even assuming turbine bypass not available, the “normal” plant response (with class 2 systems available) Steam generator + SFW(A,C2)+CVS(A,C2), followed by RNS(M,C2). AC power from offsite or, from standby diesel generators Two diverse cases listed. First one is for core cooling. Second one is for anticipated transient without trip (ATWT). ATWT turbine trip is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of flow for core damage (Fault 1.13.1a). ATWT systems available for this event are reported; however, limiting ATWT case which models mechanical rod insertion failure reaches safe stable steady-state condition but a manual action would be required to terminate event. This ATWT case bounds the ATWT case assuming a PMS common cause failure (which only credits DAS protection functions). ATWT core cooling is aided by steam relief from the RCS via the safety relief valves and from the secondary loop via the steam generator PORVs.	Mode 1 is discussed in Section 9.2.3, "Turbine Trip".

							PMS(A,C1) – High-2 Containment Temperature	PCS(C1) CI(C1)		
1.12.9	Loss of load and turbine trip	None, turbine already tripped.	N/A	3-6	N/A				N/A	Modes 2, 3, 4, 5, and 6 are discussed in Section 9.8.4.2.1, "Loss of Load and Turbine Trip".
1.12.10	Not Used									
1.12.11	Reactor trip – spurious, or initiated by human error, or in response to progression of fault sequences initiated by events identified elsewhere in this list.	Increase in reactor fuel and coolant temperatures and coolant pressure.	<1E00 per reactor year DB2	1-2	Spurious Reactor Trip		See Comments		Same Mitigation SSCs as frequent fault Loss of Load / Turbine Trip (Fault 1.12.8)This fault is not applicable to Modes 3, 4, 5 and 6 since the reactor is already tripped.	See Section 9.2.3, "Turbine Trip".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.13 Loss of RCS Flow										
1.13.1	Partial loss of forced reactor coolant flow	Increase in reactor fuel and coolant temperatures and coolant pressure	1.7E-02 per reactor year DB2	1-2	PMS(A,C1) – Low-2 RCS Flow	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The IEF presented is the failure of power supply to the RCPs and includes a number of initiating events resulting in a loss of flow and covers faults such as a loss of component cooling. Partial loss of forced reactor coolant flow is due to: failure of power supply to the RCP, random failure of pump variable speed controller, flow blockage, pumps cavitation during startup, or operator error. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control. Anticipated transient without trip (ATWT) partial loss of forced reactor coolant flow is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of forced reactor coolant flow (Fault 1.13.1a) for core damage. ESF systems available for this event are reported; however, limiting ATWT reaches safe stable steady-state condition but a manual action would be required to terminate event.	Modes 1 and 2 are discussed in Section 9.3.1, "Partial Loss of Forced Reactor Coolant Flow".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2)- High Hot Leg Temperature	Rod MG Set breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2)- High Hot Leg Temperature	Rods fail to insert	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
							DAS(A,C2) – Low-2 SG WR Level	CMT(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
1.13.1a	Complete loss of forced reactor coolant flow	Increase in reactor fuel and coolant temperatures and coolant pressure.	1.7E-02 per reactor year DB2	1-2	PMS(A,C1) – Low-2 RCP Speed	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The IEF presented is the failure of power supply to the RCPs and includes a number of initiating events resulting in a loss of flow and covers faults such as a loss of component cooling. Complete loss of forced reactor coolant flow is due to: maintenance or operator error, loss of electrical supply, common cause failure of pump bearings due to gas build-up during startup. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control. Two diverse cases listed. First one is for core cooling. Second one is for Anticipated transient without trip (ATWT). ATWT complete loss of forced reactor coolant flow is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and is the limiting ATWT event for core damage. ESF systems available for this event are reported; however, limiting ATWT case does not credit trip rod cluster control assembly (RCCA) insertion or actuation of PRHR and CMT. As discussed in Section 9.3.2.3.1.3, the DAS trip on High hot leg temperature initiates a turbine trip, with a consequent reduction in reactivity for this case. The plant reaches safe stable steady-state condition and manual action would be required to terminate event.	Modes 1 and 2 are discussed in Section 9.3.2, "Complete Loss of Forced Reactor Coolant Flow".

					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.13.2	Partial and complete loss of forced RCS flow	None	N/A	3-5 with RCS Intact	N/A				Below Mode 2, forced RCS flow is not needed because margin to departure from nucleate boiling (DNB) is not an issue	Modes 3, 4 and 5 are discussed in Section 9.8.4.3.1, "Partial and Complete Loss of Forced RCS Flow".
1.13.3	Partial and complete loss of forced RCS flow	None	N/A	5 with RCS Open, 6	N/A				RCP's are not running in these modes.	N/A
1.13.4 – 1.13.10	Not Used									
1.13.11	Reactor coolant pump shaft seizure (Locked Rotor)	Pump flywheel and shaft would be disengaged from the shaft and the motor is assumed to continue running. Rapid reduction in flow, resulting in reactor trip on low flow signal. Combine with 1.13.12 if possible.	<1E-04 per reactor year DB1	1-2	PMS(A,C1) – Low-2 RCS Flow	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Since the initial rate of reduction of coolant flow is greater for the reactor coolant pump rotor seizure event, this is taken to be the most limiting fault condition for mechanical failure of an RCP. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control. This event at any shutdown mode is less limiting than the at-power conditions for which a DB is analysed.	Modes 1 and 2 are discussed in Section 9.3.3, "Reactor Coolant Pump Shaft Seizure (Locked Rotor)". Mode 2 is discussed in Section 9.8.4.3.2, " Reactor Coolant Pump Shaft Seizure or Break ".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.13.11a	Reactor coolant pump shaft seizure (Locked Rotor)	Pump flywheel and shaft would be disengaged from the shaft and the motor is assumed to continue running. Rapid reduction in flow, resulting in reactor trip on low flow signal.	N/A	3-6	N/A				This event at any shutdown mode is less limiting than the at-power conditions for which a DB is analysed. RCPs are not operated in Mode 6.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.3.2, " Reactor Coolant Pump Shaft Seizure or Break ".
1.13.12	Reactor Coolant Pump Shaft Break	Impeller is assumed to be free to rotate. Flow through affected loop is rapidly reduced.	<1E-04 per reactor year DB1	1-2	PMS(A,C1) – Low-2 RCS Flow	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	This event at any shutdown mode is less limiting than the at-power conditions for which a DB is analysed.	Modes 1 and 2 are discussed in Section 9.3.4, "Reactor Coolant Pump Shaft Break".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.13.12a	Reactor Coolant Pump Shaft Break	Impeller is assumed to be free to rotate. Flow through affected loop is rapidly reduced.	N/A	3-6	N/A				This event at any shutdown mode is less limiting than the at-power conditions for which a DB is analysed. RCPs are not operated in Mode 6.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.3.2, " Reactor Coolant Pump Shaft Seizure or Break ".

1.15 Core Power Excursions										
1.15.1	Uncontrolled rod cluster control assembly bank withdrawal from a subcritical or low-power startup condition	Uncontrolled addition of reactivity to the reactor core.	<1E-02 per reactor year DB2	2	PMS(A,C1) – Power Range High Neutron Flux (low setting)	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The ATWT uncontrolled RCCA withdrawal from sub-critical or low power condition is bounded by RCCA withdrawal at power (Fault 1.15.4).	Mode 2 is discussed in Section 9.4.1, "Uncontrolled Rod Cluster Control Assembly Bank Withdrawal from a Subcritical or Low-Power Startup Condition".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
1.15.2	Uncontrolled rod cluster control assembly bank withdrawal from a subcritical or low-power startup condition	Uncontrolled addition of reactivity to the reactor core.	<1E-02 per reactor year DB2	3-5	PMS(A,C1) – Power Range High Neutron Flux (low setting)	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The limiting case is initiated from shutdown with rods already inserted, which produces minimum initial shutdown. Note that rods are already inserted at the beginning of the event for lower modes; event is caused from a withdrawal of an assembly bank which would be stopped by reactor trip.	Modes 3, 4, and 5 are discussed in Section 9.8.4.4.1, "Uncontrolled RCCA Bank Withdrawal from a Subcritical Condition".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C1) – High Hot Leg Temperature	Rod MG Set breakers (C2)	DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
1.15.3	Uncontrolled rod cluster control assembly bank withdrawal from a subcritical or low-power startup condition	None	N/A	6	N/A	Rods already inserted	N/A		Rod control is not applicable in Mode 6.	Modes 3, 4, and 5 are discussed in Section 9.8.4.4.1, "Uncontrolled RCCA Bank Withdrawal from a Subcritical Condition".

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.15.4	Uncontrolled rod cluster control assembly bank withdrawal at power	Increase in core heat flux and reactor coolant temperature.	<1E-02 per reactor year DB2	1	PMS(A,C1) – OTΔT or OPΔT or High Power Range Positive Flux Rate	Rod Breakers (A,C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Bounding case is taken to be the uncontrolled withdrawal of a single RCCA when the reactor is operating at power. Two diverse cases listed. First one is for core cooling. Second one is for Anticipated transient without trip (ATWT). ATWT RCCA withdrawal at power is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of flow (Fault 1.13.1a) for core damage. ATWT Safety functions available for this event are reported; however, limiting ATWT case terminates event after DAS reactor trip.	Mode 1 is discussed in Section 9.4.2, "Uncontrolled Rod Cluster Control Assembly Bank Withdrawal at Power". Not applicable by definition in Modes 2, 3, 4, 5, and 6.
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set breakers (C2)	DAS(A,C2) - High Hot Leg Temperature	PRHR (C1)		
							DAS(A,C2) - Low-2 SG WR Level	CMT (C1)		
							DAS(A,C2) - High Containment Temperature	PCS (C1) CI(C1)		
1.15.5	Rod cluster control assembly misalignment due to system malfunction or operator error (Statically Misaligned RCCA)	Altered radial and axial power distribution.	<1E-02 per reactor year DB2	1	N/A (See Comments)				The most severe static misalignments do not require any automatic mitigation as DNB would not be reached; thus, no SSCs are credited. Following the identification of an RCCA group misalignment condition by the operator, they would take action as required by the plant Technical Specifications and operating instruction to restore the plant to an acceptable condition.	Mode 1 is discussed in Section 9.4.3, "Rod Cluster Control Assembly Misalignment (System Malfunction or Operator Error)".
1.15.5a	Rod cluster control assembly misalignment due to system malfunction or operator error (Dropped RCCA or RCCA Bank)	Rod control system response leads to power overshoot and adverse power shapes in the core.	<1E-02 per reactor year DB2	1	PMS(A,C1) – Low-2 Pressuriser Pressure	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The ATWT diversity case did not credit reactor trip or function of the P-17 rod block function. It concludes that ATWT acceptance criteria are met for all feasible scenarios. Since ATWT diversity case reaches safe stable steady-state condition, no engineered safety functions are specified. Operator action would be required to terminate the event.	Mode 1 is discussed in Section 9.4.3, "Rod Cluster Control Assembly Misalignment (System Malfunction or Operator Error)".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					Not Credited (See Comments)		N/A	ACCUM(C1)

							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.15.5b	Rod cluster control assembly misalignment due to system malfunction or operator error (Single rod cluster control assembly withdrawal)	Increase in core power and reactor coolant temperature leads to DNB and core damage.	<1E-04 per reactor year DB1	1-2	PMS(A,C1) - Low-2 Pressuriser Pressure or OTΔT	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	A more realistic initiating event frequency of less than 1E-04 events per year is assumed for this fault and not determined by PSA. Multiple failures (either electrical or operator error) would be required for single RCCA withdrawal. This frequency is estimated based on the probability of an open wire (or terminal) failure being 1.6E-08 faults per hour per MIL-HDBK-217F, which can be converted to 1.4E-04 events per year. Additional coincident failures (electrical or operator detection based) would be required, and as such those would drop the frequency below 1E-04 and therefore make this event an infrequent fault, classified as a DB1 fault. A Mode 2 event is less limiting than the at-power conditions for which a DB is analysed.	Mode 1 is discussed in Section 9.4.3, "Rod Cluster Control Assembly Misalignment (System Malfunction or Operator Error)".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.15.5c	Rod cluster control assembly misalignment due to system malfunction or operator error (all types)	N/A	N/A	2-6	N/A				Misaligned RCCAs have no effect in the absence of a critical neutron flux and are not a concern below Mode 2. Mode 2 for Fault 1.15.15b addressed by that fault entry.	Modes 2, 3, 4, 5, and 6 are discussed in Section 9.8.4.4.3, "RCCA Misalignment".
1.15.6	Startup of an inactive reactor coolant pump at an incorrect temperature	Cooler water entering core could lead to insertion of positive reactivity.	N/A	N/A	N/A				The Technical Specifications require all RCPs to be operating while the plant is in operating modes 1 and 2. For lower modes, the reactor will initially be subcritical. There will be no increase in core power and therefore no protective action is required.	Modes 1 and 2 are discussed in Section 9.4.4, "Startup of an Inactive Reactor Coolant Pump at an Incorrect Temperature". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.4.4, "Startup of an Inactive Reactor Coolant Pump at an Incorrect Temperature".
1.15.7	Chemical and volume control system malfunction that results in a decrease in the boron concentration in the reactor coolant	Insertion of positive reactivity to the core.	<1E-02 per reactor year DB2	1-2	PMS(A,C1) – OTΔT or High Source Range Neutron Flux	Rod Breakers (C1) and Isolation of dilution sources (C1)	PMS(A,C1) – Low-2 SG NR level coincident with Low-2 SFW flow	PRHR(C1)	Boron dilution can be due to controller, operator, or mechanical failure of CVS. Two diverse cases listed. First one is for core cooling. Second one is for Anticipated transient without trip (ATWT). The limiting ATWT boron dilution event is presented here. In some analysed scenarios, manual action would be required to terminate the boron dilution event (isolate dilution source). In addition, CMT manual actuation is available for mechanical failures that prohibit rod insertion.	Modes 1, 2, 3, 4, and 5 are discussed in Section 9.4.6, "Chemical and Volume Control System Malfunction that Results in a Decrease in the Boron Concentration in the Reactor Coolant".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rods fail to insert	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
					PMS(A,C1) – OTΔT	Isolation of dilution sources (C1)	DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

1.15.8	Chemical and volume control system malfunction that results in a decrease in the boron concentration in the reactor coolant	Insertion of positive reactivity to the core.	<1E-02 per reactor year DB2	3-5	N/A	Rods Already Inserted	N/A		Three diverse cases listed. First one is for core cooling. Second one is for ATWT. The third one is for a Xenon decay transient. The limiting ATWT boron dilution event assuming common cause PMS failure is presented here. For all cases, the DAS Intermediate Range trip results in isolation of CVS and RNS and trip of RCPs in addition to CMT actuation. These actions have been shown to be adequate to prevent core power reaching the point of adding heat. As noted in section 9.4.6.3.1.3.2, simplified boron dilution calculations have shown that cases with only RNS pumps operating are not as challenging as cases with the RCPs running. Results reported apply to cases with RCPs running.	Modes 1, 2, 3, 4, and 5 are discussed in Section 9.4.6, "Chemical and Volume Control System Malfunction that Results in a Decrease in the Boron Concentration in the Reactor Coolant".
					PMS(A,C1) – High source range neutron flux	Isolation of dilution sources (C1)				
					PMS(A,C1) - Flux Doubling	Isolation of dilution sources (C1)	PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS (A, C2) – High Intermediate Range Nuclear Detector	Isolation of dilution sources (C1)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2)- High Containment Temperature	PCS(C1) CI(C1)		
					DAS (A, C2) – High Intermediate Range Nuclear Power	Isolation of dilution sources (C1) Rod MG Set breakers (C2)	DAS(A, C2) – High Intermediate Range Nuclear Detector	CMT(C1) RNS isolation (C1)		
1.15.9	Chemical and volume control system malfunction that results in a decrease in the boron concentration in the reactor coolant	N/A	N/A	6	N/A				Boron dilution transient cannot occur during mode 6 due to administrative controls.	Mode 6 is discussed in Section 9.4.6, "Chemical and Volume Control System Malfunction that Results in a Decrease in the Boron Concentration in the Reactor Coolant" and 9.8.4.4.5, "Chemical and Volume Control System Malfunction that Results in a Decrease in the Boron Concentration in the Reactor Coolant".
1.15.10	Inadvertent loading and operation of a fuel assembly in an improper position	Increased heat fluxes in the core.	DB0	1-6	N/A				In the unlikely event that a loading error occurs, analyses confirm that resulting power distribution effects are either readily detected by the online core monitoring system prior to reaching full power, or cause a sufficiently small perturbation to be acceptable within the uncertainties allowed between nominal and design power shapes. This event is not applicable in the subcritical modes, Modes 3 through 6.	Modes 1 and 2 are discussed in Section 9.4.7, "Inadvertent Loading and Operation of a Fuel Assembly in an Improper Position". Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.4.6, "Inadvertent Loading of a Fuel Assembly in an Improper Position".

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
1.15.11	Spectrum of rod cluster control assembly ejection accidents	Rapid reactivity insertion causing a rapid rise in the reactor power, which would also cause a breach in the RCS pressure boundary resulting in a subsequent depressurisation and loss of reactor coolant.	<1E-04 per reactor year DB1	1-2	PMS(A, C1) – High Power Range Positive Flux Rate	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	While the group comprises a single fault, the ejection of an RCCA assembly form the core, analysis has been performed to establish the most limiting conditions for the fault. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control.	Modes 1 and 2 are discussed in Section 9.4.8, "Spectrum of Rod Cluster Control Assembly Ejection Accidents".
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – Low CMT Level	ADS(C1)		
							N/A	ACCUM(C1)		
							PMS(A,C1) – Low CMT Level	IRWST(C1)		
							PMS(A,C1) – Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.15.12	Spectrum of rod cluster control assembly ejection accidents	Loss of coolant with a subsequent de-pressurisation of the RCS and pressure decrease in the pressuriser.	2.5E-05 per reactor year DB1	3-6	N/A				In the lower modes (3 and lower), there is not enough reactivity in a single rod that, if ejected, would cause the reactor to go critical. Rod ejection then becomes a small LOCA. See Fault 1.8.3 to 1.8.4.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.4.7, "RCCA Ejection".
1.15.13	Feedwater system malfunctions that result in a decrease in feed water temperature	Reductions in feedwater temperature cause an increase in core power by decreasing reactor coolant temperature.	>1E-03 per reactor year DB2	1-5 with RCS Intact	Not Credited (See Comments)		PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	The behaviour and consequences of this fault are bounded by the 1.15.18 (Excessive load Increase). It is noted that the bounding DBA (Fault 1.15.18) does not produce a reactor trip but stabilizes in safe condition. Two diverse cases listed. First one is for core cooling. Second one is for ATWT. The ATWT result is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of flow (Fault 1.13.1a) for core damage. ATWT systems available for this event are reported; however, limiting ATWT case reaches safe stable steady-state condition but manual operator action would be required to end the transient.	Modes 1 and 2 are discussed in Section 9.1.1, "Feedwater System Malfunctions that Result in a Decrease in Feedwater Temperature" and Modes 3 and 4 are discussed in Section 9.8.4.1.1, "Feedwater System Malfunctions Which Increase Heat Removal from the Primary System"
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)

							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
1.15.20	Flooding of water from IRWST causes external cooling of RCS.	Cooling of RCS could cause negative reactivity insertion.	N/A	N/A	N/A				Fault not considered credible. Since the RCS components are thermally insulated, external flooding of the lower RCS components in this event would only cause a slight increase in heat loss from the RCS, and lead to a very minor temperature perturbation.	Fault is not addressed further.
1.15.21	Pump speed fault leading to higher than expected primary coolant flow rate	Excess cooling of RCS could cause positive reactivity insertion.	<1E-02 per reactor year DB2	1-2	Not Credited (See Comments)		PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	This fault is bounded by the excessive load increase fault (Fault 1.15.18). In comparison to the excessive load increase fault, an increase in RCS flow fault would not result in a sustained power demand increase; therefore, any reactor power increase would be transitory (eventually, primary power would match the normal steam load demand). [ ]	Fault is discussed in Section 9.1.0.1, "Increase in Heat Removal Faults (Excluding MSLB)". This fault will be examined in more detail to confirm claims and arguments presented during site licensing.

1.16.7	Inadvertent closure of Main Steam Isolation Valves (MSIVs)	Rapid reduction in steam flow from the steam generators and a heat up of the primary side.	>1E-03 per reactor year DB2	1-6	PMS(A,C1) – High-2 Pressuriser Pressure or Overtemperature ΔT or Low-2 RCP speed	Rod breakers (C1)	PMS(A,C1) - Low-2 SG NR level coincident with Low-2 SFW flow	PRHR(C1)	Inadvertent closure of the main steam isolation values leads to a turbine trip with no credit for the turbine bypass system. Main feedwater flow is lost. Bounded by Fault 1.12.8. Two diverse cases listed. First one is for core cooling. Second one is for anticipated transient without trip (ATWT). This fault leads to an ATWT turbine trip (Fault 1.2.8), which is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of flow (Fault 1.13.1a) for core damage. ATWT systems available for this event are reported; however, limiting ATWT case reaches safe stable steady-state condition but a manual action would be required to terminate event. Event in Modes 2, 3, or 4 are bounded by Fault 1.12.8 at full power. In Modes 5 and 6, the event is not applicable.	Mode 1 is discussed in Section 9.2.4, "Inadvertent Closure of Main Steam Isolation Valves" and Modes 2 through 6 are discussed in Section 9.8.4.2.1, "Loss of Load, Turbine Trip, Inadvertent MSIV closure, and Loss of Condenser Vacuum"

1.16.8	Feedwater system pipe break	Loss of feedwater flow to both SGs with blowdown of faulted SG after reactor trip.	6.6E-04 per reactor year DBL/DB1	1-2	PMS(A,C1) – Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level	PRHR(C1)	The IEF presented is documented in LTR-AP1000-PRA-16-041. This fault represents a non-isolatable break. Isolatable feedline breaks are included in fault 1.16.1. The DBL class applies to the larger breaks in the spectrum, up to full double ended breaks. Smaller break sizes would be in the DB1 class; however, the credited mitigation equipment and limiting DB analysis presented would bound all break sizes. The following worst limiting case is considered. After reactor trip, a full double-ended rupture of the feed water line is assumed between the check valve and the SG such that the faulted steam generator blows down through the break and no main feed water is delivered to the intact steam generator. Pressuriser safety valve is credited in the analysis for reactor coolant system pressure control.	Modes 1 and 2 are discussed in Section 9.2.8, "Feedwater System Pipe Break"
							PMS(A,C1) – Low-2 Steamline Pressure	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
1.16.9	Feedwater system pipe break	Loss of feedwater flow to both SGs.	3.3E-05 per reactor year (See Note 1 in 8A.1) DBL/DB1	3-4 before RNS alignment	N/A	Rods already inserted	PMS(A,C1) – Low-2 SG NR Level	PRHR(C1)	This fault represents a non-isolatable break. Isolatable feedline breaks are included in fault 1.16.2. The DBL class applies to the larger breaks in the spectrum, up to full double ended breaks. Smaller break sizes would be in the DB1 class; however, the credited mitigation equipment and evaluation presented would bound all break sizes.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.2.4, "Feedwater System Pipe Break"

1.22 Main Steam Line Stuck Open Safety Valve										
1.22.1	Inadvertent opening of a steam generator relief or safety valve.	Steam release from SG leads to heat removal from the RCS and a concomitant reduction in coolant temperature.	2.4E-03 per reactor year DB2	1-2	PMS(A,C1)	Rod Breakers (C1) (See Comments)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Fault covers the spurious actuation of a main steam line safety valve for Modes 1 and 2. The limiting case analysed is initiated from shutdown (Mode 2) with rods already inserted, which bounds the less limiting case in Mode 1. Two diverse cases listed. First one is for core cooling. Second one is for ATWT. The ATWT result is bounded by ATWT loss of normal feedwater (Fault 1.16.1) for peak RCS pressure and by ATWT complete loss of flow (Fault 1.13.1a) for core damage. ATWT systems available for this event are reported; however, limiting ATWT case reaches safe stable steady-state condition similar to excessive load increase. No reactor trip is required for plant protection and manual operator action would be required to end the transient.	Modes 1 and 2 are discussed in Section 9.1.4, "Inadvertent Opening of a Steam Generator Relief or Safety Valve".

							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					N/A	Rods Already Inserted	DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2)- High Containment Temperature	PCS(C1) CI(C1)		
1.22.2a	Inadvertent opening of a steam generator relief or safety valve.	Steam release from SG leads to heat removal from the RCS and a concomitant reduction in coolant temperature.	N/A	5-6	N/A				RCS is borated and effectively isolated for secondary system in Modes 5 and 6 that such a cooldown-induced power excursion cannot be postulated.	Modes 3, 4, 5, and 6 are discussed in Section 9.8.4.1.3, "Steamline Breaks".

2. Additional Reactor Internal Faults										
2.1 Failure of RNS During Shutdown Conditions										
2.1.1	Not Used									
2.1.2	Failure of normal residual heat removal system	Loss of decay heat removal.	1E-03 per reactor year DB2	4-5 with RCS Intact	N/A	Rods already inserted	PMS(A,C1) – Low-2 Pressuriser Level	PRHR(C1) CMT(C1) CI(C1)	RNS is not aligned until Mode 4; therefore event is not possible during Modes 1-3. Includes various initiators, including loss of offsite power, pump failures, loss of component cooling water, loss of service water, and loss of compressed air. Manual PRHR actuation at 30 minutes, no actuation of ADS/IRWST injection occurs. Without manual actuation, CMT/PRHR would still automatically actuate at approximately 2.2 hours after loss of RNS on Low Pressuriser Level. Note that overpressure protection is provided by RNS relief valves. There is no need to consider ATWT event in shutdown, since rods already inserted.	Fault is discussed in Section 9.8.5.1, "Loss of RNS During Mode 4 and 5, with RCS Intact". Diversity cases to be analysed during site licensing.
							PMS(A,C1) – Low CMT Level	ADS(C1) IRWST(C1)

					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
2.3 LOCA Events Involving RNS										
2.3.1	Rupture of the normal residual heat removal system piping	Loss-of-coolant accident.	1.6E-05 per reactor year DB1	4-5 with RCS Intact	N/A	Rods already inserted	PMS(A,C1) - Low-2 Pressuriser Level	CMT(C1)	RNS is not aligned until Mode 4; therefore event is not possible during Modes 1-3. Breaks inside containment would be bounded by this fault, but with reduced radiological consequences. Fault includes additional initiators, such as inadvertent or spurious operation of RNS-V024. RNS isolation provided by containment isolation signal on Low CMT level.	Fault is discussed in Section 9.8.5 3, "Loss of Coolant Accidents Involving RNS".
							PMS(A,C1) - Low CMT Level	ADS(C1) IRWST(C1) CI(C1) RNS Isolation (C1)		
							PMS(A,C1) - Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
2.3.2	Rupture of the normal residual heat removal system piping	Loss-of-coolant accident.	1.6E-05 per reactor year DB1	5 with RCS Open	N/A	Rods already inserted	PMS(A,C1) - Low Hot Leg Level	ADS 4(C1) IRWST(C1) CI(C1) RNS Isolation(C1)	Breaks inside containment would be bounded by this fault, but with reduced radiological consequences. ADS-4 and IRWST injection are actuated after a 25 minute delay upon reaching Low Hot Leg Level setpoint. Fault includes additional initiators, such as inadvertent or spurious operation of RNS-V024, or over-draining of RCS while going to mid-loop level. RNS isolation provided by containment isolation signal on Low CMT level.	Fault is discussed in Section 9.8.5 3, "Loss of Coolant Accidents Involving RNS".
							PMS(A,C1) - Low IRWST Level	RECIRC(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
2.3.3	Rupture of the normal residual heat removal system piping	Loss-of-coolant accident.	1.6E-05 per reactor year DB1	6	N/A	Rods already inserted	PMS(M,C1)	RNS Isolation (C1) ADS 4(C1) IRWST(C1) RECIRC(C1)	Breaks inside containment would be bounded by this fault, but with reduced radiological consequences. ADS-4 is only needed if the reactor internals are installed; otherwise, sufficient vent area exists. Fault includes additional initiators, such as inadvertent or spurious operation of RNS-V024, or over-draining of RCS while going to mid-loop level. RNS isolation assumed to be actuated manually prior to High-2 containment pressure signal.	Fault is discussed in Section 9.8.5 3, "Loss of Coolant Accidents Involving RNS".
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1) CI(C1)		
2.4 Reactor Internal Events Specific to Refuelling Operations										
2.4.1	Uncontrolled rod cluster control assembly bank withdrawal during refuelling	None	N/A	6	N/A				Keff for a fully fuelled core in mode 6 is maintained at, or below, 0.95 with control rods and soluble boron. The core is maintained sufficiently sub-critical, that removal of rod cluster control assemblies will not result in criticality. Control rod breakers are required to be open preventing uncontrolled withdrawal. No difference from Fault 1.15.3.	Modes 3, 4, and 5 are discussed in Section 9.8.4.4.1, "Uncontrolled RCCA Bank Withdrawal from a Subcritical Condition".
2.4.2	Inadvertent loading of a fuel assembly in an improper position in core during refuelling.	None	N/A	6	N/A				Shutdown margin with borated coolant and RCCAs fully inserted will exceed any local reactivity perturbation caused by fuel misloading. Only a potential issue on return to power. Included in Fault 1.15.10.	Section 9.8.4.4.6, "Inadvertent Loading of a Fuel Assembly in an Improper Position".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
2.4.3	Loss or reduction of boration in refuelling cavity due to: -faulty boron concentration measurement - uncontrolled dilution/addition of unborated water (e.g. from fire protection system (FPS))	Criticality Event	N/A	6	N/A				Criticality assessment demonstrates that complete loss of boron in the refuelling cavity would not result in a criticality event. See related Fault 1.15.9.	Fault not considered further.
2.4.4	Loss of configuration of reactor core due to dropped loads (including integrated head package, or above core internals)	Criticality Event	N/A	6	N/A				Large, heavy loads such as the integrated head package, or above core internals, would not fit within the open RPV and damage to fuel would be restricted to the uppermost regions. In such cases the consequences would only be radiological see Fault 2.4.7 below. The criticality risks posed by smaller dropped loads, due to assembly deformation, are considered to be bounded by a dropped load onto fuel assemblies in the Spent Fuel Pool – see Fault 3.2.2. Assessment shows this fault has no criticality consequences.	Fault not considered further.
2.4.5	Dropped fuel assembly (spent or new) onto, or into reactor core	Criticality Event	N/A	6	N/A				The boron concentration is maintained sufficiently high during refuelling to prevent criticality. A dropped assembly would result in geometry less conducive to approaching criticality than the standard configuration. The consequences of the event are therefore negligible regarding criticality; fuel damage is considered in Fault 2.4.9.	Fault not considered further.
2.4.6	Displacement of control rods (e.g. seismic)	Criticality Event	N/A	6	N/A				During refuelling, core inserts remain in the fuel assemblies and travel with the fuel to the spent fuel racks in the Auxiliary Building. Also, core boron concentration is kept at 2700 ppm to keep the core 5 percent $\Delta k/k$ subcritical during refuelling operations. This fault is therefore not a credible event.	Fault not considered further.
2.4.7	Damage to reactor core due to dropped loads (including integrated head package, or above core internals)	Radioactivity release	N/A	6	N/A				The polar crane is designed according to NUREG-0554, supplemented by ASME NOG-1 for a Type I failure proof crane. The crane is single failure proof, and is designed to stop and hold a critical load following the credible failure of a single component. A heavy loads analysis is performed to evaluate postulated load drops from heavy load handling systems located in safety-related areas of the plant, specifically the nuclear island. No evaluations are required for critical loads handled by the containment polar crane, the cask handling crane, the containment equipment hatch hoist, and the containment maintenance hatch hoist since a load drop is unlikely.	Fault not considered further.

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
2.4.8	Start of refuelling operations before fuel is adequately cooled	Potential for fuel overheating and damage.	N/A	6	N/A				Initiating event not considered credible. Higher than expected average decay heat levels in core would have been recognized earlier by coolant temperature/pressure remaining above expected levels. Commencement of refuelling operations requires RCS to have been cooled down to (140 F/60 C) in mode 5, with RNS operative. Refuelling operations would be deferred until these conditions are met.	Fault not considered further.
2.4.9	Damage to fuel assembly/core following drop of assembly on reactor core	Potential fuel damage and radioactivity release.	<1E-03 Per reactor year DB1	6	Same Mitigation SSC as infrequent dropped fuel assembly in spent fuel assembly in spent fuel pool (Fault 3.2.11)				Radioactivity release Consequences < BSL for Target 4 for both onsite and offsite doses. Bounded by Fault 3.2.11. Frequency is assessed in Section 9.14.5.6.	This fault is discussed in Section 9.9.5, "Dropped Fuel Assembly onto Other Fuel".
3. Non-Reactor Faults										
3.1 Faults Involving Fuel (Spent/New) Transfer Route										
3.1.1	Loss of water from refuelling cavity (failure of seal between RPV and reactor cavity, cracking of wall due to seismic event)	Loss of coolant	DB0	6	N/A				Both the refuelling cavity and the permanent cavity seal ring are seismic category 1, so this event is extremely unlikely. Nonetheless, adequate inventory would remain in the spent fuel pool area to keep the spent fuel covered for a minimum of 72 hours, depending on the amount of fuel transferred to the spent fuel pool from the core. The spent fuel pool-transfer canal weir gate or the transfer tube valve may also be closed to isolate the spent fuel pool from the refuelling cavity. Should an assembly be in the cavity or transfer canal at the time of the event, the fuel handling machine would remain operable and would transfer the assembly to a safe position in the spent fuel pool area. Should a single failure coincident with the loss of water event cause a loss of power to the fuel handling machines, manual operator action is available to transfer the assembly.	Fault not considered further.
3.1.2	Element stuck in fuel handling machine	Restriction in convective cooling over extended period	DB0	6	N/A				Refuelling machine mast is designed to support natural convection cooling of a fuel assembly. A stuck fuel assembly would pose no radiological concerns as long as the refuelling cavity water level is maintained at the minimum operating level for fuel movement. Further, all fuel handling equipment drive motors are equipped with hand wheels to support manual operation.	Fault not considered further.
3.1.3	Element stuck in transfer tube	Restriction in convective cooling over extended period	DB0	6	N/A				The fuel transfer car basket is designed to support natural convection cooling of a fuel assembly. A stuck fuel assembly would pose no radiological concerns as long as the refuelling cavity water level is maintained at the minimum operating level for fuel movement. Further, all fuel handling equipment drive motors are equipped with hand wheels to support manual operation.	Fault not considered further.

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.1.4	Damage to fuel assembly (spent or new) due to drop in refuelling cavity	Potential fuel damage and radioactivity release.	<1E-03 per reactor year DB1	6	Same Mitigation SSC as infrequent dropped fuel assembly in spent fuel assembly in spent fuel pool (Fault 3.2.11)				Bounded by Fault 3.2.11.	Fault is discussed in Section 9.9.5, "Dropped Fuel Assembly onto Other Fuel".
3.1.5	Operator falls into flooded refuelling cavity	Operator radiation exposure, dose < BSO	DB0	6	N/A					Fault is discussed in Section 9.10.4, "Operator Falls into Flooded Refuelling Cavity or Fuel Storage Pool".
3.1.6	Water level fall in refuelling cavity (shielding lost)	Operator radiation exposure, dose < BSO	DB0	6	N/A					Fault is discussed in Section 9.10.5, "Water Level Fall in the Refuelling Cavity or Storage Pool".
3.1.7	Over-raising fuel in refuelling cavity (shielding lost)	Operator radiation exposure, dose < BSO	DB0	6	N/A				Design of RM mast places a geometric constraint on the height to which a fuel assembly can be raised. Fault is precluded by design.	Fault screened out Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.1.8	Flooding of new fuel with un-borated water or oil: - in new fuel assembly inspection area (with concrete reflection) - in new fuel storage rack (dry buffer store)	Criticality event	N/A	N/A	N/A				For a single fuel assembly in the inspection area flooded or sprayed with water and with concrete reflection on both sides, the reactivity is expected to be less than that for a fully loaded new fuel storage rack covered in water.	Fault not considered further.
3.1.9	Dropped fuel cask in rail car bay	Potential damage to cask seals and fuel content.	DB0	N/A	N/A				There is no release for this fault. Drop could occur due to operator error or failure of lifting equipment. Risk considered to be ALARP.	This fault is discussed in Section 9.9.4, "Dropped Fuel Cask in Rail Car Bay".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.2 Spent Fuel Pool Faults										
3.2.1	Loss or reduction of boration in spent fuel pool due to: -faulty boron concentration measurement - uncontrolled dilution/addition of unborated water (e.g. from FPS)	Criticality event Radiation doses < Target 4 BSL	N/A	N/A	N/A				Boron is not credited in criticality analysis.	Fault is screened out deterministically in Section 9.7.1.2,
3.2.2	Loss of configuration of fuel in storage racks (e.g. seismic or dropped load) - dropped fuel assembly lying on top of rack (toppled) -.vertical misalignment of fuel assembly relative to neutron absorbing panels - change in rod pitch to a more reactive configuration (possibly outside rack) - distortion of rack geometry (e.g. bringing fuel assemblies closer together) - displacement of racks closer together, or with more concrete reflection	Criticality event	N/A	N/A	N/A				PSCR Section 9.11 concludes that there is no reactivity increase and therefore no release for a fuel assembly dropped on top of the rack. For other faults, there would only be an activity rise if there was a coincident boron dilution event, which is screened out on frequency grounds.	Fault is screened out deterministically in Section 9.7.1.2,
3.2.3	Misplaced fuel assembly in spent fuel pool: - in space next to fuel racks - placed in wrong region (R1 instead of R2) - vertical misalignment of fuel assembly relative to neutron absorber panels	Criticality event	N/A	N/A	N/A				PCSR Section 9.11 concludes that there is no increase in activity since the design is for all fresh fuel anyway.	Fault is screened out deterministically in Section 9.7.1.2,

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.2.4	Increased reactivity after incomplete repair of fuel assembly (some fuel rods removed but not replaced)	Criticality event	N/A	N/A	N/A				Fault involves the disassembly and incorrect re-assembly of a fuel assembly in the SFP. Even if this happened, a number of sequential errors would have to occur before there was any criticality event.	Fault is screened out deterministically in Section 9.7.1.2,
3.2.5	Loss of water from spent fuel storage pool. Class 2 8 inch SFS suction/return pipe break	Loss of cooling water	<1E-05 per reactor year DB1	N/A	N/A		Spent fuel pool cooling system (SFS)(C1) – Low-2 SFP Water Level	SFP(C1) FTC(C1) Cask washdown pit (CWP)(C1) cask loading pit (CLP) (C1) passive containment system water storage tank (PCCWST(C1))	The 8” Class 2 SFS suction and return piping connections to the SFP are the only non-Class 1 connections. The SFS return line has a 1-inch hole that is 3 ft (.61 m) below the operating deck that acts as a siphon break to prevent the pool from draining. A break in the SFS suction connection to the SFP will cause the water level to drop to the bottom of the SFS suction piping. Since the RNS suction and return connections are below the SFS connections, an RNS pump/HX train can be used to cool the pool. Any of the signals listed will alert the operator of decreased inventory. The amount of makeup required to maintain a safe level in the SFP depends on the time in the fuel cycle that the event occurs. During the majority of time in a typical fuel cycle, the water inventory in the SFP and fuel transfer canal (FTC) after the break is sufficient to maintain level for at least 72 hours after the break.	Fault discussed in section 9.7.2.4 “Postulated Loss of Water Inventory from the SFP”
3.2.6	Loss of water from spent fuel storage pool. Class 1 8 inch RNS suction/return pipe break	Loss of cooling water	<1E-05 per reactor year DBL	N/A	N/A		SFS(A,C1) – Low-2 SFP Water Level	SFP(C1) FTC(C1) CWP(C1) CLP(C1) PCCWST(C1)*	Analysed as a DB1 design basis infrequent fault. The RNS return line to the SFP has a hole that is below the operating deck that acts as a siphon break to prevent the pool from draining. A break in the RNS suction line will cause the SFP water level to drop to the bottom of the RNS suction connection, resulting in a loss of cooling scenario. Conservative analysis shows that the operator will have at least 24 hours available to align any of the sources of makeup listed. Any of the signals listed will alert the operator of decreased inventory. The amount of makeup required to maintain a safe level in the SFP depends on the time in the fuel cycle that the event occurs. During the majority of time in a typical fuel cycle, the water inventory in the SFP and FTC after the break is sufficient to maintain level for at least 72 hours after the break. *Water from the PCCWST (and passive containment cooling ancillary water storage tank (PCCAWST)) must be aligned to the SFP through the Class 2 spray lines.	Fault discussed in section 9.7.2.4 “Postulated Loss of Water Inventory from the SFP”

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
3.2.7	Loss of water from spent fuel storage pool. Class 1 6 inch FTC drain line pipe break	Loss of cooling water	<1E-05 per reactor year BDB	N/A	N/A		See Fault 3.2.5		Analysed as a DB1 design basis infrequent fault. A break in the 6" Class 1 FTC drain line will drain the pool to the gate elevation if the FTC gate is open to the SFP. If instrument air is available, the FTC gate can be closed to prevent further SFP draining. Assuming the SFP drains to the gate level, the operator will have at least 2 hours to align a makeup source during normal operation before boiling occurs and at least 1 hour during a refuelling outage.	Fault discussed in section 9.7.2.4 "Postulated Loss of Water Inventory from the SFP"
3.2.8	Loss of water from spent fuel storage pool. Class 1 6 inch CLP pipe break	Loss of cooling water	<1E-05 per reactor year BDB	N/A	N/A		See Fault 3.2.5		Analysed as a DB1 design basis infrequent fault. Bounded by larger diameter pipe breaks.	Fault discussed in section 9.7.2.4 "Postulated Loss of Water Inventory from the SFP"
3.2.9	Loss of water from spent fuel storage pool. Class 1 instrument line pipe break	Loss of cooling water	N/A	N/A	N/A		See Fault 3.2.5		Bounded by larger diameter pipe breaks.	Fault discussed in section 9.7.2.4 "Postulated Loss of Water Inventory from the SFP"
3.2.10	Loss of spent fuel storage pool cooling due to equipment failure, loss of offsite power or station blackout.	Loss of fuel decay heat removal	4.4E-03 per reactor year DB1	N/A	N/A		See Fault 3.2.5		The loss of SFP cooling is bounded by loss of cooling water scenarios where the level drops below the SFS suction connections and cooling capability is therefore lost with less water inventory in SFP. The high temperature alarm will alert the operator of a loss of cooling. If there is an extended loss of cooling, boiling will occur and the water level will begin to drop. The signals and devices available are then equivalent to those outlined in 3.2.5.	Fault discussed in section 9.7.2.3 "Loss of Spent Fuel Pool Cooling Capability".
3.2.11	Dropped fuel assembly in spent fuel storage pool	Potential fuel damage and radioactivity release.	<1E-03 per reactor year DB0	N/A	N/A		VAS(A,C3) – Activity in-air	N/A	To minimize the operator exposure to airborne activity, the fuel handling activity in-air monitor will alert operators to evacuate the area immediately. High efficiency particulate air (HEPA) filters and charcoal absorbers in the VFS reduce the dose to members of the public	This fault is discussed in Section 9.9.5, "Dropped Fuel Assembly onto Other Fuel".
3.2.12	Dropped fuel cask in spent fuel storage pool (spent or new)	Potential fuel damage and radioactivity release.	N/A	N/A	N/A				Cask handling crane is prevented from travelling over the SFP, therefore the fault cannot occur.	Fault is discussed in Section 9.9.2, "Analysis of Faults" in Section 9.9, "Dropped Loads."

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.2.13	Operator falls into spent fuel storage pool	Operator radiation exposure, dose < BSO	<1E-03 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO.	Fault is discussed in Section 9.10.4, "Operator Falls into Flooded Refuelling Cavity or Fuel Storage Pool".
3.2.14	Water level fall in storage pool (shielding lost)	Operator radiation exposure, dose < BSO	<1E-03 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Minimum allowable water depths above active fuel in a fuel assembly during fuel handling are 2.67 m in the reactor cavity and 2.67 m in the fuel transfer canal and spent fuel pool. (This limits the dose to personnel on the spent fuel pool handling machine to less than 0.025 mSv/hr for an assembly in a vertical position.)	Fault is discussed in Section 9.10.5, "Water Level Fall in the Refuelling Cavity or Storage Pool".
3.2.15	Over-raising of fuel in spent fuel storage pool (shielding lost)	Operator radiation exposure	N/A	N/A	N/A				Design of fuel handling machine places a geometric constraint on the height to which a fuel assembly can be raised. Fault is precluded by design.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.2.16	Exposure in areas contaminated by pool water (over time)	Operator radiation exposure	N/A	N/A	N/A				Assessed levels of contamination in the form of a puddle of spilt water would give very low dose rates, would be readily detectable by HP and are easily cleaned.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.3 Operator Exposure Associated with NDT, Maintenance, and Calibration Activities										
3.3.1	Unauthorized operator entry into active areas	Operator radiation exposure	N/A	N/A	N/A				Ingress and egress of plant operating personnel to radiologically restricted areas will be strictly controlled and monitored in accordance with HP principles. The arrangements will be as effective as, or better than, at existing operational pressurised water reactor (PWR) plant in general.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.3.2	Inappropriate handling or use of other sources (e.g. radiography, neutron and HP calibration sources)	Operator radiation exposure	N/A	N/A	N/A				No significant neutron or radioactive sources are present outside of the reactor fuel. All other radioactive sources required for use on the station such as X-ray machines for radiography or test sources for radiation monitoring equipment will be subject to controls as required by the Ionising Radiations Regulations (IRR). All such radiation sources would be held and used only under the local control of Health Physics (HP).	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.4 Faults in CVS and WLS (All Plant States)										
3.4.1	Failure of small lines carrying primary coolant outside containment	Limited release of primary coolant outside containment.	>1E-03 per reactor year HFLC	1-6	N/A				Bounded by Fault 1.9.2	Fault is discussed in Section 9.6.2, "Failure of Small Lines Carrying Primary Coolant Outside Containment"

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

					Signals	Devices	Signals	Devices		
3.4.2	Fault in handling spent resins intermediate level waste (ILW). Leakage during transfer to collection tank, tank overfill, or tank rupture /leakage solid radwaste system (WSS)	Local contamination/ loss of shielding, dose < BSO	<1E-03 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is discussed in Section 9.12.16, "Loss of Containment of Spent Resin".
3.4.3	Fault in handling spent resins low level waste ((LLW) and WSS)	Local contamination, dose < BSO	<1E-03 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is discussed in Section 9.12.16, "Loss of Containment of Spent Resin".
3.4.4	Fault in handling wet activated carbon gaseous radwaste system (WGS)	Possible airborne contamination and loss of shielding, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.4.5	Fault in handling Steam Generator blowdown material (resins) (WLS)	Local contamination/ loss of shielding, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.4.6	Fault in handling Steam Generator blowdown material (membranes) (WLS)	Local contamination/ loss of shielding, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.4.7	Fault in handling spent filters (higher activity)	Potential for airborne release, local contamination and loss of shielding	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.4.8	Fault in handling spent filters (higher activity)	Potential for airborne release, local contamination, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.4.9	Unauthorised operator entry into areas of high dose	Operator radiation exposure	N/A	N/A	N/A				Comments similar to those for Fault 3.3.1.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.4.10	Failure to adequately control chemistry to manage dose rates	Operator radiation exposure	N/A	N/A	N/A				Operators required to work in potentially active areas for water chemistry will be monitored and access will be controlled. Individual doses will be controlled by HP arrangements (see also Faults 3.3.1 and 3.4.9)	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.5 HVAC Faults										
3.5.1	Failure of HVAC filter	Potential external release of radioactivity, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Bounded by Fault 3.5.6.	Fault is discussed in Section 9.11.6, "Failure of Filters in the Heating, Ventilation, and Air Conditioning System".
3.5.2	Blockage of HVAC filter	Increase in air radioactivity level in affected working area, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Bounded by Fault 3.5.6.	Fault is discussed in Section 9.11.8, "Reduced Airflow".
3.5.3	Failure of HVAC fans	Increase in air radioactivity level in affected working area, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Bounded by Fault 3.5.6.	Fault is discussed in Section 9.11.8, "Reduced Airflow".
3.5.4	Failure of HVAC dampers	Increase in air radioactivity level in certain areas, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Bounded by Fault 3.5.6.	Fault is discussed in Section 9.11.8, "Reduced Airflow".
3.5.5	Leakage	Increase in air radioactivity level in certain areas, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Filters are designed with replaceable cells clamped in place. When replaced, the filters are pressure tested to ensure that are seated correctly to maintain pressure. Alarms will sound if filters are incorrectly stalled, thus leakage is not considered a fault.	Fault is discussed in Section 9.11.4, "Analysis of Faults" in Section 9.11, "Safety Assessment of Heating, Ventilation, and Air Conditioning Faults".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.5.6	Fire	Potential external release of radioactivity, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Release of trapped activity from filters if involved in fire. Breakdown of filters and volatilization of deposited activity on ductwork.	Fault is discussed in Section 9.11.6, "Failure of Filters in the Heating, Ventilation, and Air Conditioning System".
3.5.7	Dropped filters	Release, suspension and dispersal of radioactivity, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Dropped filters can occur during handling (filter exchange, transfer to, or processing in radwaste building	Fault is discussed in Section 9.11.7, "Dropped Filters".
3.5.8	Failure of gaseous radwaste system beds	Potential release of radioactive gas, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO.	Fault is discussed in Section 9.11.6, "Failure of Filters in the Heating, Ventilation, and Air Conditioning System".
3.5.9	Failure of stack monitoring system	Inability to monitor routine discharges, dose < BSO	DB0	N/A	N/A				DB0 due to radiological consequences less than BSO. Fault is not a sequence initiator in its own right. Fault is an operability issue that does not result in any abnormal discharges.	Fault is discussed in Section 9.11.4, "Analysis of Faults" in Section 9.11, "Safety Assessment of Heating, Ventilation, and Air Conditioning Faults".
3.6 Waste Management										
3.6.1	Drop/impact of solid waste (LLW and WSS)	Potential release, suspension and dispersal of radioactivity, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO.	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.6.2	Drop/impact of solid waste (ILW and WSS)	Potential release, suspension and dispersal of radioactivity, dose < BSO	6.7E-04 per reactor year DB0	N/A	N/A				DB0 due to radiological consequences less than BSO.	Fault is Discussed in Section 9.12.7, "Radioactive Exchangeable Items (Filters and Charcoal Absorbers)".
3.6.3	Setting fire to solid waste	Contamination, airborne release of radioactivity in open air. Potential off-site release	N/A	N/A	N/A				Fault screened out. Potential for a fire is controlled by good housekeeping procedures, ensuring a lack of combustible materials stored near potential sources of ignition.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
3.6.4	Operator exposure from stored waste due to inadequate shielding or waste consignment error.	Operator radiation exposure	N/A	N/A	N/A				Shielding is provided as necessary for the waste storage areas to meet radiation zone and access requirements. HP will control the monitoring of radwaste.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.6.5	Incorrect consignment of waste due to assessment, clerical or sampling errors.	Operator radiation exposure	N/A	N/A	N/A				Packaging is done in accordance with local and national requirements. HP will control the monitoring of radwaste.	Fault screened out in Table 9.10-1, "Screened-out Faults" in Section 9.10, "Operator Exposure Faults".
3.6.6	Spills of liquid waste (leak to ground from vessel or pipe work)	Contamination to environment, potential dose to public	N/A	N/A	N/A				Fault screened out. Includes leaks from the spent fuel cooling system pumps and liquid radwaste system.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".
3.6.7	Spills of liquid waste (leak to drain)	Contamination to environment, potential dose to public	N/A	N/A	N/A				Fault screened out.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".
3.6.8	Un-authorized discharge of gaseous waste	Contamination to environment, potential dose to public	N/A	N/A	N/A				Fault screened out.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".
3.6.9	Un-authorized discharge of liquid waste	Higher activity (than routine or permitted) discharges via routine discharge route. Contamination to environment / dose to public	N/A	N/A	N/A				Fault screened out.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".
3.6.10	Mispackaging of waste for off-site disposal	Potential dose to operator and public. Also potential for contamination to environment if package integrity is inadequate and compromised.	N/A	N/A	N/A				Fault screened out.	Fault is discussed in Section 9.12.4, "Analysis of Faults" in Section 9.12, "Radioactive Waste Handling".

					Signals	Devices	Signals	Devices		
4. Internal Hazards										
4.1 Internal Fires										
4.1.1	Design Basis Fire	Fire is assumed to fail all SSCs in area (zone) of fire unless otherwise specified. Spurious actuations need to be considered unless evidence is provided that shows otherwise. See comments.	>1E-04 per reactor year DB2	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Diversity is not claimed for fires in locations that would compromise DAS; this is discussed and justified in Section 8.2.4.1.	See Sections 10.16 (PSA Internal Fire Analysis) and 11.2 (Internal Hazards Internal Fire) for additional details on this hazard.
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
							DAS(A,C2) - Low-2 SG WR Level	CMT(C1)		
							DAS(A,C2) - High Containment Temperature	PCS (C1) CI(C1)		
4.1.2	Fire in Main Control Room	MCR is abandoned	<1E-04 per reactor year DB1	1-6	PMS(M,C1)	Rod Breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Operators perform manual RT in MCR before leaving. They also de-energize MCR controls after leaving and proceeding to Remote Shutdown Room. This is the only credible initiator that causes MCR evacuation; independent initiating events do not occur during MCR evacuation. RSR provides Class 1 displays to allow operators to verify plant is safe. RSR provides Class 1 system level controls in case Class 1 automatic controls fail to function properly.	See Section 11.2 for additional details on this hazard.
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.2 Internal Floods										
4.2.1	Flooding inside containment	Dependent on individual scenario	DB1/DB2	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Specific scenarios are linked to fault entries as shown in the internal flooding hazard schedules (See Tables 11.3-3). Scenarios that do not directly result in a fault presented in the fault schedule could lead to (if at power) either a controlled plant shutdown or a reactor trip.	See Sections 10.15 (PSA Internal Flooding Analysis) and 11.3 (Internal Hazards Internal Flood) for additional details on this hazard.
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.2.2	Flooding outside containment	Dependent on individual scenario	<1E-04 per reactor year DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Specific scenarios are linked to fault entries as shown in the internal flooding hazard schedules (See Tables 11.3-3). Scenarios that do not directly result in a fault presented in the fault schedule could lead to (if at power) either a controlled plant shutdown or a reactor trip.	See Sections 10.15 (PSA Internal Flooding Analysis) and 11.3 (Internal Hazards Internal Flood) for additional details on this hazard.
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
4.2.3	Failures (false signals, human errors or mechanical ruptures) that result in inadvertent operation of IRWST recirculation squib valves	Draining of IRWST and flooding of sump into reactor vessel cavity	<1E-07 Per reactor year BDB	1-6	See Comments				The potential for a failure to initiate spurious IRWST recirculation is so low it is a BDB event. All failures are considered including mechanical ruptures and inadvertent actuation signals. Note that spurious failures not due to software are assumed to be less than 1E-05 events per year. Failures that could cause spurious squib valve opening are discussed in PCSR Chapters 10.4, 17.5 and 19.2. Additional information is available in the Squib Valve Safety Case, UKP-GW-GL-200. Consequences acceptable in all Modes. Operators will likely be able to mitigate transient quickly by closing adjacent MOV to squib valve.	This beyond design basis fault is discussed in Section 10.4.
4.3 Other Internal Hazards										
4.3.1	Pressure Part Failure	Dependent on individual scenario	Dependent on individual scenario	1-6	See Comments				Specific scenarios are linked to fault entries as shown in the pressure part failure hazard schedules (See Tables 11.4-1 and 11.4-2).	See Section 11.4 for additional details on this hazard
4.3.2	Internal Explosions	Dependent on individual scenario	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Specific scenarios are linked to fault entries as shown in the explosions hazard schedule (See Table 11.5-2). Scenarios that do not directly result in a fault presented in the fault schedule could lead to (if at power) either a controlled plant shutdown or a reactor trip.	See Section 11.5 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.3.3	Internal Missiles	Dependent on individual scenario	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Specific scenarios are linked to fault entries as shown in the missiles hazard schedule (See Table 11.6-1). Scenarios that do not directly result in a fault presented in the fault schedule could lead to (if at power) either a controlled plant shutdown or a reactor trip.	See Section 11.6 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.3.4	Release of toxic, corrosive, or flammable material	Reduction in personnel to minimum staffing levels; controlled shutdown possible	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Assumed that operators would remain in MCR and utilise emergency ventilation systems as necessary. No direct impact to any credited Class 1 SSCs. A frequent fault version of this event would result in less onerous consequences than the infrequent fault limiting case presented. Additionally, the diverse mitigation capabilities and safety functions of Fault 1.12.8 “Turbine Trip / Loss of External Electrical Load” would not be prevented due to this event.	See Section 11.7 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
	Fault	Consequences			Reactivity Control(short term)		Safety Functions			
					Signals	Devices	Signals	Devices		
4.3.5	Dropped loads and load mishandling	Possible damage to equipment and structures in direct load path	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Credible (i.e., design basis) dropped load events inside containment are only postulated during modes 5 and 6 (operation of cranes in containment is prevented by administrative control during higher modes). Specific drop scenarios are linked to fault entries in as shown in the dropped loads hazard schedule (See Table 11.8-3). Dropped load events outside containment that do not directly result in a fault presented in the fault schedule could lead to (if at power) either a controlled plant shutdown or a reactor trip. For all modes, in the event of any dropped load impacting the SFP, actions would be initiated to maintain SFP water level.	See Section 11.8 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.3.6	Biological Agents	Reduction in personnel to minimum staffing levels; controlled shutdown possible	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Assumed that operators would remain in MCR and utilise emergency ventilation systems as necessary. No direct impact to any credited Class 1 SSCs. A frequent fault version of this event would result in less onerous consequences than the infrequent fault limiting case presented. Additionally, the diverse mitigation capabilities and safety functions of Fault 1.12.8 “Turbine Trip / Loss of External Electrical Load” would not be prevented due to this event.	See Section 11.9 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.3.7	Onsite Transport	No breach of containment, but damage to auxiliary and other supporting buildings possible	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Consequences bounded by total compartment loss evaluations (e.g., internal fire or flood) A frequent fault version of this event would result in less onerous consequences than the infrequent fault limiting case presented. Additionally, the diverse mitigation capabilities and safety functions of Fault 1.12.8 “Turbine Trip / Loss of External Electrical Load” would not be prevented due to this event.	See Section 11.10 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
4.3.8	Electromagnetic Interference (EMI)	No consequences to Class 1 SSCs; reactor trip possible for significant event	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Fail-safe nature of Class 1 SSCs would preclude impact due to EMI hazard; additionally, all applicable Class 1 SSCs have qualification requirements to preclude EMI impacts. A frequent fault version of this event would result in less onerous consequences than the infrequent fault limiting case presented. Additionally, the diverse mitigation capabilities and safety functions of Fault 1.12.8 “Turbine Trip / Loss of External Electrical Load” would not be prevented due to this event.	See Section 11.11 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
5. External Hazards										
5.1 Seismic Events										
5.1.1	Safe Shutdown Earthquake	Reactor Trip using Class 1 SSCs	<1E-04 per reactor year DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	All Class 1 SSCs qualified for to perform their safety function in the event of a SSE.	See Section 12.6 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
5.1.2	Small earthquake	Equivalent to an operating basis earthquake; no significant damage to plant expected	>1E-03 per reactor year DB2	1-3	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Magnitude of small earthquake is assumed to be same an OBE (1/3 SSE) Two diverse cases listed. First one is for core cooling. Second one is for Anticipated transient without trip (ATWT). ATWT during this event is bounded by ATWT loss of normal feedwater for peak RCS pressure and by ATWT complete loss of flow for core damage. ATWT Safety functions available for this event are reported; however, limiting ATWT case terminates event after DAS reactor trip.	See Section 12.6 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
							DAS(A,C2) - Low-2 SG WR Level	CMT(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
5.1.3	Review Level Earthquake (RLE)	Damage to plant expected; however safe shutdown achievable via additional margin in necessary SSCs credited for SSE.	DBL*	1-3	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Assumes acceleration equal to 1.67 times SSE * Probability is less than design basis earthquake, and site dependent	See Section 10.18 “Seismic Margins Assessment” and 12.6.3.4 “Seismic Margin Analysis”
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

5.2 Wind Loading / Missiles										
5.2.1	Design Basis Wind event	None	<1E-04 per reactor year DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Based on standard AP1000 plant design tornado (peak wind speed of 300 mph) and associated wind driven missiles	See Section 12.12 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
5.2.2	Small wind event	None	1E-03 per reactor year DB2	1-3	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Based on standard AP1000 plant hurricane (peak winds at 140 mph) and associated wind driven missiles	See Section 12.12 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
							DAS(A,C2) - Low-2 SG WR Level	CMT(C1)		
							DAS(A,C2) - High Containment Temperature	PCS (C1) CI(C1)		
5.2.3	Beyond design basis wind event	Dependent on the severity of the wind event	DBL*	1-6	See Comments				None defined since 5.2.1 is so conservative * Probability is less than design basis wind	See Section 12.12 for additional details on this hazard
5.3 External Floods										
5.3.1	Design basis flood	No immediate consequences, could result in a controlled shutdown	<1E-04 per reactor year DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Flood level less than plant grade	See Section 12.7 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		

Table 8A-2 AP1000 PCSR Composite Fault List for Reactor Internal and Non-internal Events and Internal and External Hazards (cont.)

Fault ID	Initiating Event		Initiating Event Frequency/ DB Class	Possible Modes Affected	Engineered Safety Functions				Comments	Further Assessment of Fault
					Reactivity Control(short term)		Safety Functions			
	Fault	Consequences			Signals	Devices	Signals	Devices		
5.3.2	Small flood	None	1E-03 per reactor year DB2	1-3	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Lower flood level than grade (assumed to be same level as 5.3.1)	See Section 12.7 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	N/A	ACCUM(C1)		
							DAS(M,C2)	ADS(C1) IRWST(C1) RECIRC(C1)		
							DAS(A,C2) - High Containment Temperature	PCS(C1) CI(C1)		
					DAS(A,C2) – High Hot Leg Temperature	Rod MG Set Breakers (C2)	DAS(A,C2) - High Hot Leg Temperature	PRHR(C1)		
							DAS(A,C2) - Low-2 SG WR Level	CMT(C1)		
							DAS(A,C2) - High Containment Temperature	PCS (C1) CI(C1)		
5.3.3	Beyond design basis flood	No immediate consequences, could result in a controlled shutdown	DBL*	1-3	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	Plant is has additional mitigation features to protect against beyond design basis flooding. Flood level is 5.3 m (fast reseeding) or 2 m (sustained >72 hr) * Probability is less than design basis flood	See Section 12.7 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)		
5.4 Other External Hazards										
5.4.1	Accidental Crash of Small Aircraft	No immediate consequences, would likely result in a controlled shutdown	DB1	1-6	PMS(A,C1) - Low-2 SG NR Level	Rod breakers (C1)	PMS(A,C1) – Low-2 SG NR Level coincident with Low-2 SFW flow	PRHR(C1)	No damage to Class 1 SSCs as this fault is within the plant design basis. A frequent fault version of this event would result in less onerous consequences than the infrequent fault limiting case presented. Additionally, the diverse mitigation capabilities and safety functions of Fault 1.12.8 “Turbine Trip / Loss of External Electrical Load” would not be prevented due to this event.	See Section 12.8 for additional details on this hazard
							PMS(A,C1) – Low-2 Cold Leg Temperature	CMT(C1) CI(C1)		
							PMS(A,C1) – High-2 Containment Pressure	PCS(C1)

Table 8A-3 AP1000 PCSR Fault List for Decommissioning and Dry Spent Fuel Storage Faults

Fault ID	Initiating Event		Comments
	Fault	Consequences	
6. Decommissioning Operations			
6.1	Refuelling faults arising during post operation clear out (POCO) activities (Stage I).	Criticality and inadvertent worker radiation exposure.	Potential range of faults is identical with and bounded by that for equivalent normal refuelling operations faults identified above under “non-reactor faults”.
6.2	Failure to contain radioactive liquid effluent during decontamination activities (Stages I and II).	Potential worker dose.	
6.3	Failure to contain radioactive solid particulate debris during cutting activities (Stages II and III).	Potential worker dose.	
6.4	Worker radiation exposure due to inadequate provision, or failure of (e.g., in a seismic event), temporary shielding during decontamination or dismantling operations (Stages I, II and III).	Potential worker dose.	
6.5	Release and dispersal of radioactive material due to aircraft impact while structures are compromised during dismantling operations (Stages II and III).	Potential radiation dose to workers and the public.	Containment/shield building and fuel handling area of auxiliary building (used as temporary decommissioning waste management facility) are removed after the bulk of the wastes (particularly ILW) have been removed. External hazard qualification of these buildings may therefore be retained.
6.6	Air suspension and release of radioactive material through ruptured temporary containment due to seismic event (Stages I, II and III).	Potential worker dose.	

Table 8A-3 AP1000 PCSR Fault List for Decommissioning and Dry Spent Fuel Storage Faults (cont.)

Fault ID	Initiating Event		Comments
	Fault	Consequences	
6.7	Decommissioning waste management faults (Stages I, II and III).	Potential worker dose.	Faults are similar to the generic waste management faults listed above under non reactor faults. Radioactive wastes include liquid and contaminated solid waste from decontamination activities and solid wastes from disassembly and cutting operations.
7. Dry Spent Fuel Storage (Proposed Holtec Hi-STORM 100 Dry Cask System)			
Cask Loading and Handling Phase			
7.1	Dropping of transfer cask into spent fuel pond or onto floor or storage overpack during handling.		
7.2	Accidental drop of fuel assembly during loading of multi-purpose canister (MPC).	Fuel damage and radioactivity release. Worker dose.	
7.3	Misloading of lower burnup fuel assembly into MPC.	Criticality. Very high local radiation doses and radioactivity release.	
7.4	Accidental spent fuel pond boron dilution prior to or during MPC loading.	Criticality	
7.5	Dropped load onto transfer cask in the cask pit.	Potential fuel damage and criticality due to distortion of fuel assemblies/MPC fuel basket.	
7.6	Fire from diesel fuel in the trackmobile used for storage cask transfer to transporter outside secondary containment.	Potential failure of overpack and internal damage or rupture of MPC. Loss of shielding.	
Cask Transfer Phase			
7.7	Failure of storage cask due to drop or tip-over onto hard surfaces.	Potential damage to MPC and fuel.	

Table 8A-3 AP1000 PCSR Fault List for Decommissioning and Dry Spent Fuel Storage Faults (cont.)

Fault ID	Initiating Event		Comments
	Fault	Consequences	
7.8	Impact from another vehicle during transfer.	Potential damage to MPC and fuel.	
7.9	Fire from diesel fuel in the transporter used for storage cask transfer to storage facility.	Potential failure of overpack and internal damage or rupture of MPC. Loss of shielding.	
Cask Storage Phase			
7.10	Abnormal external floodwater loading on the intermediate storage facility	Structural damage to installation and casks contained within.	
7.11	Impulsive loads on intermediate storage facility due to impact by heavy objects including aircraft and external vehicles.	Structural damage to installation and casks contained within.	
7.12	Shockwaves from external explosions.	Structural damage to installation and casks contained within.	
7.13	Overheating of storage casks due to vent blockage.	Thermal damage to casks.	
7.14	Lightning damage to storage casks.	Cracking of casks.	
7.15	Fire from external or site-specific fuel source. Includes aircraft crash, gas main, and forest fire.	Potential for over-pressurisation of storage casks and excessive differential thermal stresses.	
7.16	Long term corrosion of MPC in high humidity, coastal, and industrial environments.	Preferential attack on welds weakening or perforation of MPC.

Notes:

1. These passive system functions self-actuate on loss of instrument air or Class 1 DC.
2. Plant can ride out failure to inset rods with DAS actuation of turbine trip, PRHR HX, and CMTs. Core moderator temperature coefficient helps reduce core power.
3. RCS makeup features provide diverse RCS heat removal and primary heat removal for LOCAs as indicated in Table 8A-2.
4. Pressuriser volume is sufficient to provide RCS overpressure protection.
5. HVAC transfers heat to the chilled water system (VWS) to support operation of these Class 2 SSCs.
6. PMS and DAS do not require HVAC as discussed in 8A.1.

Table 8A-5 AP1000 SSCs Used for Long-Term Passive System Support

	Component	Location	Comment
Primary Case			
Water makeup	Self-power pumps	Offsite	For PCS and SFP
Electrical power	DGs	Offsite	For PMS and fans
PMS room cooling	Fans	Offsite	Circulates outside air
MCR cooling	Fans	Offsite	Circulates outside air
Backup Case (1)			
Water makeup	PCS recirculation pumps	Installed (1)	For PCS & SFP
Electrical power	Ancillary DGs	Installed (1)	For PMS & fans
PMS room cooling	Ancillary PMS Fans	Installed (1)	Circulates outside air
MCR cooling	Ancillary MCR fans	Installed (1)	Circulates outside air

Notes:

1. These installed SSCs are considered Class 2 although they are not the primary means of providing these Class 2 functions. The offsite SSCs are the primary means of providing these long-term functions. The function of these installed SSCs is to reduce the probability that the offsite SSCs will need to be brought to the plant.

WRS	radioactive waste drain system
WSS	solid radwaste system
ZAS	main generation system
ZOS	onsite standby power system

9 INTERNALLY INITIATED FAULTS

9.0 Introduction

The safety case for the AP1000 plant is required to demonstrate that regulatory targets are met and that the risks from all modes of normal operation and fault conditions are shown to be as low as reasonably practicable (ALARP). The internally initiated fault assessment presented in this chapter is central to both of these requirements and provides a foundation for the safety case.

The internally initiated fault assessment consists of a design basis assessment (DBA) for each identified fault to provide a robust demonstration that the engineering design and the provision of safety measures lead to a high degree of fault tolerance. This includes both frequent and infrequent faults as discussed below. Design basis (DB) faults are those abnormal events that have the potential to give radiation doses above the basic safety level (BSL) specified in Target 4 of the Office of Nuclear regulation (ONR) Safety Assessment Principles (SAPs) (Reference 9.0-1).

The DBA presented for each frequent and infrequent fault are directly applicable to the United Kingdom (UK) design reference point (DRP), UKP-GW-GL-060 (Reference 9.0-22). These design basis analyses are appropriately conservative to bound a significant set of potential plant conditions and are therefore considered to be appropriate to the plant safety case and UK AP1000 plant design. At this time, there are a few design changes that have been approved to resolve UK-specific issues that have not been incorporated into the design reference point and this analysis. Examples include a reactor coolant pump (RCP) from a different vendor and a revised normal residual heat removal system (RNS) design. The design change with the biggest potential to impact the presented analyses is the change to the alternate RCP vendor. The RNS change is less likely to impact the analyses since it is not credited in most of the Chapter 9 faults due to its safety classification. Key reactor coolant pump parameters used in the safety analysis, such as flow coastdown versus time, will be used as a part of the pump design specification for the future vendor to meet. As a result, it is expected that the overall conclusions of the analysis will continue to show that the AP1000 design satisfies the applicable safety criteria with appropriate margins.

In addition to the DBA analyses, diverse protection analyses are provided for the frequent faults identified in Table 8A-2 (initiating event frequencies (IEFs) $>10^{-3}$/yr). These analyses, which may use relaxed analysis assumptions and success criteria, demonstrate that diverse protection is provided to mitigate the events. For frequent faults, two different diverse analyses are provided, one for core cooling and another for reactor shutdown (anticipated transients without trip, (ATWT)). Reference 9.0-23 provides a systematic assessment of the frequent faults and identifies the systems, structures and components (SSCs) credited to provide diverse mitigation. Each frequent fault is either analysed in detail or else is shown to be bounded by another fault that is analysed in detail.

UKP-SSAR-GLR-001 (Reference 9.0-24) documents the sources of technical information providing the basis for the overall safety case of the AP1000 contained in Chapter 9 and justification for the use of these analyses. Appendix A of Reference 9.0-24 provides a listing of all AP1000 standard plant analysis documents that serve as the basis for the text in Chapter 9. Appendix B of Reference 9.0-24 provides a listing of all UK specific analysis documents that provide a basis for additional text in Chapter 9 including UK specific radiological consequences, frequent fault diversity, shutdown mode faults, spent fuel pool faults, and ATWT.

Finally, other reasonably practicable protection or mitigation measures are considered to provide additional evidence that the risks from operation and the fault conditions are ALARP. As part of the development process for the AP1000 plant design, the design adhered to the principles of ALARP by keeping the design safe, proven, and simple, without relying on alternating current (ac) power for safety functions. In addition, for the UK application of the AP1000 design a few changes to the standard AP1000 design have been determined to be ALARP and incorporated. Refer to section 9.0.15 for additional discussion on ALARP considerations with respect to internally initiated faults.

A systematic, auditable, and comprehensive identification of fault conditions is presented in the previous chapter and the fault list given in Appendix 8A. Chapter 9 provides the safety case for all internally initiated faults (that is, faults that originate within the reactor system itself or in other active systems or processes of the plant).

Internally initiated faults are typically those initiated by failures of normally operating systems or services, through inadvertent actuation of safety systems or through human errors. Internally initiated faults are distinguished from internal hazards, which, although they originate on the site, are events that may directly cause harm or damage, and consequently present a threat to fundamental safety functions. Internal hazards are discussed in Chapter 11 of the Pre-Construction Safety Report (PCSR).

This chapter covers internally initiated faults in the following areas:

- Reactor during all modes of operation
- Spent fuel handling and storage
- Radwaste management
- Active ventilation systems

For internally initiated faults in the reactor, all modes of operation are considered. These modes are shown in Table 9.0-1, taken from the AP1000 reactor fault schedule given in Appendix 8A.

In each of the fault areas itemised above, a number of faults have been identified, as described in Section 8.3. Faults that have generally similar properties (for example, reactor faults that lead to an increase in heat removal from the reactor coolant system (RCS) are allocated to a number of classes. Each fault class is the subject of a section in this chapter and presented in Table 8A-2.

Many of the faults develop in a similar way, and the protection provided to prevent their development or mitigate their consequences is the same. These faults are therefore dealt with as fault groups as described in Section 8.4 and presented in Chapter 9. Some of the fault classes consist of a single fault group, while others are subdivided into two or more groups.

The assessment of each fault has the same basic elements: a description of the fault, a design basis analysis, a diverse analysis (ATWT and core cooling) for frequent faults, and an ALARP assessment. Sections 9.1 to 9.6 describe the safety case for each fault identified in Table 8A-2 for internally initiated reactor faults initiating in at-power modes (Typically Modes 1 or 2). Each fault is first described and the initial event frequency and the design basis class are provided.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Mitigation
- Diverse Mitigation for ATWT and Core Cooling for Frequent Faults
- Assessment of the Radiological Consequences
- ALARP Assessment
- Conclusions

The safety case for each fault also includes a summary of credited SSCs for all primary DBA cases as well as all diversity cases, as applicable. These sections are meant to provide a linkage to Table 8A-2 and the listed engineered safety features (ESFs) for the detailed fault progression discussions that follow. Specific safety features are listed with Control & Instrumentation (C&I) actuation signals where applicable. Manual actuations are also identified and linked with the C&I system that would provide indication to the operator. Passively acting components, such as accumulators or pressuriser relief valves are noted, but not linked with a specific C&I system or actuation signal. For additional information regarding the treatment of credited SSCs, see Appendix 8A.

Section 9.8 provides an evaluation of faults that could be initiated during lower modes of operation. As most of these faults see the most limiting consequences during higher power modes, many of the sections of 9.8 refer back to the at-power descriptions provided in Sections 9.1-9.6. However, each section does clarify the event classification, radiological consequences, and a conclusion using the information from all valid modes where the fault may occur.

Sections 9.7 and 9.9 to 9.12 describe in detail non-reactor faults identified in Table 8A-2. Each section provides an overview of the system or systems that have the potential to present a hazard to operators or members of the public.

The fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Fault Description
- IEF and Design Basis Class
- Fault Progression
- Assessment of the Radiological Consequences
- ALARP Assessment
- Conclusions

9.0.1 Fault Groupings

Faults are arranged in groups to facilitate their understanding and analysis. These groupings are based on the faults having similar initiators and/or impacts on the reactor. This grouping is shown in the fault schedule within Chapter 8 and continues in the fault evaluations presented throughout Chapter 9. For each fault, an assessment is given for the unmitigated consequences (that is, without the provision of essential safety functions) and the IEF. These two parameters are used to assign the fault to a DB class, as described in Section 8.2.3.

Faults in classes BDB and DB0, as described in Section 8.2.3, are screened out and not analysed further in this chapter, as they are outside the DB. However, their contribution to the total risk is accounted for in the PSA presented in Chapter 10.

9.0.2 Design Basis Assessment

The AP1000 design has a number of SSCs designed to provide essential safety functions in the event of a fault. The DBA provides a robust, conservative, and deterministic analysis of the fault progression to demonstrate that design basis dose targets (SAP Target 4) are met with these safety provisions in place and correctly operating. The DB classes are identified and explained in Section 8.2.3. Fault sequences with various identified SSCs not operating are also identified. For the events where there may be additional acceptance criteria, this criteria identified in Table 9.0-3.

For faults in the DB1, DB2 and DBL classes, the SSCs identified as being the principal means of providing the (Category A) safety functions are designated as Class 1. For faults in the DB2 class, there is a requirement to identify a diverse means of providing the Category A safety function. A diverse protection analysis is provided for these frequent fault events.

For faults in the high frequency, low consequence (HFLC) class, a similar assessment leads to the designation of the principal means of providing the safety functions (Category B in this case) as Class 2. In these cases, further SSCs may be identified as providing defence in depth.

In addition to the above, any operator actions[1] required to actuate or realign SSCs to achieve the necessary safety functions, or to protect the operators from exposure to radiation (for example, evacuation), are identified and classified, as are any operating limits or conditions (usually, already identified in Technical Specifications (Tech Specs)) that must be met to meet the acceptance criteria and the risks have been reduced to be ALARP.

DBA dose calculations to assess radiological consequences for comparison with targets have been performed in accordance with Reference 9.0-2. The verification and validation status of the codes and methods used for the transient analyses required to complete the DBA is summarised in Appendix 9B.

9.0.2.1 Assumptions within the Design Basis Assessment

The DBA presented in this chapter relies on a large number of transient and other analyses. These analyses demonstrate that the SSCs identified are adequate to ensure that the plant remains within DB limits following any DB fault or event.

For every fault, the corresponding analysis assumes that the plant is operating within certain parameters or in specified conditions at the start of the fault. The progression of the fault and its consequences will depend critically on these assumptions. The assumptions will include those about such things as initial pressures and temperatures and about the availability and status of SSCs designated to protect the plant or mitigate the consequence of the fault.

The safety case depends critically on these assumptions since they define the bounds of the applicability of the analysis. During subsequent operation of the plant, it is necessary to ensure that operations remain within the boundaries defined by these assumptions because otherwise the safety case supported by these transient analyses may not be valid.

These assumptions fall into two groups:

- Limits and conditions that define the operating envelope of the plant and therefore define the initial conditions before any transient

1. The operator actions are summarised in Chapter 13.

- Limits and conditions that ensure that the Class 1 SSCs identified in the DB analysis operate according to their design and as assumed in the DB analysis.

These assumptions correspond to Technical Specifications.

A number of similar limits and conditions apply to the operation of Class 2 SSCs identified as providing defence in depth. These limits and conditions are defined in short-term availability controls relating to those SSCs.

The limits and conditions assumed in the safety analysis are listed in Table 9.0-4.

Further limits and conditions are identified in the fault analyses that constitute requirements for plant operations to ensure that doses from certain DB faults remain within DB limits. These are identified and listed in the corresponding fault analysis.

In addition to the limits and condition discussed above, each fault assessment also makes a number of assumptions to define a bounding case. These assumptions are usually about such things as state of the fuel cycle or pre-existing or coincident single failures that lead to conservative conditions for the analysis. As such, they do not have any implications for how the plant should be operated and are not identified as bounding limits or conditions. They are identified in the text in the corresponding fault analysis in this chapter.

9.0.2.2 Design Plant Conditions

Table 9.0-5 lists the principal power rating values assumed in the analyses performed at power. The thermal power output includes the effective thermal power generated by the reactor coolant pumps. Selected AP1000 plant loop layout elevations are shown in Figure 9.0-2 to aid in interpreting plots shown in Chapter 9 sections.

The values of other plant parameters used in the accident analyses are given in Table 9.0-7.

9.0.2.3 Initial Conditions

For most accidents that are departure from nucleate boiling (DNB) limited, nominal values of initial conditions are assumed. The allowances on power, temperature, and pressure are determined on a statistical basis and are included in the departure from nucleate boiling ratio (DNBR) design limit values (see Section 22.7.1.1), as described in WCAP-11397-P-A (Reference 9.0-4). This procedure is known as the Revised Thermal Design Procedure (RTDP).

For most accidents that are not DNB limited, or for which the revised thermal design procedure is not used, the initial conditions are obtained by adding the maximum steady-state errors to rated values. The following conservative steady-state errors are assumed in the analysis:

Core power	$\pm$ 1 percent allowance for calorimetric error.
Average reactor coolant temperature	$\pm$ 4.4°C (8.0°F) allowance for controller deadband and measurement errors
Pressuriser pressure	$\pm$ 0.34 MPa (50 psi) allowance for steady-state fluctuations and measurement errors

Initial values for core power, average reactor coolant system temperature, and pressuriser pressure are selected to minimize the initial DNBR unless otherwise stated in the sections

describing the specific accidents. Table 9.0-6 summarizes the initial conditions and computer codes used in the accident analyses.

9.0.2.4 Power Distribution

The transient response of the reactor system is dependent on the initial power distribution. The nuclear design of the reactor core minimizes adverse power distribution through the placement of fuel assemblies and control rods. Power distribution may be characterized by the nuclear enthalpy rise hot channel factor ($F_{\Delta H}$) and the total peaking factor (F_q). Unless specifically noted otherwise, the peaking factors used in the accident analyses are those presented in Chapter 22.

For transients that may be DNB limited, the radial peaking factor is important. The radial peaking factor increases with decreasing power level due to control rod insertion. This increase in $F_{\Delta H}$ is included in the core limits illustrated in Figure 9.0-1. Transients that may be departure from nucleate boiling limited are assumed to begin with an $F_{\Delta H}$, consistent with the initial power level defined in the Technical Specifications.

The axial power shape used in the DNB calculation is a chopped cosine, as discussed in Section 22.7.1.1, for transients analysed at full power and the most limiting power shape calculated or allowed for accidents initiated at non-full power or asymmetric rod cluster control assembly (RCCA) conditions.

The radial and axial power distributions just described are input to the VIPRE-01 code as described in Section 22.7.1.1.

For transients that may be overpower-limited, the total peaking factor (F_q) is important. Transients that may be overpower-limited are assumed to begin with plant conditions, including power distributions, which are consistent with reactor operation as defined in the Technical Specifications.

For overpower transients that are slow with respect to the fuel rod thermal time constant (for example, the chemical and volume control system malfunction that results in a slow decrease in the boron concentration in the reactor coolant system as well as an excessive increase in secondary steam flow) and that may reach equilibrium without causing a reactor trip, the fuel rod thermal evaluations are performed as discussed in Section 22.7.1.

For overpower transients that are fast with respect to the fuel rod thermal time constant (for example, the uncontrolled RCCA bank withdrawal from subcritical or lower power startup and RCCA ejection incident, both of which result in a large power rise over a few seconds), a detailed fuel transient heat transfer calculation is performed.

9.0.2.5 Reactivity Coefficients

The transient response of the reactor system is dependent on reactivity feedback effects, in particular, the moderator temperature coefficient and the Doppler power coefficient. These reactivity coefficients are discussed in Section 22.6.2.11.

In the analysis of certain events, conservatism requires the use of large reactivity coefficient values; while for other events, the use of small reactivity coefficient values is conservative. The values used are given in Figure 9.0-3, which shows the upper and lower bound Doppler power coefficients as a function of power, used in the transient analysis. The justification for use of conservatively large versus small reactivity coefficient values is treated on an event-by-event basis. In some cases, conservative combinations of parameters are used to bound the

effects of core life, although these combinations may not represent possible realistic situations.

9.0.2.6 Protection and Safety Monitoring System Setpoints and Time Delays to Trip

A reactor trip signal acts to open two trip breaker sets connected in series, feeding power to the control rod drive mechanisms. The loss of power to the mechanism coils causes the mechanisms to release the RCCAs, which then fall by gravity into the core. There are various instrumentation delays associated with each trip function including delays in signal actuation, in opening the trip breakers, and in the release of the rods by the mechanisms. The total delay to trip is defined as the time delay from the time that trip conditions are reached to the time the rods are free and begin to fall. Limiting trip setpoints assumed in accident analyses and the time delay assumed for each trip function are given in Table 9.0-8. Reference is made in that table to overtemperature ΔT (OTΔT) and overpower ΔT (OPΔT) trip shown in Figure 9.0-1. As mentioned in Chapter 19 and in Reference 9.0-18, the OTΔT protects the core from exceeding the DNB design limit, and the OPΔT protects the core from exceeding the design overpower limit. As shown on the figure, the OTΔT setpoint plus all error allowances tracks the core DNB design limits, except that the setpoint may include an upper limit on allowable inlet temperature.

Table 9.0-8 also summarizes the setpoints and the instrumentation delay for ESF functions used in accident analyses. Time delays associated with equipment actuated (such as valve stroke times) by ESF functions are summarized in Table 9.0-9.

The difference between the limiting setpoint assumed for the analysis and the nominal setpoint represents an allowance for instrumentation channel error and setpoint error. Nominal setpoints are specified in the plant Technical Specifications. During plant startup tests, it is demonstrated that actual instrument time delays are equal to or less than the assumed values. Additionally, protection system channels are calibrated and instrument response times are determined periodically in accordance with the plant Technical Specifications.

9.0.3 Instrumentation Drift and Calorimetric Errors

The calorimetric uncertainty is the uncertainty assumed in the determination of core thermal power as obtained from secondary plant measurements. On a daily basis, this measurement is compared with the ΔT power signal (Reference 9.0-18) and with the total ion chamber current (sum of the top and bottom currents) and those signals are adjusted if necessary for acceptable conformance with the calorimetric power measurement.

The secondary power is obtained from measurement of feedwater flow, feedwater inlet temperature to the steam generators, and steam pressure. Installed plant instrumentation is used for these measurements.

9.0.4 Plant Systems and Components Available for Mitigation of Accident Effects

The plant is designed to afford proper protection against the possible effects of natural phenomena, postulated environmental conditions, and dynamic effects of the postulated accidents. In addition, the design incorporates features that minimize the probability and effects of fires and explosions.

Chapter 5 discusses the quality assurance program that is implemented to provide confidence that the plant systems satisfactorily perform their assigned safety functions. The incorporation of these features in the plant, coupled with the reliability of the design, provides confidence

that the normally operating systems and components listed in Table 9.0-10 are available for mitigation of the events discussed in Chapter 9.

Table 9.0-12 summarizes the non-Class 1 systems assumed in the analyses to mitigate the consequences of events. Except for the cases listed in Table 9.0-12, control system action is not used for mitigation of accidents.

9.0.5 Optimisation of Control Systems

A control system setpoint study is performed prior to plant operation to simulate performance of the primary plant control systems and overall plant performance. In this study, emphasis is placed on the development of the overall plant control systems that automatically maintain conditions in the plant within the allowed operating window and with optimum control system response and stability over the entire range of anticipated plant operating conditions. The control system setpoints are developed using the nominal protection and safety monitoring system setpoints implemented in the plant. Where appropriate (such as in margin to reactor trip analyses), instrumentation errors are considered and are applied in an adverse direction with respect to maintaining system stability and transient performance. The accident analysis and plant control system setpoint study in combination show that the plant can be operated and meet both safety and operability requirements throughout the core life and for various levels of power operation.

The plant control system setpoint study is comprised of analyses of the following control systems: plant control, axial offset control, rapid power reduction, steam dump (turbine bypass), steam generator level, pressuriser pressure, and pressuriser level.

9.0.6 Rod Cluster Control Assembly Insertion Characteristics

The negative reactivity insertion following a reactor trip is a function of the acceleration of the RCCAs as a function of time and the variation in rod worth as a function of rod position. For accident analyses, the critical parameter is the time of insertion up to the dashpot entry, or approximately 85 percent of the rod cluster travel. In analyses where all of the reactor coolant pumps are coasting down prior to, or simultaneous, with RCCA insertion, a time of 2.3 seconds is used for insertion time to dashpot entry.

In Figure 9.0-4, the curve labelled “complete loss of flow transients” shows the RCCA position versus time normalized to 2.3 seconds assumed in accident analyses where all reactor coolant pumps are coasting down. In analyses where some or all of the reactor coolant pumps are running, the RCCA insertion time to dashpot is conservatively taken as 2.7 seconds. The RCCA position versus time normalized to 2.7 seconds is also shown in Figure 9.0-4.

The use of such a long insertion time provides conservative results for accidents and is intended to apply to all types of RCCAs, which may be used throughout plant life. Drop time testing requirements are specified in the Technical Specifications.

Figure 9.0-5 shows the fraction of total negative reactivity insertion versus normalized rod position for a core where the axial distribution is skewed to the lower region of the core. An axial distribution skewed to the lower region of the core can arise from an unbalanced xenon distribution. This curve is used to compute the negative reactivity insertion versus time following a reactor trip, which is input to the point kinetics core models used in transient analyses. The bottom-skewed power distribution itself is not an input into the point kinetics core model.

There is inherent conservatism in the use of Figure 9.0-5 in that it is based on a skewed flux distribution, which would exist relatively infrequently. For cases other than those associated with unbalanced xenon distributions, significantly more negative reactivity is inserted than that shown in the curve, due to the more favourable axial distribution existing prior to trip.

The normalized RCCA negative reactivity insertion versus time is shown in Figure 9.0-6. The curves shown in this figure were obtained from Figures 9.0-4 and 9.0-5. A total negative reactivity insertion following a trip of 4 percent Δk (shutdown margin) is assumed in the transient analyses except where specifically noted otherwise. This assumption is conservative with respect to the calculated trip reactivity worth available.

The normalized RCCA negative reactivity insertion versus time curve for an axial power distribution skewed to the bottom (Figure 9.0-6) is used in those transient analyses for which a point kinetics core model is used. Where special analyses require use of three-dimensional or axial one-dimensional core models, the negative reactivity insertion resulting from the reactor trip is calculated directly by the reactor kinetics code and is not separable from the other reactivity feedback effects. In this case, the RCCA position versus time of Figure 9.0-4 is used as code input.

9.0.7 Fission Product Inventories

The sources of radioactivity for release are dependent on the specific accident. Activity may be released from the primary coolant, from the secondary coolant, and from the reactor core if the accident involves fuel damage. The radiological consequences analyses use the conservative design basis source terms identified in Appendix 9A.

9.0.8 Residual Decay Heat

9.0.8.1 Total Residual Heat

Residual heat in a subcritical core is calculated for the loss-of-coolant accident (LOCA) according to the requirements as described in WCAP-10054-P-A, WCAP-12945-P-A, and WCAP-16009-P-A (References 9.0-5, 9.0-6, and 9.0-17). The large-break LOCA methodology considers uncertainty in the decay power level. The small-break LOCA events and post-LOCA long-term cooling analyses use decay heat, which assumes infinite irradiation time before the core goes subcritical to determine fission product decay energy. For all other accidents, the same models are used, except that fission product decay energy is based on core average exposure at the end of an equilibrium cycle. Margins applied to design basis analyses are as described above; for diversity analyses, this margin is often reduced to reflect a more realistic analysis with appropriately reduced uncertainties.

9.0.8.2 Distribution of Decay Heat Following a Loss-of-Coolant Accident

During a LOCA, the core is rapidly shut down by void formation, RCCA insertion, or both, and a large fraction of the heat generation considered comes from fission product decay gamma rays. This heat is not distributed in the same manner as steady-state fission power. Local peaking effects, which are important for the neutron-dependent part of the heat generation, do not apply to the gamma ray contribution. The steady-state factor, which represents the fraction of heat generated within the cladding and pellet, drops to 95 percent or less for the hot rod in a LOCA.

For example, consider the transient resulting from the postulated double-ended break of the largest reactor coolant system pipe; one-half second after the rupture, about 30 percent of the heat generated in the fuel rods is from gamma ray absorption. The gamma power shape is less

peaked than the steady-state fission power shape, reducing the energy deposited in the hot rod at the expense of adjacent colder rods. A conservative estimate of this effect on the hot rod is a reduction of 10 percent of the gamma ray contribution or 3 percent of the total heat. Because the water density is considerably reduced at this time, an average of 98 percent of the available heat is deposited in the fuel rods; the remaining 2 percent is absorbed by water, thimbles, sleeves, and grids. Combining the 3 percent total heat reduction from gamma redistribution with this 2 percent absorption produce as the net effect a factor of 0.95, which exceeds the actual heat production in the hot rod. The actual hot rod heat generation is computed during the large-break LOCA transient as a function of core fluid conditions.

9.0.9 Computer Codes Used

Summaries of some of the principal computer codes used in transient analyses are given as follows. Other codes – in particular, specialized codes in which the modelling has been developed to simulate one given accident, such as those used in the analysis of the reactor coolant system pipe rupture (see Sections 9.6.4 and 9.6.5) – are summarized in their respective accident analyses sections. The codes used in the analyses of each transient are listed in Table 9.0-6. WCAP-15644-P (Reference 9.0-13) provides the basis for use of analysis codes. Additional information is provided in Appendix 9B.

9.0.9.1 FACTRAN Computer Code

FACTRAN (Reference 9.0-7) calculates the transient temperature distribution in a cross section of a metal-clad UO_2 fuel rod and the transient heat flux at the surface of the cladding using as input the nuclear power and the time-dependent coolant parameters (pressure, flow, temperature, and density). The code uses a fuel model which simultaneously exhibits the following features:

- A sufficiently large number of radial space increments to handle fast transients
- Material properties which are functions of temperature and a sophisticated fuel-to-clad gap heat transfer calculation
- The necessary calculations to handle post-DNB transients: film boiling heat transfer correlations, zircaloy-water reaction, and partial melting of the materials

FACTRAN is further discussed in WCAP-7908-A (Reference 9.0-7).

9.0.9.2 LOFTRAN Computer Code

The LOFTRAN (Reference 9.0-8) program is used for studies of transient response of a pressurised water reactor system to specified perturbations in process parameters. LOFTRAN simulates a multi-loop system by a model containing reactor vessel, hot and cold leg piping, steam generator (tube and shell sides), and pressuriser. The pressuriser heaters, spray, and safety valves are also considered in the program. Point model neutron kinetics, and reactivity effects of the moderator, fuel, boron, and rods are included. The secondary side of the steam generator uses a homogeneous, saturated mixture for the thermal transients and a water level correlation for indication and control. The protection and safety monitoring system is simulated to include reactor trips on high neutron flux, power range high positive flux rate, overtemperature ΔT, high and low pressure, low flow, and high pressuriser level. Control systems are also simulated, including rod control, steam dump, feedwater control, and pressuriser level and pressure control. The emergency core cooling system, including the accumulators, is also modelled.

LOFTRAN is a versatile program suited to both accident evaluation and control studies as well as parameter sizing.

LOFTRAN also has the capability of calculating the transient value of DNBR based on the input from the core limits illustrated in Figure 9.0-1. The core limits represent the minimum value of DNBR as calculated for typical or thimble cell.

The LOFTRAN code is modified to allow the simulation of the passive residual heat removal (PRHR) heat exchanger, core makeup tanks, and associated protection and safety monitoring system actuation logic. A discussion of these models and additional validation is presented in WCAP-14234 (Reference 9.0-12).

LOFTTR2 is a modified version of LOFTRAN with a more realistic break flow model, a two-region steam generator secondary side, and an improved capability to simulate operator actions during a steam generator tube rupture (SGTR) event.

The LOFTTR2 code is modified to allow the simulation of the PRHR heat exchanger, core makeup tanks, and associated protection system actuation logic. The modifications are identical to those made to the LOFTRAN code. A discussion of these models is presented in WCAP-14234 (Reference 9.0-12).

9.0.9.3 TWINKLE Computer Code

The TWINKLE (Reference 9.0-9) program is a multidimensional spatial neutron kinetics code, which is patterned after steady-state codes currently used for reactor core design. The code uses an implicit finite-difference method to solve the two-group transient neutron diffusion equations in one, two, and three dimensions. The code uses six delayed neutron groups and contains a detailed multiregion fuel-clad-coolant heat transfer model for calculating pointwise Doppler and moderator feedback effects. The code handles up to 2000 spatial points and performs its own steady-state initialization. Aside from basic cross-section data and thermal-hydraulic parameters, the code accepts as input basic driving functions, such as inlet temperature, pressure, flow, boron concentration, control rod motion, and others. Various edits are provided (for example, channelwise power, axial offset, enthalpy, volumetric surge, point-wise power, and fuel temperatures).

The TWINKLE code is used to predict the kinetic behaviour of a reactor for transients that cause a major perturbation in the spatial neutron flux distribution.

9.0.9.4 VIPRE-01 Computer Code

The VIPRE-01 core model is used with the applicable DNB correlations to determine DNBR distributions along the hot channels of the reactor core under all expected operating conditions. The VIPRE-01 code is described in detail in Reference 9.0-20, including discussions on code validation with experimental data. The VIPRE-01 modelling method is described in Reference 9.0-21, including empirical models and correlations used. The effect of crud on the flow and enthalpy distribution in the core is not directly accounted for in the VIPRE-01 evaluations. However, conservative treatment by the Westinghouse VIPRE-01 modelling method has been demonstrated to bound this effect in DNBR calculations (Reference 9.0-21).

Extensive additional experimental verification of VIPRE-01 is presented in Reference 9.0-20. The VIPRE-01 analysis is based on a knowledge and understanding of the heat transfer and hydrodynamic behaviour of the coolant flow and the mechanical characteristics of the fuel elements. The use of the VIPRE-01 analysis provides a realistic evaluation of the core

performance.

VIPRE-01 is capable of transient DNB analysis. The conservation equations in the VIPRE-01 code contain the necessary accumulation terms for transient calculations. The input description can include one or more of the following time dependent arrays:

1. Inlet flow variation
2. Core heat flux variation
3. Core pressure variation
4. Inlet temperature or enthalpy variation

At the beginning of the transient, the calculation procedure is carried out as in the steady state analysis. The time is incremented by an amount determined either by the user or by the time step control options in the code itself. At each new time step the calculations are carried out with the addition of the accumulation terms which are evaluated using the information from the previous time step. This procedure is continued until a preset maximum time is reached. At time intervals selected by the user, a complete description of the coolant parameter distributions as well as DNBR is printed out. In this manner the variation of any parameter with time can be readily determined.

9.0.9.5 COAST Computer Program

The COAST computer program is used to calculate the reactor coolant flow coastdown transient for any combination of active and inactive pumps and forward or reverse flow in the hot or cold legs. The program is described in Reference 9.0-15 and was referenced in Reference 9.0-14. The program was approved in Reference 9.0-16.

The equations of conservation of momentum are written for each of the flow paths of the COAST model assuming unsteady one-dimensional flow of an incompressible fluid. The equation of conservation of mass is written for the appropriate nodal points. Pressure losses due to friction and geometric losses are assumed proportional to the flow velocity squared. Pump dynamics are modelled using a head-flow curve for a pump at full speed and using four-quadrant curves, which are parametric diagrams of pump head and torque on coordinates of speed versus flow, for a pump at other than full speed.

9.0.9.6 ANC Computer Code

The ANC computer code is used to solve the two-group neutron diffusion equation in three spatial dimensions. ANC can also solve the three-dimensional kinetics equations for six delayed neutron groups. The ANC code is described in Section 22.6.3.3.

9.0.9.7 RELAP Computer Code

Some of the events, such as loss of reactor coolant flow have small amount of steam void generated. The LOFTRAN model assumes homogeneous flow in the RCS outside the reactor vessel. The validity of the LOFTRAN model for these cases will be verified by analysis with a LOCA code such as NOTRUMP or RELAP.

For RCS depressurisation, a LOCA code such as NOTRUMP or RELAP, is used when void formation in the RCS goes beyond the point where LOFTRAN is useful.

The RELAP family of codes developed to perform analyses of postulated accidents in nuclear power plants.

The RELAP5 computer code (Reference 9.0-19) performs calculations to simulate multi-dimensional thermal-hydraulics, heat transfer, and control systems. The thermal hydraulics behaviour under single phase and two phase conditions is simulated. The hydrodynamics models track the flow of liquid, vapour and non-condensable gases. RELAP5 includes component models of valves, separators, dryers, pumps, electric heaters, turbines, and accumulators. The control system models include functions for trip logic and arithmetic functions for simulation of system filters.

RELAP has been used to analyse the diverse core cooling response to several faults during the AP1000 generic design assessment. Westinghouse has committed to update these analyses during site licensing with an appropriately benchmarked and validated analysis tool, such as NOTRUMP for SBLOCA.

9.0.10 Component Failures

9.0.10.1 Active Failures

An active failure results in the inability of a component to perform its intended function.

An active failure is defined differently for different components. For valves, an active failure is the failure of a component to mechanically complete the movement required to perform its function. This includes the failure of a remotely operated valve to change position on demand. The spurious, unintended movement of the valve is also considered as an active failure. Failure of a manual valve to change position under local operator action is included.

Spring-loaded safety or relief valves that are designed for and operate under single-phase fluid conditions are not considered for active failures to open or close when pressure rises above or reduces below the valve set point. However, when valves designed for single-phase flow are challenged with two-phase flow, such as a steam generator or pressuriser safety valve, the failure to reseat is considered as an active failure.

For other active equipment – such as pumps, fans, and rotating mechanical components – an active failure is the failure of the component to start or to remain operating.

For electrical equipment, the loss of power, such as the loss of offsite power or the loss of a diesel generator, is considered as a single failure. In addition, the failure to generate an actuation signal, either for a single component actuation or for a system-level actuation, is also considered as an active failure.

Spurious actuation of an active component is considered as an active failure for active components in safety-related passive systems. An exception is made for active components if specific design features or operating restrictions are provided that can preclude such failures (such as power lockout, confirmatory open signals, or continuous position alarms).

A single omitted operator action in response to an initiating event is also considered as an active failure; the error is limited to manipulation of safety-related equipment and does not include thought-process errors or similar errors that could potentially lead to common cause or multiple errors.

9.0.10.2 Passive Failures

A passive failure is the structural failure of a static component that limits the effectiveness of the component in carrying out its design function. A passive failure is applied to fluid systems and consists of a breach in the fluid system boundary. Examples include cracking of

pipes, sprung flanges, or valve packing leaks.

Passive failures are not assumed to occur until 24 hours after the start of the event. Consequential effects of a pipe leak – such as flooding, jet impingement, and failure of a valve with a packing leak – must be considered.

Where piping is significantly overdesigned or installed in a system where the pressure and temperature conditions are relatively low, passive leakage is not considered a credible failure mechanism. Line blockage is also not considered as a passive failure mechanism.

9.0.10.3 Limiting Single Failures

The most limiting single failure (where one exists) of safety-related equipment, is identified in each analysis description. The consequences of this failure are described therein. In some instances, because of redundancy in protection equipment, no single failure that could adversely affect the consequences of the transient is identified. The failure assumed in each analysis is listed in Table 9.0-11.

9.0.11 Operator Actions

There are several events analysed in the following sections that require operator action to terminate or mitigate the event. The loss of normal feedwater (Section 9.2.7), the inadvertent actuation of a core makeup tank (Section 9.5.1), and the chemical and volume control system malfunction (Section 9.5.2) assume operator action, after the High-2 pressuriser water level setpoint is reached, to open the safety grade reactor vessel head vent. This action prevents filling the pressuriser and allowing water to escape through the pressuriser safety valves. The analysis of the boron dilution for Mode 1 operation with automatic rod control (Section 9.4.6) relies on the operator to terminate the dilution source, after the rod insertion limit alarm, before the required shutdown margin is lost. The small line break outside containment event (Section 9.6.2) assumes the operator will isolate the break. In all cases where operator actions are credited, no operator actions are required within the first 30 minutes of the transient. For these events, before operator action is required, numerous alarms and indications would be available to the operator to diagnose the transient and ensure that the proper action is taken.

For events where the PRHR heat exchanger is actuated, the plant automatically cools down to the safe shutdown condition. Where a stabilized condition is reached automatically following a reactor trip, it is expected that the operator may, following event recognition, take manual control and proceed with orderly shutdown of the reactor using available Class 2 and 3 SSCs in accordance with the normal, abnormal, or emergency operating procedures. The exact actions taken and the time at which these actions occur depend on what systems are available and the plans for further plant operation.

However, for these events, operator actions are not required to maintain the plant in a safe and stable condition. Appendix 9C provides more details on the systems used to achieve safe shutdown.

9.0.12 Loss of Offsite ac Power

As required, accidents are analysed assuming a loss of offsite ac power. The loss of offsite power is not considered as a single failure, and the analysis is performed without changing the event category. In the analyses, the loss of offsite ac power is considered to be a potential consequence of the event.

A loss of offsite ac power will be considered a consequence of an event due to disruption of

the grid following a turbine trip during the event. Event analyses that do not result in a possible consequential disruption of offsite ac power do not assume offsite power is lost.

For those events where offsite ac power is lost, an appropriate time delay between turbine trip and the postulated loss of offsite ac power is assumed in the analyses. A time delay of 3 seconds is used. This time delay is traditionally based on the inherent stability of the offsite power grid. Following the time delay, the effect of the loss of offsite ac power on plant auxiliary equipment – such as reactor coolant pumps, main feedwater pumps, condenser, startup feedwater pumps, and RCCAs – is considered in the analyses. Turbine trip occurs 5 seconds following a reactor trip condition being reached. This delay is part of the AP1000 reactor trip system.

Design basis LOCA analyses are governed by the requirement to consider the loss of offsite power. For the AP1000 design, in which all the Class 1 systems are passive; the availability of offsite power is significant only regarding reactor coolant pump operation for LOCA events. A sensitivity study for AP1000 has shown that for large-break LOCAs, assuming the loss of offsite power coincident with the inception of the LOCA event is nonlimiting relative to assuming continued reactor coolant pump operation until the automatic reactor coolant pump trip occurs following an "S" signal less than 10 seconds into the transient. For small-break LOCA events, the AP1000 automatic reactor coolant pump trip feature prevents continued operation of the reactor coolant pumps from mixing the liquid and vapour present within a two-phase reactor coolant system inventory to increase the liquid break flow and deplete the reactor coolant system mass inventory rapidly. The automatic reactor coolant pump trip occurs early enough during AP1000 small-break LOCA transients that emergency core cooling system performance is not affected by the loss of offsite power assumption because the total break flow is approximately equivalent for reactor coolant pump trip occurring either at time zero or as a result of the safeguards, or "S" signal. Whether a loss of offsite power is postulated at the inception of the LOCA event or occurs automatically later on is unimportant in the Section 9.6.6 long-term cooling analyses because with either assumption, the reactor coolant pumps are tripped long before the long-term cooling timeframe.

The AP1000 protection and safety monitoring system and passive safeguards systems are not dependent on offsite power or on any backup diesel generators. Following a loss of ac power, the protection and safety monitoring system and passive safeguards are able to perform the safety functions and there are no additional time delays for these functions to be completed.

9.0.13 Treatment of Diverse Protection Systems

For every frequent fault two diverse analyses are performed that address the ability to shutdown the reactor core (ATWT) and the ability to cool the core. These two sets of analyses are discussed further in the following.

Summary of ATWT analysis

For all frequent faults, a conservative analysis shows that there is an alternative means of bringing the reactor to a safe shutdown if the normal means (insertion of control rods) fails. The alternative means depends on whether the failure of the normal system is due to failure within the protection and safety monitoring system (PMS) (leading to failure to generate a PMS trip signal) or to mechanical failure such as the inability of the control rods to insert. In the former case, the diverse means of shutdown is insertion of the control rods by diverse actuation system (DAS) actuation signals; in the latter case, it is operation of the core makeup tank (CMT) and the trip of the RCPs. The tripping of the RCPs results in void formation in

the core which causes a rapid reduction in the core power. The CMTs inject sufficient borated water into the primary circuit to bring about final shutdown.

In all cases, there is a significant margin to violation of any safety limit. The detailed ATWT analysis is presented in Reference 9.0-3 and summarized in the associated frequent fault sections of this PCSR chapter. The analyses show that there is no expected violation of the DNB criterion and hence no core damage; and that the primary circuit pressure never exceeds the American Society of Mechanical Engineers (ASME) service limit C level, so that the integrity of the reactor coolant circuit pressure boundary is ensured. The analysis does not consider in detail the integrity of the containment, because the early challenges to the containment from ATWT scenarios are far smaller than those from, for example, a large-break LOCA; any late challenges (arising from the slow heatup of heat sinks such as the in-containment refuelling water storage tank (IRWST)) would occur significantly later than 30 minutes after the start of the transient and could easily be prevented by operator action. Table 9.0-13 summarizes the key acceptance criteria used for the ATWT diversity analyses.

Summary of Diverse Core Cooling Analysis

Each frequent fault is shown to tolerate common cause failures (CCFs) that affect the ability of the Class 1 SSCs to provide core cooling. These frequent faults are either analysed in detail or are shown to be bounded by another fault that is analysed in detail. For each frequent fault, it is shown that the plant can tolerate a CCF affecting one of the Class 1 SSCs credited in providing core cooling and still provide adequate core cooling using diverse SSCs. The general approach is to provide two completely separate and diverse sets of SSCs including C&I out through the ultimate heat sink. However, as necessary additional sets of SSCs can be defined where they are able to meet a single CCF and they are supported by additional plant analysis.

Diverse core cooling analyses and the associated assumptions and acceptance criteria are discussed further with the individual faults.

9.0.13.1 Classification of Frequent Fault Initiating Events

In the analyses and evaluations presented here, frequent faults will include events with expected frequencies of occurrence equal to or greater than $1x10^{-3}$ per reactor year (UK class DB2).

Table 8A-2 identifies the frequent faults, for which diverse analysis is required.

9.0.13.2 Common Cause Failures Considered in ATWT Cases

Frequent faults are required to be analysed with a single CCF. Two different analyses are performed; one where the CCF affects the ability to shutdown the reactor (ATWT) and the other where the CCF affects the ability to cool the core. A CCF is the failure of two or more SSCs in the same manner or mode due to a single event or cause. Generally, the CCFs that prevent reactor scram from occurring are divided into two broad groups: electrical CCFs and mechanical CCFs. A mechanical CCF is assumed to be a mechanical fault that prevents the RCCA from inserting into the core. The electrical CCF is assumed to be either a fault of the protection system logic, sensors supplying input to the protection system or a fault in the reactor trip breakers. The CCF resulting in an ATWT is assumed to be due to one of the following groups:

1. Electrical CCF of the PMS
2. Electrical CCF of the reactor trip breakers

3. Mechanical CCF that prevents RCCA insertion

Reference 9.0-3 provides additional details regarding the unique analysis assumptions employed when performing the ATWT diversity analyses. Table 9.0-14 summarises the operability assumptions for the PMS and DAS assuming one of the above three types of CCFs occurs.

9.0.14 Description of Systems and Components Used in the Analyses

9.0.14.1 Protection and Safety Monitoring System

During normal operation, administrative procedures and plant control systems serve to maintain the reactor in a safe state, preventing damage to the three barriers (fuel clad, reactor coolant system, and reactor containment building) that prevent the spread of radioactive material to the environment. Accident conditions causing one or more of the barriers to be threatened can occur. The PMS monitors key plant parameters and will automatically initiate required protective functions to prevent violation of any of the three barriers. If violation of a barrier cannot be prevented, the PMS will maintain the integrity of the remaining barriers. This ensures that, given a design-basis event, the site boundary radiological consequences will be below design limits. The system performs its functions by actuating a variety of electrical and mechanical equipment and by monitoring the plant process using a variety of sensors and operations that perform calculations, comparisons, and logic based on the sensor inputs.

The protective functions use two basic classes of safety features to prevent damage to the reactor fuel elements and the release of radioactive material: the reactor trip feature and ESFs. The reactor trip feature uses neutron-absorbing control rods that can be rapidly inserted by gravity into the reactor core to shut down the chain reaction and dramatically reduce the power output of the reactor. In some cases, additional measures are needed to cool the reactor or containment building, isolate possible release paths for radioactive materials, prevent excessive cooling of the reactor, or prevent inadvertent core criticality. The ESFs actuate or isolate various processes to perform these functions. The PMS includes the equipment from the process sensor and manual control inputs through to the power switching devices that actuate the equipment controlled by the PMS.

9.0.14.2 Plant Control System

The plant control system (PLS) provides control and coordination of the plant during startup, ascent to power, power operation, and shutdown conditions. The PLS integrates the automatic and manual control of the reactor, reactor coolant, and various reactor support processes for required normal and off-normal conditions. The PLS also provides control of the Class 2 and Class 3 decay heat removal systems during shutdown. As a result, parts of PLS are Class 2 while other parts are Class 3. The PLS accomplishes these functions through use of the following:

- Rod control
- Pressuriser pressure and level control
- Steam generator water level control
- Turbine bypass (steam dump) control
- Rapid power reduction

The PLS provides automatic regulation of reactor and other key system parameters in response to changes in operating limits (load changes). The PLS acts to maximise margins to

plant safety limits and maximise the plant transient performance. The PLS also provides the capability for manual control of plant systems and equipment. Redundant control logic is used in some applications to increase single-failure tolerance. The PLS includes the equipment from the process sensor input circuitry through to the modulating and non-modulating control outputs, as well as the digital signals to other plant systems. Modulating control devices include valve positioners, pump speed controllers, and the control rod equipment. Non-modulating devices include motor starters for motor-operated valves and pumps, breakers for heaters, and solenoids for actuation of air-operated valves. The PLS cabinets contain the process sensor inputs and the modulating and non-modulating outputs. The PLS also includes equipment to monitor and control the control rods.

9.0.14.3 Diverse Actuation System

The DAS is a C&I system that provides a diverse backup to the PMS. This diverse backup system is included in the C&I system design to support the AP1000 plant risk goals by reducing the probability of a severe accident, which could potentially result from the unlikely coincidence of postulated transients and postulated CCF in the PMS and the PLS.

The purpose of the DAS is to lessen the probability of plant damage if the PMS fails to function when required and to reduce the frequency of the fuel core melting or containment failure in the probabilistic safety assessment (PSA). The specific functions performed by the DAS are selected based on the AP1000 plant PSA evaluation. The DAS functional requirements are based on an assessment of the protection system CCF probabilities combined with the event probability. The DAS supports both automatic and manual actuations.

9.0.14.4 Passive Core Cooling System

The passive core cooling system (PXS) is designed to perform the following major safety functions:

- Emergency RCS makeup and boration
- Safety injection
- Emergency core decay heat removal
- Post-accident containment pH control

The safety functions of the PXS provide for the integrity of the reactor coolant pressure boundary, the capability to shut down the reactor and maintain it in a safe shutdown condition, or the capability to prevent or mitigate the consequences of accidents that could result in potential offsite exposures. These safety functions are provided by Class 1 equipment with redundancy to deal with single failures, environmental qualification, and protection from external hazards. These functions are available during all normal modes of RCS operation, including hot and cold shutdowns and refuelling.

For diverse core cooling scenarios, the PXS provides the same safety functions with some exceptions. First, as it is a diversity evaluation, Class 2 SSCs are included if necessary; most notably RNS cooling. In addition, these analyses may assume CCF within the PXS to demonstrate adequate diversity with the primary case mitigation.

During an ATWT, the PXS is used to remove sufficient heat to adequately cool the plant and inject sufficient boron to shut down the core. Of particular importance to ATWT events are the emergency RCS boration (including tripping of the RCPs) and the emergency core decay

heat removal functions. Emergency boration by the PXS is performed with the CMTs during ATWT events. Emergency core heat removal is provided by the PRHR heat exchanger.

9.0.15 As Low As Reasonably Practicable Assessment

In the UK, meeting the DB and probabilistic targets alone are not sufficient to demonstrate that the plant is adequately safe. There is the additional requirement that the risk must be demonstrated to be ALARP.

The ALARP assessment determines if there are any reasonably practicable means to further reduce the risk from individual faults, including the identification of SSCs for defence in depth and in the safety case as a whole. As a result of the ALARP assessment, other SSCs may be identified as providing defence in depth or reducing risk in other ways.

Section 14.6 provides an extensive review of overall ALARP case for the AP1000 design. It reviews major design decisions taken during the evolution of the design from the previous generation of PWRs, giving a brief explanation of why certain features were selected and others rejected, to demonstrate that the evolution process has resulted in an improved design from the point of view of safety. The ALARP assessment discussed in Section 14.6 consists of a number of inputs from different phases of the development and assessment of the design. Many of these exercises have been aimed at risk reduction rather than ALARP as such, but they have led to many risk reduction measures being incorporated into the design that contribute to achieving an overall plant risk judged to be ALARP.

In addition to the discussion of the historical development activities of the AP1000 design, Section 14.6 also discusses changes incorporated into the UK AP1000 design specifically for ALARP reasons. There is also discussion of additional changes that could have been made but were rejected because they were not considered ALARP.

Note that adding additional safety SSCs can increase the overall safety of the plant. However, adding more SSCs increases the design complexity which can offset the benefits. The more complex the design, the greater the chance of additional failures of SSCs and the greater the chance of adverse interactions. More SSCs require more inservice inspection and testing which tends to increase radiation exposure to plant personnel. Thus, adding additional safety components and systems may only increase safety in small increments and possibly even decrease safety.

Finally, given that the total AP1000 plant large release frequency (refer to Chapter 10) is about an order of magnitude below the SAP Target 9 BSO (1E-7 pa), the ONR internal licensing guidance is that little additional effort should be expended to further reduce the risk.

In spite of this extensive effort already put into reducing risk in the AP1000 design, the following Chapter 9 sections include additional ALARP discussions of further improvements.

9.0.16 Conclusion

The basis for the faults analysed in this Chapter is predominantly the design basis faults identified in Table 8A-2. The faults are addressed in Sections 9.1 to 9.12. Section 9.13 contains the conclusions of the chapter.

It is noted that Sections 9.1 to 9.6 provide a discussion of faults related to reactor internally initiated events at power (Modes 1 and 2 from Table 9.0-1). Section 9.7 provides a discussion of faults associated with the spent fuel pool (SFP). All reactor faults are discussed in Sections 9.1 to 9.6 are revisited for consideration during all shutdown modes (Modes 3, 4, 5, and 6) in

Section 9.8, which also includes reactor-specific potential faults in shutdown conditions. Sections 9.9 – 9.12 provide a discussion of various faults: dropped loads; operator exposure faults; heating, ventilation, and air conditioning (HVAC) faults; and radioactive-waste-related faults.

• Dose consequences do not exceed design limits</td></tr>
<tr><td>Loss-of-Coolant Accidents Resulting from a Spectrum of Postulated Piping Breaks Within the Reactor Coolant Pressure Boundary</td><td>• The calculated maximum fuel element cladding temperature shall not exceed 1204°C (2200°F)
• Localized cladding oxidation shall not exceed 17 percent of the total cladding thickness before oxidation
• Changes in core geometry are such that the core remains amenable to cooling</td></tr>
</table>

Table 9.0-3 (Sheet 5 of 5). Summary of Safety Analysis Events and Main Acceptance Criteria

Safety Analysis Group	Safety Analysis Event	Main Acceptance Criteria
Radioactive Release from a Subsystem or Component	Gas Waste Management System Leak or Failure	• Failure of the gaseous radwaste system results in a minor release of activity that is not significant
	Liquid Waste Management System Leak or Failure (Atmospheric Release)	• Liquid radwaste system tanks do not contain significant levels of gaseous activity
	Release of Radioactivity to the Environment Due to a Liquid Tank Failure	• Site specific dose consequences do not exceed design limits
	Fuel Handling Accident	• Dose consequences do not exceed design limits
	Spent Fuel Cask Drop Accident	• The spent fuel cask handling crane is prevented from travelling over the spent fuel

Table 9.0-4 (Sheet 1 of 2). Limits and Conditions Assumed in Safety Case

Limit or Condition	Technical Specification Identification and Notes
Limits and conditions defining the safe operating envelope and initial conditions	
Core DNBR	2.1.1 Reactor Core Safety Limits: 2.1.1.1 The DNBR shall be maintained ≥ 1.14 for the WRB-2M DNB correlations
Core peak clad temperature	2.1.1 Reactor Core Safety Limits: 2.1.1.2 The peak fuel centreline temperature shall be maintained < 2804.44°C (5080°F), decreasing by 14.44°C (58°F) per 10,000 MWD/MTU of burn up.
RCS pressure	2.1.2 RCS Pressure Safety Limits: In Modes 1, 2, 3, 4, and 5 the RCS pressure shall be maintained ≤ 18.847 MPa gauge (2734 psig)
Shutdown margin (SDM)	3.1.1 Shutdown Margin (SDM): In Mode 2 with keff < 1.0, Modes 3, 4, and 5 SDM to be within defined limits
Shutdown rod insertion limits	3.1.5 Shutdown bank position Within insertion limits specified in the Core Operating Limit Report (COLR)
Control rod insertion limits	3.1.6 Control rod position Within insertion, sequence and overlap limits specified in the COLR
Power distribution limits	3.2.5 Peal power/length(Z), $F_{\Delta H}^{N}$, DNBR and SDM Within operating limits specified in the COLR
RCS temperature & pressure	3.4.3 RCS pressure, temperature and heatup and cooldown rates Within the limits specified in the Pressure and Temperature Limits Report (PTLR)
Steam Generator (SG) tube integrity	3.4.18 SG integrity shall be maintained and all SG tubes satisfying the tube repair criteria shall be plugged in accordance with the SG programme
Limits and Conditions determining Class 1 SSC operation	
Accumulator isolation valves open	3.5.1 Accumulators (SR 3.5.1.1)
Accumulator water volume	3.5.1 Accumulators (SR 3.5.1.2)
Accumulator nitrogen pressure	3.5.1 Accumulators (SR 3.5.1.3)
Accumulator boron concentration	3.5.1 Accumulators (SR 3.5.1.4)
CMT water temperature	3.5.2 CMTs – Operating (SR 3.5.2.1)
CMT water volume	3.5.2 CMTs – Operating (SR 3.5.2.2)

Table 9.0-4 (Sheet 2 of 2). Limits and Conditions Assumed in Safety Case

Limit or Condition	Technical Specification Identification and Notes
CMT inlet isolation valves fully open	3.5.2 CMTs – Operating (SR 3.5.2.3)
CMT boron concentration	3.5.2 CMTs – Operating (SR 3.5.2.5)
PRHR outlet isolation valve open	3.5.4 PRHR HX – Operating (SR 3.5.4.1)
PRHR inlet isolation valve open	3.5.4 PRHR HX – Operating (SR 3.5.4.2)
PRHR free from non-condensable gas	3.5.4 PRHR HX – Operating (SR 3.5.4.3)
IRWST water temperature	3.5.6 IRWST – Operating (SR 3.5.6.1)
IRWST water volume	3.5.6 IRWST – Operating (SR 3.5.6.2)
IRWST boron concentration	3.5.6 IRWST – Operating (SR 3.5.6.3)
Containment isolation valves closed	3.6.3 Containment Isolation Valves (SR 3.6.3.1)
Containment pressure	3.6.4 Containment Pressure (SR 3.6.4.1)
Passive Containment Cooling Water Storage Tank (PCCWST) water temperature	3.6.6 Passive Containment Cooling System (PCS) – Operating (SR 3.6.6.1)
PCCWST water volume	3.6.6 PCS – Operating (SR 3.6.6.2)
Essential Electrical Supply System (IDS) dc voltage	3.8.1 Direct current (DC) Sources – Operating (SR 3.8.1.1)
IDS ac voltage	3.8.3 Inverters – Operating (SR 3.8.3.1)

Note:
SR indicates a Surveillance Requirement associated with the corresponding Tech Specs.

Table 9.0-5. Nuclear Steam Supply System Power Ratings

Thermal power output (MWt)	3415
Effective thermal power generated by the reactor coolant pumps (MWt)	15
Core thermal power (MWt)	3400

Table 9.0-6 (Sheet 1 of 5). Summary Of Initial Conditions And Computer Codes Used

Section	Faults	Computer Codes Used	Reactivity Coefficients Assumed			Initial Thermal Power Output Assumed (MWt)
			Moderator Density ($\Delta k/gm/cm^3$)	Moderator Temperature (pcm/°C)	Doppler	
9.1	Increase in heat removal from the primary system					
	Feedwater system malfunctions causing a reduction in feedwater temperature	Bounded by excessive increase in secondary steam flow	–	–	–	–
	Feedwater system malfunctions that result in an increase in feedwater flow	LOFTRAN	0.470	–	Upper curve of Figure 9.0-3	0 and 3415
	Excessive increase in secondary steam flow	LOFTRAN	0.0 and 0.470	–	Upper and lower curves of Figure 9.0-3	3415
	Inadvertent opening of a steam generator relief or safety valve	LOFTRAN, VIPRE-01	Function of moderator density (see Figure 9.1.4-1)	–	See Section 9.1.4.	0 (subcritical)
	Steam system piping failure	LOFTRAN, VIPRE-01	Function of moderator density (see Figure 9.1.4-1) for zero-power case 0.470 for full-power case	–	See Section 9.1.5 for zero-power case; upper curve of Figure 9.0-3 for full-power case	0 (subcritical) and 3415
	Inadvertent operation of the PRHR heat exchanger	N/A	N/A	–	N/A	3415

Table 9.0-6 (Sheet 2 of 5). Summary Of Initial Conditions And Computer Codes Used

Section	Faults	Computer Codes Used	Reactivity Coefficients Assumed			Initial Thermal Power Output Assumed (MWt)
			Moderator Density ($\Delta k/gm/cm^3$)	Moderator Temperature (pcm/°C)	Doppler	
9.2	Decrease in heat removal by the secondary system					
	Loss of external electrical load and/or turbine trip	LOFTRAN, FACTRAN, VIPRE-01	0.470 and function of moderator density	–	Lower and upper curves of Figure 9.0-3	3415 and 3449.15 (a)
	Inadvertent closure of main steam isolation valves	Bounded by turbine trip event	–	–	–	–
	Loss of condenser vacuum and other events resulting in turbine trip	Bounded by turbine trip event	–	–	–	–
	Loss of nonemergency ac power to the plant auxiliaries	LOFTRAN	0.0	–	Lower curve of Figure 9.0-3	3449.15 (a)
	Loss of normal feedwater flow	LOFTRAN	0.0	–	Lower curve of Figure 9.0-3	3449.15 (a)
	Feedwater system pipe break	LOFTRAN	0.0	–	Lower curve of Figure 9.0-3	3449.15 (a)
9.3	Decrease in reactor coolant system flow rate					

Table 9.0-6 (Sheet 3 of 5). Summary Of Initial Conditions And Computer Codes Used

Section	Faults	Computer Codes Used	Reactivity Coefficients Assumed			Initial Thermal Power Output Assumed (MWt)
			Moderator Density ($\Delta k/gm/cm^3$)	Moderator Temperature (pcm/°C)	Doppler	
9.3	Partial and complete loss of forced reactor coolant flow	LOFTRAN, FACTRAN, COAST, VIPRE-01	0.0 and function of moderator density	–	Lower curve of Figure 9.0-3	3415
	Reactor coolant pump shaft seizure (locked rotor) and reactor coolant pump shaft break	LOFTRAN, FACTRAN, COAST, VIPRE-01	0.0 and function of moderator density	–	Lower curve of Figure 9.0-3	3415 and 3449.15 (a)
9.4	Reactivity and power distribution anomalies					
	Uncontrolled RCCA bank withdrawal from a subcritical or low power startup condition	TWINKLE, FACTRAN, VIPRE-01	–	0.0	Coefficient is consistent with a Doppler defect of -0.90%Δk	0
	Uncontrolled RCCA bank withdrawal at power	LOFTRAN	0.0 and 0.470	–	Upper and lower curves of Figure 9.0-3	10%, 60%, and 100% of 3415
	RCCA misalignment	LOFTRAN, VIPRE-01	NA	–	NA	3415
	Startup of an inactive reactor coolant pump at an incorrect temperature	NA	NA	–	NA	NA

Table 9.0-6 (Sheet 4 of 5). Summary Of Initial Conditions And Computer Codes Used

Section	Faults	Computer Codes Used	Reactivity Coefficients Assumed			Initial Thermal Power Output Assumed (MWt)
			Moderator Density ($\Delta k/gm/cm^3$)	Moderator Temperature (pcm/°C)	Doppler	
9.4	Chemical and volume control system malfunction that results in a decrease in the boron concentration in the reactor coolant	NA	NA	–	NA	0 and 3415
	Inadvertent loading and operation of a fuel assembly in an improper position	ANC	NA	–	NA	3415
	Spectrum of RCCA ejection accidents	ANC, VIPRE	Refer to Section 9.4.8	Refer to Section 9.4.8	Refer to Section 9.4.8	Refer to Section 9.4.8
9.5	Increase in reactor coolant inventory					
	Inadvertent operation of the core makeup tanks during power operation	LOFTRAN	0.0	–	Upper curve of Figure 9.0-3	3449.15 (a)
	Chemical and volume control system malfunction that increases reactor coolant inventory	LOFTRAN	0.0	–	Upper curve of Figure 9.0-3	3449.15 (a)

Table 9.0-6 (Sheet 5 of 5). Summary Of Initial Conditions And Computer Codes Used

Section	Faults	Computer Codes Used	Reactivity Coefficients Assumed			Initial Thermal Power Output Assumed (MWt)
			Moderator Density ($\Delta k/gm/cm^3$)	Moderator Temperature (pcm/°C)	Doppler	
9.6	Decrease in reactor coolant inventory					
	Inadvertent opening of a pressuriser safety valve and inadvertent operation of ADS	LOFTRAN, FACTRAN, VIPRE-01	0.0	–	Upper curve of Figure 9.0-3	3415
	Steam generator tube failure	LOFTTR2	0.0	–	Lower curve of Figure 9.0-3	3449.15 (a)
	A break in an instrument line or other lines from the reactor coolant pressure boundary that penetrate containment	NA	NA	–	NA	NA
	LOCAs resulting from the spectrum of postulated piping breaks within the reactor coolant pressure boundary	NOTRUMP WCOBRA/ TRAC	See Section 9.6.5 references	–	See Section 9.6.5 references	3434.0 (a) (b)

Notes:

a. The non-LOCA analyses assume an initial power of 101% of the nuclear steam supply system (NSSS) power (NSSS power = rated thermal power (RTP) plus 15 MWt for pump heat), and the LOCA analyses assume an initial power of 101% of RTP.

b. Section 9.6.4 describes the large-break LOCA analysis methodology, which includes treatment of the initial thermal power output uncertainty.

Table 9.0-7. Nominal Values Of Pertinent Plant Parameters Used In Accident Analyses

	RTDP With 10% Steam Generator Tube Plugging	Without RTDP[a]	
		Without Steam Generator Tube Plugging	With 10% Steam Generator Tube Plugging
Thermal output of NSSS (MWt)	3415	3415	3415
Core inlet temperature (°C/°F)	279.9 / 535.8	279.7 / 535.5	279.4 / 535.0
Vessel average temperature (°C/°F)	300.9 / 573.6	300.9 / 573.6	300.9 / 573.6
Reactor coolant system pressure (MPa/psia)	15.51 / 2250.0	15.51 / 2250.0	15.51 / 2250.0
Reactor coolant flow per loop (m^3/hr / gpm)	34250 /15.08 E+04	34046 / 14.99 E+04	33614/ 14.8 E+04
Steam flow from NSSS (kg/hr / lbm/hr)	6.79E+06 / 14.96 E+06	6.79E+06 / 14.96 E+06	6.78E+06 / 14.96 E+06
Steam pressure at steam generator outlet (MPa/psia)	5.531 / 802.2	5.612 / 814.0	5.488 / 796.0
Assumed feedwater temperature at steam generator inlet (°C/°F)	226.7 / 440.0	226.7 / 440.0	226.7 / 440.0
Average core heat flux (W/m^2 / Btu/-hr-ft^2)	6.28E+05 / 1.99 E+05	6.28E+05 / 1.99 E+05	6.28E+05 / 1.99 E+05

Note:

a. Steady-state errors discussed in Section 9.0.2 are added to these values to obtain initial conditions for most transient analyses.

Table 9.0-8 (Sheet 1 of 2). Protection And Safety Monitoring System Setpoints And Time Delay Assumed In Accident Analyses

Function	Limiting Setpoint Assumed in Analyses	Time Delays (seconds)
Reactor trip on power range high positive flux rate	15% with 60-second time constant	0.9
Reactor trip on power range high neutron flux, low setting	35%	0.9
Reactor trip on source range neutron flux reactor trip	Not applicable	0.9
Overtemperature ΔT	Variable (see Figure 9.0-1)	2.0
Overpower ΔT	Variable (see Figure 9.0-1)	1.0
Reactor trip on High-2 pressuriser pressure	16.96 MPa (2460 psia)	2.0
Reactor trip on Low-2 pressuriser pressure	12.41 MPa (1800 psia)	2.0
Reactor trip on Low-2 reactor coolant flow in either hot leg	87% loop flow	1.45
Reactor trip on reactor coolant pump under speed	90%	0.65
Reactor trip on Low-2 steam generator narrow range level	0% of span	2.0
High steam generator narrow range level coincident with reactor trip (P-4)	85% of narrow range level span	2.0 (startup feedwater isolation) 2.0 (chemical and volume control system makeup isolation)
High-3 steam generator level	95% of narrow range level span	2.0 (reactor trip) 0.0 (turbine trip) 2.0 (feedwater isolation)
Reactor trip on High-3 pressuriser water level	76% of span	2.0
PRHR actuation on Low-2 steam generator wide range level	22.3%	2.0
“S” signal and steam line isolation on Low-2 T_{cold}	260°C (500°F) lower bound 265.6°C (510°F) upper bound	2.0

Table 9.0-8 (Sheet 2 of 2). Protection And Safety Monitoring System Setpoints And Time Delay Assumed In Accident Analyses

Function	Limiting Setpoint Assumed in Analyses	Time Delays (seconds)
"S" signal and steam line isolation on Low-2 steam line pressure	2.79 MPa (405 psia) (with an adverse environment assumed)	2.0
	3.69 MPa (535 psia) (without an adverse environment assumed)	
"S" signal on Low-3 pressuriser pressure	11.721 MPa (1700 psia)	2.0
Reactor trip on PRHR discharge valves not closed	Valve not closed	1.25
"S" signal on High-2 containment pressure	0.055 MPa (8 psig)	2.0
Reactor coolant pump trip following "S"	–	5.0 5.3 (LBLOCA)
PRHR actuation on High-3 pressuriser water level	76% of span	2.0 (plus 15.0-second timer delay)
Chemical and volume control system isolation on High-2 pressuriser water level	69% of span	2.0
Chemical and volume control system isolation on high-1 pressuriser water level coincident with "S" signal	33% of span	2.0
Boron dilution block on source range flux doubling	3 over 50 minutes	80.0
ADS Stage 1 actuation on core makeup tank low level signal	67.5% of tank volume	32.0 seconds for control valve to begin to open
ADS Stage 4 actuation on core makeup tank low-low level signal	20% of tank volume	2.0 seconds for squib valve to begin to open
CMT actuation on pressuriser Low-2 water level	0% of span	2.0

Note:

1. The table includes only protection functions (reactor trip and ESF actuation) credited in the safety analysis in Chapter 9. Other protection functions are available and may act. Table 9.0-10 lists all protection functions that may act for each Chapter 9 event.

Table 9.0-9. Limiting Delay Times For Equipment Assumed In Accident Analyses

Component	Time Delays (seconds)
Feedwater isolation valve closure, feedwater control valve closure, or feedwater pump trip	10 (maximum value for non-LOCA) 5 (maximum value for mass/energy)
Steam line isolation valve closure	5
Core makeup tank discharge valve opening time	15 (maximum) 10 (nominal value for best-estimate LOCA)
Chemical and volume control system isolation valve closure	30
PRHR discharge valve opening time	15 (maximum) 10 (nominal value for best-estimate LOCA) 1.0 second (small-break LOCA value: follows a 15-second interval of no valve movement)
Demineralized water transfer and storage system isolation valve closure time	20
Steam generator power-operated relief valve block valve closure	44
Automatic depressurisation system (ADS) valve opening times	See Table 9.6.5-10.

Table 9.0-10 (Sheet 1 of 5). Plant Systems And Equipment Available For Transient And Accident Conditions

Incident	Reactor Trip Functions	ESF Actuation Functions	ESF and Other Equipment
Section 9.1			
Increase in heat removal from the primary system			
Feedwater system malfunctions that result in an increase in feedwater flow	High-3 Steam Generator Level, Power range high positive flux rate and high neutron flux, overpower ΔT, overtemperature ΔT, manual	High-3 steam generator level produced feedwater isolation and turbine trip	Feedwater isolation valves
Excessive increase in secondary steam flow	Power range high positive flux rate and high neutron flux, overtemperature ΔT, overpower ΔT, manual	–	–
Inadvertent opening of a steam generator safety valve	Power range high positive flux rate and high neutron flux, overtemperature ΔT, overpower ΔT, Low-2 pressuriser pressure, “S”, manual	Low-3 pressuriser pressure, Low-2 compensated steam line pressure, Low-2 T_{cold}, low-2 pressuriser level	Core makeup tank, feedwater isolation valves, main steam isolation valves (MSIVs), startup feedwater isolation, accumulators
Steam system piping failure	Power range high positive flux rate and high neutron flux, overtemperature ΔT, overpower ΔT, Low-2 pressuriser pressure, “S”, manual	Low-3 pressuriser pressure, Low-2 compensated steam line pressure, high-2 containment pressure, Low-2 T_{cold}, manual	Core makeup tank, feedwater isolation valves, MSIVs, accumulators, startup feedwater isolation
Inadvertent operation of the PRHR	PRHR discharge valve position	Low-3 pressuriser pressure, Low-2 T_{cold}, Low-2 pressuriser level	Core makeup tank

Table 9.0-10 (Sheet 2 of 5). Plant Systems And Equipment Available For Transient And Accident Conditions

Incident	Reactor Trip Functions	ESF Actuation Functions	ESF and Other Equipment
Section 9.2			
Decrease in heat removal by the secondary system			
Loss of external load/turbine trip	High-2 pressuriser pressure, High-3 pressuriser water level, overtemperature ΔT, overpower ΔT, Steam generator Low-2 narrow range level, Low-2 RCP speed, manual	–	Pressuriser safety valves, steam generator safety valves
Loss of nonemergency ac power to the station auxiliaries	Steam generator Low-2 narrow range level, High 2 pressuriser pressure, High-3 pressuriser level, low RCP speed, manual	Steam generator low narrow range level coincident with low startup water flow, steam generator low wide range level	PRHR, steam generator safety valves, pressuriser safety valves
Loss of normal feedwater flow	Steam generator Low-2 narrow range level, High-2 pressuriser pressure, High-3 pressuriser level, manual	Steam generator low narrow range level coincident with low startup water flow, steam generator low wide range level	PRHR, steam generator safety valves, pressuriser safety valves, reactor vessel head vent
Feedwater system pipe break	Steam generator Low-2 narrow range level, High-2 pressuriser pressure, High-3 pressuriser level, overtemperature ΔT, manual	Steam generator low narrow range level coincident with low startup feedwater flow, Steam generator low wide range level, Low-2 steam line pressure, high-2 containment pressure	PRHR, core makeup tank, MSIVs, feedline isolation, pressuriser safety valves, steam generator safety valves

Table 9.0-10 (Sheet 3 of 5). Plant Systems And Equipment Available For Transient And Accident Conditions

Incident	Reactor Trip Functions	ESF Actuation Functions	ESF and Other Equipment
Section 9.3			
Decrease in reactor coolant system flow rate			
Partial and complete loss of forced reactor coolant flow	Low flow, underspeed, manual	–	Steam generator safety valves, pressuriser safety valves
Reactor coolant pump shaft seizure (locked rotor)	Low flow, High-2 pressuriser pressure, manual	–	Pressuriser safety valves, steam generator safety valves
Section 9.4			
Reactivity and power distribution anomalies			
Uncontrolled RCCA bank withdrawal from a subcritical or low power startup condition	Source range high neutron flux, intermediate range high neutron flux, power range high neutron flux (low setting), power range high neutron flux (high setting), power range high positive flux rate, manual	–	–
Uncontrolled RCCA bank withdrawal at power	Power range high neutron flux, power range high positive flux rate, overtemperature ΔT, over-power ΔT, High-2 pressuriser pressure, High-3 pressuriser water level, manual	–	Pressuriser safety valves, steam generator safety valves
RCCA misalignment	Overtemperature ΔT, low pressuriser pressure, manual	–	–
Startup of an inactive reactor coolant pump at an incorrect temperature	Power range high positive flux rate, low flow (P-10 interlock), manual	–	–

Table 9.0-10 (Sheet 4 of 5). Plant Systems And Equipment Available For Transient And Accident Conditions

Incident	Reactor Trip Functions	ESF Actuation Functions	ESF and Other Equipment
Section 9.4 (Cont.)			
Chemical and volume control system malfunction that results in a decrease in boron concentration in the reactor coolant	Source range high flux, power range high positive flux rate, overtemperature ΔT, manual	Source range flux doubling, intermediate range high flux (Modes 3-6)	Chemical and volume control system (CVS) to RCS isolation valves, makeup pump suction isolation valves, from the demineralized water transfer and storage system
Spectrum of RCCA ejection accidents	Power range high flux, high positive flux rate, manual	–	Pressuriser safety valves
Section 9.5			
Increase in reactor coolant inventory			
Inadvertent operation of the CMT during power operation	High-2 pressuriser pressure, manual, “safeguards” trip, High-3 pressuriser level	High-3 pressuriser level, Low-2 T_{cold}	Core makeup tank, pressuriser safety valves, chemical and volume control system isolation, PRHR, steam generator safety valves, reactor vessel head vent
Chemical and volume control system malfunction that increases reactor coolant inventory	High-2 pressuriser pressure, “safeguards” trip, high pressuriser level, manual	High-3 pressuriser level, Low-2 T_{cold}, Low-2 steam line pressure	Core makeup tank, pressuriser safety valves, chemical and volume control system isolation, PRHR, reactor vessel head vent
Section 9.6			
Decrease in reactor coolant inventory			
Inadvertent opening of a pressuriser safety valve or ADS path	Low-2 pressuriser pressure, overtemperature ΔT, manual	Low-3 pressuriser pressure	Core makeup tank, accumulator

Table 9.0-10 (Sheet 5 of 5). Plant Systems And Equipment Available For Transient And Accident Conditions

Incident	Reactor Trip Functions	ESF Actuation Functions	ESF and Other Equipment
Section 9.6 (Cont.)			
Steam generator tube rupture	Low-2 pressuriser pressure, overtemperature ΔT, safeguards (“S”), manual	Low-3 pressuriser pressure, high-2 steam generator water level, high steam generator level coincident with reactor trip (P-4), Low-2 steam line pressure, Low-2 pressuriser level	Core makeup tank, PRHR, steam generator safety and/or relief valves, MSIVs, radiation monitors (air removal, steam line, and steam generator blowdown), startup feedwater isolation, chemical and volume control system pump isolation, pressuriser heater isolation, steam generator power-operated relief valve isolation
LOCAs resulting from the spectrum of postulated piping breaks within the reactor coolant pressure boundary	Low-2 pressuriser pressure, safeguards (“S”), manual	High-2 containment pressure, Low-3 pressuriser pressure	Core makeup tank, accumulator, ADS, steam generator safety and/or relief valves, PRHR, IRWST

Table 9.0-11 (Sheet 1 of 2). Single Failures Assumed In Accident Analyses

Event Description	Failure
Feedwater temperature reduction[a]	–
Excessive feedwater flow	One protection division
Excessive steam flow[a]	
Inadvertent secondary depressurisation	One core makeup tank discharge valve
Steam system piping failure	One core makeup tank discharge valve (zero-power case) One protection division (full-power case)
Inadvertent operation of the PRHR	One protection division
Steam pressure regulator malfunction[b]	–
Loss of external load	One protection division
Turbine trip	One protection division
Inadvertent closure of main steam isolation valve	One protection division
Loss of condenser vacuum	One protection division
Loss of ac power	One PRHR discharge valve
Loss of normal feedwater	One PRHR discharge valve
Feedwater system pipe break	One PRHR discharge valve
Partial loss of forced reactor coolant flow	One protection division
Complete loss of forced reactor coolant flow	One protection division
Reactor coolant pump locked rotor	One protection division
Reactor coolant pump shaft break	One protection division
RCCA bank withdrawal from subcritical	One protection division
RCCA bank withdrawal at power	One protection division
Dropped RCCA, dropped RCCA bank	One protection division
Statically misaligned RCCA[c]	–
Single RCCA withdrawal	One protection division

Notes:

a. No protection action required

b. Not applicable to AP1000

c. No transient analysis

Table 9.0-11 (Sheet 2 of 2). Single Failures Assumed In Accident Analyses

Event Description	Failure
Flow controller malfunction[b]	–
Uncontrolled boron dilution	One protection division
Improper fuel loading[c]	–
RCCA ejection	One protection division
Inadvertent CMT operation at power	One PRHR discharge valve
Increase in reactor coolant system inventory	One PRHR discharge valve
Inadvertent reactor coolant system depressurisation	One protection division
Failure of small lines carrying primary coolant outside containment[c]	–
Steam generator tube rupture	Ruptured steam generator power-operated relief valve fails open
Spectrum of LOCA Small breaks Large breaks	 One ADS Stage 4 valve One CMT valve
Post-LOCA Long-term cooling	One ADS Stage 4 valve

Notes:

a. No protection action required

b. Not applicable to AP1000 design

c. No transient analysis

Table 9.0-12. Non-Class 1 SSCs Credited For Mitigation Of Accidents

Event	Non-Class 1 System and Equipment
9.1.2 Feedwater system malfunctions that result in an increase in feedwater flow	Main feedwater pump trip
9.1.4 Inadvertent opening of a steam generator relief or safety valve	MSIV backup valves[1] Main steam branch isolation valves
9.1.5 Steam system piping failure	MSIV backup valves[1] Main steam branch isolation valves
9.2.7 Loss of normal feedwater	Pressuriser heater block
9.5.1 Inadvertent operation of the core makeup tanks during power operation	Pressuriser heater block
9.5.2 Chemical and volume control system malfunction that increases reactor coolant inventory	Pressuriser heater block
9.6.3 Steam generator tube rupture	Pressuriser heater block MSIV backup valves(1) Main steam branch isolation valves
9.6.5 Small-break LOCA	Pressuriser heater block

Note:

1. These include the turbine stop or control valves, the turbine bypass valves, and the moisture separator reheater 2nd stage steam isolation valves.

Table 9.0-13 Key Acceptance Criteria for ATWT Diversity Studies

ATWT Acceptance Criterion	Assessments used to Demonstrate Criterion is Met
Coolable geometry for reactor core is maintained	Demonstrate that DNB does not occur. As such, all ATWT core damage criteria are met.
Reactor coolant pressure boundary integrity is maintained	Calculated reactor coolant system pressure transient should be limited such that the stress does not exceed the ASME Service Level C limits. For the AP1000 plant, ASME Service Level C limits correspond to a RCS pressure of 3200 psig (22.06 MPa-g).
Containment vessel integrity is maintained	As discussed in Section 9.0.13, this criterion was not explicitly evaluated because other design transients bound ATWT events for this criterion.

Table 9.0-14. Summary of Equipment Operability Analysis Assumptions for ATWT CCF Types

Systems and Functions		CCF Group		
		PMS CCF	Reactor Trip Breakers CCF	Mechanical RCCA CCF

9.1 Increase in Heat Removal From the Primary System

A number of faults that could result in an increase in heat removal from the reactor coolant system are postulated. The events are discussed in this section. Detailed analyses are presented for the most limiting of the primary system heat removal increase events.

9.1.0 Introduction and Overview of Faults

Increase in heat removal from the reactor coolant circuit can be caused by a number of initiating faults that are split into two parts:

- Increase in heat removal events
    - Feedwater system malfunctions that result in a decrease in feed water temperature
    - Feedwater system malfunctions that result in an increase in feed water flow
    - Inadvertent operation of PRHR heat exchanger due to operator error or false actuation signal
    - Excessive increase in secondary steam flow due to administrative violation or equipment malfunction
    - Turbine generator causing random event failure
    - Pump speed fault (flow higher than demanded)
    - Power-operated relief valve (PORV) actuates prematurely and does not reclose due to human error or hardware failure
    - Spurious actuation of main steam line safety valve
- Main steam line break (MSLB)
    - Main steam line break inside containment, downstream of MSIV
    - Main steam line break outside containment, downstream of MSIV
    - Main steam line break inside containment, upstream of MSIV

Overcooling of the primary circuit causes an increase in reactor power as a result of the negative moderator temperature coefficient. Such transients are attenuated by the thermal capacity of the secondary plant and of the RCS before the overpower or overtemperature protection leads to reactor trip.

The potential reactivity injection associated with these faults may be enhanced if the effect of the cooldown is maximised (for example, if the reactor is in hot standby conditions with no significant decay heat).

The MSLB accident is considered separately, as it differs significantly from the other increase-in-heat-removal events because it involves a rapid loss of secondary coolant accompanied by a rapid cooldown of the primary circuit.

This section considers these faults in turn. Each fault is first described; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are then described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences

- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

ATWT analyses presented herein are based on References 9.1-5 and 9.1-10.

9.1.0.1 Increase in Heat Removal Faults (Excluding MSLB)

Description

A number of transients and accidents could increase the heat removal from the RCS. Such faults are shown below:

- Feedwater system malfunctions, causing a reduction in feedwater temperature (Fault 1.15.13)
- Feedwater system malfunctions, causing an increase in feedwater flow (Fault 1.15.14)
- Excessive increase in secondary steam flow (Fault 1.15.18)
- Inadvertent opening of a SG relief or safety valve (Fault 1.22.1)
- Inadvertent operation of the passive residual heat removal heat exchanger (PRHR HX) (Fault 1.15.15)
- Stuck-open SG relief or safety valve (effectively, a steam system piping failure, Fault 1.22.1)

Separate analyses for the non-break faults listed above are included. They are analysed separately since there may be different PMS reactor trip or Engineered Safeguards Features necessary to mitigate the consequences of each event.

Other faults that could cause an increase in heat removal are shown below:

- Failure of the turbine generator casing (Fault 1.15.19)

- Pump speed fault leading to higher than expected primary coolant flow rate (Fault 1.15.21)

Initiating Event Frequency[1]

The increase in heat removal faults, as summarised above, comprise a number of faults identified in Table 8A-2 under the "Core Power Excursion" heading, with IEFs greater than 1.0E-3/yr. It is therefore appropriate to consider the increase in heat removal faults as representative of a frequent fault (DB2).

Design Basis Class

The unmitigated consequences of increase in heat removal faults are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

1 As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

9.1.0.2 Main Steam Line Break

Description

The AP1000 design PSA considers three categories of steam system piping failure:

- MSLB MSIV
- MSLB downstream of the MSIV
- Main steam line valve stuck open

For the DBA, only major ruptures of the main steam line (i.e., MSLBs) are addressed as steam line breaks. The stuck-open safety valve and minor secondary system pipe breaks are addressed with the increase in heat removal faults, as explained previously.

Separate analyses for the MSLB faults are included to address differences in failures at hot zero power (9.1.5) and at full power (9.1.6).

Initiating Event Frequency

The fault schedule (Appendix 8A) gives the frequency of the MSLB initiating events as 5.38E-04/yr (summed values), which makes the fault an infrequent fault in the UK definition.

Design Basis Class

The unmitigated consequences of a MSLB accident are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.1.1 Feedwater System Malfunctions that Result in a Decrease in Feedwater Temperature (Fault 1.15.13)

9.1.1.1 Identification of Causes and Accident Description

In the presence of a negative moderator temperature coefficient, reductions in feedwater temperature cause an increase in core power by decreasing reactor coolant temperature. Such transients are attenuated by the thermal capacity of the secondary plant and of the reactor coolant system. The overpower/overtemperature protection (high positive neutron flux rate, overtemperature, and overpower ΔT trips) prevents a power increase that could lead to a DNBR that is less than the design limit values.

A reduction in feedwater temperature may be caused by a low-pressure heater train or a high-pressure heater train out of service or bypassed. At power, this increased subcooling creates an increased load demand on the reactor coolant system.

With the plant at no-load conditions, the addition of cold feedwater may cause a decrease in reactor coolant system temperature and a reactivity insertion due to the effects of the negative moderator coefficient of reactivity. However, the rate of energy change is reduced as load and feedwater flows decrease, so the no-load transient is less severe than the full-power case. The net effect on the reactor coolant system due to a reduction in feedwater temperature is similar to the effect of increasing secondary steam flow; that is, the reactor reaches a new equilibrium condition at a power level corresponding to the new steam generator ΔT.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.1.1.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The main steam system (MSS) pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified.

9.1.1.2.1 DBA Method of Analysis

This transient is analysed by calculating conditions at the feedwater pump inlet following the removal of a low-pressure feedwater heater train from service. These feedwater conditions are then used to recalculate a heat balance through the high-pressure heaters. This heat balance gives the new feedwater conditions at the steam generator inlet.

The following assumptions are made:

- Initial plant power level corresponding to 100-percent nuclear steam supply system thermal output.

- The worst single failure in the pre-heating section of the Main Feedwater System, resulting in the maximum reduction in feedwater temperature, occurs.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

9.1.1.2.2 DBA Credited SSCs

Plant systems and equipment available to mitigate the effects of the accident are the same as for an excessive steam flow increase (Section 9.1.3) and are discussed in Section 9.0.4 and listed in Table 9.0-10.

9.1.1.2.3 DBA Results

A fault in the feedwater heaters section of the Feedwater System causes a reduction in feedwater temperature that increases the thermal load on the primary system. The maximum reduction in feedwater enthalpy, due to a single failure in the feedwater system, is bounded by the equivalent enthalpy reduction associated with the excessive increase in secondary steam flow event described in Section 9.1.3.

9.1.1.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.1.1.3.1 Diverse Mitigation for ATWT

Because this fault will not result in a power increase sufficient to require reactor trip (i.e., No PMS or DAS setpoints are exceeded during the transient as demonstrated by the bounding DBA

analysis in Section 9.1.3), ATWT diversity is not required for this fault. The transient increase in core power does not challenge any fuel design limits. The reactor coolant pressure does not increase and challenge reactor coolant boundary design limits. There are no energy releases to containment during this event and the containment integrity is not challenged. Should the reactor operator attempt a manual trip or shutdown of the reactor and this action fails, manual reactor trip or manual actuation of the CMTs would be available via DAS.

9.1.1.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.1.1.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

ATWT is not applicable to this event. The diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.1.1.5 As Low as Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for Inadvertent Opening of a Steam Generator Relief or Safety Valve event, as described in Section 9.1.4.5.

9.1.1.6 Conclusions

The decrease in feedwater temperature transient is bounded by the excessive increase in secondary steam flow event. Based on the results presented in Section 9.1.3, the applicable evaluation criteria for the decrease in feedwater temperature event are met.

This event has also been adequately assessed with respect to ATWT considerations. This event was not explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.1-9. However, the evaluation conducted to closeout FS-03 demonstrated with a subset of events (Reference 9.1-10) that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the subset of events confirmed the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.2 Feedwater System Malfunctions that Result in an Increase in Feedwater Flow (Fault 1.15.14)

9.1.2.1 Identification of Causes and Accident Description

Addition of excessive feedwater causes an increase in core power by decreasing reactor coolant temperature. Such transients are attenuated by the thermal capacity of the secondary plant and the reactor coolant system. The overpower/overtemperature protection (neutron overpower, overtemperature, and overpower ΔT trips) prevents a power increase that leads to a DNBR less than the safety analysis limit value.

An example of excessive feedwater flow is a full opening of a feedwater control valve due to a feedwater control system malfunction or an operator error. At power, this excess flow causes an increased load demand on the reactor coolant system due to increased subcooling in the steam generator.

With the plant at no-load conditions, the addition of cold feedwater may cause a decrease in reactor coolant system temperature and a reactivity insertion due to the effects of the negative moderator coefficient of reactivity.

Continuous addition of excessive feedwater is prevented by the steam generator high-3 water level signal trip, which closes the feedwater isolation valves and feedwater control valves and trips the turbine, main feedwater pumps, and reactor.

Plant systems and equipment available to mitigate the effects of the accident are discussed in Section 9.0.4 and listed in Table 9.0-10.

A loss of offsite power is assumed to occur as a consequence of the turbine trip for the excessive feedwater flow case initiated from full-power conditions. As discussed in Section 9.0.12, an excessive feedwater flow transient initiated with the plant at no-load conditions need not consider a consequential loss of offsite power. With the plant initially at zero-load, the turbine would not have been connected to the grid, so any subsequent reactor or turbine trip would not disrupt the grid and produce a consequential loss of offsite ac power.

9.1.2.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified.

9.1.2.2.1 DBA Method of Analysis

The excessive heat removal due to a feedwater system malfunction transient is analysed using the LOFTRAN computer code (Reference 9.1-1). LOFTRAN simulates a multiloop system, neutron kinetics, pressuriser, pressuriser safety valves, pressuriser spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables, including temperatures, pressures, and power level.

The transient is analysed to demonstrate plant behaviour if excessive feedwater addition occurs because of system malfunction or operator error that allows a feedwater control valve to open fully. The following four cases are analysed assuming a conservatively large negative moderator temperature coefficient:

- Accidental opening of one feedwater control valve (single-loop) with the reactor just critical at zero-load conditions.
- Accidental opening of both feedwater control valves (multiloop) with the reactor just critical at zero-load conditions.
- Accidental opening of one feedwater control valve (single-loop) with the reactor in manual and automatic rod control at full power.
- Accidental opening of both feedwater control valves (multiloop) with the reactor in manual and automatic rod control at full power.

The reactivity insertion rate following a feedwater system malfunction is calculated with the following assumptions:

- For the feedwater control valve accident at full power, each faulted feedwater control valve is assumed to malfunction resulting in a step increase to 120 percent of nominal feedwater flow to the faulted steam generator.
- For the feedwater control valve accident at zero-load condition, a feedwater control valve malfunction occurs, which results in a step increase in flow to the faulted steam generator from 0 to 120 percent of the nominal full-load value.
- For the zero-load condition, feedwater temperature is at a conservatively low value of 120°C (248°F).
- No credit is taken for the heat capacity of the reactor coolant system and steam generator thick metal in attenuating the resulting plant cooldown.

- The feedwater flow resulting from a fully open control valve is terminated by a steam generator high-3 level trip signal, which closes feedwater control and isolation valves and trips the main feedwater pumps, the turbine, and the reactor.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

Normal reactor control systems are not required to function. The protection and safety monitoring system may function to trip the reactor because of overpower or high-3 steam generator water level conditions. No single active failure prevents operation of the protection and safety monitoring system.

The analysis assumes that the turbine trip during the case initiated from full power results in a consequential loss of offsite power that produces the coastdown of the reactor coolant pumps. As described in Section 9.0.12, the loss of offsite power is modelled to occur 3.0 seconds after the turbine trip. The excessive feedwater flow analysis conservatively delays the start of rod insertion until 2.0 seconds after the reactor trip signal is generated. Turbine trip occurs 5.0 seconds following a reactor trip condition being reached. This delay is part of the AP1000 reactor trip system. Complete rod insertion occurs in less than 5 seconds so that the loss of offsite power has no impact on the feedwater malfunction analysis.

9.1.2.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser safety valves (SVs) and steam generator SVs. The PMS provides the following:

- Reactor trip (RT) and Feedwater Isolation on High-3 SG narrow-range (NR) level in either SG
- PRHR actuation on Low-2 SG NR level coincident with Low-2 startup feedwater (SFW) flow
- CMTs and containment isolation on Low-2 cold leg (CL) temperature
- PCS on High-2 containment pressure

9.1.2.2.3 DBA Results

In the case of an accidental full opening of both feedwater control valves with the reactor at zero power and the preceding assumptions, the maximum reactivity insertion rate is less than the maximum reactivity insertion rate analysed in Section 9.4.1 for an uncontrolled (RCCA) bank withdrawal from a subcritical or low-power startup condition. Therefore, the results of the analysis are not presented here. If the incident occurs with the unit just critical at no-load, the reactor may be tripped by the power range high neutron flux trip (low setting) set at approximately 25-percent nominal full power, or by the power range high positive flux rate trip.

The full-power case (maximum reactivity feedback coefficients, automatic rod control, and multi-loop malfunction) results in the greatest power increase. Assuming the rod control system to be in the manual control mode results in a slightly less severe transient.

When the steam generator water level in the faulted loop reaches the high-3 level setpoint, the feedwater control valves and feedwater isolation valves are automatically closed and the main feedwater pumps are tripped. This prevents continuous addition of the feedwater. In addition, a turbine trip and a reactor trip are initiated.

Transient results show the increase in nuclear power and ΔT associated with the increased thermal load on the reactor (see Figures 9.1.2-1 and 9.1.2-2). A new equilibrium condition is reached and all the plant parameters, except for the SG water level, remain almost constant until the reactor trips on High-3 SG level. The minimum DNBR is predicted to occur before the reactor trip and the reactor coolant pump coastdown caused by the loss of offsite power. The minimum DNBR predicted is well above the design limit described in Section 22.7.1.1. Following the reactor trip, the plant approaches a stabilized and safe condition; standard plant shutdown procedures may then be followed to further cool down the plant.

Because the power level rises by a maximum of about 12 percent above nominal during the excessive feedwater flow incident, the fuel temperature also rises until after reactor trip occurs. The core heat flux lags behind the neutron flux response because of the fuel rod thermal time constant. Therefore, the peak value does not exceed 118 percent of its nominal value (the assumed overpower ΔT trip setpoint). The peak fuel temperature thus remains well below the fuel melting temperature.

The transient results show that DNB does not occur at any time during the excessive feedwater flow incident. Thus, the capability of the primary coolant to remove heat from the fuel rods is not reduced and the fuel cladding temperature does not rise significantly above its initial value during the transient.

The calculated sequence of events for this accident is shown in Table 9.1.2-1.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events**.**

9.1.2.3 Diverse Mitigation

Diverse mitigation capabilities for this event are the same as for loss of normal feedwater fault, as described in Section 9.2.7.3.

9.1.2.3.1 Diverse Mitigation for ATWT

Excessive feedwater flow events could be postulated to occur due to faults in the main feedwater system or the startup feedwater system. The flow capacity of the main feedwater system is significantly larger than that of the startup feedwater system. The evaluations presented here focus on those occurring in the main feedwater system, as discussed in the primary DBA analysis.

The following sections evaluate the consequences of an excessive feedwater event with an assumed mechanical, PMS or reactor trip breaker CCF, which prevents reactor trip from occurring.

In these cases the initial portion of the transient would be identical to the primary safety case. The core power reaches an equilibrium value equal to the steam generator heat removal. Design limits are not challenged during this period.

9.1.2.3.1.1 Diverse ATWT Method of Analysis

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The excessive feedwater flow analyses presented in this section consider the following events:

- Excessive feedwater flow with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Excessive feedwater flow with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Excessive feedwater flow with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.1.2.3.1.2 Diverse ATWT Credited SSCs

For all ATWT feedwater malfunction flow increase scenarios, long-term transient response is bounded by Turbine Trip ATWT (Section 9.2.3) As noted in Section 9.2.3.3.1.2, the Turbine Trip ATWT is bounded by Section 9.2.7.3.1 which considers the turbine trip and simultaneous loss of feedwater ATWT. As such, no claimed SSCs (PMS or DAS functions) are credited to initiate passive safety features for this limiting ATWT. Instead, the plant will reach a stable steady-state power condition and ATWT criteria would be met. Ultimately, manual operator action would be required to shut down the plant. Section 9.2.7.3.1 considers the turbine trip and simultaneous loss of feedwater ATWT.

9.1.2.3.1.3 Diverse ATWT Results

Feedwater System Malfunctions that Result in an Increase in Feedwater Flow with a Mechanical CCF

This section discusses a main feedwater system malfunction that results in an increase in flow with an assumed RCCA mechanical CCF. The PMS is assumed to be operable in this case;

however, the RCCAs do not insert when a trip signal is generated. The DAS is also operable; however, the mechanical failure also prevents rod insertion on a DAS reactor trip signal.

The additional feedwater flow causes the steam generator level to increase until the PMS High-3 steam generator level setpoint is exceeded. The PMS High-3 steam generator level function generates a signal to trip the turbine, to isolate all feedwater flow by closing control and isolation valves and to trip the feedwater pumps. The High-3 steam generator level function also generates a reactor trip signal. However, in this case, due to the assumed mechanical CCF, the RCCAs do not insert.

From this point on, the transient will behave similarly to the turbine trip scenario where feedwater flow is lost (see Section 9.2.7.3.1). The excessive feedwater scenario, which leads to a turbine trip, will be less severe than the turbine trip cases because at the time the turbine is tripped and feedwater flow is terminated, fluid inventory in the steam generators is significantly above the nominal operating amount. As discussed in Section 9.2.7.3.1, for turbine trip cases with feedwater lost and a mechanical CCF that prevents reactor trip, the design limits for a turbine trip with a loss of feedwater are not exceeded.

Feedwater System Malfunctions that Result in an Increase in Feedwater Flow with a PMS CCF

This section discusses an excessive feedwater flow transient with an assumed PMS CCF that prevents reactor trip from occurring. The PMS is inoperable in this scenario. The DAS is operable, and RCCAs are assumed to be able to insert on a DAS reactor trip signal.

When steam generator level reaches the PMS High-2 setpoint, a turbine trip will not occur because of the PMS failure.

The operator can then terminate the power excursion transient by using DAS to manually trip the reactor. In the event that excessive feedwater flow continues and the turbine is not tripped, then liquid entrainment in the steam lines will increase and will eventually lead to accelerated turbine wear/erosion and likely turbine damage. A turbine trip, such as on turbine vibration, is an expected result. Once turbine trip has occurred, the transient is similar to the turbine trip events addressed in Section 9.2.3.3.1.

Feedwater System Malfunctions that Result in an Increase in Feedwater Flow with a Reactor Trip Breaker CCF

This section discusses an excessive feedwater flow transient with an assumed reactor trip breaker CCF that prevents reactor trip from occurring. The PMS is assumed to be operable in this case; however, the RCCAs do not insert when a trip signal is generated, The DAS is also operable, and RCCAs are assumed to be able to insert on a DAS reactor trip signal.

The additional feedwater flow causes the steam generator level to increase until the PMS High-3 steam generator level setpoint is exceeded. The PMS High-3 steam generator level function generates a signal to trip the turbine, isolate all feedwater flow by closing control and isolation valves and by tripping of feedwater pumps. The High-3 steam generator level function also generates a reactor trip signal. However, in this case, due to the assumed reactor trip breaker CCF, the RCCAs will not insert at this time. From this point on, the transient will behave similarly to the turbine trip scenario where feedwater flow is lost with an assumed trip breaker CCF (see turbine trip case in Section 9.2.7.3.1). The excessive feedwater scenario, which leads to a turbine trip, will be less severe than the turbine trip cases presented in Section 9.2.7.3.1, because at the time the turbine is tripped and feedwater flow is terminated, the steam generators will have a fluid

inventory significantly above nominal amounts. As discussed in Section 9.2.7.3.1, the RCCAs will be inserted when the DAS automatically trips the MG sets on low wide range steam generator level. For turbine trip cases with feedwater lost and a reactor trip breaker CCF that prevents reactor trip, design limits for a turbine trip with a loss of feedwater are not exceeded.

9.1.2.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.1.2.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.1.2.5 As Low as Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for Inadvertent Opening of a Steam Generator Relief or Safety Valve event, as described in Section 9.1.4.5.

9.1.2.6 Conclusions

The results of the analysis show that the minimum DNBR encountered for an excessive feedwater addition at power is above the design limit value. The DNBR design basis is described in Section 22.7.1.1.

Additionally, the reactivity insertion rate that occurs at no-load conditions following excessive feedwater addition is less than the maximum value considered in the analysis of the rod withdrawal from subcritical condition analysis (see Section 9.4.1).

This event has also been adequately assessed with respect to ATWT considerations. This event was not explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.1-9. However, the evaluation conducted to closeout FS-03 demonstrated with a subset of events (Reference 9.1-10) that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the subset of events confirmed the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.3 Excessive Increase in Secondary Steam Flow (Fault 1.15.18)

9.1.3.1 Identification of Causes and Accident Description

An excessive increase in secondary system steam flow (excessive load increase incident) results in a power mismatch between the reactor core power and the steam generator load demand. The plant control system is designed to accommodate a 10-percent step load increase or a 5-percent-per-minute ramp load increase in the range of 25- to 100-percent full power. Any loading rate in excess of these values may cause a reactor trip actuated by the protection and safety monitoring system. Steam flow increases greater than 10 percent are analysed in Sections 9.1.4, 9.1.5 and 9.1.6.

This accident could result from either an administrative violation such as excessive loading by the operator or an equipment malfunction in the steam dump control or turbine speed control.

During power operation, turbine bypass to the condenser is controlled by reactor coolant condition signals. A high reactor coolant temperature indicates a need for turbine bypass. A single controller malfunction does not cause turbine bypass. An interlock blocks the opening of the valves unless a large turbine load decrease or a turbine trip has occurred.

Protection against an excessive load increase accident is provided by the following protection and safety monitoring system signals:

- Overpower ΔT
- Overtemperature ΔT
- Power range high positive flux rate
- Power range high neutron flux

The possible consequence of this accident (assuming no protective functions) is a departure from nucleate boiling with subsequent fuel damage. The accident is typically characterized by an approach of parameter values to the protection setpoints without the setpoints actually being reached. However, the reactor trip setpoints (high neutron flux, overpower ΔT, and overtemperature ΔT) could be reached during the analysis of the excessive load increase event.

These protection functions are defeated in the analysis to preclude reactor trip, ensure the most severe DNB condition is reached, and demonstrate that the plant reaches a new equilibrium condition at a higher power level corresponding to the increase in steam flow.

Determination of the effects produced by a possible consequential loss of offsite power during the excessive load increase event is not applicable to this event. As discussed in Section 9.0.12, the loss of offsite power need be considered only as a direct consequence of a turbine trip occurring while the plant is operating at power. For the four excessive load increase cases presented, reactor and turbine trips are not predicted to occur. However, even if a reactor trip were to occur, a consequential loss of ac power would not adversely affect the analysis results. This conclusion is based on a review of the time sequence of events associated with a consequential loss of ac power in comparison to the reactor shutdown time for the event. The primary effect of the loss of ac power is the coastdown of the RCPs. The PMS includes a five-second minimum delay between the reactor trip and the turbine trip. In addition, a three-second delay between the turbine trip and the loss of offsite ac power is assumed, consistent with Section 9.0.12. Considering these delays between the time of the reactor trip and RCP coastdown due to the loss of ac power, it is clear that the plant shutdown sequence will have passed the critical point and the control rods will have been completely inserted before the RCPs begin to coast down. Therefore, the consequential loss of ac power does not adversely affect this analysis because the plant will be shut down well before the RCPs begin to coast down.

9.1.3.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified.

9.1.3.2.1 DBA Method of Analysis

This accident is primarily analysed using the LOFTRAN computer code (Reference 9.1-1). LOFTRAN simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generator, steam generator safety valves, and feedwater system. The code computes pertinent plant variables including temperatures, pressures, and power level.

Four cases are analysed to demonstrate plant behaviour following a 10-percent step load increase from rated load. These cases are as follows:

- Reactor control in manual with minimum moderator reactivity feedback
- Reactor control in manual with maximum moderator reactivity feedback
- Reactor control in automatic with minimum moderator reactivity feedback
- Reactor control in automatic with maximum moderator reactivity feedback

For the minimum moderator feedback cases, the core has the least negative moderator temperature coefficient of reactivity; therefore, reductions in coolant temperature have the least impact on core power. For the maximum moderator feedback cases, the moderator temperature coefficient of reactivity has its highest absolute value. This results in the largest amount of reactivity feedback

due to changes in coolant temperature. For all the cases analysed both with and without automatic rod control, no credit is taken for ΔT trips on overtemperature or overpower in order to demonstrate the inherent transient capability of the plant. Under actual operating conditions, such a trip may occur, after which the plant quickly stabilizes.

A 10-percent step increase in steam demand is assumed, and each case is analysed without credit being taken for pressuriser heaters. At initial reactor power, reactor coolant system pressure and temperature are assumed to be at their full power values. Uncertainties in initial conditions are included in the limit DNBR as described in WCAP-11397-P-A (Reference 9.1-2). Plant characteristics and initial conditions are further discussed in Section 9.0.2.

Normal reactor control systems and engineered safety systems are not required to function.

9.1.3.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA does not generate a reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and steam generator SVs. The PMS provides the following:

- No RT credited
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.1.3.2.3 DBA Results

Figures 9.1.3-1 through 9.1.3-10 show the transient with the reactor in the manual control mode and no reactor trip signals occur. At the beginning of the minimum moderator feedback case, there is a slight power increase and the average core temperature shows a large decrease. This results in a DNBR that increases above its initial value. At the beginning of the maximum moderator feedback manually controlled case, there is a much faster increase in reactor power due to the moderator feedback. A reduction in the DNBR occurs, but the DNBR remains above the design limit (see Section 22.7.1.1).

Figures 9.1.3-11 through 9.1.3-20 show the transient assuming the reactor is in the automatic control mode. At the beginning of the maximum moderator feedback case, the core power increases and the coolant average temperature and pressuriser pressure decrease slowly. For this case, no reactor trip signal is generated. For the minimum moderator feedback case, a reactor trip signal setpoint is reached, but conservatively, reactor trip is not credited. At the beginning of the minimum moderator feedback case, the core power increases, but the coolant average temperature and pressuriser pressure decrease rapidly. For this case, the transients oscillate and eventually stabilize. For both of these cases, the minimum DNBR remains above the design limit (see Section 22.7.1.1).

The excessive load increase incident is an overpower transient for which the fuel temperature rises. Reactor trip is not credited in any of the cases analysed, and the plant reaches a new equilibrium condition at a higher power level corresponding to the increase in steam flow.

Because DNB does not occur during the excessive load increase transients, the capability of the primary coolant to remove heat from the fuel rod is not reduced. Thus, the fuel cladding temperature does not rise significantly above its initial value during the transient.

The calculated sequence of events for the excessive load increase cases with no reactor trip are shown in Table 9.1.2-1.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.1.3.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.1.3.3.1 Diverse Mitigation for ATWT

For the primary DBA safety case, the excessive load increases were limited to 10% flow increase and were divided into two types of cases: an excessive load increase due to an administrative violation (such as an excessive loading by the operator), and an excessive load increase due to an equipment malfunction. Larger excessive load increases are bounded by the hot full power steamline break event. For the ATWT diversity analysis, an investigation of the expected frequency of occurrence of various secondary-side steam load increases was performed (Reference 9.1-10).

The ATWT diversity cases studied cover three distinct initiating faults: a fault that results in an increase in turbine load, an inadvertent opening of a secondary-side valve, and a secondary-side line break. Since the maximum steam load capacity of the AP1000 turbine is less than 110% of nominal full-power steam flow, no further consideration is given in this study to this fault, as it is already covered by the DBA. As such, the excessive steam load increase scenarios to be considered are those initiated by the opening of one or more secondary-side valves, or by a break in a secondary-side line.

9.1.3.3.1.1 Diverse ATWT Method of Analysis

The ATWT investigation considered various failures, including steam breaks up to approximately 0.037 m^2 (0.4 ft^2), the opening of up to two steam generator power-operated relief or safety valves, or the opening of all six turbine bypass valves. These ATWT scenarios would conservatively bound (i.e., lower expected frequency) the frequent fault limit.

ATWT cases can generally be divided into symmetric cooldown cases (those where the fault affects steam flow for both secondary loops) and asymmetric cooldown cases (those where the fault affects steam flow for one of the secondary loops). For the ATWT diversity cases, all reactor trip safety functions were disabled. Otherwise, the DBA transient analysis methodology described in Section 9.1.3 is followed for the symmetric cases and the DBA case transient analysis methodology of Section 9.1.6 is followed for the asymmetric cases.

The following ATWT acceptance criteria are applicable to this event:

- A coolable geometry for reactor core is maintained
- The reactor coolant pressure boundary integrity is maintained
- The containment vessel integrity is maintained

For the ATWT excessive load diversity cases, the primary acceptance criterion is maintaining a coolable geometry. During the event, the reactor coolant pressure decreases due to the large cooldown; therefore, the reactor coolant pressure boundary integrity is not challenged. The containment vessel integrity is maintained by diverse actuation of the containment cooling system via a high containment temperature DAS setpoint, if the incident were to involve a steam line rupture inside containment.

Five potential fuel failure criteria were considered to confirm that a coolable geometry is maintained: DNB, fuel melt, rod internal pressure, transient clad stress, and clad corrosion. The assessments of these five potential fuel failure mechanisms were performed for an expected maximum duration of [ ] ; appropriate operator action to terminate the transient would be expected within this timeframe.

The minimum DNBR for each case considered was calculated using the VIPRE-01 code. Due to the relatively low power levels reached and the decrease in RCS temperature, the DNBR limits were not challenged for these cases.

The fuel melt, rod internal pressure, transient clad stress and clad corrosion criteria were all confirmed using detailed core design and fuel rod design codes. These calculations were performed without the uncertainties typically applied to frequent fault calculations. The calculations showed that fuel melt is precluded. They also showed that rod internal pressure, transient clad stress and clad corrosion were all within the applicable frequent fault limits.

9.1.3.3.1.2 Diverse ATWT Credited SSCs

For all ATWT excessive load cases, no claimed SSCs (PMS or DAS functions) are credited to initiate passive safety features. Instead, the plant will reach an equilibrium power condition and ATWT criteria would be met for sustained operation at power for at least 30 minutes. Ultimately, manual operator action would be required to shut down the plant.

9.1.3.3.1.3 Diverse ATWT Results

The limiting cases are a 40% steam load increase caused by the opening of all six turbine bypass valves that results in a symmetric cooldown, and a 0.045 m^2 (0.48 ft^2) rupture of the steam line that results in an asymmetric cooldown. As stated previously, all acceptance criteria required to maintain a coolable geometry, including minimum DNBR, fuel centerline melt, rod internal pressure, transient clad stress, and clad corrosion, were met.

The sequence of events for these ATWT cases is presented in Table 9.1.3-1. Transient plots for the symmetric case are presented in Figures 9.1.3-21 through 9.1.3-25. Transient plots for the asymmetric case are presented in Figures 9.1.3-26 through 9.1.3-30.

9.1.3.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.1.3.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the DBA case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the ATWT and the diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.1.3.5 As Low As Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for Inadvertent Opening of a Steam Generator Relief or Safety Valve event, as described in Section 9.1.4.5.

9.1.3.6 Conclusions

The DB analysis presented in this section demonstrates that for a 10-percent step load increase, the DNBR remains above the design limit. The design basis for DNB is described in Section 22.7.1.1. The plant rapidly reaches a stabilized condition following the load increase.

This event has also been adequately assessed with respect to ATWT considerations and all credible cases meet ATWT criteria.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.4 Inadvertent Opening of a Steam Generator Relief or Safety Valve (Fault 1.22.1)

9.1.4.1 Identification of Causes and Accident Description

The most severe core conditions resulting from an accidental depressurisation of the main steam system are associated with an inadvertent opening of a single steam dump, relief, or safety valve. The analyses performed assuming a rupture of a main steam line are given in Sections 9.1.5 and 9.1.6.

The steam release, as a consequence of this accident, results in an initial increase in steam flow which decreases during the accident as the steam pressure falls. The energy removal from the reactor coolant system causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in an insertion of positive reactivity.

The objective of the DB analysis is to demonstrate that the DNBR criterion is met.

Assuming the most reactive stuck RCCA, with offsite power available, and assuming a single failure in the engineered safety features system, there will be no consequential damage to the fuel or reactor coolant system after reactor trip for a steam release equivalent to the spurious opening, with failure to close, of the largest of any single steam dump, relief, or safety valve. This criterion is met by showing the DNB design basis is not exceeded.

9.1.4.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified.

9.1.4.2.1 DBA Method of Analysis

The analysis of a secondary system steam release is performed to determine the following:

- The core heat flux and reactor coolant system temperature and pressure resulting from the cooldown, due to the steam release. The LOFTRAN code (References 9.1-1 and 9.1-6) is used to model the system transient.

- The thermal-hydraulic behaviour of the core due to the steam release. A detailed thermal-hydraulic digital computer code, VIPRE-01 (Reference 9.1-7), is used to determine if DNB occurs for the core transient conditions computed by the LOFTRAN code.

The following conditions are assumed to exist at the time of a secondary system steam release:

- End-of-life shutdown margin at no-load, equilibrium xenon conditions, and with the most reactive RCCA stuck in its fully withdrawn position. Operation of RCCA mechanical shim

and axial offset banks during core burnup is restricted by the insertion limits so that shutdown margin requirements are satisfied.

- A most negative moderator temperature coefficient corresponding to the end-of-life rodded core with the most reactive RCCA in the fully withdrawn position. The variation of the coefficient with temperature is included. The k_{eff} (considering moderator temperature and density effects) versus temperature corresponding to the negative moderator temperature coefficient used is shown in Figure 9.1.4-1. The core power is calculated as a function of core mass flow, core boron concentration, and core inlet temperature.

- Minimum capability for injection of boric acid solution corresponding to the most restrictive single failure in the passive core cooling system. There are no single failures that prevent core makeup tank injection; however, the analysis models the failure of one core makeup tank discharge valve. Low-concentration boric acid must be swept from the core makeup tank lines downstream of isolation valves before delivery of boric acid (3400 ppm) to the reactor coolant loops. This effect has been accounted for in the analysis.

- The case analysed models a flow area of 0.02 m^2 (0.2 ft^2), which is based on a steam flow of 235.9 kg/sec (520 lbm/s) at 8.274 MPa abs (1200 psia) with offsite power available. This conservatively bounds the maximum capacity of any single steam dump, relief, or safety valve.

- Initial hot shutdown conditions at time zero are assumed because this represents the most conservative initial conditions. Should the reactor be just critical or operating at power at the time of a steam release, the reactor is tripped by the normal overpower protection when power level reaches a trip point. Following a trip at power, the reactor coolant system contains more stored energy than at no-load. This is because the average coolant temperature is higher than at no-load, and there is appreciable energy stored in the fuel. The additional stored energy is removed via the cooldown caused by the steam release before the no-load conditions of the reactor coolant system temperature and shutdown margin assumed in the analyses are reached. After the additional stored energy is removed, the cooldown and reactivity insertions proceed in the same manner as in the analysis that assumes no-load condition at time zero. However, because the initial steam generator water inventory is greatest at no-load, the magnitude and duration of the reactor coolant system cooldown are less for a steam line release occurring at power:

- In computing the steam flow, the Moody Curve (Reference 9.1-3) for f(L/D) = 0 is used.

- Perfect moisture separation occurs in the steam generator.

- Offsite power is available, because this maximises the cooldown.

- Maximum cold startup feedwater flow is assumed.

- Four reactor coolant pumps are initially operating.

- Manual actuation of the PRHR system at time zero is conservatively assumed to maximise the cooldown.

9.1.4.2.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The available Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after CMT boron injection ends the return-to-power transient

(core subcritical); however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. Other SSCs include the feedwater isolation valves, steamline isolation valves, CMTs, containment isolation, pressuriser SVs and steam generator SVs. The PMS provides the following:

- RT is available, but not credited; rods already inserted for limiting case
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.1.4.2.3 DBA Results

The calculated sequence of events for the analysed case is shown in Table 9.1.2-1. The results presented conservatively bound the events that would occur assuming a secondary system steam release because it is postulated that the conditions described in Section 9.1.4.2.1 exist simultaneously.

Figures 9.1.4-2 through 9.1.4-12 show the transient results for the event.

Core makeup tank injection and the associated tripping of the reactor coolant pumps are initiated automatically by the Low-2 T_{cold} "S" signal. Boron solution at 3400 ppm enters the reactor coolant system, providing enough negative reactivity to prevent a significant return to power and core damage. Later in the transient, as the reactor coolant pressure continues to fall, the accumulators actuate and inject boron solution at 2600 ppm.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events**.**

The analysis demonstrates that the DNB design basis, as described in Section 22.7.1.1, is met for the inadvertent opening of a steam generator relief or safety valve. As shown in Figure 9.1.4-2, no significant return to power occurs and, therefore, DNB does not occur. The minimum DNBR is conservatively calculated and is above the 95/95 limit.

9.1.4.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.1.4.3.1 Diverse Mitigation for ATWT

The inadvertent opening of a SG PORV or safety valve will not increase power to the point at which a reactor trip is needed. Therefore, diverse mitigation for ATWT for the inadvertent opening of a steam generator relief or safety valve is not addressed further.

9.1.4.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.1.4.4 Radiological Consequences

Design Basis

Since there is no fuel damage and the primary circuit remains intact, only secondary coolant and any primary coolant that leaks into the secondary circuit during the event will be released through the stuck-open SG valve. Therefore, the radiological consequences are limited and no dose calculations have been obtained specifically for this case. However, doses have been calculated for the SGTR accident discussed in Section 9.6.3. An SG relief valve is also assumed to stick open during the SGTR accident, but in the SGTR there is a direct pathway for the release of primary coolant to the environment via the ruptured tube and the stuck valve. Therefore, the dose associated with the SGTR accident bounds the dose that arises from the stuck-open SG relief valve event. The SGTR doses from Section 9.6.3 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.91 mSv Worker dose: 4.8 mSv

These doses for the SGTR accident, which significantly bound the doses associated with the stuck-open SG relief or safety valve event, are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

ATWT is not applicable to this event. The diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.1.4.5 As Low as Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

The diverse mitigation functions, including other Class 1 safety functions and the DAS function, which is Class 2, is also shown by analysis to meet the corresponding requirements for this event. See Reference 9.1-12 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy/diversity which is provided by Class 2 defence in depth (DiD) systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- SFW with steam dump for short–term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the component cooling water system (CCS) and service water system (SWS) cooling water systems.

- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment / start automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (Reference 9.1-11). However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

As discussed in Chapter 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000 development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.1.4.6 Conclusions

The analysis shows that the key fuel failure criterion is satisfied. For an inadvertent opening of any single steam dump or a steam generator relief or safety valve, the DNB design basis is met.

This event has also been adequately assessed with respect to ATWT considerations.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences for the SGTR accident, which significantly bound those associated with the stuck-open SG relief or safety valve event, are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.5 Steam System Piping Failure at Hot Zero Power (Fault 1.21.1a)

9.1.5.1 Identification of Causes and Accident Description

The steam release arising from a rupture of a main steam line results in an initial increase in steam flow, which decreases during the accident as the steam pressure falls. The energy removal from the reactor coolant system causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in an insertion of positive reactivity.

A fast-acting main steam isolation valve is provided in each steam line. These valves are modelled to fully close within 10 seconds of actuation following a large break in the steam line. For breaks

downstream of the main steam line isolation valves, closure of the isolation valves will terminate the blowdown. For any break in any location, no more than one steam generator would experience an uncontrolled blowdown even if one of the main steam line isolation valves fails to close.

Flow restrictors are installed in the steam generator outlet nozzle, as an integral part of the steam generator. The effective throat area of the nozzles is 0.13 m^2 (1.4 ft^2), which is considerably less than the main steam pipe area; thus, the flow restrictors serve to limit the maximum steam flow for a break at any location.

If the most reactive RCCA is assumed stuck in its fully withdrawn position after reactor trip, there is an increased possibility that the core will become critical and return to power. A return to power following a steam line rupture is a potential problem mainly because of the existing high-power peaking factors, assuming the most reactive RCCA to be stuck in its fully withdrawn position. The core is ultimately shut down by the boric acid solution delivered by the passive core cooling system.

Assuming the most reactive stuck RCCA with or without offsite power and assuming a single failure in the engineered safety features system, the core cooling capability is maintained. As shown in Section 9.1.5.4, radiological consequences are within the guidelines.

Effects of minor secondary system pipe breaks are bounded by the analysis presented in this section.

The steam line rupture at full-power conditions is explicitly analysed and discussed in Section 9.1.6.

9.1.5.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified. It is noted that DNB and possible cladding perforation following a steam pipe rupture are not necessarily unacceptable. However, the DB analysis shows that the DNB design basis is not exceeded for any steam line rupture, assuming the most reactive RCCA is stuck in its fully withdrawn position.

9.1.5.2.1 DBA Method of Analysis

The major rupture of a steam line is the most limiting cooldown transient and is analysed at zero power with no decay heat. Decay heat retards the cooldown and thereby reduces the likelihood that the reactor returns to power. A detailed analysis of this transient with the most limiting break size, a double-ended rupture, is presented here. Certain assumptions used in this analysis are discussed in WCAP-9226-P-A (Reference 9.1-4). WCAP-9226-P-A also contains a discussion of the spectrum of break sizes and power levels analysed.

The analysis of the steam pipe rupture is performed to determine the following:

- The core heat flux and reactor coolant system temperature and pressure resulting from the cooldown following the steam line break. The LOFTRAN code (References 9.1-1 and 9.1-6) is used to model the system transient.

- The thermal-hydraulic behaviour of the core following a steam line break. A detailed thermal-hydraulic digital computer code, VIPRE-01 (Reference 9.1-7), is used to determine if DNB occurs for the core transient conditions computed by the LOFTRAN code.

The following conditions are assumed to exist at the time of a main steam line break accident:

- End-of-cycle shutdown margin at no-load, equilibrium xenon conditions, and the most reactive RCCA stuck in its fully withdrawn position. Operation of RCCA mechanical shim and axial offset banks during core burnup is restricted by the insertion limits so that shutdown margin requirements are satisfied.

- A most negative moderator temperature coefficient corresponding to the end-of-life rodded core with the most reactive RCCA in the fully withdrawn position. The variation of the coefficient with temperature is included. The k_{eff} (considering moderator temperature and density effects) versus temperature corresponding to the negative moderator temperature coefficient used is shown in Figure 9.1.4-1. The core power is calculated as a function of core mass flow, core boron concentration, and core inlet temperature.

  The moderator properties used in the LOFTRAN code for feedback calculations are generated by combining those in the sector nearest the affected steam generator with those associated with the remaining sector. The resultant properties reflect a combination process that accounts for inlet plenum fluid mixing and a conservative weighting of the fluid properties from the coldest core sector.

  In verifying the conservatism of this method, the power predictions of the LOFTRAN modelling are confirmed by comparison with detailed core analysis for the limiting conditions of the cases considered. This core analysis conservatively models the hypothetical core configuration (that is, stuck RCCA, non-uniform inlet temperatures, pressure, flow, and boron concentration) and directly evaluates the total reactivity feedback including power, boron, and density redistribution in an integral fashion. The effect of void formation is also included.

  Comparison of the results from the detailed core analysis with the LOFTRAN predictions verifies the overall conservatism of the methodology. That is, the specific power, temperature, and flow conditions used to perform the DNB analysis are conservative.

- Minimum capability for injection of boric acid solution corresponding to the most restrictive single failure in the passive core cooling system. The core makeup tanks and the accumulators are the portions of the passive core cooling system used in mitigating a steam line rupture. There are no single failures that prevent core makeup tank injection; however, the analysis models the failure of one core makeup tank discharge valve. Low-concentration boric acid must be swept from the core makeup tank lines downstream of the isolation valves before delivery of boric acid (3400 ppm) to the reactor coolant loops. This effect has been accounted for in the analysis.

- The maximum overall fuel-to-coolant heat transfer coefficient is used to maximise the rate of cooldown.

- Because the steam generators are provided with integral flow restrictors with a 0.13 m^2 (1.4 ft^2) throat area, any rupture in a steam line with a break area greater than 0.13 m^2

(1.4 ft^2), regardless of location, has the same effect on the primary plant as the 0.13 m^2 (1.4-ft^2) double-ended rupture. The limiting case considered in determining the core power and reactor coolant system transient is the complete severance of a pipe, with the plant initially at no-load conditions and full reactor coolant flow with offsite power available. The results of this case bound the loss of offsite power case for the following reasons:

- Loss of offsite power results in an immediate reactor coolant pump coastdown at the initiation of the transient. This reduces the severity of the reactor coolant system cooldown by reducing primary-to-secondary heat transfer. The lessening of the cooldown, in turn, reduces the magnitude of the return to power.

- Following its actuation, the core makeup tank provides borated water that injects into the reactor coolant system. Flow from the core makeup tank increases if the reactor coolant pumps have coasted down. Therefore, the analysis performed with offsite power and continued reactor coolant pump operation reduces the rate of boron injection into the core and is conservative.

- The protection system automatically provides a safety-related signal that initiates the coastdown of the reactor coolant pumps in parallel with core makeup tank actuation. Because this reactor coolant pump trip function is actuated early during the steam line break event (right after core makeup tank actuation), there is very little difference in the predicted DNBR between cases with and without offsite power.

- Because of the passive nature of the safety injection system, the loss of offsite power does not delay the actuation of the safety injection system.

- Power peaking factors corresponding to one stuck RCCA are determined at the end of core life. The coldest core inlet temperatures are assumed to occur in the sector with the stuck rod. The power peaking factors account for the effect of the local void in the region of the stuck RCCA during the return to power phase following the steam line break. This void in conjunction with the large negative moderator coefficient partially offsets the effect of the stuck RCCA. The power peaking factors depend upon the core power, temperature, pressure, and flow and, therefore, may differ for each case studied.

- The analysis assumes initial hot standby conditions at time zero in order to present a representative case which will yield limiting post-trip DNBR results for this transient. If the reactor is just critical or operating at power at the time of a steam line break, the reactor is tripped by the overpower protection system when power level reaches a trip point.

  Following a trip at power, the reactor coolant system contains more stored energy than at no-load because the average coolant temperature is higher than at no-load, and there is energy stored in the fuel. The additional stored energy reduces the cooldown caused by the steam line break before the no-load conditions of reactor coolant system temperature and shutdown margin assumed in the analyses are reached. After the additional stored energy has been removed, the cooldown and reactivity insertions proceed in the same manner as in the analysis that assumes a no-load condition at time zero. However, because the initial steam generator water inventory is greatest at no-load, the magnitude and duration of the reactor coolant system cooldown are less for a steam line break occurring at power.

- In computing the steam flow during a steam line break, the Moody Curve (Reference 9.1-3) for f(L/D) = 0 is used.

- Perfect moisture separation occurs in the steam generator.
- Maximum cold startup feedwater flow plus nominal 100 percent main feedwater flow is assumed.
- Four reactor coolant pumps are initially operating.
- Manual actuation of the PRHR system at time zero is conservatively assumed in order to maximise the cooldown.

9.1.5.2.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The available Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends after CMT boron injection turns around the return-to-power transient; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. Other SSCs include the CMTs, containment isolation, steam line isolation valves and SG flow restrictors. The PMS provides the following:

- RT is available, but not credited; rods already inserted at start of analysis
- PRHR actuation on Low-2 SG WR Level, but is assumed to actuate at start of transient (maximizes cooldown)
- CMTs and containment isolation on Low-2 steam line pressure
- PCS on High-2 containment pressure

9.1.5.2.3 DBA Results

The calculated sequence of events for the analysed case is shown in Table 9.1.2-1. The results presented conservatively indicate the events that would occur assuming a steam line rupture because it is postulated that the conditions described in Section 9.1.5.2.1 exist simultaneously.

Figures 9.1.5-1 through 9.1.5-13 show the transient results following a main steam line rupture (complete severance of a pipe) at initial no-load condition.

Offsite power is assumed available so that, initially, full reactor coolant flow exists. During the course of the event, the reactor protection system initiates a trip of the reactor coolant pumps in conjunction with actuation of the core makeup tanks. The transient shown assumes an uncontrolled steam release from only one steam generator. Steam release from more than one steam generator is prevented by automatic trip of the main steam isolation valves in the steam lines by Low-2 steam line pressure signals. Even with the failure of one valve, release is limited to approximately 10 seconds for the other steam generator while the one generator blows down. The main steam isolation valves fully close in less than 10 seconds from receipt of a closure signal.

As shown in Figure 9.1.5-1, the core attains criticality with the RCCAs inserted (with the design shutdown assuming the most reactive RCCA stuck) before boron solution at 3400 ppm (from core makeup tanks) or 2600 ppm (from accumulators) enters the reactor coolant system. A peak core power significantly lower than the nominal full-power value is attained.

The calculation assumes that the boric acid is mixed with and diluted by the water flowing in the reactor coolant system before entering the reactor core. The concentration after mixing depends upon the relative flow rates in the reactor coolant system and from the core makeup tanks or

accumulators (or both). The variation of mass flow rate in the reactor coolant system due to water density changes is included in the calculation. The variation of flow rate from the core makeup tanks or accumulators (or both) due to changes in the reactor coolant system pressure and temperature and the pressuriser level is also included. The reactor coolant system and passive injection flow calculations include line losses.

At no time during the analysed steam line break event does the core makeup tank level approach the setpoint for actuation of the automatic depressurisation system. During non-LOCA events, the core makeup tanks remain filled with water. The volume of injection flow leaving the core makeup tank is offset by an equal volume of recirculation flow that enters the core makeup tanks via the reactor coolant system cold leg balance lines.

The PRHR system provides a passive, long-term means of removing the core decay and stored heat by transferring the energy via the PRHR heat exchanger to the IRWST. The PRHR heat exchanger is normally actuated automatically when the steam generator level falls below the Low-2 wide-range level. For the main steam line rupture case analysed, the PRHR exchanger is conservatively actuated at time zero to maximise the cooldown.

The case analysed conservatively models the expected behaviour of the plant during a steam system piping failure. This includes the tripping of the reactor coolant pumps coincident with core makeup tank actuation. A DNB analysis was performed using limiting assumptions that bound those of Section 9.1.5.2.1.

Under the low flow (natural circulation) conditions present in the transient, the return to power is severely limited by the large negative feedback due to flow and power. The minimum DNBR is conservatively calculated and remains above the 95/95 limit.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.1.5.3 Diverse Mitigation

As this is an infrequent fault (DB1), a diverse mitigation assessment is not required.

9.1.5.4 Radiological Consequences

Design Basis

The evaluation of the radiological consequences of a postulated main steam line break outside containment assumes that the reactor has been operating with a limited number of fuel rods containing cladding defects and that leaking steam generator tubes have resulted in a buildup of activity in the secondary coolant.

Following the rupture, startup feedwater to the faulted loop is isolated and the steam generator is allowed to steam dry, releasing all activity initially present. Any radionuclides carried from the primary coolant into the faulted steam generator via leaking tubes are assumed to be released directly to the environment. It is assumed that the intact loop is isolated from the faulted loop via the MSIV, and that the passive systems are removing decay heat, thus the intact SG is not modelled in the dose analysis.

Assumptions are chosen to bound both hot zero power and full power scenarios.

9.1.5.4.1 Source Term

There is no fuel damage as a result of the accident. Therefore, the most significant radionuclide releases from the MSLB are the noble gases, alkali metals, and iodines that are present in the primary and secondary coolants, become airborne, and are released to the environment as a result of the accident.

The methodology assesses two different reactor coolant iodine source terms, both of which consider the iodine-spiking phenomenon. In one case, the initial iodine concentrations are assumed to be those associated with the equilibrium operating limit for primary coolant iodine activity. The iodine spike is assumed to be initiated by the accident, with the spike causing an increasing level of iodine in the reactor coolant.

The second case assumes that the iodine spike occurs prior to the accident and that the maximum resulting reactor coolant iodine concentration exists at the time the accident occurs.

The secondary coolant iodine and alkali metal concentrations are assumed to be 10 percent of the primary concentrations. Noble gases are not assumed to accumulate in the secondary coolant

9.1.5.4.2 Release Pathways

There are two components to the accident releases.

- The secondary coolant in the steam generator of the faulted loop is assumed to be released out the break as steam. Any iodine and alkali metal activity contained in the coolant is assumed to be released.

- The reactor coolant leaking into the steam generator of the faulted loop is assumed to be released to the environment without any credit for partitioning or plateout onto the interior of the steam generator.

9.1.5.4.3 Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.1.5.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.1.5-1.

9.1.5.4.5 Doses

Design Basis

The highest doses are found to be for the accident-initiated iodine spike. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 9.3 mSv Worker dose: 78 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.1.5-2. The Table 9.1.5-2 values ensure the Target 4 BSLs are met.

9.1.5.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

Diverse mitigation functions are only required for more probable events including smaller pipe breaks and stuck open valves. The plant is able to ride out these small load increases as shown in reference 9.1-12, such that diverse mitigation is not required. However, diverse mitigation functions are available for this event (see Table 9.1.5-3). These features include other Class 1 safety functions and the DAS function, which is Class 2. See Reference 9.1-12 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy/diversity that is provided by the DiD systems for these smaller break sizes. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- SFW with steam dump for short-term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the CCS and SWS cooling water systems.
- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment / start automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (Reference 9.1-11). However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

Potential operator actions are listed in Table 9.1.5-4. As discussed in Chapter 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000 development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.1.5.6 Conclusions

DNB and possible cladding perforation are not unacceptable consequences following a steam pipe rupture based on the applicable acceptance criteria. Nevertheless, the preceding analysis shows that no DNB, and therefore, no cladding perforation occurs for the main steam line rupture assuming the most reactive RCCA stuck in its fully withdrawn position.

DBA radiological consequences for the steam system piping failure are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.6 Steam System Piping Failure at Full Power (Fault 1.21.1)

9.1.6.1 Identification of Causes and Accident Description

A rupture in the main steam system piping from an at-power condition creates an increased steam load, which extracts an increased amount of heat from the reactor coolant system via the steam generators. This results in a reduction in reactor coolant system temperature and pressure. In the presence of a strong negative moderator temperature coefficient, typical of end-of-life conditions, the colder core inlet coolant temperature causes the core power to increase from its initial level due to the positive reactivity insertion. The power approaches a level equal to the total steam flow.

Depending upon the break size, the reactor may be tripped on any of the following trip signals to provide the necessary protection against the rupture of a main steam line:

- Overpower ΔT
- Low pressuriser pressure
- Safeguards (“S”) actuation signal
  - Low steam line pressure
  - Low cold leg temperature

The steam system piping failure accident analysis described in Section 9.1.5 is performed assuming a hot zero-power initial condition with the control rods inserted in the core, except for the most reactive rod in the fully withdrawn position out of the core. That condition could occur while the reactor is at hot shutdown at the minimum required shutdown margin or after the plant has been tripped manually or by the reactor protection system following a steam line break from an at-power condition. For an at-power break, the analysis in Section 9.1.5 represents the limiting condition with respect to core protection for the time following reactor trip. This section describes the analysis of a steam system piping failure occurring from an at-power initial condition to demonstrate that core protection is maintained before and immediately following reactor trip. The analysis initiated from hot full power does not extend into the portion of the transient where the PRHR or core makeup tanks are actuated.

9.1.6.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to the peak RCS and MSS pressure criteria, this event is bounded by the Turbine Trip DB analysis in Section 9.2.3 and is not explicitly verified. Also, pressuriser fill criterion is not challenged for this event, and is not explicitly verified.

9.1.6.2.1 DBA Method of Analysis

The analysis of the steam line rupture is performed in the following stages:

- The LOFTRAN code (References 9.1-1 and 9.1-6) is used to calculate the nuclear power, core heat flux, and reactor coolant system temperature and pressure transients resulting from the cooldown following the steam line break.

- The core radial and axial peaking factors are determined using the thermal-hydraulic conditions from LOFTRAN as input to the nuclear core models. A detailed thermal-hydraulic code, VIPRE-01 (Reference 9.1-7), is then used to calculate the DNBR for the limiting time during the transient.

This accident is analysed with the RTDP as described in WCAP-11397-P-A (Reference 9.1-2).

The following assumptions are made in the transient analysis:

- Initial conditions – RTDP DNB methodology was used; therefore, the uncertainties in the initial conditions are included in the DNBR limits. Thus, nominal full-power values are used in LOFTRAN. The reactor coolant system minimum measured flow is used.

- Break size – A spectrum of break sizes was analysed. Small breaks do not result in a reactor trip. Intermediate breaks result in a reactor trip on overpower ΔT. Larger break sizes result in a reactor trip on low steam line pressure safeguards actuation.

- Break flow – In computing the steam flow during a steam line break, the Moody curve (Reference 9.1-3) for $fL/D = 0$ is used.

- Reactivity coefficients – The analysis assumes maximum moderator reactivity feedback and minimum Doppler power feedback to maximise the power increase following the break.

- Protection system – The protection system features that mitigate the effects of a steam line beak are described in Section 9.1.5. This analysis considers only the initial phase of the transient initiated from an at-power condition. Protection in this phase of the transient is provided by reactor trip, if necessary (specifically overpower ΔT and low steam line pressure safeguards actuation).

- Control systems – Control systems are not credited in the accident analysis unless their function would result in more severe consequences. The only control system that is assumed to function during the hot full-power steam line break event is the main feedwater system. For this event, the feedwater flow is assumed to match the steam flow.

Anticipated operational occurrences and postulated accidents are analysed assuming a loss of offsite ac power. The loss of offsite power is not considered as a single failure, and the analysis is performed without changing the event category. In the analyses, the loss of offsite ac power is considered to be a potential consequence of an event due to disruption of the grid following a turbine trip during the event.

For those events where offsite ac power is lost, an appropriate time delay between turbine trip and the postulated loss of offsite ac power is assumed in the analyses. A time delay of 3 seconds is used. This time delay is based on the inherent stability of the offsite power grid. Following the time delay, the effect of the loss of offsite ac power on plant auxiliary equipment – such as reactor coolant pumps, main feedwater pumps, condenser, startup feedwater pumps, and RCCAs – is

considered in the analyses. Turbine trip occurs 5 seconds following a reactor trip condition being reached. This delay is part of the reactor trip system and was chosen to allow the reactor to be tripped and have the rods inserted to the bottom of the core before a turbine trip signal. As a result, reactor coolant pump coastdown would be delayed an additional 5 seconds, the control rods would be fully inserted, and there would be no adverse DNB impact from the resulting core flow reduction. Thus, there is no need for an explicit analysis of this event with loss of offsite ac power.

9.1.6.2.2 DBA Credited SSCs

For the DB, no claim is placed on systems that are not Class 1. For this fault, the available Class 1 systems are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. Other SSCs include the CMTs, containment isolation, steam line isolation valves and SG flow restrictors. The PMS provides the following:

- RT on (dependent on break size):
  - Overpower ΔT
  - Low-2 steam line pressure
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.1.6.2.3 DBA Results

A spectrum of steam line break sizes was analysed from 0.01 m^2 (0.1 ft^2) to 0.13 m^2 (1.4 ft^2). The results show that for small break sizes up to and including 0.03 m^2 (0.35 ft^2), a reactor trip is not generated. In this case, the event is similar to an excessive load increase event; the core reaches a new equilibrium condition at a higher power equivalent to the increased steam release. For break sizes from 0.03 m^2 (0.36 ft^2) up to and including 0.08 m^2 (0.87 ft^2), the reactor trips on overpower ΔT. For break sizes from 0.08 m^2 (0.88 ft^2) to 0.13 m^2 (1.4 ft^2), the reactor trips on the low steam line pressure safeguards actuation signal.

The limiting case for demonstrating DNB and kW/ft (kW/m) protection is the 0.08 m^2 (0.87 ft^2) break, the largest break size that results in a trip on overpower ΔT. The time sequence of events for this case is shown on Table 9.1.6-1. Figures 9.1.6-1 through 9.1.6-7 show the transient response.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.1.6.3 Diverse Mitigation

Diverse mitigation for this event is not required as it is an infrequent fault classified as DB1. The diversity analyses for large excessive load increase events which are classified as frequent faults are presented in Section 9.1.3.3.

9.1.6.4 Radiological Consequences

The main steamline break doses presented in Section 9.1.5.4 are based on assumptions chosen to bound both hot zero power and full power scenarios. Therefore, the main steamline break doses from Section 9.1.5.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 9.3 mSv Worker dose: 78 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

Thus, the identified Class 1 SSCs are adequate to meet DB requirements for this fault.

9.1.6.5 As Low as Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for the main steamline break at hot zero power, as described in Section 9.1.5.5.

9.1.6.6 Conclusions

The analysis shows that the DNB and fuel centreline melt (kW/ft (kW/m)) design bases are met for the limiting DB case. Although DNB and possible cladding perforation following a steam pipe rupture are not necessarily precluded by the criteria, the above analysis shows that the minimum DNBR remains above the limit value for any rupture occurring from an at-power condition before and immediately following a reactor trip.

Radiological consequences for the steam system piping failure are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.1.7 Inadvertent Operation of the PRHR Heat Exchanger (Fault 1.15.15)

9.1.7.1 Identification of Causes and Accident Description

The inadvertent actuation of the PRHR heat exchanger causes an injection of relatively cold water into the reactor coolant system. This produces a reactivity insertion in the presence of a negative moderator temperature coefficient. To prevent this reactivity increase from causing reactor power increase, a reactor trip is initiated when either PRHR discharge valve comes off of its fully shut seat.

The inadvertent actuation of the PRHR heat exchanger could be caused by operator error or a false actuation signal, or by malfunction of a discharge valve. Actuation of the PRHR heat exchanger involves opening one of the isolation valves, which establishes a flow path from one reactor coolant system hot leg, through the PRHR heat exchanger, and back into its associated steam generator cold leg plenum.

The PRHR heat exchanger is located above the core to promote natural circulation flow when the reactor coolant pumps are not operating. With the reactor coolant pumps in operation, flow through the PRHR heat exchanger is enhanced. The heat sink for the PRHR heat exchanger is provided by the IRWST, in which the PRHR heat exchanger is submerged. Because the fluid in the heat exchanger is in thermal equilibrium with water in the tank, the initial flow out of the PRHR heat exchanger is significantly colder than the reactor coolant system fluid. Following this initial insurge, the reduction in cold leg temperature is limited by the cooling capability of the PRHR heat exchanger. Because the PRHR heat exchanger is connected to only one reactor coolant system loop, the cooldown resulting from its actuation is asymmetric with respect to the core.

The response of the plant to an inadvertent PRHR heat exchanger actuation with the plant at no-load conditions is bounded by the analyses performed for the inadvertent opening of a steam generator relief or safety valve event (Section 9.1.4) and the steam system piping failure event (Section 9.1.5). Both of these events are conservatively analysed assuming PRHR heat exchanger actuation coincident with the steam line depressurisation. Therefore, only the response of the plant to an inadvertent PRHR initiation with the core at power is considered.

The effects of a possible consequential loss of ac power during an inadvertent PRHR heat exchanger actuation event have been evaluated to not adversely impact the analysis results. This conclusion is based on a review of the time sequence associated with a consequential loss of ac power in comparison to the reactor shutdown time for an inadvertent PRHR heat exchanger actuation event. The primary effect of the loss of ac power is to cause the RCPs to coast down. The protection and safety monitoring system includes a 5-second minimum delay between the reactor trip and the turbine trip. In addition, a 3-second delay between the turbine trip and the loss of offsite ac power is assumed, consistent with Section 9.0.12. Considering these delays between the time of the reactor trip and RCP coastdown due to the loss of ac power, it is clear that the plant shutdown sequence will have passed the critical point and the control rods will have been completely inserted before the RCPs begin to coast down. Therefore, the consequential loss of ac power does not adversely impact this inadvertent PRHR heat exchanger actuation analysis because the plant will be shut down well before the RCPs begin to coast down.

Plant systems and equipment available to mitigate the effects of the accident are discussed in Section 9.0.4 and listed in Table 9.0-10. Due to the potential consequences as a result of the reactivity excursion, a reactor trip has been designed so that upon an inadvertent PRHR actuation, a reactor trip will occur. This reactor trip is generated when either of the discharge valves is not closed. This ensures that the reactor will be tripped prior to a power increase due to the cold water injection.

9.1.7.2 Design Basis Mitigation

Since a reactor trip is initiated as soon as the PRHR discharge valves are not fully closed, this event is essentially a reactor trip from the initial condition and requires no separate transient analysis. Table 9.1.2-1 shows the sequence of events for the inadvertent PRHR heat exchanger actuation.

9.1.7.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.1.7.3.1 Diverse Mitigation for ATWT

A reactor trip has been designed so that upon an inadvertent PRHR actuation, a reactor trip will occur. Failure of this reactor trip would allow a power increase due to the cold water injection.

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The inadvertent operation of the PRHR analysis documented in this section is performed to bound the following events:

- Inadvertent operation of the PRHR with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Inadvertent operation of the PRHR with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Inadvertent operation of the PRHR with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.1.7.3.1.1 Diverse ATWT Method of Analysis

For the inadvertent operation of the PRHR with a PMS CCF a short-term analysis of the out surge of cold water from the PRHR heat exchanger was performed. All PMS reactor trip and engineered safeguards automatic functions are assumed inoperable in this scenario.

For the mechanical failure of control rods to drop scenario, two outcomes are possible, depending on whether a PMS reactor trip setpoint is exceeded or not. If no PMS reactor trip setpoints are reached, the plant will reach an equilibrium power level equal to the combined heat removal rates of the PRHR and the turbine load. The results will be the same as the analyses results for an inadvertent operation of the PRHR with a PMS failure. If a PMS reactor trip setpoint is reached, the turbine will trip and the RCCAs are assumed not to insert due to the postulated mechanical CCF. Following the turbine trip, the event will be similar to the turbine trip events discussed in Section 9.2.3.5, where feedwater flow is assumed to be available. The turbine trips analyses show

that maximum reactor coolant pressure is limited to less than 110 percent of reactor coolant design pressure.

For the reactor trip breaker CCF scenario, the PMS is assumed to be operable. However, when a reactor trip signal is generated, all trip breakers are assumed to fail to open such that the control rods do not insert. All DAS functions (including reactor trip by tripping of the M-G sets) are operable. The response for this scenario is similar to that discussed for the case with a mechanical CCF, except that the operator may trip the rods using the DAS.

9.1.7.3.1.2 Diverse ATWT Credited SSCs

For the PMS CCF ATWT cases presented, no available SSCs (PMS or DAS functions) are credited to initiate passive safety features. Instead, the plant will reach a stable steady-state power condition and ATWT criteria would be met for sustained operation at the stabilized power. Ultimately, manual operator action using PMS or DAS would be required to shut down the plant. The SSCs modelled as available for this analysis are listed in Table 9.0-14.

9.1.7.3.1.3 Diverse ATWT Results

Results from this analysis with a PMS CCF are shown in Figures 9.1.7-1 to 9.1.7-4 and a sequence of events is provided in Table 9.1.7-1. Figure 9.1.7-1 shows the short term nuclear power transient following activation of the PRHR from full-power conditions. Due to the initial cold water at containment temperature, there is a rapid nuclear power increase to about 119 percent. Once the initial water in the PRHR is purged, the temperature of the water exiting from the PRHR is limited by the cooling capacity of the PRHR and the fluid temperature entering the PRHR from the hot leg (see Figure 9.1.7-3). Core power then decreases until it reaches an equilibrium power equal to the steam generator load plus the PRHR heat removal capacity (see Figure 9.1.7-2).

The maximum core average heat flux obtained for this case was 118.7 percent. The power level remained low enough that the local linear power did not result in fuel melting. The minimum DNBR was above the limit value. Thus the ATWT acceptance criteria are met for the short-term period of an inadvertent PRHR.

Eventually, equilibrium conditions will be reached with the core at approximately 110 percent power, reactor coolant pressure near the nominal value and temperature in the PRHR loop slightly lower than the normal operating value.

During the transient, the pressuriser safety valves are not opened, and no challenge to the pressure integrity of the reactor coolant boundary occurs. Once diagnosed by the operator, the operator uses the DAS to trip and recover the plant.

9.1.7.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.1.7.4 Radiological Consequence

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. Therefore, the radiological consequences are limited and no dose calculations have been obtained specifically for this case. However, the doses have been calculated for the loss of offsite power in Section 9.2.6.4. Operation of the PRHR at the start of the event would reduce the steam generator releases. Therefore, the dose associated with the loss of offsite power bounds the dose associated with the inadvertent opening of the PRHR. The loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Thus, the identified Class 1 SSCs are adequate to meet DB requirements for this fault.

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.1.7.5 As Low As Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for Inadvertent Opening of a Steam Generator Relief or Safety Valve event, as described in Section 9.1.4.5.

9.1.7.6 Conclusions

Inadvertent actuation of the PRHR does not result in violation of the core thermal design limits (DNB and linear power generation) or RCS overpressure.

This event has also been adequately assessed with respect to ATWT considerations. This event was not explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.1-9. However, the evaluation conducted to closeout FS-03 demonstrated with a subset of events (Reference 9.1-10) that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the subset of events confirmed the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Thus, the identified Class 1 SSCs are adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.2 Decrease in Heat Removal by the Secondary System

A number of faults that could result in a decrease in heat removal by the secondary system are postulated. The events are discussed in this section. Detailed analyses are presented for the most limiting of the primary system heat removal decrease events.

9.2.0 Introduction and Overview of Faults

Decrease in heat removal from the secondary side can be caused by a number of initiating faults, represented by loss of main feedwater, all of which have similar behaviours.

A loss of normal feedwater (from pump failures, valve malfunctions, loss of ac power sources, or a break in the feedwater line) results in a reduction in the capability of the secondary system to remove the heat generated in the reactor core.

The normal response of the plant to this fault is to trip the reactor and provide SG feed from the SFW system. However, the most limiting fault occurs if the loss of feed results from a double-ended rupture of the feedwater line, so that no main feedwater (MFW) or SFW is delivered to the faulted SG. In the longer term, decay heat removal is via the RNS.

If SFW is not available, the Class 1 passive residual heat removal heat exchanger (PRHR HX) is actuated automatically by the PMS on either a low SG water level (narrow range) coincidentally with a low SFW flow rate signal or a low SG water level (wide range) signal. The PRHR HX transfers the core decay heat and sensible heat to the IRWST, so that core heat removal is uninterrupted following a loss of normal feedwater and SFW.

For this report the faults are split into two parts:

- Feedwater line break accident
  - Main feed line break upstream of main feedwater isolation valves (MFWIVs)
  - Main feed line break downstream of MFWIVs
- All other loss of MFW events
  - Loss of main feedwater to one SG
  - Loss of main feedwater to both SGs
  - Loss of condenser
  - Loss of compressed air
  - Loss of offsite power

The feedwater line break accident is considered separately, as it differs significantly from the other loss of MFW events because:

- Secondary inventory is lost though the break.
- As noted above, SFW cannot be delivered to the faulted SG.
- The transient is strongly asymmetric.

Each fault is first described; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are then described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

ATWT analyses presented herein are based on Reference 9.2-11.

9.2.0.1 Decrease in Heat Removal Faults (excluding Feedline Break)

Description

A number of transients and accidents could result in a reduction of the capacity of the secondary system to remove heat generated in the RCS. These faults are as follows (Appendix 8A):

- Steam pressure regulator malfunction or failure that results in decreasing steam flow
- Loss of external electrical load (Fault 1.12.8)
- Turbine trip (Fault 1.12.8)
- Inadvertent closure of main steam isolation valves (MSIVs) (Fault 1.16.7)
- Loss of condenser vacuum and other events resulting in turbine trip (Fault 1.18.1)
- Loss of offsite ac power to the station auxiliaries (Fault 1.19.1)
- Loss of normal feedwater flow (Fault 1.16.1)

Spurious reactor trip is also included here, as this initiator leads to a turbine trip after a short delay, and therefore is bounded by the turbine trip fault.

Possible causes of a loss of normal feedwater to one SG (Fault 1.17.1) are:

- Instabilities in flow as a result of operator error
- Instabilities in flow as a result of mechanical causes
- Feed heater blockage

The feedwater line break accident, which also leads to a loss of feedwater, is considered separately and is discussed in the next section.

Other faults that could cause a decrease in heat removal are:

- Loss of circulating water (Fault 1.18.1)
- Condenser leakage (Fault 1.18.1)
- Loss of compressed air (Fault 1.20.1)
- Loss of ultimate heat sink (Fault 1.18.1)

In practice, there are no steam pressure regulators in the AP1000 plant for which failure or malfunction would cause a steam flow transient with loss of external load, inadvertent closure of the MSIVs, and loss of condenser vacuum, all leading to a turbine trip event.

Initiating Event Frequency[1]

The AP1000 design PSA gives the IEF for loss of MFW to both SGs as 8.9E-2/yr and the loss of feed to one SG as 1.92E-1/yr (Table 8A-2). There are also other faults that could result in a reduction of the capacity of the secondary system to remove heat generated in the RCS and are considered in this section along with the loss of MFW, and therefore this is classified as a frequent fault.

Design Basis Class

The unmitigated consequences of these faults are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

9.2.0.2 Feedwater Line Break Fault

Description

This fault is a break in an SG feedwater line (Fault 1.16.8).

A feedwater line rupture reduces the ability to remove heat generated by the core from the RCS for the following reasons:

- Feedwater flow to the SGs is reduced, causing the reactor coolant temperatures to increase prior to reactor trip.
- Fluid in the SG may be discharged through the break and not be available for decay heat removal after trip.
- The break may be large enough to prevent the addition of MFW or SFW after trip.

Depending upon the size of the break and the plant operating conditions at the time of the break, the break could cause either an RCS cooldown (by excessive energy discharge through the break) or an RCS heatup. Potential RCS cooldown resulting from a secondary pipe rupture is essentially the same as the MSLB fault (see Section 9.1.5) and is not considered further here. Therefore, only the RCS heatup effects are evaluated for a feedwater line rupture in this section.

The severity of the feedwater line rupture transient depends on a number of system parameters, including the break size, initial reactor power, and the functioning of various control and safety systems. Sensitivity studies (Reference 9.2-4) have shown that the most limiting feedwater line rupture is a double-ended rupture of the largest feedwater line. At the beginning of the transient, the MFW control system is assumed to malfunction because of an adverse environment. Interactions between the break and the MFW control system result in no feedwater flow being injected or lost through the SG feedwater nozzles. This assumption causes the water levels in both SGs to decrease equally until the low SG level (narrow range) reactor trip setpoint is reached.

[1] As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

After reactor trip, a full double-ended rupture of the feedwater line is assumed, such that the faulted SG blows down through the break and no MFW is delivered to the intact SG. These assumptions conservatively bound the most limiting feedwater line rupture that can occur.

Initiating Event Frequency

An examination of the AP1000 design PSA provides reasonable assurance that the revised PSA will yield a full double-ended rupture feedwater line break probability of no greater than 6.6E-4/yr (Table 8A-2), which makes the event an infrequent fault.

Design Basis Class

The unmitigated consequences of a feedwater line break are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DBL class.

9.2.1 Not Used

9.2.2 Loss of External Electrical Load (Fault 1.12.8)

9.2.2.1 Identification of Causes and Accident Description

A major load loss on the plant can result from a loss of electrical load due to an electrical system disturbance. The ac power remains available to operate plant components such as the reactor coolant pumps; as a result, the standby onsite diesel generators do not function for this event. Following the loss of generator load, an immediate fast closure of the turbine control valves occurs. The automatic turbine bypass system accommodates the excess steam generation. Reactor coolant temperatures and pressure do not significantly increase if the turbine bypass system and pressuriser pressure control system function properly. If the condenser is not available, the excess steam generation is relieved to the atmosphere. Additionally, main feedwater flow is lost if the condenser is not available. For this transient, feedwater flow is maintained by the startup feedwater system.

For a loss of electrical load without subsequent turbine trip, no direct reactor trip signal is generated. The plant trips from the PMS if a safety limit is approached. A continued steam load of approximately 5 percent exists after total loss of external electrical load because of the steam demand of plant auxiliaries.

If a safety limit is approached, protection is provided by High-2 pressuriser pressure, high pressuriser water level, and overtemperature ΔT trips. Voltage and frequency relays associated with the reactor coolant pump provide no additional safety function for this event. Following a complete loss of external electrical load, the maximum turbine overspeed is not expected to affect the voltage and frequency sensors. Any increased frequency to the reactor coolant pump motors results in a slightly increased flow rate and subsequent additional margin to safety limits. For postulated loss of load and subsequent turbine-generator overspeed, an overfrequency condition is not seen by the PMS equipment or other safety-related loads. Safety-related loads and the PMS equipment are supplied from the 120-Vac instrument power supply system, which in turn is supplied from the inverters. The inverters are supplied from a dc bus energised from batteries or by a regulated ac voltage.

If the steam dump valves fail to open following a large loss of load, the steam generator safety valves may lift and the reactor may be tripped by the High-2 pressuriser pressure signal, the high pressuriser water level signal, or the overtemperature ΔT signal. This would cause steam generator

shell side pressure and reactor coolant temperature to increase rapidly. However, the pressuriser safety valves and steam generator safety valves are sized to protect the reactor coolant system and steam generator against overpressure for load losses, without assuming the operation of the turbine bypass system, pressuriser spray, or automatic rod cluster control assembly control.

The steam generator safety valve capacity is sized to remove the steam flow at the nuclear steam supply system thermal rating from the steam generator, without exceeding 110 percent of the steam system design pressure. The pressuriser safety valve capacity is sized to accommodate a complete loss of heat sink with the plant initially operating at the maximum turbine load. The pressuriser safety valves can then relieve sufficient steam to maintain the reactor coolant system pressure within 110 percent of the reactor coolant system design pressure.

A discussion of overpressure protection can be found in WCAP-7769, Revision 1 (Reference 9.2-1) and WCAP-16779 (Reference 9.2-9).

A loss-of-external-load event results in a plant transient that is bounded by the turbine trip event analysed in Section 9.2.3. Therefore, a detailed transient analysis is not presented for the loss-of-external-load event.

The primary side transient is caused by a decrease in heat transfer capability, from primary to secondary, due to a rapid termination of steam flow to the turbine, accompanied by an automatic reduction of feedwater flow (should feedwater flow not be reduced, a larger heat sink is available and the transient is less severe). Reduction of steam flow to the turbine following a loss-of-external load event occurs due to automatic fast closure of the turbine control valves. Following a turbine trip event, termination of steam flow occurs via turbine stop valve closure, which occurs in approximately 0.15 seconds. The transient in primary pressure, temperature, and water volume is less severe for the loss-of-external-load event than for the turbine trip due to a slightly slower loss of heat transfer capability.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.2.2.2 Design Basis Mitigation

Refer to Section 9.2.3.2 for the method used to analyse the limiting transient (turbine trip) in this set of events. The results of the turbine trip event analysis bound those expected for the loss-of-external-load event, as discussed in Section 9.2.2.1.

Plant systems and equipment that may be required to function in order to mitigate the effects of a complete loss of load are discussed in Section 9.0.4 and listed in Table 9.0-10.

The PMS may be required to terminate core heat input and to prevent DNB. Depending on the magnitude of the load loss, pressuriser safety valves and/or steam generator safety valves may open to maintain system pressures below allowable limits. No single active failure prevents operation of any system required to function. Normal plant control systems and engineered safety systems are not required to function. The PRHR system may be automatically actuated following a loss of main feedwater, further mitigating the effects of the transient.

9.2.2.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.2.2.3.1 Diverse Mitigation for ATWT

A decrease in heat removal by the secondary system can result from a loss of electrical load due to an electrical system disturbance. In this situation, the ac power remains available to operate plant auxiliaries such as reactor coolant pumps and feedwater to the steam generators. If the main electrical generator is disconnected from the grid and a turbine trip does not occur, the main turbine control system will reduce steam flow to the turbine to match the electrical power demand to station auxiliaries.

Normally, for large step change load reductions, steam is bypassed directly to the condenser via the turbine bypass system. If the turbine bypass system is not available or not sufficient, steam may be vented to the atmosphere via the power-operated atmospheric relief valves and the main steam safety valves.

The sudden reduction in steam flow due to the turbine trip will cause the RCS to heat up. This may result in a reactor trip on high pressuriser pressure and opening of pressuriser safety valves. Like the inadvertent turbine trip event, the loss of external electrical load is a type of load rejection incident. Therefore, the results and conclusions of the turbine trip analysis can be applied to bound the loss of external electrical load event.

The turbine trip event, as analysed in Section 9.2.3.3.1, was determined to be bounding of this event.

9.2.2.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.2.2.4 Radiological Consequences

Refer to Section 9.2.3.4 for the design basis radiological consequences for the limiting transient (turbine trip) in this set of events. The results of the turbine trip event analysis bound those expected for the loss-of-external-load event, as discussed in Section 9.2.2.1.

9.2.2.5 As Low As Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for the loss of normal feedwater fault event, as described in Section 9.2.7.5.

9.2.2.6 Conclusions

Based on results obtained for the turbine trip event and considerations described in Section 9.2.2.1, the evaluation criteria for a loss-of-external-load event are met (see Section 9.2.3).

This event has also been adequately assessed with respect to ATWT considerations.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.2.3 Turbine Trip (Fault 1.12.8)

9.2.3.1 Identification of Causes and Accident Description

The turbine stop valves close rapidly (about 0.15 seconds) on loss of trip fluid pressure actuated by one of a number of possible turbine trip signals. Turbine trip initiation signals include:

- Generator trip
- Low condenser vacuum
- Loss of lubricating oil
- Turbine thrust bearing failure
- Turbine overspeed
- Manual trip
- Reactor trip

Upon stop valve closure due to a turbine trip, steam flow to the turbine stops abruptly. Sensors for the Turbine First Stage Pressure detect the loss in steam flow and initiate turbine bypass. The loss of steam flow results in a rapid increase in secondary system temperature and pressure, with a resultant primary system transient, described in Section 9.2.2.1, for the loss-of-external-load event. A slightly more severe transient occurs for the turbine trip event due to the rapid loss of steam flow caused by the abrupt valve closure.

The automatic turbine bypass system accommodates up to 40 percent of rated steam flow. Reactor coolant temperatures and pressure do not increase significantly if the turbine bypass system and pressuriser pressure control system are functioning properly. If the condenser is not available, the excess steam generation is relieved to the atmosphere and main feedwater flow is lost. For this situation, feedwater flow is maintained by the startup feedwater system to provide adequate residual and decay heat removal capability. Should the turbine bypass system fail to operate, the steam generator safety valves may lift to provide pressure control. See Section 9.2.2.1 for a further discussion of the transient.

A turbine trip is a more limiting than a loss-of-external-load event, loss of condenser vacuum, and other events which result in a turbine trip. As such, this event is analysed and presented in Section 9.2.3.2.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.2.3.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

9.2.3.2.1 DBA Method of Analysis

In this analysis, the behaviour of the unit is evaluated for a complete loss of steam load from 100 percent of full power, without rapid power reduction, primarily to show the adequacy of the pressure-relieving devices, and to demonstrate core protection margins. The turbine is assumed to

trip without actuating the rapid power reduction system. This assumption delays reactor trip until conditions in the reactor coolant system result in a trip due to other signals. Thus, the analysis assumes a bounding transient. In addition, no credit is taken for the turbine bypass system. Main feedwater flow is terminated at the time of turbine trip, with no credit taken for startup feedwater or the PRHR heat exchanger (except for long-term recovery) to mitigate the consequences of the transient.

Analyses are performed to evaluate the effects produced by a possible consequential loss of offsite power during a complete loss of steam load. As discussed in Section 9.0.12, the loss of offsite power is considered as a direct consequence of a turbine trip occurring while the plant is operating at power. The primary effect of the loss of offsite power is to cause the reactor coolant pumps to coast down.

The turbine trip transients are analysed by using a modified version of the LOFTRAN code (Reference 9.2-2) as described in Reference 9.2-6. The program simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generator, and steam generator safety valves. The program computes pertinent plant variables, including temperatures, pressures, and power level.

In the turbine trip analyses, which include a primary coolant flow coastdown caused by a consequential loss of offsite power, a combination of three computer codes is used to perform the DNBR analyses. First, the LOFTRAN code (References 9.2-2 and 9.2-6) is used to calculate the plant system transient. The FACTRAN code (Reference 9.2-7) or the VIPRE-01 fuel rod model (Reference 9.2-8), which is equivalent to FACTRAN, is then used to calculate the core heat flux based on nuclear power and reactor coolant flow from LOFTRAN. Finally, the VIPRE-01 code is used to calculate the DNBR using heat flux from FACTRAN (or the VIPRE-01 fuel rod model) and flow from LOFTRAN.

The major assumptions used in the analysis are summarised below.

Initial Operating Conditions

Two sets of initial operating conditions are used. Cases performed to evaluate the minimum DNBR obtained are analysed using the revised thermal design procedure. Initial core power, reactor coolant temperature, and pressure are assumed to be at their nominal values consistent with steady-state full-power operation. Uncertainties in initial conditions are included in the DNBR limit as described in WCAP-11397-P-A (Reference 9.2-5). Instrument bias on the RCS temperature signal is also considered to ensure it is reflected in either the modelled initial conditions or the safety analysis DNBR limit value.

Cases performed to evaluate the maximum calculated RCS pressure include uncertainties on the initial conditions. Initial core power, reactor coolant temperature, and pressure are assumed to be at the nominal full-power values plus or minus uncertainties. The direction of the uncertainties is chosen to maximise the RCS pressure.

Reactivity Coefficients

Two cases are analysed:

- Minimum reactivity feedback – A least-negative moderator temperature coefficient and a least-negative Doppler-only power coefficient are assumed (see Figure 9.0-3).

- Maximum reactivity feedback – A conservatively large negative moderator temperature coefficient and a most-negative Doppler-only power coefficient are assumed (see Figure 9.0-3).

Rod Control

From the standpoint of the maximum RCS pressure and minimum DNBR attained, it is conservative to assume that the reactor is in manual rod control. If the reactor is in automatic rod control, the control rod banks move prior to trip and reduce the severity of the transient.

Steam Release

No credit is taken for the operation of the turbine bypass system or steam generator power-operated relief valves. The steam generator pressure rises to the safety valve setpoint where steam release through safety valves limits secondary steam pressure at the setpoint value.

Pressuriser Spray

Two cases for both the minimum and maximum reactivity feedback cases are analysed:

- Full credit is taken for the effect of pressuriser spray in reducing or limiting the coolant pressure. Safety valves are also available. These cases are analysed primarily to address DNBR concerns.

- No credit is taken for the effect of pressuriser spray in reducing or limiting the coolant pressure. Safety valves are operable. These cases are analysed to address RCS overpressure concerns.

Feedwater Flow

Main feedwater flow to the steam generators is assumed to be lost at the time of turbine trip. No credit is taken for startup feedwater flow or the PRHR heat exchanger, because a stabilized plant condition is reached before initiation of the startup feedwater or the PRHR heat exchanger is normally assumed to occur. The startup feedwater flow or PRHR heat exchanger removes core decay heat following plant stabilization.

Reactor Trip

Reactor trip is actuated by the first reactor trip setpoint reached, with no credit taken for the rapid power reduction on the turbine trip. Trip signals are expected due to High-2 pressuriser pressure, overtemperature ΔT, Low-2 RCP speed, high pressuriser water level, or low steam generator water level.

Plant characteristics and initial conditions are further discussed in Section 9.0.2. Plant systems and equipment that may be required to function in order to mitigate the effects of a turbine trip event are discussed in Section 9.0.4 and listed in Table 9.0-10.

The PMS may be required to function following a turbine trip. Pressuriser safety valves and/or steam generator safety valves may be required to open to maintain system pressures below allowable limits. No single active failure prevents operation of systems required to function. Cases are analysed, both with and without the operation of pressuriser spray, to determine the worst case for presentation.

Availability of Offsite Power

Each case is analysed with and without offsite power available. As discussed in Section 9.0.12, the loss of offsite power is considered to be a consequence of an event due to disruption of the electrical grid following a turbine trip during the event. The grid is assumed to remain stable for 3 seconds following the turbine trip. In the analysis for the complete loss of steam load, the event is initiated by a turbine trip. Therefore, offsite power is assumed to be lost 3 seconds after the start of the event. For the loss of steam load analysis, the primary impact of the loss of offsite power is a coastdown of the reactor coolant pumps.

Main Steam System Pressure

Additional cases are performed to evaluate the maximum MSS pressure, with initial condition uncertainties chosen to maximize MSS pressure. The additional cases include cases with and without offsite power available for minimum and maximum reactivity feedback.

9.2.3.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and steam generator SVs. The PMS provides the following:

- RT on one of the following (scenario dependent):
  - High-2 pressuriser pressure
  - Overtemperature ΔT
  - Low-2 RCP speed
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.2.3.2.3 DBA Results

The transient responses for a turbine trip from 100 percent of full-power operation are shown for eight cases. The eight analysis cases are performed assuming minimum and maximum reactivity feedback, with and without credit for pressuriser spray, and with and without offsite power available. The results of the analyses are shown in Figures 9.2.3-1 through 9.2.3-26. The calculated sequence of events for the accident is shown in Table 9.2-1. Additional cases performed to address maximum MSS pressure concerns confirm that the steam generator safety valves provide sufficient pressure relief to prevent overpressurisation of the MSS.

Minimum Reactivity Feedback, With Pressuriser Spray, With and Without Offsite Power Available

Figures 9.2.3-1 through 9.2.3-7 show the transient responses for two cases analysed for DNBR concerns with and without offsite power available. In the case with offsite power available, the reactor is tripped by the overtemperature ΔT trip function. The transient DNBR is shown in

Figure 9.2.3-6; the minimum DNBR remains above the safety analysis DNBR limit value at all times. Based on this, the DNB design basis defined in Section 22.7.1.1 is met.

The case without offsite power is tripped by the low reactor coolant pump speed trip function. The minimum DNBR remains above the safety analysis DNBR limit value at all times, as shown in Figure 9.2.3-6; therefore, the DNBR design basis defined in Section 22.7.1.1 is met. This case is the limiting case with respect to the DNBR margin of the turbine trip cases.

Maximum Reactivity Feedback, With Pressuriser Spray, With and Without Offsite Power Available

Figures 9.2.3-8 through 9.2.3-14 show the transient responses for the other two cases analysed for DNBR concerns, with and without offsite power available. In the case with offsite power available, the reactor is tripped by the overtemperature ΔT trip function. The transient DNBR is shown in Figure 9.2.3-13; the minimum DNBR remains above the safety analysis DNBR limit value at all times. Based on this, the DNBR design basis defined in Section 22.7.1.1 is met for this case.

The case without offsite power is tripped by the low reactor coolant pump speed trip function. The DNBR transient is similar to, and bounded by, the minimum feedback case with pressuriser spray and without offsite power discussed above. The minimum DNBR remains above the safety analysis DNBR limit value at all times, as shown in Figure 9.2.3-13; therefore, the DNBR design basis defined in Section 22.7.1.1 is met.

Minimum Reactivity Feedback, Without Pressuriser Spray, With and Without Offsite Power Available

Figures 9.2.3-15 through 9.2.3-20 show the transient responses for two cases analysed to address RCS overpressure concerns, with and without offsite power available. In the case with offsite power available, the reactor is tripped by the high pressuriser pressure trip function. The case without offsite power is tripped by the low reactor coolant pump speed reactor trip function. The pressuriser safety valves actuate in both of these cases and maintain the reactor coolant system pressure below 110 percent of the design value. RCS pressure for these cases is shown in Figure 9.2.3-16. Note that with and without offsite power cases have different assumptions regarding initial pressure. The initial pressure assumptions were based upon sensitivities that were run. With respect to maximum reactor coolant system pressure, the case with offsite power available is the most limiting for turbine trip cases.

Maximum Reactivity Feedback, Without Pressuriser Spray, With and Without Offsite Power Available

Figures 9.2.3-21 through 9.2.3-26 show the transient responses for the two other cases analysed to address RCS pressure concerns, with and without offsite power available. In the case with offsite power available, the reactor is tripped by the High-2 pressuriser pressure function. The case without offsite power is tripped by the low reactor coolant pump speed trip function. The pressuriser safety valves actuate in both of these cases and maintain the reactor coolant system pressure below 110 percent of the design value. RCS pressure for both cases is shown in Figure 9.2.3-22. Note that with and without power cases have different assumptions regarding initial pressure. The initial pressure assumptions were based upon sensitivities that were run.

9.2.3.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.2.3.3.1 Diverse Mitigation for ATWT

Turbine trip events are characterised by a reduction in steam flow from the steam generator. The reduction in steam flow causes the RCS and secondary system to heat up. The turbine trip event produces a transient that is similar to a loss of generator electrical load, the closure of the main steam isolation valves, and a loss of the condenser. In general, these events produce a turbine trip and a sudden reduction of steam flow from the steam generators.

The turbine trip analyses documented in this section are performed to bound the following events:

- As discussed in Section 9.2.2.4, the loss of generator electrical load can result in the turbine control system tripping the turbine. AC power for plant auxiliary loads is then supplied by offsite power. The condenser would be expected to be available in this case. With the condenser available, turbine bypass and the feedwater system would also be operable.

- The closure of the main steam isolation valves (Section 9.2.4) results in termination of the steam flow from the steam generators, similar to a turbine trip. Closure of the main steam isolation valves also isolates the turbine bypass system from the steam generators.

- The loss of condenser event (Section 9.2.5) results in an immediate turbine trip. If the condenser is unavailable, then turbine bypass which exhausts to the condenser will also be unavailable. Without exhaust steam from the turbine or the turbine bypass system to the condenser, the inventory for the feedwater system will be depleted after some time.

The scenarios with turbine trip and simultaneous loss of feedwater are analysed in Section 9.2.7.

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The turbine trip analysis documented in this section is performed to bound the following events:

- Turbine trip with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Turbine trip with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Turbine trip with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).
- There is no significant fuel damage.
- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.2.3.3.1.1 Diverse ATWT Method of Analysis

The analysis uses the methods outlined for the DBA, with revised assumptions. The assumptions used for the limiting ATWT turbine trip, a common cause failure of the PMS, are discussed below.

- Plant initial conditions are at the nominal full power values.
- No measurement/instrumentation errors are assumed.
- Core kinetics parameters and initial boron concentration are both assumed to be at beginning of cycle (BOC) values.
- Moderator temperature coefficient (MTC) is modelled as discussed in Reference 9.2-11.
- Pressuriser pressure and level control systems are not credited in the analyses.
- SG power operated relief valves are assumed to be operable for all cases.
- The turbine bypass system is assumed to be operable. It is noted that the assumption of turbine bypass operability is conservative, [ ] The RCS temperature reduction will increase core reactivity.

9.2.3.3.1.2 Diverse ATWT Credited SSCs

As noted in 9.2.3.3.1.3, no available SSCs (PMS or DAS functions) are credited to initiate passive safety features for this limiting ATWT. Instead, the plant will reach an equilibrium power condition and ATWT criteria would be met. Ultimately, manual operator action would be required to shut down the plant. Section 9.2.7.3.1 considers the turbine trip and simultaneous loss of feedwater ATWT, which bounds this event.

9.2.3.3.1.3 Diverse ATWT Results

Turbine Trip with PMS CCF

This section describes a turbine trip with a CCF of the PMS. The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power, turbine bypass, and feedwater are also assumed available. It is noted that turbine trip with simultaneous loss of normal feedwater (LONF) with a PMS CCF is addressed in the Section 9.2.7.3.1.

Table 9.2.3-1 shows the sequence of events for the fault. The transient response of the event is shown in Figures 9.2.3-27 to 9.2.3-31.

At the start of the event, the turbine is tripped and all steam flow from the steam generators is terminated. The feedwater system and main coolant pumps are assumed to continue operating normally. The feedwater control system maintains SG level. The loss of secondary side steam flow causes the secondary and primary systems to heatup.

The turbine bypass system control logic block in the PLS is cleared due to the turbine trip detection and the turbine bypass system starts to open in average temperature (T_{avg}) mode. Several seconds after the turbine trip, the turbine bypass valves are fully open. However, the turbine bypass system is unable to remove all of the energy transferred to the secondary side, and secondary side pressure increases until the SG PORVs are opened.

The RCS heatup causes fluid expansion and an increase in pressuriser water level and is accompanied by an increase in pressure until the pressuriser safety valves open for a short period. PMS reactor trip high pressuriser pressure and level setpoints are reached, but no PMS action occurs due to the PMS mode failure. There are no parameters monitored by DAS which would cause DAS system intervention. As the reactor coolant temperature increases, core power decreases due to moderator feedback. Core power decreases to an equilibrium value that is equal to the energy removal rate of the turbine bypass system and the steam generator relief valves.

Without turbine steam flow, extraction steam for feedwater heaters will be lost, and feedwater temperature will decrease toward the condenser hot well temperature, thus increasing the amount of energy the turbine bypass can remove from the nuclear steam supply system (NSSS). Atmospheric relief would carry off any excess steam generation. If this steam is not replenished, the SG liquid inventory will eventually decrease to the point at which heat transfer from the primary is diminished. This would cause further heating of the RCS and reduction of core power. If feedwater is lost entirely, the event becomes a LONF from a reduced power and is bounded by the analyses in Section 9.2.7.3.1. Otherwise, the stable power would continue until terminated by manual action.

To shut down the reactor from these stable conditions, operator action will be necessary.

This fault is less limiting for RCS overpressure than the loss of feedwater ATWT event as analysed in Section 9.2.7.3, less limiting for core damage than the complete loss of RCS flow ATWT event as analysed in Section 9.3.2.3, and does not involve substantial energy release to containment. Therefore, since those events are shown to meet the ATWT acceptance criteria, the AP1000 design meets the ATWT acceptance criteria for the turbine trip event.

9.2.3.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.2.3.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios (bounded by the loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2) demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.2.3.5 As Low As Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for the loss of normal feedwater fault event, as described in Section 9.2.7.5.

9.2.3.6 Conclusions

Results of the DB analyses show that a turbine trip presents no challenge to the integrity of the reactor coolant system or the main steam system. Pressure-relieving devices incorporated in the two systems are adequate to limit the maximum pressures to within the design limits.

The DB analyses show that the predicted DNBR is greater than the safety analysis DNBR limit value at any time during the transient. Thus, the departure from nucleate boiling design basis, as described in Section 22.7.1.1, is met.

The ATWT acceptance criteria are met. This event was explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.2-13. The evaluation conducted to closeout FS-03 (Reference 9.2-14) demonstrated that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.2.4 Inadvertent Closure of Main Steam Isolation Valves (Fault 1.16.7)

Inadvertent closure of the main steam isolation valves results in a turbine trip with no credit taken for the turbine bypass system. Turbine trips are discussed in Section 9.2.3.

The inadvertent closure of the main steam isolation valves ATWT event is bounded by the analysis of the turbine trip ATWT event discussed in Section 9.2.3.5. There are two justifications for this assertion: one is related to the physical difference between valve stroke times, and the other is related to conservatisms in modelling.

The turbine admission valves can close in tenths of a second. In contrast, the main steam isolation valves require several seconds to close. Therefore, if other parameters are equal, the faster closing valve will cause the more severe pressure increase.

In reality, the other parameters are not equal. There is considerable steam piping volume between the isolation valves and the turbine, which will attenuate the pressure increase. However, it is Westinghouse practice to assume zero steam piping volume for simplicity and conservatism. That practice is continued on these ATWT analyses. Thus, instantaneous closure of the isolation valves is identical to instantaneous closure of the turbine admission valves (with no turbine bypass).

For these reasons, an inadvertent closure of main steam isolation valves ATWT event is bounded by the analysis of the turbine trip ATWT event in Section 9.2.3.5.

9.2.5 Loss of Condenser Vacuum and Other Events Resulting in Turbine Trip (Fault 1.18.1)

Loss of condenser vacuum is one of the events that can cause a turbine trip. Turbine trip initiating events are described in Section 9.2.3. A loss of condenser vacuum prevents the use of steam dump to the condenser. Because steam dump is assumed to be unavailable in the turbine trip analysis, no additional adverse effects result if the turbine trip is caused by loss of condenser vacuum. Therefore, the analysis results and conclusions contained in Section 9.2.3 apply to the loss of the condenser vacuum. In addition, analyses for the other possible causes of a turbine trip, listed in Section 9.2.3.1, are covered by Section 9.2.3. Possible overfrequency effects, due to a turbine overspeed condition, are discussed in Section 9.2.2.1 and are not a concern for this type of event.

Loss of condenser will result in an immediate reactor trip. The difference from other ATWT turbine trips (Section 9.2.3.3.1) is that turbine bypass is not available. If SG steam release is necessary, unavailability of turbine bypass would cause atmospheric steam release at a slightly higher steam pressure. The higher steam pressure would cause a slightly higher RCS cold-leg and core inlet temperature, which is beneficial for RCS overpressure. The increased core inlet temperature would also provide better reactivity feedback and would reduce the equilibrium core power, which is beneficial for DNB. Therefore, a separate assessment of this event is not necessary.

9.2.6 Loss of ac Power to the Plant Auxiliaries (Fault 1.19.1)

9.2.6.1 Identification of Causes and Accident Description

The loss of power to the plant auxiliaries is caused by a complete loss of the offsite grid accompanied by a turbine-generator trip. The onsite standby ac power system remains available but is not credited to mitigate the accident.

From the decay heat removal point of view, in the long term this transient is more severe than the turbine trip event analysed in Section 9.2.3 because, for this case, the decrease in heat removal by the secondary system is accompanied by a reactor coolant flow coastdown, which further reduces the capacity of the primary coolant to remove heat from the core. The reactor will trip:

- Upon reaching one of the trip setpoints in the primary or secondary systems as a result of the flow coastdown and decrease in secondary heat removal.

- Due to the loss of power to the control rod drive mechanisms as a result of the loss of power to the plant.

Following a loss of ac power with turbine and reactor trips, the sequence described below occurs:

- Plant vital instruments are supplied from the Class 1E and uninterruptable power supply.

- As the steam system pressure rises following the trip, the steam generator power-operated relief valves may be automatically opened to the atmosphere. The condenser is assumed not to be available for turbine bypass. If the steam flow path through the power-operated relief valves is not available, the steam generator safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual decay heat produced in the reactor.

- The onsite standby power system, if available, supplies ac power to the selected plant non-safety loads.

- As the no-load temperature is approached, the steam generator power-operated relief valves (or safety valves, if the power-operated relief valves are not available) are used to dissipate the residual decay heat and to maintain the plant at the hot shutdown condition if the startup feedwater is available to supply water to the steam generators.

- If startup feedwater is not available, the PRHR heat exchanger is actuated.

During a plant transient, core decay heat removal is normally accomplished by the startup feedwater system if available, which is started automatically when low levels occur in either steam generator. If that system is not available, emergency core decay heat removal is provided by the PRHR heat exchanger. The PRHR heat exchanger is a C-tube heat exchanger connected, through inlet and outlet headers, to the reactor coolant system. The inlet to the heat exchanger is from the reactor coolant system hot leg, and the return is to the steam generator outlet plenum. The heat exchanger is located above the core to provide natural circulation flow when the reactor coolant pumps are not operating. The IRWST provides the heat sink for the heat exchanger. The PRHR heat exchanger, in conjunction with the passive containment cooling system, keeps the reactor coolant subcooled for greater than 14 days. After the IRWST water reaches saturation, steam starts to vent to the containment atmosphere. The condensation that collects on the containment steel shell (cooled by the passive containment cooling system) returns to the IRWST, maintaining fluid level for the PRHR heat exchanger heat sink. The analysis shows that the natural circulation flow

in the reactor coolant system following a loss of ac power event is sufficient to remove residual heat from the core.

Upon the loss of power to the reactor coolant pumps, coolant flow necessary for core cooling and the removal of residual heat is maintained by natural circulation in the reactor coolant and PRHR loops.

This event is more limiting with respect to long-term heat removal than the turbine trip initiated decrease in secondary heat removal without loss of ac power, which is discussed in Section 9.2.3. A loss of offsite power to the plant auxiliaries will also result in a loss of normal feedwater.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.2.6.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault. It also demonstrates the capability of the PRHR heat exchanger to sufficient decay heat following a loss of normal feedwater. Those systems show that the safety criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect to fuel damage and RCS/MSS pressure criteria, therefore, these limits are not explicitly confirmed for this event. Accordingly, Pressuriser filling is the primary criterion for this analysis.

9.2.6.2.1 DBA Method of Analysis

A modified version of the LOFTRAN code (Reference 9.2-2), described in WCAP-15644 (Reference 9.2-6), is used to simulate the system transient following a plant loss of offsite power. The simulation describes the plant neutron kinetics and reactor coolant system, including the natural circulation, pressuriser, and steam generator system responses. The digital program computes pertinent variables, including the steam generator level, pressuriser water level, and reactor coolant average temperature.

The assumptions used in this analysis minimize the energy removal capability of the PRHR heat exchanger and maximise the coolant system expansion.

The assumptions used in the analysis are as follows:

- The plant is initially operating at 101 percent of the design power rating with initial reactor coolant temperature 4.4°C (8°F) below the nominal value and the pressuriser pressure 0.345 MPa (50 psi) above the nominal value.

- Core residual heat generation is based on ANSI/ANS 5.1-1979 (Reference 9.2-3). ANSI 5.1 is a conservative representation of the decay energy release rates.

- Reactor trip occurs on RCP speed-low.

- A heat transfer coefficient is assumed in the steam generator associated with reactor coolant system natural circulation flow conditions following the reactor coolant pump coastdown.

- The PRHR heat exchanger is actuated by the Low-2 steam generator water level (narrow range coincident with Low-2 start up feed water flow).

- For the loss of ac power to the station auxiliaries and following reactor trip, the main safety function required is core decay heat removal. That is accomplished by the secondary steam relief through the steam generator safety valves and by the PRHR heat exchanger. One of two parallel valves in the PRHR outlet line is assumed to fail to open. This is the worst single failure.

- The pressuriser safety valves are assumed to function.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

Plant systems and equipment necessary to mitigate the effects of a loss of ac power to the station auxiliaries are discussed in Section 9.0.4 and listed in Table 9.0-10. Normal reactor control systems are not required to function. The PMS is required to function following a loss of ac power. The PRHR heat exchanger is required to function with an overall minimum capability to extract heat from the reactor coolant system. No single active failure prevents operation of any system required to function.

Parameters used in the analysis are selected to maximise the pressuriser water volume. Input parameters are not selected to maximise the transient primary side and secondary side pressure. Transient primary side and secondary side pressures during a loss of ac power to station auxiliaries are bounded by those calculated for the turbine trip analyses described in Section 9.2.3.

With respect to DNB concerns, the loss of ac power to station auxiliaries event is bounded by the loss of ac power case analysed for the turbine trip event described in Section 9.2.3.

9.2.6.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends before CMT actuation; however, the long term safe shutdown analysis (Appendix 9C) bounds safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and steam generator SVs. The PMS provides the following:

- RT on Low-2 RCP speed

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow

- CMTs and containment isolation on Low-2 CL temperature

- PCS on High-2 containment pressure

9.2.6.2.3 DBA Results

The transient response of the reactor coolant system following a loss of ac power to the plant auxiliaries is shown in Figures 9.2.6-1 through 9.2.6-12. The calculated sequence of events for this event is listed in Table 9.2-1.

The loss of ac power event results in a pressuriser water volume increase until the actuation of the steam generator safety valves. Actuation of the steam generator safety valves attenuates the

pressuriser water volume until actuation of the PRHR, which turns around the pressuriser water volume increase. PRHR heat extraction and steam generator safety valve relief results in a consequential decrease in the pressuriser water volume until the safety valve relief stops. After the steam generator safety valve flow stops, the pressuriser water volume begins a slight increase until the PRHR heat extraction matches and then exceeds the decay heat addition resulting in a reduction in the pressuriser water volume.

9.2.6.3 Diverse Mitigation

Diverse mitigation capabilities are the same as for the loss of normal feedwater fault, as described in Section 9.2.7.3.

9.2.6.3.1 Diverse Mitigation for ATWT

Loss of ac power to the station auxiliaries will cause loss of RCS flow, loss of main feedwater and immediate turbine trip, and loss of power to the rod control system (causing immediate reactor trip regardless of whether any PMS or DAS signal exists). This would become an ATWT event only if a control rod mechanical failure is postulated that prevents control rod insertion. In the event of postulated failure of the control rods to insert, this event becomes similar to a loss of feedwater with turbine trip, addressed in Section 9.2.7.3.1, with the only difference being that a loss of ac power would result in a trip of RCPs at the beginning of the transient. An immediate trip of RCPs is beneficial for RCS overpressure and does not cause DNB (as shown in Section 9.3.2.5). Therefore, no separate assessment of this event is required to demonstrate that the AP1000 design meets the ATWT acceptance criteria.

9.2.6.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.2.6.4 Radiological Consequences

Design Basis

The DBA evaluation of the radiological consequences of a postulated loss of offsite power assumes that the reactor has been operating with a limited number of fuel rods containing cladding defects and that leaking steam generator tubes have resulted in a build-up of activity in the secondary coolant.

It is determined that no fuel rods are damaged as a result of the accident such that the activity contained in the fuel-cladding gap is released to the reactor coolant.

Two separate accident scenarios are addressed. In the first scenario, it is assumed that the non-safety grade SFW system is not available to provide feedwater to the steam generators. In this event, the water level in the steam generators drops, resulting in PRHR actuation. The period of steaming is terminated when the capacity of the PRHR system exceeds the decay heat generation rate.

In the second scenario, it is assumed that SFW is available to maintain water level in the steam generators such that PRHR is not actuated, resulting in a longer period of steaming releases. The period of steaming is terminated when RNS is in service and its capacity exceeds the decay heat generation rate.

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.2.6.4.1 DBA Source Term

There is no fuel damage as a result of the accident. Therefore, the most significant radionuclide releases are the noble gases, alkali metals, and iodines that are present in the primary and secondary coolants, become airborne, and are released to the environment as a result of the accident.

The initial reactor coolant system iodine concentrations are assumed to be those associated with the equilibrium operating limit for primary coolant iodine activity. An iodine spike is assumed to be initiated by the accident, with the spike causing an increasing level of iodine in the reactor coolant.

The secondary coolant iodine and alkali metal concentrations are assumed to be 10 percent of the primary concentrations. Noble gases are not assumed to accumulate in the secondary coolant

9.2.6.4.2 DBA Release Pathways

The reactor coolant leaking into the steam generators is assumed to mix with the secondary coolant. As steam is released, a portion of the iodine and alkali metal activity in the coolant is released. The fraction of activity released is defined by the reducing conditions within the steam generator. Volatile (elemental) iodines are treated as a direct release from the RCS to the environment. Non-volatile (particulate) iodines and alkali metals are assumed to enter the secondary coolant. Release from the secondary coolant is limited by the assumed moisture carryover. The noble gas activity entering the secondary side is released to the environment. These releases are terminated when the steam releases stop.

9.2.6.4.3 DBA Dose Calculation Models

The models used to calculate offsite and control room doses are provided in Appendix 9A.

9.2.6.4.4 DBA Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.2.6-1.

9.2.6.4.5 DBA Doses

The highest doses are found to be for the case with SFW available. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.2.6-2. The Table 9.2.6-2 values ensure the Target 4 BSLs are met.

9.2.6.5 As Low As Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for the loss of normal feedwater fault event, as described in Section 9.2.7.5.

9.2.6.6 Conclusions

Results of the DB analysis show that for the loss of ac power to plant auxiliaries event, all safety criteria are met. The heat extraction provided by the steam relief capacity of the steam generator safety valves and the operation of the PRHR is sufficient to prevent water relief through the pressuriser safety valves.

The DB analysis demonstrates that sufficient long-term reactor coolant system heat removal capability exists, via the steam generator safety valves, natural circulation, and the PRHR heat exchanger, following reactor coolant pump coastdown to prevent fuel or cladding damage and reactor coolant system overpressure.

This event has also been adequately assessed with respect to ATWT considerations.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.2.7 Loss of Normal Feedwater Flow (Fault 1.16.1)

9.2.7.1 Identification of Causes and Accident Description

A loss of normal feedwater (from pump failures or valve malfunctions) results in a reduction in the capability of the secondary system to remove the heat generated in the reactor core. If startup feedwater is not available, the Class 1 PRHR heat exchanger is automatically aligned by the PMS to remove decay heat.

A small secondary system break can affect normal feedwater flow control, causing low steam generator levels prior to protective actions for the break. This scenario is addressed by the assumptions made for the feedwater system pipe break (see Section 9.2.8).

The following occurs upon loss of normal feedwater (assuming main feedwater pump fails or valve malfunctions):

- The steam generator water inventory decreases as a consequence of the continuous steam supply to the turbine. The mismatch between the steam flow to the turbine and the feedwater flow leads to the reactor trip on a low steam generator water level signal. The same signal also actuates the startup feedwater system (see Section 9.2.6.1).

- As the steam system pressure rises following the trip, the steam generator power-operated relief valves are automatically opened to the atmosphere. The condenser is assumed to be unavailable for turbine bypass. If the steam flow path through the power-operated relief valves is not available, the steam generator safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual decay heat produced in the reactor.

- As the no-load temperature is approached, the steam generator power-operated relief valves (or safety valves, if the power-operated relief valves are not available) are used to dissipate the decay heat and to maintain the plant at the hot shutdown condition, if the startup feedwater is used to supply water to the steam generator.

- If startup feedwater is not available, the PRHR heat exchanger is actuated on either a Low -2 steam generator water level (narrow range) coincident with a low startup feedwater flow rate signal or a low steam generator water level (wide range) signal.

- The PRHR heat exchanger extracts heat from the reactor coolant system causing a temperature reduction and an "S" signal on a Low Tcold signal. This actuates the core makeup tanks and trips the RCPs. Both core makeup tanks inject mass into the reactor coolant system. For some time the pressuriser level continues to decrease as the combined cooling from the PRHR and the CMTs (with them injecting colder water) continues. As the CMT water heats up, its cooling effect decreases and the RCS begins to heat up. The RCS heatup causes a pressuriser level increase transient. The operators will be alerted that a potential filling event is occurring by the High-2 pressuriser level signal. The operator action assumed in the analysis is to open the reactor vessel head vent following receipt of the High-3 pressuriser level signal; this action is at least 30 minutes after the operator has been alerted by the High-2 pressuriser level signal. When the head vent is opened, the pressuriser level increase slows and ultimately the level begins to decrease.

- Later in the transient, the PRHR heat transfer matches decay heat the RCS heatup is stopped and the RCS temperature begins to decrease.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.2.7.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault. It also demonstrates the capability of the PRHR heat exchanger to remove sufficient decay heat following a loss of normal feedwater. Those systems in conjunction with the operator action to open the reactor head vent show that the safety criteria are satisfied including::

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect to RCS/MSS pressure criteria, therefore, these limits are not explicitly confirmed for this event.

9.2.7.2.1 DBA Method of Analysis

An analysis using a modified version of the LOFTRAN code (Reference 9.2-2), described in WCAP-15644 (Reference 9.2-6), is performed to obtain the plant transient following a loss of normal feedwater. The simulation describes the neutron kinetics, reactor coolant system (including the natural circulation), pressuriser, and steam generators. The program computes pertinent variables, including the steam generator level, pressuriser water level, and reactor coolant average temperature.

Two cases are analysed. One case assumes a consequential loss of ac power to the plant auxiliaries resulting from the turbine trip after reactor trip. The loss of ac power results in a coastdown of the reactor coolant pumps. A second case does not assume the consequential loss of ac power, which maintains the reactor coolant pumps at normal speed until automatically tripped when the core makeup tanks are actuated.

The assumptions used in the analysis are as follows:

- The plant is initially operating at 101 percent of the design power rating.
- Reactor trip occurs on steam generator Low-2 (narrow range) level.
- The principal safety function required after reactor trip is the core decay heat removal. That function is carried out by the PRHR heat exchanger. The worst single failure is assumed to occur in the PRHR heat exchanger. The actuation of the PRHR heat exchanger requires the opening of one of the two fail-open valves arranged in parallel at the PRHR heat exchanger discharge. Because no single failure can be assumed that impairs the opening of both valves, the failure of a single valve is assumed.

  The PRHR heat exchanger is actuated by the Low-2 steam generator water level narrow range signal coincident with Low-2 startup feedwater flow, or by the Low-2 steam generator water level wide range signal.
- Plant cooldown with the PRHR heat exchanger may cause a reduction in the low cold leg temperature such that the Safeguards setpoint is reached, which will actuate the core makeup tanks. The additional borated fluid added by the core makeup tanks may cause excessive pressuriser water volume. Prevention of pressuriser filling is accomplished by an operator action to open the reactor head vent.
- Secondary system steam relief is achieved through the steam generator safety valves.
- The initial reactor coolant average temperature is 4.4°C (8°F) lower than the nominal value, and initial pressuriser pressure is 0.345 MPa (50 psi) lower than nominal.

The loss of normal feedwater analyses are performed to demonstrate the adequacy of the PMS and the PRHR heat exchanger in removing long-term decay heat. Such decay heat removal prevents excessive heatup of the reactor coolant system with possible resultant reactor coolant system overpressurisation or loss of reactor coolant system water. The assumptions used in this analysis minimize the energy removal capability of the system, and maximise the coolant system expansion.

With respect to the overpressure evaluation, the loss of normal feedwater transient with and without ac power available events are bounded by the turbine trip event presented in Section 9.2.3.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

Plant systems and equipment necessary to mitigate the effects of a loss of normal feedwater accident are discussed in Section 9.0.4 and listed in Table 9.0-10. Normal reactor control systems are not required to function. The PMS is required to function following a loss of normal feedwater. The PRHR heat exchanger is required to function with an overall minimum capability to extract heat from the reactor coolant system. No single active failure prevents operation of any system to perform its required function.

9.2.7.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs, and reactor vessel head vent valves. The PMS provides the following:

- RT on Low-2 SG narrow-range water level in either SG
- Manual head vent valve operation on High-2 pressuriser level
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.2.7.2.3 DBA Results

The transient responses for a loss of main feedwater flow are shown for cases without and with a consequential loss of ac power.

Loss of Normal Feedwater flow with ac power available

The calculated sequence of events for this accident is listed in Table 9.2-1. Figures 9.2.7-1 through 9.2.7-13 show the significant plant parameters following a loss of normal feedwater.

The loss of main feedwater results in an increase in the pressuriser water volume until reactor trip on low steam generator water level (narrow range). The pressuriser water volume then decreases briefly due to the reactor trip. However, due to loss of secondary heat removal capacity and injection from the CVS, the pressuriser water volume begins to increase. The pressuriser water volume then increases until the PRHR actuates.

The capacity of the PRHR heat exchanger, when the reactor coolant pumps are operating, is much larger than the decay heat, and in the first part of the transient, the reactor coolant system is cooled down. The cooldown continues until the reactor coolant temperature reaches the low T_{cold} setpoint. When the low T_{cold} setpoint is reached, the reactor coolant pumps are tripped, CVS is isolated, and the core makeup tanks are actuated.

The pressuriser water volume then increases due to the cold borated water injected by the core makeup tanks and the reduced PRHR efficiency due to the loss of forced flow resulting from the reactor coolant pump trip. Pressuriser water volume increases during this period. The operators are alerted to the pressuriser level increase when the level exceeds the High-2 pressuriser level

setpoint. The operator action assumed in this analysis is to open the reactor vessel head vent following receipt of the High-3 pressuriser level signal; this action is at least 30 minutes after the operator has been alerted by the High-2 pressuriser level signal. After that point, the pressuriser water volume begins to decrease. The operator action to open the reactor vessel head vent and the capacity of the PRHR heat exchanger is sufficient to avoid water relief through the pressuriser safety valves.

The DNBR transient for the loss of normal feedwater event is shown in Figure 9.2.7-12.

Loss of Normal Feedwater flow with a consequential loss of ac power

The calculated sequence of events for this accident is listed in Table 9.2-1. Figures 9.2.7-14 through 9.2.7-26 show the significant plant parameters following a loss of normal feedwater with a consequential loss of ac power to plant auxiliaries.

The first increase in pressuriser water volume is turned around by the heat extraction provided by the steam generator safety valves. Due to the steam generator safety valve relief, the pressuriser water volume decreases until the heat extraction provided by the steam generator safety valves relief stops once the steam pressure decreases below the steam generator safety valve setpoints. With no steam generator safety valve relief, the pressuriser water volume begins to increase until the PRHR heat extraction approaches the magnitude of the decay heat addition. Once this occurs, pressuriser water volume decreases for the remainder of the transient.

9.2.7.3 Diverse Mitigation

In addition to the Class 1 passive systems credited in the DBA, the plant also provides diverse mitigation capability that is able to supply the Category A safety functions for frequent faults. The diverse features are also Class 1 except for the diverse C&I, which is Class 2.

Two different diverse mitigation analyses are provided in the following subsections. One demonstrates the reactor can be shut down when a CCF prevents control rod insertion. Such an event is defined as an ATWT event. The other demonstrates that adequate core cooling can be provided when a CCF affects the core cooling credited in the DBA. In the diverse core cooling case rod insertion is assumed to occur.

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

In these diverse mitigation analyses, the containment function is provided by the fuel cladding and by the RCS, neither of which is threatened in the DBA. The containment building provides diverse containment and is identified as a Class 1 system on that basis for this fault.

Table's 9.2.7-3 and Table 9.2.7-4 summarize the SSCs credited in these diverse fault assessments. The information provided in Table 9.2.7-3 is from Reference 9.2-10, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions.

9.2.7.3.1 Diverse Mitigation for ATWT

The loss of main feedwater produces a large imbalance in the heat source/sink relationship. When feedwater flow to the steam generators is terminated, the secondary subcooled feed system can no longer remove all the heat that is generated in the reactor core. This excess primary system heat causes the RCS temperature and pressure to rise and the pressuriser water level to increase, due to

the insurge of expanding reactor coolant. Water levels in the steam generators drop as the remaining water in the secondary system is boiled off. When the steam generator water level falls to the point where the steam generator tubes are uncovered, primary to secondary heat transfer is reduced, causing the reactor coolant temperature and pressure to increase at a greater rate. This rate of primary system temperature and pressure increase is maintained as the pressuriser fills and discharges water through the safety valves. Reactivity feedback effects, due to the higher primary system temperature, reduce core power. Eventually, the balance between the heat source and sink is re-established, system temperature and pressure decreases, and a steam bubble is formed in the pressuriser again.

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The LONF analysis documented in this section is performed to bound the following events:

- Complete or Partial LONF with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Complete or Partial LONF with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Complete or Partial LONF with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.2.7.3.1.1 Diverse ATWT Method of Analysis

The analysis uses the methods outlined for the DBA, with revised assumptions. The assumptions used for the limiting ATWT LONF, a complete LONF with a RCCA mechanical CCF, are discussed below. No measurement/instrumentation errors are assumed.

- Plant initial conditions are at the nominal full power values

- Core kinetics parameters and initial boron concentration are both assumed to be at BOC values.

- MTC is modelled as discussed in Reference 9.2-11.

- Pressuriser spray is assumed to be available because it results in a slightly higher peak pressure.

- Turbine trip on reactor trip function is assumed to be operable. Not tripping the turbine would cause worse ATWT consequences, since it would draw more steam from the SG and more heat would be removed from the primary system early in the transient. As a consequence, core power level would stay relatively high during the period when SG heat transfer degrades. This would result in higher pressuriser insurge and peak pressure. For this reason, diverse actuation of the turbine trip following loss of heat sink (i.e., low SG water level) is required on all Westinghouse PWRs.

  Turbine trip is assumed after the reactor trip setpoint is reached. A scenario with turbine trip at the beginning of the event would be almost the same. The only difference is that the switch of turbine bypass to pressure mode would happen sooner.

- Startup Feedwater system is not credited in the analyses.

- PMS and DAS automatic actions are available for this event except that rod insertion fails due to the RCCA CCF.

- ac power is assumed to be available since it is more likely and produces worse results.

9.2.7.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT all of the claimed SSCs are Class 1 except for the DAS. The claimed Class 1 SSCs are listed in Table 9.0-14. For the limiting ATWT case, the PMS and DAS provide the following:

- PMS PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow

- PMS PCS and containment isolation on High-2 containment pressure

- DAS PRHR[2] and CMT actuation on Low-2 SG wide range (WR) level

9.2.7.3.1.3 Diverse ATWT Results

Complete LONF with a RCCA CCF (limiting case)

Table 9.2.7-1 shows the event progression for the limiting ATWT diversity LONF case. Transient response of this event is shown in Figures 9.2.7-27 to 9.2.7-32.

At the start of the event, all main feedwater is terminated completely. SG water is boiled off in a higher rate because of the loss of subcooled feedwater. The turbine control system throttles turbine valves to maintain nominal load and secondary pressure increases slowly. The decreased load demand causes the primary temperature to increase resulting in a slow power decrease due to moderator feedback. SG water level decreases continually but SG heat transfer is still maintained. Eventually, SG water level decreases and reaches narrow range low SG level PMS reactor trip

2 As analysed, the DAS actuation occurs simultaneously as the PMS actuation; as such, both are presented.

setpoint value. As the result of reactor trip signal, the turbine is tripped and turbine bypass control switches to pressure mode.

Several seconds after the turbine trip, the turbine bypass valves open fully (in steam pressure control mode). The turbine bypass system is unable to remove all of the energy transferred to the secondary side and the secondary pressure increases until SG PORV and then safety valves are opened. As the reactor coolant temperature increases, core power decreases due to moderator feedback. The heatup of the reactor coolant causes fluid expansion which increases the pressuriser level and pressure until the pressuriser safety valves open.

Eventually, core power decreases to a value that is equal to the energy removal rate of the turbine bypass system and the steam generator relief and safety valves. This reduced core power is approximately 70 percent of RTP when the liquid inventory in the steam generators has been depleted to the point where full heat transfer through the tube bundle cannot be maintained. At this point, heat transfer through the tube bundle continues to degrade as the remaining liquid in the steam generators is boiled off.

The reduction in steam generator heat transfer causes the primary side temperatures to begin rising again. As reactor coolant temperature increases, core power again decreases due to moderator feedback. When the steam generator level reaches wide range low level setpoint in both steam generators, the PMS and DAS actuate PRHR, the DAS actuates the CMT, and the RCPs are tripped.

The heatup caused by the reduction of heat transfer in the SG causes the pressuriser level to increase until the pressuriser fills. Liquid relief from the pressuriser safety valves occurs at this time and RCS pressure increases to a peak value. Reactor coolant pressure then begins to decrease as core power is reduced due to moderator feedback. The PRHR cycle is established, and it transfers core power to the IRWST. The SG heat transfer ceases. Eventually, the hot-leg temperatures in both loops approach saturation while the cold-leg temperature in loop 2 reaches saturation. However, since the PRHR is connected to the loop 1 SG plenum, the inlet loop 1 cold leg temperature remains subcooled. Core power is reduced by moderator temperature feedback, and it eventually reaches equilibrium with the PRHR heat removal rate. Reactor coolant pressure continues to decrease and the pressuriser safety valves close. Eventually, the CMT-induced boration of the RCS will bring the reactor to subcritical conditions.

The peak RCS pressure is less than the limit of 22.06 MPa-rel (3200 psig).

There is no significant core damage, as evidenced by the bounding analysis for a loss of flow ATWT in Section 9.3.

The rate and duration of energy release to containment is much less than for the design basis loss of coolant accident.

9.2.7.3.2 Diverse Mitigation for Core Cooling

Analysis is performed considering several different CCFs that can affect the SSCs used to provide core cooling to demonstrate the adequacy of the SSCs not affected by the CCF. The same safety criteria as those for the ATWT are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage. The fuel peak clad temperature is less than 1204°C (2200°F)

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.2.7.3.2.1 Diverse Core Cooling Method of Analysis

An analysis using a RELAP 5 Mod 3.3 code (Reference 9.2-12), is performed to obtain the plant transient following a loss of normal feedwater. The simulation describes the neutron kinetics, reactor coolant system (including the natural circulation), pressuriser, and steam generators. The program computes pertinent variables, including the steam generator level, pressuriser water level, and reactor coolant average temperature.

A conservative bounding case is analysed with multiple CCFs. Multiple CCFs are assumed such that only one additional diverse analysis case is required to demonstrate diverse core cooling. Table 9.2.7-4 compares the SSCs credited in the DBA case (Section 9.2.7.2.1) with this bounding diverse core cooling case.

The general assumptions used in this analysis are the same as those used in the diverse ATWT LONF (Section 9.2.7.3.1) case except for the differences in the SSCs credited.

At the start of this event, all main feedwater is terminated. As a result, the SG water level decreases rapidly. Since PMS is assumed to be unavailable (due to a CCF) the SG level drops to the low SG WR DAS setpoint before the RT occurs. Due to the initiating event and the delayed RT, the SG heat removal stops early in the transient. At this point the reactor decay heat causes the RCS temperature to increase to the saturation point at the pressuriser safety valve setpoint. Due to the heatup of the reactor coolant, the pressuriser fills and the pressuriser SVs discharge water. Pressuriser SV discharge continues until ADS stage 1 valves are manually opened via DAS.

Once the ADS valves are opened the RCS pressure decreases and accumulator injection occurs. As the RCS pressure decreases further, the IRWST also provides injection; DAS manual is used to open these valves.

9.2.7.3.2.2 Diverse Core Cooling Credited SSCs

Table 9.2.7-4 lists the major SSCs credited in this analysis. Since the PMS is assumed to have suffered a CCF it is not credited for any actuation. Other SSCs include the accumulators, containment isolation, and pressuriser SVs. The DAS provides the following:

- RT motor-generator (MG) set field breakers on Low SG WR level

- PCS and containment isolation (CI) on high containment temperature

- Manual actuations of ADS 1- 4, IRWST injection, and containment recirculation

In addition, self-actuation of the accumulators is also credited.

9.2.7.3.2.3 Diverse Core Cooling Results

Table 9.2.7-2 shows the event progression. Transient response to this event is shown in Figures 9.2.7-33 to 9.2.7-38. Due to the CCF of the PMS, operator actions are credited in this analysis. The timing of these actions has an important impact on the results. Typically 30 minute action times are considered reasonable, especially for events like this that are very low probability (requiring multiple CCFs). In this case the operator action has been delayed for an additional 10 minutes (40 minutes total) to add additional margin.

At the start of this event, all main feedwater is terminated. As a result, the SG water level decreases rapidly. Since PMS is assumed to be unavailable (due to a CCF) the SG level drops to the low SG WR DAS setpoint before the RT. Due to the initiating event and the delayed RT, the SG heat removal stops early in the transient. At this point the reactor decay heat causes the RCS temperature to increase to the saturation point at the pressuriser SV setpoint. Due to the heatup of the reactor coolant the pressuriser fills and the pressuriser SVs then discharge water. Pressuriser SV discharge continues until ADS stage 1 valves are manually opened via DAS at 40 minutes.

Once the ADS valves are opened the RCS pressure decreases and accumulator injection occurs. As the RCS pressure decreases further, the IRWST also provides injection; DAS manual is used to open these valves.

Due to the loss of reactor coolant out the pressuriser SVs, there is some fuel uncovery and heatup. The peak clad temperature is reached at about the time that accumulator injection starts (about 2600 seconds). Accumulator injection quickly decreases the clad temperature. There is a small second clad temperature rise that occurs between the time the accumulators empty and the IRWST injection starts. After this time the fuel clad temperature remains stable.

Note that this case actually assumes three separate CCF; one each for PMS, PRHR and CMTs even though ONR guidance only requires that one be assumed. This approach is taken so that fewer analysis cases are required. The following discusses the impact of assuming fewer failures.

- PMS failure only – DAS would automatically trip the reactor and start PRHR. Manual actions and use of passive feed and bleed would not be required.

- PRHR failure only – PMS would automatically actuate CMTs. The CMTs would feed the reactor when heated up after the boil off of the SG inventory. When the CMT levels decreased ADS would be automatically actuated. Not operator action would be required and core uncover would not be expected.

- PMS and PRHR failures only – In this case the CMTs would be automatically actuated by DAS. Their availability would delay SG dry out by about 1000 seconds. In addition, they would provide additional water injection during the RCS depressurization. Operator action would still be required but more time would be available, on the order of 1 hour total.

The peak RCS pressure is 17.8 MPa abs (2582 psia) which is well below the acceptance criteria.

The peak clad temperature is of 847°C (1556°F) which is well below the acceptance criteria.

The mass energy input to the containment will be much less than that for a large break LOCA.

9.2.7.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.2.7.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

The diverse mitigation functions, including other Class 1 safety functions and the DAS function, which is Class 2, is also shown by analysis to meet the corresponding requirements for this event. See Reference 9.2-10 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy provided by the DiD systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- SFW with steam dump for decay heat removal
- Pressuriser spray and auxiliary spray for RCS pressure control
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the CCS and SWS cooling systems.
- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment and actuation automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (See Section 9.1.4.5). However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

As discussed in Chapter 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000 development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.2.7.6 Conclusions

Results of the DB analyses show that a loss of normal feedwater or a loss of normal feedwater with a consequential loss of ac power to the plant auxiliaries does not adversely affect the core, the reactor coolant system, or the steam system. The heat removal capacity of the PRHR heat exchanger, the steam generator safety valves, and the fluid relief capacity of the reactor vessel head vent is such that reactor coolant water is not relieved from the pressuriser safety valves and the pressuriser does not fill. DNBR always remains above the design limit values, and RCS and MSS pressures remain below 110 percent of their design values.

The ATWT acceptance criteria are met for this event. This event was explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.2-13. The evaluation conducted to closeout FS-03 (Reference 9.2-14) demonstrated that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.2.8 Feedwater System Pipe Break (Fault 1.16.8)

9.2.8.1 Identification of Causes and Accident Description

A major feedwater line rupture is a break in a feedwater line large enough to prevent the addition of sufficient feedwater to the steam generators in order to maintain shell-side fluid inventory in the steam generators. If the break is postulated in a feedwater line between the check valve and the steam generator, fluid from the steam generator may also be discharged through the break. (A break upstream of the feedwater line check valve would affect the plant only as a loss of feedwater. This case is covered by the evaluation in Section 9.2.7.)

Depending upon the size of the break and the plant operating conditions at the time of the break, the break could cause either a reactor coolant system cooldown (by excessive energy discharge through the break) or a reactor coolant system heatup. Potential reactor coolant system cooldown resulting from a secondary pipe rupture is evaluated in Section 9.1.5. Therefore, only the reactor coolant system heatup effects are evaluated for a feedwater line rupture in this section.

The feedwater line rupture reduces the ability to remove heat generated by the core from the reactor coolant system for the following reasons:

- Feedwater flow to the steam generators is reduced. Because feedwater is subcooled, its loss may cause reactor coolant temperatures to increase prior to reactor trip.

- Fluid in the steam generator may be discharged through the break and would not be available for decay heat removal after trip.

- The break may be large enough to prevent the addition of main feedwater after trip.

The severity of the feedwater line rupture transient depends on a number of system parameters, including the break size, initial reactor power, and the functioning of various control and safety-related systems. Sensitivity studies presented in WCAP-9230 (Reference 9.2-4) illustrate that the most limiting feedwater line rupture is a double-ended rupture of the largest feedwater line. At the beginning of the transient, the main feedwater control system is assumed to malfunction due to an adverse environment. Interactions between the break and the main feedwater control system result in no feedwater flow being injected or lost through the steam generator feedwater nozzles. This assumption causes the water levels in both steam generators to decrease equally until the Low-2 steam generator level (narrow range) reactor trip setpoint is reached. After reactor trip, a full double-ended rupture of the feedwater line is assumed such that the faulted steam generator blows down through the break and no main feedwater is delivered to the intact steam generator. These assumptions conservatively bound the most limiting feedwater line rupture that can occur. Analysis is performed at full power assuming the loss of offsite power at the time of the reactor trip. This is more conservative than the case where power is lost at the initiation of the event. The case with offsite power available is not explicitly examined because, due to the fast generation of "S" signal (generated by the Low-2 steam line pressure), the reactor coolant pumps would be tripped by the PMS shortly after the reactor trip. The only difference between the cases with and without offsite power available would be a small difference in when the reactor coolant pumps are tripped.

9.2.8.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety criteria are satisfied including:

- The reactor coolant system pressure criterion is met (demonstrating the adequacy of these systems in preventing excessive heatup.)
- Subcooling is maintained in the RCS (demonstrating core cooling capability is maintained).

Some fuel damage may occur as a consequence of infrequent faults, such as the feedwater line break accident. In practice, the results of the DB analysis presented below show that no fuel damage is expected to occur since DNB does not occur.

9.2.8.2.1 DBA Method of Analysis

An analysis using a modified version, described in WCAP-15644 (Reference 9.2-6), of the LOFTRAN code (Reference 9.2-2) is performed to determine the plant transient following a feedwater line rupture. The code describes the reactor thermal kinetics, reactor coolant system (including natural circulation), pressuriser, steam generators, and feedwater system responses and computes pertinent variables, including the pressuriser pressure, pressuriser water level, and reactor coolant average temperature.

The case analysed assumes a double-ended rupture of the largest feedwater pipe at full power. Major assumptions used in the analysis are as follows:

- The plant is initially operating at 101 percent of the design plant rating. The main feedwater flow measurement supports a 1-percent power uncertainty.

- Initial reactor coolant average temperature is 4.4°C (8°F) above the nominal value, and the initial pressuriser pressure is 0.345 MPa (50 psi) below its nominal value.

- The pressuriser spray is turned on.

- Initial pressuriser level is at a conservative maximum value and a conservative initial steam generator water level is assumed in both steam generators.

- At the start of the transient, interaction between the break in the feedline and the main feedwater control system is assumed to result in a complete loss of feedwater flow to both steam generators. No feedwater flow is delivered to or lost through the steam generator nozzles.

- Reactor trip is assumed to be initiated by the Low-2 steam generator water level (narrow range) signal on the ruptured steam generator. A two second delay is assumed following the low level setpoint being reached to allow for the system response times.

- After reactor trip, the faulted steam generator blows down through a double-ended break area of 0.10 m^2 (1.117 ft^2). A saturated liquid discharge is assumed until all the water inventory is discharged from the faulted steam generator. This minimizes the heat removal capability of the faulted steam generator and maximises the resultant heatup of the reactor coolant. The PRHR heat exchanger is assumed to be actuated by the Low-2 steam generator water level

(wide range) signal. A 17-second delay is assumed following the low level setpoint being reached to allow for the system response times and the valve stroke time.

- Credit is taken for heat energy deposited in reactor coolant system metal during the reactor coolant system heatup.
- No credit is taken for charging or letdown.
- Pressuriser safety valve setpoint is assumed to be at its minimum value.
- Steam generator heat transfer area is assumed to decrease as the shell-side liquid inventory decreases. The heat transfer remains approximately 100 percent in the faulted steam generator until the liquid mass reaches about 11 percent. The heat transfer is then reduced to 0 percent with the liquid inventory.
- Conservative core residual heat generation is assumed based upon long-term operation at the initial power level preceding the trip (Reference 9.2-3).
- No credit is taken for the following four PMS reactor trip signals to mitigate the consequences of the accident:
  - High-2 pressuriser pressure
  - Overtemperature ΔT
  - High pressuriser water level
  - High containment pressure

The PRHR heat exchanger is initiated once the steam generator water level drops to the Low-2 steam generator level (wide range). Similarly, receipt of a Low-2 steam line pressure signal in at least one steam line initiates a steam line isolation signal that closes all main steam line and feed line isolation valves. This signal also gives an "S" signal that initiates flow of cold borated water from the core makeup tanks to the reactor coolant system.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

No credit is taken for the plant control system to mitigate the consequences of the event. The PMS is required to function following a feedwater line rupture as analysed here. No single active failure prevents operation of this system. The single failure assumed is the failure of one of the two parallel discharge valves in the PRHR outlet line (see Table 9.0-11).

9.2.8.2.2 DBA Credited SSCs

For the DB, all the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, steam line isolation valves and pressuriser SVs. The PMS provides the following:

- RT on Low-2 SG narrow-range water level in either SG
- PRHR actuation on Low-2 SG WR level
- CMTs and containment isolation on Low-2 steamline pressure
- PCS on High-2 containment pressure

9.2.8.2.3 DBA Results

Calculated plant parameters following a major feedwater line rupture are shown in Figures 9.2.8-1 through 9.2.8-10. The calculated sequence of events for the case analysed is listed in Table 9.2-1.

The results presented in Figures 9.2.8-5 and 9.2.8-7 show that pressures in the reactor coolant system and main steam system remain below 110 percent of the respective design pressures.

In the first part of the transient, due to the conservative analysis assumptions, the system response following the feedwater line rupture is similar to the loss of normal feedwater with consequent loss of ac power (Section 9.2.7). For transient period prior to rod insertion, the feedwater line rupture event is bounded by the turbine trip event presented in Section 9.2.3 with respect to DNB concerns.

After the trip, the core makeup tanks are actuated on Low-2 steam line pressure in the ruptured loop while the PRHR heat exchanger is actuated on a Low-2 steam generator water level (wide range).

The addition of the PRHR heat exchanger and flows from the core makeup tanks help to cool down the primary system and to provide sufficient fluid to keep the core covered with water.

Pressuriser safety valves open due to the mismatch between decay heat and the heat transfer capability of the PRHR heat exchanger. In the first part of the transient, there is a cooling effect due to the core makeup tanks that inject cold water into the reactor coolant system and receive hot water from the cold leg. This effect decreases due to the heatup of the core makeup tanks from recirculation flow. Also, the injection driving head is lowered as the core makeup tanks heat up.

Reactor coolant system temperatures are low (with the hot leg temperature of the faulted loop at approximately 265.56°C (510°F) at about 2,200 seconds) and, in this condition, the PRHR heat exchanger cannot remove the entire decay heat load. Reactor coolant system temperatures then increase until approximately 21,500 seconds due to the limited heat removal capability of the PRHR heat exchanger. At approximately 23,990 seconds, the heat removal capability of the PRHR exceeds the decay heat power and the reactor coolant system pressure begins to decrease. Since subcooling is maintained throughout the transient and the reactor coolant system inventory increases (i.e., net core makeup tank injection exceeds net pressuriser safety valve relief), core cooling capability is maintained.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.2.8.3 Diverse Mitigation

As this is a low probability design basis fault (DBL), a diverse mitigation assessment is not required.

9.2.8.4 Radiological Consequences

Design Basis

With no fuel damage and no threat to containment, a significant release of radioactivity to the environment can only occur if the feedwater line break is outside the containment. Activity release will be limited to that present in the secondary coolant prior the event and any activity present in reactor coolant prior to the event that leaks into the SG during the event. These releases are the same as those considered in main steam line break doses presented in Section 9.1.5.4. Therefore,

the main steam line break doses from Section 9.1.5.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 9.3 mSv Worker dose: 78 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

9.2.8.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions (Table 9.2.8-1) as Class 1 SSCs has been shown to be adequate to meet DB requirements.

Diverse mitigation features, similar to those for the loss of normal feedwater event are also available for mitigation of this infrequent fault, although not required. Table 9.2.8-2 lists operator actions available in the event of a primary protection failure.

Refer to Section 9.2.7.5 for additional discussion on DiD levels of defence that are available and on ALARP that applies to this event.

9.2.8.6 Conclusions

Results of the analyses show that for the postulated feedwater line rupture, the capacity of the PRHR heat exchanger is adequate to remove decay heat, to prevent overpressurisation of the reactor coolant system, and to maintain the core cooling capability. Radioactivity doses from postulated ruptures of the feedwater lines are less than those presented for the postulated main steam line break. The evaluation criteria are therefore met.

DBA Radiological consequences are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

Table 9.2-1 (Sheet 1 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
I. Turbine trip		
A.1. With pressuriser spray, minimum reactivity feedback, with offsite power available	Turbine trip; loss of main feedwater	0.0
	Minimum DNBR occurs	9.9
	Initiation of steam release from steam generator safety valves	11.09
	Overtemperature ΔT reactor trip setpoint reached	19.1
	Rods begin to drop	21.1
A.2. With pressuriser spray, minimum reactivity feedback, without offsite power available	Turbine trip; loss of main feedwater	0.0
	Offsite power lost, reactor coolant pumps begin coasting down	3.0
	Low reactor coolant pump speed reactor trip setpoint reached	3.50
	Rods begin to drop	4.15
	Minimum DNBR occurs	5.9
	Initiation of steam release from steam generator safety valves	15.99

Table 9.2-1 (Sheet 2 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
B.1. With pressuriser spray, maximum reactivity feedback, with offsite power available	Turbine trip; loss of main feedwater flow	0.0
	Minimum DNBR occurs	0.0
	Initiation of steam release from steam generator safety valves	11.2
	Overtemperature ΔT reactor trip setpoint reached	20.9
	Rod motion begins	22.9
B.2. With pressuriser spray, maximum reactivity feedback, without offsite power available	Turbine trip; loss of main feedwater	0.0
	Offsite power lost, reactor coolant pumps begin coasting down	3.0
	Low reactor coolant pump speed reactor trip setpoint reached	3.50
	Rods begin to drop	4.15
	Minimum DNBR occurs	4.9
	Initiation of steam release from steam generator safety valves	17.7

Table 9.2-1 (Sheet 3 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
C.1. Without pressuriser spray, minimum reactivity feedback, with offsite power available	Turbine trip; loss of main feedwater flow	0.0
	High-2 pressuriser pressure reactor trip point reached	5.2
	Rods begin to drop	7.2
	Initiation of steam release from steam generator safety valves	8.5
	Peak RCS pressure occurs	8.7
C.2. Without pressuriser spray, minimum reactivity feedback, without offsite power available	Turbine trip; loss of main feedwater	0.0
	Offsite power lost, reactor coolant pumps begin coasting down	3.0
	Low reactor coolant pump speed reactor trip setpoint reached	3.50
	Rods begin to drop	4.15
	Peak RCS pressure occurs	6.2
	Initiation of steam release from steam generator safety valves	10.2

Table 9.2-1 (Sheet 4 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
D.1. Without pressuriser spray, maximum reactivity feedback, with offsite power available	Turbine trip; loss of main feedwater flow	0.0
	High-2 pressuriser pressure reactor trip	5.1
	Rods begin to drop	7.1
	Peak RCS pressure occurs	8.0
	Initiation of steam release from steam generator safety valves	8.5
D.2. Without pressuriser spray, maximum reactivity feedback, without offsite power available	Turbine trip; loss of main feedwater	0.0
	Offsite power lost, reactor coolant pumps begin coasting down	3.0
	Low reactor coolant pump speed reactor trip setpoint reached	3.50
	Rods begin to drop	4.15
	Peak RCS pressure occurs	5.8
	Initiation of steam release from steam generator safety valves	10.4

Table 9.2-1 (Sheet 5 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
II.A. Loss of ac power to the plant auxiliaries	Offsite ac power is lost, feedwater is lost, RCPs begin to coast down, turbine trip	0.0
	RCP speed-low reactor trip set point is reached	0.5
	Rods begin to drop	1.3
	Pressuriser safety valves open	~ 3.0
	Maximum pressuriser pressure reached	4.0
	Pressuriser safety valves close	~8.0
	Pressuriser safety valves open	49.0 (1)
	Steam generator 1 safety valves open	73.6 (1)
	Steam generator 2 safety valves open	76.0 (1)
	PRHR heat exchanger actuation on low steam generator water level (narrow range coincident with low start up feedwater flow rate)	510.5
	Maximum pressuriser water volume reached	511.0
	PRHR heat exchanger extracted heat matches decay heat	~20000

Note:

1. The pressuriser safety valves cycle open and closed from 49.0 seconds until ~435 seconds. The steam generator safety valves in both Loops 1 and 2 also cycle open and close from approximately 75 seconds, until approximately 2500 seconds. After this time, only the steam generator safety valves for the loop without the PRHR (Loop 2) continued to relieve steam intermittently until ~20,000 seconds.

Table 9.2-1 (Sheet 6 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
III.A. Loss of normal feedwater flow	Feedwater is lost	0.0
	Low-2 steam generator water level (narrow range) reactor trip reached	48.2
	Rods begin to drop	50.2
	Minimum DNBR is reached	51.0
	PRHR heat exchanger actuation on Low-2 steam generator water level (narrow range coincident with Low-2 start up feedwater flow rate)	230.2
	Cold leg temperature reaches Low-2 T_{cold} setpoint	1570.8
	High-2 pressuriser level setpoint reached	1576.0
	Reactor coolant pump trip on Low-2 T_{cold} "S" signal	1577.6
	Steam line isolation on Low-2 T_{cold} "S" signal	1582.9
	Core makeup tank actuation on Low-2 T_{cold} "S" signal	1587.9
	The chemical and volume control system is isolated on "S" signal and pressuriser water level – High-1	1608.4
	Pressuriser safety valves open	2080.0
	High-3 pressuriser level setpoint reached	3128.0
	Operator opens reactor vessel head vent (at least 30 minutes after High-2 pressuriser level setpoint is reached)	4350.0
	Pressuriser safety valves reclose	~4350.0
	Maximum pressuriser water volume reached	5628.0

Table 9.2-1 (Sheet 7 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
III.B. Loss of normal feedwater flow with a consequential loss of ac power	Feedwater is lost	10.0
	Low-2 steam generator water level setpoint is reached	58.2
	Rods begin to drop	60.2
	Minimum DNBR is reached	61.0
	Reactor coolant pump trip due to loss of ac power	68.2
	Steam generator safety valves open	94.3
	Pressuriser safety valves open	~107.0
	PRHR heat exchanger actuation on Low-2 steam generator water level (narrow range coincident with Low-2 startup flow rate)	240.2
	Steam generator safety valves close	~2100.0 (1)
	Pressuriser safety valves close	~2450.0(2)
	PRHR heat extraction matches decay heat addition	~2800.0
	Maximum pressuriser water volume reached	3306.0

Notes:

1. Between 94.3 seconds and 2100 seconds the steam generator safety valves cycle open and closed. After 2100 seconds the steam generator safety valves intermittently relieve steam, but with a relief rate that is minimal and has a negligible effect on the transient.
2. Between approximately 107 seconds and 2450 seconds the pressuriser safety valves cycle open and closed.

Table 9.2-1 (Sheet 8 of 8). DBA Time Sequence Of Events For Incidents Which Result In A Decrease In Heat Removal By The Secondary System

Accident	Event	Time (seconds)
IV. Feedwater system pipe break	Main feedwater flow to both steam generators stops due to interaction between the break and the main feedwater control system	10.0
	Low steam generator water level (narrow range) setpoint reached	60.3
	Rods begin to drop	62.3
	Reverse flow from the faulted steam generator through a full double-ended rupture starts	62.3
	Loss of offsite power	70.3
	Low steam line pressure setpoint is reached	76.7
	Core makeup tank valves fully opened	76.7
	Low steam generator water level (wide range) setpoint reached	81.6
	All steam isolation valves close	88.7
	PRHR heat exchanger actuation on low steam generator water level (wide range)	98.6
	Faulted steam generator empties	122.0
	Intact steam generator safety valves open for the first time	251.7
	Pressuriser safety valves open for the first time	1,718
	PRHR heat exchanger extracted heat matches decay heat	23,990

Table 9.2.3-1. ATWT Time Sequence Of Events For Turbine Trip with PMS CCF

Event	Time (Sec)
Turbine trip	5
Rapid power reduction system drops selected bank of rods to reduce power below 50 percent power	not credited
Turbine bypass start to open in T_{avg} mode	5.4
Pressuriser sprays begins to operate	not credited
CVS control system begins to open letdown valve	not credited
Pressuriser safety valves opens	12.2
SG PORV Loops 1&2 open	43
Pressuriser safety valves closes	63

Table 9.2.6-1 (Sheet 1 of 2). DBA Parameters Used In Evaluating The Radiological Consequences Of A Loss Of Offsite Power

Reactor coolant iodine activity	Initial activity equal to the operating limit for reactor coolant activity of 9.25E6 Bq/kg (0.25 μCi/g) dose equivalent I-131 (see Table 9A-1) with an assumed iodine spike that increases the rate of iodine release from fuel into the coolant (see Table 9A-2) by a factor of 335. Duration of spike is 8 hours.
Reactor coolant noble gas activity	Equal to the operating limit for reactor coolant activity of 2.6E9 Bq/kg (70 μCi/g) dose equivalent Xe-133 (see Table 9A-1)
Reactor coolant alkali metal activity	Design basis activity (see Table 9A-1)
Secondary coolant initial iodine and alkali metal activity	10% of design basis reactor coolant concentrations at maximum equilibrium conditions
Reactor coolant mass	1.684E5 kg (3.713E5 lbm)
Condenser	Not available
Primary to secondary leak rate	0.79(1) kg/min (1.74 lbm/min)
Partition coefficient in steam generators Volatile (iodine) Particulates (iodine, alkali metals)	See Appendix 9A.4 1.0 0.0005
Accident scenario in which startup feedwater is not available Duration of accident Duration of flashing Steam release rate Minimum secondary coolant mass	 1.5 hr 1.5 hr 54.44 kg/sec (120 lbm/sec) 3.4E4 kg (7.5E4 lbm)

Table 9.2.6-1 (Sheet 2 of 2). DBA Parameters Used In Evaluating The Radiological Consequences Of A Loss Of Offsite Power

Accident scenario in which startup feedwater is available Duration of accident Duration of flashing Steam release rate Minimum secondary coolant mass	 8.0 hr Not applicable 27.22 kg/sec (60 lbm/sec) 1.32E5 kg (2.92E5 lbm)
Volatile iodine fraction With primary-to-secondary flashing Without primary-to-secondary flashing	See Appendix 9A.5.3 0.002 0.001
Offsite atmospheric dispersion factors	See Table 9A-5
Control room modelling	See Appendix 9A

Notes:
1. Equivalent to 567.8 L (150 gal) per day per SG cooled liquid at 1000 kg/m^3 (62.4 lbm/ft^3).

Table 9.2.6-2. DBA Loss Of Offsite Power Technical Specifications Used In Dose Analysis

Limit or Condition	Tech Spec Identification and Notes
Primary-to-secondary leakage rate	3.4.7 leak rate to be < 567.8 L (150 gal) per day for any one SG
Primary coolant specific activity	3.4.10 dose equivalent specific activity to be < 9.25E6 Bq/kg (0.25 µCi/g) for I-131 and < 2.6E9 Bq/kg (70 µCi/g) for Xe-133
Secondary coolant specific activity	3.7.4 dose equivalent I-131 specific activity to be < 9.25E5 Bq/kg (0.025 µCi/g)

Table 9.2.7-1. ATWT Time Sequence Of Events For LONF With RCCA Mechanical CCF

Event	Time (Sec.)
Loss of Feedwater	5
Pressuriser sprays begins to operate	12
CVS control system begins to open letdown valve	not credited
Narrow Range Low SG Level reactor trip PMS setpoint reached in loops 1&2 generates turbine trip signal, clears turbine bypass block and switch turbine bypass to pressure mode	51.7
Startup Feedwater Pump actuation	not credited
Turbine is tripped	58.7
Turbine bypass start to open	61.4
Pressuriser safety valves open	62.9
SG PORVs and then safety valves open in loops 1 & 2	63.6
Wide range Low SG Level setpoint reached in loops 1& 2, generates signals for PMS PRHR actuation, DAS CMT actuation, DAS RCP trip	71.3
RCPs are tripped on DAS WR Low SG1+SG2 level signal (1)	78.8
PRHR valves full flow on PMS wide range Low SG level signal (1)	80.8
CMT valves full flow on DAS wide range Low SG1+SG2 level signal (1)	85.8
SG safety valves and then SG PORVs close, in loops 1 & 2	86.6
Low Steam Pressure setpoint 4.14 MPa (600 psi) reached	87.15
Pressuriser fills water solid	88.2
Steam line isolation on Low Steam Pressure	99.2
Peak RCS pressure 19.93 MPa (2890 psia) reached	111.8
Pressuriser safety valves close	183
Saturation reached in loop 2 cold leg	184
Subcooling reached in loop 2 cold leg	295

Note:
1. PRHR, CMT and RCP trip actuation delays include instrumentation and control delays (both – inherent and intentional) and valves alignment.

Table 9.2.7-2. Diverse Core Cooling For LONF With PMS CCF

Event	Time (Sec.)
Loss of Feedwater	0
Turbine trip (low SG WR level)	62
CMT actuated (low SG WR level)	62
RCP trip (low SG WR level)	62
Pressuriser safety valves open	65
Reactor trip (low SG WR level + 5 s)	67
SG safety valves open	80
SG safety valves close	710
ADS stage 1 manual actuation	2400
Pressuriser safety valves close	2415
Accumulator injection start	2520
Peak clad temperature 847°C (1556°F)	2608
Accumulator empty	2890
ADS stage 4 manual actuation	3300
IRWST inject manual actuation	3450

9.3 Decrease in Reactor Coolant System Flow Rate

A number of faults that could result in a decrease in the reactor coolant system flow rate are postulated. The events are discussed in this section. Detailed analyses are presented for the most limiting of the RCS flow decrease events.

9.3.0 Introduction and Overview of the Faults

Decrease in reactor coolant flow as a consequence of RCP failure can be caused by a number of initiating faults that are split into two parts:

- Loss of forced reactor coolant flow (excluding major mechanical pump failure)
    - Partial loss of flow (PLOF)
        - Failure of power supply to the RCP
        - Random failure of pump variable speed controller
        - Flow blockage
        - Pump cavitation during start-up
        - Partial loss of forced reactor coolant flow – maintenance or operator error
    - Complete loss of flow (CLOF)
        - Complete loss of forced reactor coolant flow - maintenance or operator error
        - Common cause failure of pumps – loss of electrical supply
        - Common cause failure of pump bearings due to gas build-up during start-up
        - Loss of component cooling water to RCS pumps either directly, due to operator error or mechanical failure or, indirectly, due to the loss of service water
- Major mechanical failure of a single RCP
    - Pump rotor impinges on stationary member and completely seizes
    - Pump shaft break due to corrosion/pre-existing defect

The behaviour of faults involving a major mechanical failure of a single RCP differs somewhat from the other loss of forced reactor coolant flow faults, because the pump that suffers the major mechanical failure will not coast down. These faults are therefore considered separately.

Reference 9.3-12 lists loss of forced reactor coolant flow (excluding major mechanical pump failure) as a frequent fault based on the frequency of these events being greater than 1E-3/yr. A frequent fault should demonstrate that diverse mitigation is provided. Sections 9.3.1.3 and 9.3.2.3 present the diverse mitigation features for the partial and complete loss of forced reactor coolant flow events and the analyses that demonstrate that the diverse mitigation is adequate for these frequent faults.

A major mechanical failure of a single RCP has an event frequency less than 1E-4/yr (Table 8A-2). This does not qualify as a frequent fault or a cliff edge fault (faults not sufficiently lower than 1E-3/yr as defined in Reference 9.3-12); therefore a diverse safety case is not assessed. This is considered an infrequent event.

Section 9.3 considers these faults in turn. Each fault is first described; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

ATWT analyses presented herein are based on Reference 9.3-10.

9.3.0.1 Loss of Forced Reactor Flow (Excluding Major Mechanical Pump Failure)

Description

There are a number of faults in which reactor coolant flow is lost when one or more RCP coasts down as a result of one of the following pump failures (see also Sections 9.3.1.1 and 9.3.2.1):

- Mechanical failure of a pump[1]
- Electrical failure of a pump
- Loss of power supply to one or more pumps
- Loss of component cooling water to one or more pumps, which causes a pump trip

The loss of forced reactor coolant flow is considered a complete loss of all reactor coolant flow if all four pumps are affected (Fault 1.13.1a) or a partial loss of reactor coolant flow if less than four of the pumps are affected (Fault 1.13.1).

Separate analyses for the complete and partial loss of reactor coolant flow events determine the adequacy of the primary reactor trip setpoints. The complete and partial loss of reactor coolant flow events are analysed individually since there are different PMS reactor trip sensors considered for each event. For the loss of reactor coolant flow events, the low primary coolant flow reactor trip signal and the reactor coolant pump under-speed reactor trip signal can be used to mitigate the transient.

The reactor trip on RCP under-speed is also provided to trip the reactor for an under-frequency condition (i.e., a frequency decay) resulting from frequency disturbances on the power grid. This trip protects the core from under-frequency events if the grid frequency decay rate is less than approximately 5 Hz/s. As part of the resolution to GI-AP1000-FS-03, a complete loss of flow case following an electrical grid frequency perturbation (not only a constant frequency decay) was specifically analysed (Reference 9.3-4). This case is discussed further in Section 9.3.2.

The reactor trip on low primary coolant loop flow is provided to protect against loss of flow conditions that affect only one or two reactor coolant loop cold legs. This function is generated by two-out-of-four, low-flow signals per reactor coolant loop hot leg. Above permissive P10, low flow in either hot leg actuates a reactor trip. Additionally, this trip function would also protect the

[1] Includes initiating events arising from maintenance or operator errors.

core from an under-frequency condition if the grid frequency decay rate is less than approximately 5 Hz/s.

The partial loss of forced reactor coolant flow is discussed in more detail in Section 9.3.1. Section 9.3.2 describes the complete loss of forced reactor coolant flow in more detail.

Initiating Event Frequency[2]

The AP1000 plant PSA gives the IEF for the failure of power supply to the RCPs as 1.7E-2/yr (Table 8A-2). This frequency includes a number of initiating events potentially resulting in a loss of flow; the loss of flow fault also covers other faults with comparable probabilities, such as a loss of component cooling (which would also lead to a consequential loss of flow). This is considered to be a frequent fault.

Design Basis Class

The unmitigated consequences of a loss of reactor coolant flow are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

9.3.0.2 Major Mechanical Failure of a Single Reactor Coolant Pump

Description

There are two faults that can cause a major mechanical failure of single RCP, causing a decrease in RCS flow rate (see also Sections 9.3.3.1 and 9.3.4.1):

- RCP impeller seizure (locked rotor) (Fault 1.13.11)
- RCP shaft break (or coupling failure) (Fault 1.13.12)

For both faults, there is no inertial coastdown of the affected pump, so flow through the single affected reactor coolant loop is rapidly reduced. The reactor trip would occur on a low-flow signal in the affected loop. The initial rate of reduction of reactor coolant flow is greater for the RCP rotor seizure event. However for a RCP shaft break event, the impeller is free to spin in the reverse direction; this results in a lower or negative flow in the reactor coolant loop later in the transient. The locked rotor transient analysis is done conservatively such that it bounds the RCP shaft break event.

The RCP locked rotor event is discussed in more detail in Section 9.3.3. Section 9.3.4 provides a brief discussion on the RCP shaft break event.

[2] As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.

Initiating Event Frequency[3]

Each RCP mechanical failure fault is classified as having a frequency <1.0E-04/yr (Table 8A-2). The summed frequency is therefore <2.0E-04/yr, which makes the fault an infrequent fault.

Design Basis Class

The unmitigated consequences of the major mechanical failure of an RCP are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.3.1 Partial Loss of Forced Reactor Coolant Flow (Fault 1.13.1)

9.3.1.1 Identification of Causes and Accident Description

A partial loss of coolant flow accident can result from a mechanical or an electrical failure of a reactor coolant pump or from a fault in the power supply to the pump or pumps. If the reactor is at power at the time of the event, the immediate effect of the loss of coolant flow is a rapid increase in the coolant temperature. For the AP1000 plant design, there are two potential partial loss of flow scenarios. These scenarios include the coast down of one reactor coolant pump and the coast down of two reactor coolant pumps in diametrically opposite loops. Although both scenarios are analysed, the loss of two reactor coolant pumps bounds the loss of one pump since it results in a more severe flow coast down. Thus, the two pump partial loss of flow is used as the basis for the discussion within this section.

Normal power for the pumps is supplied through four busses connected to the generator. When a generator trip occurs, the busses are supplied from offsite power and the pumps continue to operate.

Protection against this event is provided by the Low-2 primary coolant flow reactor trip signal, which is actuated by two-out-of-four low-flow signals. Above permissive P10, Low-2 flow in either hot leg actuates a reactor trip (see Section 19.2).

The effects of a loss of offsite power are considered in evaluating partial loss of forced reactor coolant flow transients. As discussed in Section 9.0.12, the loss of offsite power is considered to be a potential consequence of the event due to disruption of the electrical grid following a turbine trip during the event. A delay of 3 seconds is assumed between the turbine trip and the loss of offsite power. In addition, turbine trip occurs 5 seconds following a reactor trip condition being reached. This delay on turbine trip is a feature of the AP1000 reactor trip system. The primary effect of the loss of offsite power is to cause the remaining operating reactor coolant pumps to coast down. However, since the loss of offsite power would occur no earlier than 8 seconds into the event, it is well beyond the critical time frame of interest for the partial loss of flow events (i.e., time of rod insertion). Thus, it is not explicitly modelled in the analysis.

[3] As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorization of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.

9.3.1.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect to RCS/MSS pressure criteria, therefore, these limits are not explicitly confirmed for this event. Also, pressuriser filling is not challenged for this event and is not explicitly confirmed.

9.3.1.2.1 DBA Method of Analysis

This transient is analysed using three computer codes. First, the LOFTRAN code (References 9.3-1 and 9.3-8) is used to calculate the core flow during the transient based on the input loop flows, the nuclear power transient, and the primary system pressure and temperature transients. The FACTRAN code (Reference 9.3-2) or the VIPRE-01 fuel rod model (Reference 9.3-7), which is equivalent to FACTRAN, is then used to calculate the heat flux transient based on the nuclear power and flow from LOFTRAN. Finally, the VIPRE-01 code is used to calculate the DNBR during the transient, based on the heat flux from FACTRAN and the flow from LOFTRAN (or directly from LOFTRAN statepoints if the the transient VIPRE-01 method is used). The calculated DNBR transient represents the minimum of the typical cell or the thimble cell. The objective of the analysis is to demonstrate that the DNBR criterion is met.

Initial Conditions

Initial reactor power, pressuriser pressure, and reactor coolant system temperature are assumed to be at their nominal values. Uncertainties in initial conditions are statistically accounted for in the DNBR limit, as described in WCAP-11397-P-A (Reference 9.3-5).

Plant characteristics and initial conditions assumed in this analysis are further discussed in Section 9.0.2.

A loss of forced reactor coolant flow at full power produces the greatest heat-up in the reactor core, placing the greatest demand on the protection systems and minimising the DNBR. Therefore, the partial loss of reactor coolant flow event during Mode 1 option at full power is the limiting condition.

Reactivity Coefficients

The reactivity feedback parameters are chosen to maximize the energy transferred to the primary coolant during the flow coastdown. A most-negative Doppler-only power coefficient (see Figure 9.0-3) is applied to maximize the positive reactivity addition during the reactor trip and rod motion, which acts to slow the rate of power reduction; the equivalent total integrated Doppler reactivity from 0 to 100-percent power is 0.016 Δk. As there is an initial heatup due to the reduction in RCS flow, a least-negative (minimum feedback) moderator temperature coefficient is most conservative. Therefore, a constant moderator density coefficient of 0.0 $\Delta k/g/cc$ is modelled. Finally, a curve of trip reactivity versus time based on a 2.7-second rod cluster control assembly insertion time to the dashpot is applied (see Section 9.0.6).

Flow Coastdowns

Conservative flow coastdowns are used to simulate the transient. The flow coastdowns are calculated externally to the LOFTRAN code using the COAST computer code which is described in Section 9.0.9.5.

9.3.1.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The diverse core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, and pressuriser SVs. The PMS provides the following:

- RT on Low-2 RCS flow, one out of two loops
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.3.1.2.3 DBA Results

The calculated sequence of events for the case analysed is shown in Table 9.3-1.

Figures 9.3.1-1 through 9.3.1-6 show the transient response for the loss of two reactor coolant pumps with offsite power available. Figure 9.3.1-6 demonstrates that the DNBR is always greater than the safety analysis limit value, which demonstrates that the DNB design basis is met. The DNB design basis is described in Section 22.7.1.1.

The affected reactor coolant pumps coast down, and the core flow reaches a new equilibrium value. The plant is tripped by the low-flow trip rapidly enough so that the capability of the reactor coolant to remove heat from the fuel rods is not greatly reduced. The average fuel and cladding temperatures do not increase significantly above their initial values. With the reactor tripped, a stable plant condition is attained and plant shutdown may then proceed.

In the event that a loss of offsite power occurs as a consequence of a turbine trip during a partial loss of reactor coolant flow, the DNB design basis continues to be met as discussed in Section 9.3.1.1.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.3.1.3 Diverse Mitigation

In addition to the Class 1 passive systems credited in the DBA, the plant also provides diverse mitigation capability that is able to supply the Category A safety functions for frequent faults. The diverse features are also Class 1 except for the C&I, which is Class 2.

Two different diverse mitigation analyses are discussed in the following subsections. One demonstrates the reactor can be shut down when a CCF prevents control rod insertion. Such an event is defined as an ATWT. The other demonstrates that adequate core cooling can be provided

when a CCF affects the core cooling credited in the DBA. In the diverse core cooling case rod insertion is assumed to occur.

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

Table 9.3-4 summarizes the SSCs credited in these diverse fault assessments. The information provided in Table 9.3-4 is from Reference 9.3-12, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions.

The following sections provide the evaluation and results of the diverse mitigation analysis cases for the partial loss of forced reactor coolant system flow.

9.3.1.3.1 Diverse Mitigation for ATWT

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The analysis documented in this section is performed to bound the following events:

- Partial loss of flow with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Partial loss of flow with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Partial loss of flow with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.3.1.3.1.1 Diverse ATWT Method of Analysis

Partial loss of reactor coolant flow has no potential for RCS overpressurisation and is bounded by loss of normal feedwater analysed in Section 9.2.7 for RCS overpressurisation. This section addresses partial loss of flow ATWT core damage potential.

The partial loss of flow event diverse mitigation analyses assumptions are:

- Plant initial conditions are at the nominal full power values

- The flow coastdown curves and time when reactor trip on low coolant flow in any hot leg is reached are calculated externally using the COAST computer code and input in the LOFTRAN code.

  The only credible cause for the two of four RCPs loss is the loss of electrical power supply at corresponding transformers. Loss of voltage at ZAS-ET-2A causes loss of RCP 1A and 2A; loss of voltage at ZAS-ET-2B causes loss of RCP 1B and 2B. RCPs 1A and 1B take suction from the SG 1 cold plenum, and RCPs 2A and 2B take suction from the SG 2 cold plenum. There is no credible single failure that could cause loss of RCPs 1A and 1B or loss of RCPs 2A and 2B.

- Core kinetics parameters and initial boron concentration are both assumed to be at BOC values.

- MTC is modelled as discussed in Reference 9.3-10.

- Pressuriser pressure and level control systems are assumed to be operable.

- The turbine bypass system is assumed to be operable. The turbine bypass system control logic blocks turbine bypass opening unless there is a sudden decrease in turbine load. The turbine bypass control is set for T_{avg} control prior to a reactor trip signal. When the T_{avg} mode is selected, the turbine bypass valves would be automatically actuated only if either a large rapid turbine load rejection or a turbine trip is detected. After a reactor trip signal is generated in PMS or DAS, the turbine bypass switches to pressure control automatically.

9.3.1.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT, the plant stabilizes at new power and flow conditions; manual operator action would be necessary to end transient. The available SSCs are listed in Table 9.0-14.

- DAS PRHR actuation on High hot leg temperature (T_{hot}) available for possible for 2 of 4 RCP partial loss of flow with RCCA insertion failures only

9.3.1.3.1.3 Diverse ATWT Results

1 of 4 Reactor Coolant Pumps Partial Loss of Flow with a PMS CCF

At the start of the event one RCP is assumed to be tripped. Core power decreases due to the initial increase in coolant average temperature and moderator density feedback results in an equilibrium power value which is equal to the energy removal rate of the turbine system.

The setpoint for the PMS reactor trip on low coolant flow is reached but no PMS action occurs due to the PMS CCF. There are no parameters monitored by DAS which would cause DAS system intervention. To shut down the reactor from these conditions, operator action will be necessary.

Figures 9.3.1-7 to 9.3.1-9 show the event progression.

2 of 4 Reactor Coolant Pumps Partial Loss of Flow with a PMS CCF

At the start of the event, one RCP in each loop is assumed to be tripped. The setpoint for the PMS reactor trip on low reactor coolant pump speed is reached, but no PMS action occurs due to the PMS CCF. Core power decreases due to the initial increase in coolant average temperature and moderator density feedback results in an equilibrium power value, which is equal to the energy removal rate of the turbine system.

The only parameter monitored by DAS that would potentially be available to initiate reactor trip is High T_{hot} in both hot legs. However, due to the fact that turbine continues to absorb steam from steam generators and thus keeps steam pressure relatively low, the primary temperature does not reach the value for High T_{hot} reactor trip. To shut down the reactor from these conditions, operator action will be necessary.

Figures 9.3.1-10 to 9.3.1-12 show the event progression.

1 of 4 RCPs Partial Loss of Flow with a Reactor Trip Breaker CCF

This scenario is very similar to the 1 of 4 RCPs PLOF with a PMS CCF scenario above. The only difference is that after the first PMS reactor trip setpoint is reached the turbine is tripped and turbine bypass control switches to the pressure control mode. Pressuriser safety valves temporarily open for a short time after turbine trip. There are no parameters monitored by DAS which would cause DAS system intervention. To shut down the reactor from these conditions, operator action will be necessary.

The turbine trip and turbine bypass switch to pressure control mode results in higher secondary pressure and higher coolant average temperature comparing to the 1 of 4 RCPs PLOF with PMS CCF scenario. As a result equilibrium power is significantly lower for the reactor trip breaker CCF scenario than for the PMS CCF scenario.

2 of 4 Reactor Coolant Pumps Partial Loss of Flow with a Reactor Trip Breaker CCF

This scenario begins in the same manner as the 2 of 4 RCPs PLOF with PMF CCF scenario above. The difference is that after the first PMS reactor trip setpoint is reached, the turbine is tripped and turbine bypass switches to the pressure control mode.

The turbine trip results in increased secondary pressure and increased RCS temperature and pressure. Pressuriser safety valves temporarily open a short time after turbine trip. Hot-leg temperature increases close to the DAS high hot-leg temperature setpoint. Depending on the time response of the turbine bypass system, the high hot-leg temperature setpoint may be reached which will actuate PRHR and a reactor trip via M-G sets being de-energised.

If the DAS high hot-leg temperature setpoint is not reached, core power would stay at an equilibrium value which is equal to the energy removal rate of the turbine bypass system. The turbine trip and turbine bypass switch to pressure control mode would result in higher secondary pressure and higher coolant average temperature compared to the PMF CCF scenario, and equilibrium power would be significantly lower for the reactor trip breaker CCF scenario than for the PMS CCF scenario.

This section describes a partial loss of flow with a mechanical CCF that prevents rods from inserting. The PMS, DAS and PLS are assumed to be operable, except that RCCAs do not insert into the core on a trip signal.

1 of 4 Reactor Coolant Pumps PLOF with an RCCA Mechanical CCF

Because there are no parameters monitored by DAS that would cause DAS system intervention for 1 of 4 RCPs PLOF, the RCCA mechanical CCF is the same as the reactor trip breaker CCF scenario.

2 of 4 Reactor Coolant Pumps PLOF with an RCCA Mechanical CCF

This scenario is the same as the 2 of 4 RCPs PLOF with reactor trip breaker CCF scenario, except that for the case when DAS high hot-leg temperature setpoint is reached, only PRHR will be actuated but RCCAs will not be dropped into the core. Actuation of PRHR will increase energy removal from the primary system. However, since the turbine is already tripped, core power will stay at an equilibrium value, which is equal to the energy removal rate of the turbine bypass system and the PRHR. This equilibrium power is significantly lower for the RCCA mechanical CCF scenario than for the PMS CCF scenario.

Departure from Nucleate Boiling Ratio Evaluation

The above scenarios were analysed for DNB using the WRB−2M correlation. DNB calculations were done using design power shape including design $F_{\Delta H}$ and flow maldistribution factors. Figure 9.3.1-13 shows WRB-2M DNBR. As can be seen from the figure, there is significant margin to the DNBR limit during PLOF ATWT scenarios.

9.3.1.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.3.1.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric

dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.3.1.5 As Low as Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

The diverse mitigation functions, including other Class 1 safety functions and the DAS function, which is Class 2, is also shown by analysis to meet the corresponding requirements for the partial loss of forced reactor coolant flow. See Reference 9.3-12 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy/diversity that is provided by the Class 2 DiD systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- Pressuriser spray and pressuriser auxiliary spray for RCS pressure control
- SFW with steam dump for short-term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal
- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment and actuation automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (See Section 9.1.4.5). However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

As discussed in Chapter 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000 development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.3.1.6 Conclusions

The DB analysis shows that for the partial loss of reactor coolant flow, the DNBR does not decrease below the safety analysis limit value at any time during the transient, which demonstrates that the DNB design basis is met. The DNB design basis is described in Section 22.7.1.1.

The ATWT acceptance criteria are met for this event. This event was not explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.3-14. However, the evaluation conducted to closeout FS-03 demonstrated with a subset of events (Reference 9.3-4) that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the subset of events confirmed the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.3.2 Complete Loss of Forced Reactor Coolant Flow (Fault 1.13.1a)

9.3.2.1 Identification of Causes and Accident Description

A complete loss of flow accident may result from a simultaneous loss of electrical supplies to the reactor coolant pumps. If the reactor is at power at the time of the event, the immediate effect of a loss of coolant flow is a rapid increase in the coolant temperature. Electric power for the reactor coolant pumps is normally supplied through busses, connected to the generator through the unit auxiliary transformers. When a generator trip occurs, the busses receive power from external power lines and the pumps continue to supply coolant flow to the core.

The following signals provide protection against this event:

- Reactor coolant pump under-speed
- Low primary coolant loop flow

The reactor trip on reactor coolant pump under-speed protects against conditions that can cause a loss of voltage to two-out-of-four reactor coolant pumps. This function is blocked below approximately 10-percent power (permissive P10). The reactor trip on reactor coolant pump under-speed protects against conditions that can cause a loss of voltage to two-out-of-four reactor coolant pumps. This function is blocked below approximately 10-percent power (permissive P10). The reactor trip on reactor coolant pump under-speed also protects against a frequency decay condition resulting from frequency disturbances on the power grid, as long as the grid frequency decay rate is less than approximately 5 hertz per second. WCAP-8424-R1 (Reference 9.3-3), provides analyses of grid frequency disturbances and the resulting protection requirements that are applicable to the AP1000 plant design. As part of addressing GI-AP1000-FS-03, a complete loss of flow was postulated to occur following a grid frequency perturbation (not just grid frequency decay) in UKP-SSAR-GLR-002 (Reference 9.3-4).

9.3.2.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and

- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect to RCS/MSS pressure criteria, therefore, these limits are not explicitly confirmed for this event. Also, pressuriser filling is not challenged for this event and is not explicitly confirmed.

9.3.2.2.1 DBA Method of Analysis

The complete loss of flow transient is analysed for a loss of power to four reactor coolant pumps.

For the scenario of a complete loss of voltage, which results in all the reactor coolant pumps coasting down, the method of analysis and the assumptions made regarding initial operating conditions and reactivity coefficients are identical to those discussed in Section 9.3.1, with two exceptions. Following the loss of power supply to all pumps at power, a reactor trip is actuated by the reactor coolant pump under-speed trip instead of the low primary coolant flow trip. Also, rather than the bounding value of 0.0 $\Delta k/g/cc$, a less limiting, yet still conservative, moderator density coefficient (MDC) curve (MDC as a function of coolant density) was modelled. Due to all pumps coasting down, a rod drop time of 2.3 seconds is assumed (see Section 9.0.6).

For the scenario of a complete loss of flow following a grid frequency perturbation, the frequency disturbance was initiated at the same initial conditions as the loss of voltage case, above. However, the frequency perturbation caused a slightly more limiting power condition at the time the reactor coolant pumps were assumed to coast down, primarily due to an increase in main feedwater pump speed caused by a grid overfrequency fault and the associated reactivity-induced power increase. The most limiting grid frequency perturbation case assumed a grid overfrequency with operable variable frequency drives on the reactor coolant pumps. This case causes an increase in feedwater pump speed, but with RCPs remaining at nominal speed. The limiting case also modelled automatic rod control, and the coastdown of all four RCPs was assumed to occur at the peak power level caused by rod control overshoot. This case is described in detail in UKP-SSAR-GSC-002 (Reference 9.3-4).

A complete loss of forced primary coolant flow can also result from a constant decay in the reactor coolant pump motor supply frequency. However, the results of the complete loss of voltage scenario (i.e., free spinning pump coastdown) bound the results of the complete loss of flow initiated by a frequency decay of up to 5 hertz per second. This is due to the reactor coolant pump design, which initially (during the critical time frame of the transient) has a more rapid coastdown as a free spinning pump than for an electrical frequency decay.

The results of the complete loss of voltage case and the grid frequency perturbation case are presented in Section 9.3.2.2.3.

9.3.2.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DB analysis ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, and pressuriser SVs. The PMS provides the following:

- RT on Low-2 RCP Speed (requires 2 of 4 RCPs underspeed)

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.3.2.2.3 DBA Results

Figures 9.3.2-1 through 9.3.2-6 show the transient response for the complete loss of voltage to all four reactor coolant pumps. Figures 9.3.2-7 through 9.3.2-12 show the transient response for the complete loss of flow following a grid frequency perturbation. The results of both cases are very similar. In both cases, the reactor is tripped on the reactor coolant pump under-speed signal. Figures 9.3.2-6 and 9.3.2-12 demonstrate that the DNBR is always greater than the safety analysis limit value, which demonstrates that the DNB design basis is met. The DNB design basis is described in Section 22.7.1.1.

The calculated sequence of events for the two cases are shown in Table 9.3-1. With respect to the DNB concerns, the event is essentially over shortly after reactor trip. However, if the event was extended beyond the time frame analysed for DNB, the reactor coolant pumps continue to coast down, and natural circulation flow would be established, as demonstrated in Section 9.2.6. With the reactor tripped, a stable plant condition is attained and plant shutdown may then proceed.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.3.2.3 Diverse Mitigation

In addition to the passive systems credited in the DBA, the plant also has a diverse mitigation capability that is able to supply the Category A safety functions for frequent faults. For this frequent fault event the diverse features are also Class 1 except for the C&I, which is Class. 2

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

Table 9.3-7 summarizes the SSCs from this fault assessment. As this is a frequent fault, a diverse means of providing the Category A safety functions is provided. The information provided in Table 9.3-7 is from Reference 9.3-12, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions. Table 9.3-8 provides the operator actions utilized in the diverse safety case.

The following sections provide the evaluation and results of the diverse mitigation analysis cases for the complete loss of forced reactor coolant system flow.

9.3.2.3.1 Diverse Mitigation for ATWT

The AP1000 design has several automatic RCP trip features that introduce mechanisms for complete loss of RC forced circulation that do not exist on standard Westinghouse PWRs. For ATWT consideration, that is a safety benefit, as a flow coastdown will cause a rapid reduction in core power because of moderator reactivity feedback.

A number of cases were considered to address different potential CCFs that can affect the PMS and its ability to insert RCCAs. The analysis documented in this section is performed to bound the following events:

- Complete loss of flow with a PMS CCF – The CCF prevents all PMS reactor trips signals and engineered safeguards features signals. The DAS is assumed to be completely operable. Offsite power and turbine bypass are also assumed available.

- Complete loss of flow with a PMS reactor trip breaker CCF - This failure prevents the PMS from inserting the rods; however, PMS logic continues to function, and all engineered safeguards features signals are operable. DAS is completely operable, including its capability to drop rods. Offsite power and turbine bypass are also assumed to be available.

- Complete loss of flow with a RCCA mechanical CCF - The PMS, DAS, and control systems are assumed to be operable except that RCCAs do not insert into the core on a trip signal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

An ATWT loss of RCS flow does not have the potential to cause RCS overpressure. In fact, it provides defence against overpressurisation since it causes [ ]
For that reason, the analysis in this section focuses on the potential for core damage (i.e., core DNB). Further, long-term recovery from a loss of flow ATWT is covered by the analysis and discussion of the loss of feedwater event in Section 9.2.7.5.

This section covers the evaluation of the various scenarios caused by different initiating events or with differing assumed failures.

9.3.1.3.1.1 Diverse ATWT Method of Analysis

The causes for trip of all RCPs are:

- Loss of all ac power to the station auxiliaries

- PMS CMT actuation (on Low-2 pressuriser water level, low wide range water level in both SGs coincident with High-1 T_{hot}, First Stage ADS actuation, or manual)

- DAS CMT actuation (Low wide range water level in both SGs, Low pressuriser water level, or manual)

- High RCP bearing water temperature in any RCP

These are evaluated in the following sections.

Bounding Loss of Reactor Coolant System Flow Scenarios

Many different scenarios can be considered. To limit the large number of cases to be addressed, a small number of limiting DNB scenarios can be constructed that can be shown to bound the core consequences of other scenarios. For the purposes of this report, two bounding scenarios are considered for DNB concerns. Other scenarios are evaluated and are shown to be less limiting for DNB, as well as shown to be covered by other analyses for other limits and long-term recovery. The two bounding scenarios are:

- Case 1: Simultaneous Trip of all RCPs from Initial Steady-State
- Case 2: Trip of all RCPs from an Elevated RCS Temperature

9.3.2.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT, the presented ATWT cases only credit turbine trip from DAS and stabilize at a new power and flow condition; a manual operator action would be required to terminate the event. The available Class 1 SSCs are listed in Table 9.0-14. DNB limits are met for this stabilised transient condition. DAS provides the following:

- Turbine trip on High hot leg temperature (T_{hot})

9.3.2.3.1.3 Diverse ATWT Results

Case 1: Simultaneous Trip of all RCPs from Initial Steady-State

Simultaneous trip of all RCPs is the initiating event with failure of control rods to insert (PMS and PLS and DAS failure) and failure of all other PMS and DAS protective actions except turbine trip on DAS high T_{hot}. The NSSS would come to a quasi-steady-state condition, with core power equal to steam load, natural circulation being driven by core power generation, and reactivity balance (all reactivity contributors summing to zero). The exact power, flow, and steam pressure will depend upon reactivity coefficients and plant conditions such as turbine bypass pressure control settings. This quasi-steady-state power will continue until some automatic or manual actuation occurs, or SG fluid inventory could no longer sustain the core power level. If adequate feedwater cannot be sustained, then the event becomes a loss of feedwater ATWT initiated from a low initial power level. Long-term recovery is covered by the analysis and discussion of the loss of feedwater ATWT event in Section 9.2.7.5. The short-term event is covered by the analysis discussed below.

Case 1 is analysed at BOC because at end of cycle (EOC) the stronger negative moderator feedback causes a much faster core power reduction than at BOC conditions.

The BOC system transient for this case is shown on Figures 9.3.2-13 to 9.3.2-16. As shown in Figures 9.3.2-13 and 9.3.2-14, the core nuclear power and heat flux decrease rapidly with the loss of flow, even though the moderator feedback is minimised at BOC. At 20 seconds, the bulk core exit begins to boil, causing the dip and small oscillations shown in Figure 9.3.2-14 at that time. (This particular oscillation is probably due to the single thermal hydraulic channel and use of the core density difference reactivity coefficient described in Reference 9.3-10). Hot-leg temperature rises rapidly, as shown in Figure 9.3.2-15, causing the DAS T_{hot} circuit to trip the turbine and reactor and actuate PRHR. (The T_{hot} setpoint was taken as 343.3°C (650°F) in this analysis, but reactor trip and PRHR actuation were not modelled.)

These conditions were then analysed for DNB using the standard Westinghouse methodology for safety analyses (i.e., design power shape including design $F_{\Delta h}$ and flow maldistribution factors) with no credit for either axial or radial power shape change during the flow coastdown. This is very conservative, as the heating of coolant in the hot channels and top of the core changes the power shape and substantially increases margins to DNB.

Two DNB correlations were considered: WRB-2M and WLOP. The WRB-2M correlation is valid up to [ ] but high steam quality may exceed its correlation limits. The WRB-2M DNB calculations did not credit any pressures above this value. However, the quality limit was exceeded about 9 seconds after the RCP trip. The WLOP correlation is valid for high quality but has an upper pressure limit that does not extend to normal operating pressure. Therefore, the DNB calculation for WLOP assumed [ ] instead of the actual system pressure. Since the critical heat flux increases with pressure (other variables being equal), the calculated DNB ratio is conservatively underestimated when the system pressure is above the correlation limit. The DNB ratios for those two correlations are shown in Figure 9.3.2-17.

The AP1000 design basis for DNB prevention uses the WRB-2M correlation. The correlation meets the 95/95 criterion for DNBR. Its use is discussed in Section 22.7.1.1. As discussed in that section, the 95/95 DNBR limit when used with the RTDP is [ ]. The RTDP includes uncertainty for flow, power, temperature, and pressure (and those uncertainties need not be included in an ATWT analysis). The 95/95 DNB ratio limit for WLOP is [ ].

Both correlations indicate the minimum DNB ratio occurs relatively early in the flow coast down. Although the WRB-2M correlation quality limit is exceeded in the later part of the flow coastdown, the WLOP correlation demonstrates that the DNB ratio is improving and continues to improve after that time.

Figure 9.3.2-18 displays the core reactivity, as calculated by LOFTRAN during the transient using the BOC reactivity coefficients described in Reference 9.3-10. The neutronics code (ANC) statepoint reactivity calculation for the transient conditions is also calculated by LOFTRAN. These were calculated using the same methodology that Westinghouse uses for steam line break analysis (see Section 9.1). That is, LOFTRAN calculated inlet temperature, flow, pressure, and total core power at various times in the transient were input into ANC and the reactivity calculated. The ANC calculation of reactivity is always significantly less than the reactivity calculated by LOFTRAN. This verifies that the reactivity coefficients used by LOFTRAN are conservative; a more exact analysis would have shown a faster drop in core power.

Case 2: Trip of all RCPs from an Elevated RCS Temperature

This bounding case assumed a loss of feedwater (which causes some initial RCS heatup and core power reduction), followed by partial SG dryout, rapid RCS heating, actuation of turbine trip and RCP trip on DAS low SG water level, and failure of all other PMS, PLS, and DAS functions. This scenario differs from Case 1 only because the loss of RCS flow begins from a higher inlet temperature and lower power. The specific analysed scenario was a very conservative total loss of feedwater with early turbine trip, delayed RCP trip, and no PRHR or CMT actuation or reactor trip. These assumptions tended to drive the core inlet temperature quite high before RCP trip.

The system transient for this case is shown on Figures 9.3.2-23 to 9.3.2-25. These cases were analysed for DNB with the same very conservative methodology as described for Case 1 above; i.e., design power distribution without credit for radial or axial beneficial improvement

in the power shape during the transient, and no credit for pressure above the correlation limit. The DNB ratio is shown in Figure 9.3.2-26 for both the WRB-2M correlation (with pressures above [ ] not credited) and the WLOP correlation (with calculations based on [ ]. The WRB-2M quality limit is not exceeded for this transient.

Figure 9.3.2-27 displays the core reactivity, as calculated by LOFTRAN during the transient for Case 2. Similar to Case 1, the ANC calculation of reactivity is always less than the reactivity calculated by LOFTRAN. This verifies that the reactivity coefficients used by LOFTRAN are conservative; a more exact analysis would have shown a faster drop in core power.

As noted previously, the loss of flow ATWT is bounded by the loss of feedwater ATWT event for peak RCS pressure concerns. Long-term recovery from a loss of flow ATWT is covered by the analysis and discussion of the loss of feedwater event in Section 9.2.7.5

9.3.2.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.3.2.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.3.2.5 As Low as Reasonably Practicable Assessment

Refer to the ALARP discussion in Section 9.3.1.5

9.3.2.6 Conclusions

The DB analysis demonstrates that for the complete loss of forced reactor coolant flow, the DNBR does not decrease below the safety analysis limit value at any time during the transient, which demonstrates that the DNB design basis is met. The DNB design basis is described in Section 22.7.1.1.

The ATWT acceptance criteria are met for this event.

This event was not explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.3-14. However, the evaluation conducted to closeout FS-03 demonstrated with a subset of events (Reference 9.3-4) that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the subset of events confirmed the change in design reference point would not invalidate the conclusions presented for this event.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks has been reduced to be ALARP.

9.3.3 Reactor Coolant Pump Shaft Seizure (Locked Rotor) (Fault 1.13.11)

9.3.3.1 Identification of Causes and Accident Description

The accident postulated is an instantaneous seizure of a reactor coolant pump rotor. Flow through the affected reactor coolant loop is rapidly reduced, leading to a reactor trip on a low-flow signal.

Following the reactor trip, heat stored in the fuel rods continues to be transferred to the coolant, causing the coolant temperature to increase and expand. At the same time, heat transfer to the shell side of the steam generator in the faulted loop is reduced because: 1) the reduced flow results in a decreased tube-side film coefficient, and 2) the reactor coolant in the tubes cools down while the shell-side temperature increases. (Consistent with the AP1000 design, the peak pressure and fuel rod thermal analyses assume a 5-second delay in turbine trip following reactor trip.) The rapid expansion of the coolant in the reactor core, combined with reduced heat transfer in the steam generators, causes an insurge into the pressuriser and a pressure increase throughout the reactor coolant system. The insurge into the pressuriser compresses the steam volume, actuates the automatic spray system, and opens the pressuriser safety valves, in that sequence. For conservatism, the pressure-reducing effect of the spray is not included in the analysis.

9.3.3.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the protection and safety monitoring system to detect and mitigate the fault and show that the safety criteria are satisfied including:

- The RCS pressure criterion is met,
- The percentage of fuel rods-in-DNB are confirmed to be bounded by failed rod assumed for radiological dose evaluation, and
- Core coolability is demonstrated by confirming that limits for peak cladding temperature and zirconium-water reaction are met.

It is noted that transient secondary system transient pressure for this event is bounded results for the turbine trip DB analysis of Section 9.2.3 and, therefore, need not considered herein.

Some fuel damage may occur as a consequence of infrequent faults, such as the locked rotor accident. The acceptability of this fuel damage is judged by the radiological consequences.

9.3.3.2.1 DBA Method of Analysis

Two digital computer codes are used to analyse this transient. The LOFTRAN code (References 9.3-1 and 9.3-8) calculates the resulting core flow transient following the pump seizure and the nuclear power following reactor trip. This code is also used to determine the peak pressure. The thermal behaviour of the fuel located at the core hot spot is investigated by using the FACTRAN code (Reference 9.3-2) used for the presented DBA or the VIPRE-01 fuel rod model (Reference 9.3-7), which is equivalent to FACTRAN. This fuel thermal calculation uses the core flow and the nuclear power calculated by LOFTRAN. The FACTRAN code includes a film-boiling heat transfer coefficient.

At the beginning of the postulated locked rotor accident (at the time the shaft in one of the reactor coolant pumps is assumed to seize), the plant is assumed to be in operation under the most adverse steady-state operating conditions, that is, maximum steady-state thermal power, maximum steady-state pressure, and maximum steady-state coolant average temperature. Plant characteristics and initial conditions are further discussed in Section 9.0.2. The accident is evaluated for both cases with and without offsite power available. For the case without offsite power available, power is lost to the unaffected pumps at 3.0 seconds following turbine/generator trip. Turbine trip occurs 5.0 seconds following a reactor trip condition being reached. This delay on turbine trip is a feature of the AP1000 reactor trip system.

For the peak pressure evaluation, the initial pressure is conservatively estimated as 0.345 MPa (50 psi) above nominal pressure (15.513 MPa [2250 psia]), which allows for errors in the pressuriser pressure measurement and control channels. This is done to obtain the highest possible rise in the coolant pressure during the transient. To obtain the maximum pressure in the primary side, conservatively high loop pressure drops are added to the calculated pressuriser pressure.

Plant systems and equipment available to mitigate the effects of the accident are discussed in Section 9.0.4 and listed in Table 9.0-10. No single active failure in any of these systems or equipment adversely affects the consequences of the accident.

9.3.3.2.1.1 Evaluation of the Pressure Transient and Fuel Rod Thermal Design Transient

After pump seizure, the neutron flux is rapidly reduced by control rod insertion. Rod motion is assumed to begin 1.45 seconds after the flow in the affected loop reaches the reactor trip setpoint. No credit is taken for the pressure-reducing effect of the pressuriser spray, steam dump, or controlled feedwater flow after plant trip. Although these operations are expected to result in a lower peak reactor coolant system pressure, an additional conservatism is provided by ignoring their effect.

The pressuriser safety valves are fully open at 17.75 MPa (2575 psia). Their capacity for steam relief is described in Section 17.3.2.

For this accident, an evaluation of the consequences with respect to fuel rod thermal transients is performed. Results obtained from analysis of this "hot spot" condition represent the upper limit with respect to cladding temperature and zirconium-water reaction.

In the evaluation, the rod power at the hot spot is conservatively assumed to be 3 times the average rod power (that is, $F_Q = 3.0$) at the initial core power level.

9.3.3.2.1.2 Evaluation of Departure from Nucleate Boiling in Core During Accident

An analysis is performed to determine the percentage of fuel rods that experience DNB. The percentage is determined to be less than the limit value used for the fraction of fuel rods that are predicted to experience a DNB in the radiological consequences calculations reported in Section 9.3.3.4.

9.3.3.2.1.3 Film-Boiling Coefficient

The film-boiling coefficient is calculated in the FACTRAN code (Reference 9.3-2) using the Bishop-Sandberg-Tong film-boiling correlation. The fluid properties are evaluated at film temperature (average between wall and bulk temperatures). The program calculates the film coefficient at every time step, based upon the actual heat transfer conditions at the time. The nuclear power, system pressure, bulk density, and mass flow rate as a function of time are used as program input.

For this analysis, the initial values of the pressure and the bulk density are used throughout the transient because they are the most conservative with respect to cladding temperature response. For conservatism, DNB is assumed to start at the beginning of the accident.

9.3.3.2.1.4 Fuel Cladding Gap Coefficient

The magnitude and time dependence of the heat transfer coefficient between fuel and cladding (gap coefficient) have a pronounced influence on the thermal results. The larger the value of the gap coefficient, the more heat is transferred between the pellet and the cladding. Based on investigations on the effect of the gap coefficient upon the maximum cladding temperature during the transient, the gap coefficient is assumed to increase from a steady-state value consistent with the initial fuel temperature to 56.8 kW/m^2-°C (10,000 Btu/h-ft^2-°F) at the initiation of the transient. Thus, the large amount of energy stored in the fuel because of the small initial value of the gap coefficient is released to the cladding at the initiation of the transient.

9.3.3.2.1.5 Zirconium-Steam Reaction

The zirconium-steam reaction can become significant above a cladding temperature of 982.2°C (1800°F). The Baker-Just parabolic rate equation is used to define the rate of the zirconium-steam reaction:

$$\frac{d(w^2)}{dt} = 33.3 \times 10^6 \exp\left(-\frac{45{,}500}{1.986\,T}\right)$$

where:

w = amount reacted (mg/cm^2)

t = time (s)

T = temperature (Kelvin)

The reaction heat is 6322 kJ/kg (1510 cal/g)

The effect of the zirconium-steam reaction is included in the calculation of the hot spot cladding temperature transient.

9.3.3.2.2 DBA Credited SSCs

For the DB analysis, all the claimed SSCs are Class 1. The available Class 1 SSCs are listed in Table 9.0-10. The presented DB analysis ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and SG relief valves. The PMS provides the following:

- RT on Low-2 RCS flow
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.3.3.2.3 DBA Results

Figures 9.3.3-1 through 9.3.3-7 show the transient results for one locked rotor with four reactor coolant pumps in operation. The without-offsite-power case bounds the results for the case with offsite power. The results of these calculations are also summarized in Table 9.3-2. The peak reactor coolant system pressure reached during the transient is less than that which causes stresses to exceed the faulted condition stress limits of the ASME Code, Section III. Also, the peak cladding surface temperature is considerably less than 1482°C (2700°F). The cladding temperature is conservatively calculated, assuming that DNB occurs at the initiation of the transient. These results represent the most limiting conditions with respect to the locked rotor event or the pump shaft break.

The calculated sequence of events for the case analysed is shown in Table 9.3-1. With the reactor tripped, a stable plant condition is eventually attained. Normal plant shutdown may then proceed.

9.3.3.3 Diverse Mitigation

Diverse mitigation for this event is not required as it is an infrequent fault classified as DB1.

9.3.3.4 Radiological Consequences

Design Basis

The evaluation of the radiological consequences of a postulated locked reactor coolant pump rotor accident assumes that the reactor has been operating with a limited number of fuel rods containing cladding defects and that leaking steam generator tubes have resulted in a build-up of activity in the secondary coolant.

A conservative analysis has been performed assuming 10 percent of the rods are damaged such that the activity contained in the fuel-cladding gap is released to the reactor coolant. Activity carried over to the secondary side because of primary-to-secondary leakage is available for release to the environment via the steam line safety valves or the power-operated relief valves. The conservative analysis assumes a loss of offsite power which results in steam releases from the steam generator relief valves.

Two separate accident scenarios are addressed. In the first scenario, it is assumed that the non-safety grade SFW is not available to provide feedwater to the steam generators. In this event, the water level in the steam generators drops, resulting in PRHR actuation. The period of steaming is terminated when the capacity of the PRHR system exceeds the decay heat generation rate.

In the second scenario, it is assumed that SFW is available to maintain water level in the steam generators such that PRHR is not actuated, resulting in a longer period of steaming releases. The period of steaming is terminated when RNS is in service and its capacity exceeds the decay heat generation rate.

9.3.3.4.1 Source Term

The significant radionuclide releases due to the locked rotor accident are the iodines, alkali metals (caesiums, rubidiums) and noble gases. All activity in the fuel rod gap of the damaged fuel is assumed to be released to the coolant. Based on Table 7.3 of Reference 9.3-13, the gap fraction is assumed to be 3 percent of the core inventory for iodines, 10 percent for noble gases, and 4 percent for alkali metals. To address the fact that the failed fuel rods may have been operating at power levels above the core average, the source term is increased by a lead rod radial peaking factor of 1.75 which bounds the COLR limit of 1.72.

Initial reactor coolant and secondary coolant activities are of secondary importance compared to the release of the gap inventory of fission products from the portion of the core assumed to fail because of the accident.

9.3.3.4.2 Release Pathways

The reactor coolant leaking into the steam generators is assumed to mix with the secondary coolant. As steam is released, a portion of the iodine and alkali metal activity in the coolant is released. The fraction of activity released is defined by the reducing conditions within the steam generator. Volatile (elemental) iodines are treated as a direct release from the RCS to the environment. Non-volatile (particulate) iodines and alkali metals are assumed to enter the secondary coolant. Release from the secondary coolant is limited by the assumed moisture carryover. The noble gas activity entering the secondary side is released to the environment. These releases are terminated when the steam releases stop.

9.3.3.4.3 Dose Calculation Models

The models used to calculate offsite and control room doses are provided in Appendix 9A.

9.3.3.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.3-3.

9.3.3.4.5 Doses

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. The highest doses are found to be for the case with SFW available. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 2.8 mSv Worker dose: 11 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.3-12. The Table 9.3-12 values ensure the Target 4 BSL are met.

9.3.3.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements. This event is not a frequent fault and as a result diverse mitigation is not required. Although not required, the AP1000 does have two additional levels of defence as discussed in Section 9.3.1.5 and for the reasons discussed in this section the design is ALARP.

9.3.3.6 Conclusions

The DB analysis demonstrates that for the locked rotor event, the RCS pressure and cladding temperature DNB design bases are met. Fuel failures based on the rods-in-DNB value are confirmed to be less than fuel failures assumed in dose analysis

Radiological consequences are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks has been reduced to be ALARP.

9.3.4 Reactor Coolant Pump Shaft Break (Fault 1.13.12)

9.3.4.1 Identification of Causes and Accident Description

The accident is postulated as an instantaneous failure of a reactor coolant pump shaft. Flow through the affected reactor coolant loop is rapidly reduced, though the initial rate of reduction of coolant flow is greater for the reactor coolant pump rotor seizure event. Reactor trip occurs on a low-flow signal in the affected loop.

Following the reactor trip, heat stored in the fuel rods continues to be transferred to the coolant, causing the coolant to expand. At the same time, heat transfer to the shell side of the steam generator in the faulted loop is reduced because: 1) the reduced flow results in a decreased tube-side film coefficient, and 2) the reactor coolant in the tubes cools down while the shell-side

temperature increases. The rapid expansion of the coolant in the reactor core, combined with reduced heat transfer in the steam generators, causes an insurge into the pressuriser and a pressure increase throughout the reactor coolant system. The insurge into the pressuriser compresses the steam volume, actuates the automatic spray system, and opens the pressuriser safety valves, in that sequence. For conservatism, the pressure-reducing effect of the spray is not included in the analysis.

9.3.4.2 Conclusion

With a failed shaft, the impeller could be free to spin in a reverse direction as opposed to being fixed in position as is the case when a locked rotor occurs. This results in a decrease in the end point (steady-state) core flow. For both the shaft break and locked rotor incidents, reactor trip occurs very early in the transient. In addition, the locked rotor analysis conservatively assumes that DNB occurs at the beginning of the transient. The calculated results presented for the locked rotor analysis bound the reactor coolant pump shaft break event.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks has been reduced to be ALARP.

9.4 Reactivity and Power Distribution Anomalies

A number of faults are postulated that result in reactivity and power distribution anomalies. Reactivity changes could be caused by control rod motion or ejection, boron concentration changes, or addition of cold water to the reactor coolant system. Power distribution changes could be caused by control rod motion, misalignment, or ejection, or by static means such as fuel assembly mislocation. These events are discussed in this section. Analyses are presented for the most limiting of these events.

9.4.0 Introduction and Overview of Faults

Reactivity changes can be caused by a number of initiating faults which are split into two parts:

- Reactivity and power distribution faults (excluding control rod ejection).
    - Uncontrolled rod cluster control assembly bank withdrawal from a subcritical or low-power startup condition
    - Uncontrolled rod cluster control assembly bank withdrawal at power
    - Rod cluster control assembly misalignment due to system malfunction or operator error
    - Inadvertent boron dilution due to controller, operator or mechanical failure of CVS
- Rod ejection faults.
    - Single rod cluster control assembly ejection fault

This section considers these faults in turn. Each fault is first described; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

ATWT analyses presented herein are based on Reference 9.4-20 and supplemented by diversity cases for lower mode accidents from Reference 9.4-23.

9.4.0.1 Reactivity and Power Distribution Faults (Excluding Control Rod Ejection)

Description

A number of transients and accidents could result in an addition of reactivity to the core. These faults are shown below:

- Uncontrolled RCCA bank withdrawal from a subcritical or low-power startup condition (Fault 1.15.1)

- Uncontrolled RCCA bank withdrawal at power (Fault 1.15.4)

- RCCA misalignment as a result of one of the following (Faults 1.15.5, 1.15.5a, and 1.15.5b):

  – One or more dropped RCCAs within the same group
  – Statically misaligned RCCA
  – Uncontrolled withdrawal of a single RCCA

- CVS malfunctions that result in a decrease in the boron concentration in the reactor coolant (Fault 1.15.7)

- Inadvertent loading and operation of a fuel assembly in an improper position (Fault 1.15.10)

An uncontrolled addition of reactivity to the core results in a power excursion. Such a transient can be caused, for example, by a malfunction of the reactor control or rod control systems. This can occur with the reactor subcritical, at hot zero power (HZP), or at power.

Although the reactor is normally brought to power from a subcritical condition by RCCA withdrawal, initial startup procedures with a clean core use boron dilution. The maximum rate of reactivity increase in the case of boron dilution is less than that assumed for the transients caused by reactivity insertion by the control rods.

The neutron flux response to a continuous reactivity insertion is characterised by a fast rise terminated by the reactivity feedback effect of the negative Doppler coefficient. This self-limitation of the power excursion restricts the power during the delay time for protective action. Should a continuous addition of reactivity accident occur, the transient is terminated by the automatic features of the PMS.

RCCA ejection accidents also result in an addition of reactivity to the core but are considered separately, since they place significant demands on additional safety systems.

Initiating Event Frequency[1]

Appendix 8A gives frequencies for various reactivity and power distribution faults as less than 0.01/yr. All these frequencies are conservative for a range of reactivity insertion scenarios, but the one for single RCCA withdrawal is judged to be overly conservative, as it would require multiple failures (either electrical failures or operator errors) to occur. A more realistic frequency is less than 1E-04/yr.

The value of less than 1E-04/yr is estimated based on the following. The probability of open wire (or terminal) failure is 1.6E-08/hr in Reference 9.4-6. The resulting yearly frequency is 1.4E-04. These wire failures would also have to occur coincidently with either a breakdown or an operator disregard of the indications mentioned above, so the frequency is considered to be <1E-04.

[1] As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.

Design Basis Class

The unmitigated consequences of reactivity faults are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the events are in the DB2 class.

9.4.0.2 Rod Ejection Faults

Description

This fault is the ejection of a single RCCA assembly from the reactor core (Fault 1.15.11).

This fault is defined as the mechanical failure of a control rod mechanism pressure housing resulting in the ejection of an RCCA from the core. This results in a rapid positive reactivity insertion with an adverse core power distribution.

In general, the reactor is operated with the RCCAs inserted only far enough to permit load following. This limits the size of the reactivity insertion caused by the RCCA ejection. The axial offset RCCAs are positioned so that the targeted axial offset can be met throughout core life. Reactivity changes caused by core depletion and xenon transients are compensated for by changes in the boron concentration of the primary coolant and mechanical shim rods. Therefore, should an RCCA be ejected from its normal position during high power operation, only a limited reactivity excursion would be expected to occur.

Occasionally, it might be desirable to operate with larger than normal insertions. For this reason, a power control and axial offset rod insertion limit is defined as a function of power level. Operation with the RCCAs above this limit provides adequate shutdown capability and an acceptable power distribution. The position of the RCCAs is continuously indicated in the main control room (MCR). An alarm occurs if a bank of RCCAs approaches its insertion limit or if one RCCA deviates from its bank. Operating instructions require boration at the low-level alarm and emergency boration at the low-low-level alarm.

Initiating Event Frequency

The AP1000 design PSA gives the frequency of control rod ejection events as less than 1.0E-04/yr (Table 8A-2), which makes the fault an infrequent fault.

Design Basis Class

The unmitigated consequences of a rod ejection are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.4.1 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal from a Subcritical or Low-Power Startup Condition (Fault 1.15.1)

9.4.1.1 Identification of Causes and Accident Description

An RCCA withdrawal accident is an uncontrolled addition of reactivity to the reactor core caused by the withdrawal of RCCAs which results in a power excursion. Such a transient can be caused by a malfunction of the reactor control or rod control systems. This can occur with the reactor subcritical, at hot zero power, or at power. The at-power case is discussed in Section 9.4.2.

The reactor may be brought to a critical condition by either RCCA withdrawal or boron dilution. The maximum rate of reactivity increase in the case of boron dilution is less than that assumed in this analysis (see Section 9.4.6).

The RCCA drive mechanisms are grouped into preselected bank configurations. These groups prevent the RCCAs from being automatically withdrawn in other than their respective banks. Power supplied to the banks is controlled such that no more than two banks are withdrawn at the same time and in their proper withdrawal sequence. The RCCA drive mechanisms are the magnetic latch type, and coil actuation is sequenced to provide variable speed travel. The maximum reactivity insertion rate analysed is that occurring with the simultaneous withdrawal of the combination of two sequential RCCA banks having the maximum combined worth at maximum speed.

The neutron flux response to a continuous reactivity insertion is characterized by a fast rise terminated by the reactivity feedback effect of the negative Doppler coefficient. This self-limitation of the power excursion limits the power during the delay time for protective action. Should a continuous RCCA withdrawal accident occur, the transient is terminated by the following automatic features of the protection and safety monitoring system:

- Source range high neutron flux reactor trip

  This trip function is actuated when two out of four independent source range channels indicate a neutron flux level above a preselected, manually adjustable setpoint. It may be manually bypassed only after an intermediate range flux channel indicates a flux level above a specified level. It is automatically reinstated when the coincident two out of four intermediate range channels indicate a flux level below a specified level.

- Intermediate range high neutron flux reactor trip

  This trip function is actuated when two out of four independent, intermediate range channels indicate a flux level above a preselected, manually adjustable setpoint. It may be manually bypassed only after two out of four power range channels are reading above approximately 10 percent of full power. It is automatically reinstated when the coincident two out of four channels indicate a power level below this value.

- Power range high neutron flux reactor trip (low setting)

  This trip function is actuated when two out of four power range channels indicate a power level above approximately 25 percent of full power. It may be manually bypassed when two out of four power range channels indicate a power level above approximately 10 percent of full power. It is automatically reinstated when the coincident two out of four channels indicate a power level below this value.

- Power range high neutron flux reactor trip (high setting)

  This trip function is actuated when two out of four power range channels indicate a power level above a preset setpoint. It is always active.

- High nuclear flux rate reactor trip

  This trip function is actuated when the positive rate of change of neutron flux on two out of four nuclear power range channels indicate a rate above a preset setpoint.

In addition, control rod stops on high intermediate range flux level (one out of two) and high power range flux level (one out of four) serve to discontinue rod withdrawal and prevent the need to actuate the intermediate range flux level trip and the power range flux level trip, respectively.

9.4.1.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect RCS/MSS pressure and pressuriser filling criteria, therefore, these limits are not explicitly confirmed for this event. Accordingly, fuel failure is the primary criterion for this event.

9.4.1.2.1 DBA Method of Analysis

The analysis of the uncontrolled RCCA bank withdrawal from subcritical accident is performed in three stages: first, an average core nuclear power transient calculation; then, an average core heat transfer calculation; and finally, the DNBR calculation. In the first stage, the average core nuclear calculation is performed using spatial neutron kinetics methods, using the code TWINKLE (Reference 9.4-1), to determine the average power generation with time, including the various total core feedback effects (Doppler reactivity and moderator reactivity).

In the second stage, the average heat flux and temperature transients are determined by performing a fuel rod transient heat transfer calculation in FACTRAN (Reference 9.4-2). In the final stage, the average heat flux is used in VIPRE-01 (described in Section 22.7.1.1) for the transient DNBR calculation.

Plant characteristics and initial conditions are discussed in Section 9.0.2. The following assumptions are made to give conservative results for a startup accident:

- Because the magnitude of the power peak reached during the initial part of the transient for any given rate of reactivity insertion is strongly dependent on the Doppler coefficient, conservatively low values, as a function of power, are used (see Table 9.0-6).

- Contribution of the moderator reactivity coefficient is negligible during the initial part of the transient because the heat transfer time between the fuel and the moderator is much longer than the neutron flux response time. After the initial neutron flux peak, the succeeding rate of power increase is affected by the moderator reactivity coefficient. A conservative value is used in the analysis to yield the maximum peak heat flux (see Table 9.0-6).

- The reactor is assumed to be at hot zero power. This assumption is more conservative than that of a lower initial system temperature. The higher initial system temperature yields a larger fuel-water heat transfer coefficient, larger specific heats, and a less negative (smaller absolute magnitude) Doppler coefficient, all of which tend to reduce the Doppler feedback effect and thereby increase the neutron flux peak. The initial effective multiplication factor (k_{eff}) is assumed to be 1.0 because this results in the worst nuclear power transient.

- Reactor trip is assumed to be initiated by the power range high neutron flux (low setting). The most adverse combination of instrument and setpoint errors, as well as delays for trip signal actuation and RCCA release, is taken into account. A 10-percent uncertainty increase is assumed for the power range flux trip setpoint, raising it to 35 percent from the nominal value of 25 percent.

  Because the rise in the neutron flux is so rapid, the effect of errors in the trip setpoint on the actual time at which the rods are released is negligible. In addition, the reactor trip insertion characteristic is based on the assumption that the highest worth RCCA is stuck in its fully withdrawn position. See Section 9.0.6 for RCCA insertion characteristics.

- The maximum positive reactivity insertion rate assumed is greater than that for the simultaneous withdrawal of the combination of the two sequential RCCA banks having the greatest combined worth at maximum speed (1.143 m [45 inches] per minute). Control rod drive mechanism design is discussed in Section 17.3.3.

- The most limiting axial and radial power shapes, associated with having the two highest combined worth banks in their high-worth position, are assumed in the DNB analysis.

- The initial power level is assumed to be below the power level expected for any shutdown condition (10^{-9} of nominal power). The combination of highest reactivity insertion rate and lowest initial power produces the highest peak heat flux.

- Four reactor coolant pumps are assumed to be in operation.

- Pressuriser pressure is assumed to be 0.345 MPa (50 psi) below nominal for steady-state fluctuations and measurement uncertainties.

Plant systems and equipment available to mitigate the effects of the accident are discussed in Section 9.0.4 and listed in Table 9.0-10. No single active failure in any of these systems or components adversely affects the consequences of the accident. A loss of offsite power as a consequence of a turbine trip disrupting the grid is not considered because the accident is initiated from a subcritical condition where the plant is not providing power to the grid.

9.4.1.2.2 DBA Credited SSCs

For the DB, all the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, steam line isolation valves and SG flow restrictors. The PMS provides the following:

- RT on power range high neutron flux (low setpoint)

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow

- CMTs and containment isolation on Low-2 CL temperature

- PCS on High-2 containment pressure

9.4.1.2.3 DBA Results

Figures 9.4.1-1 through 9.4.1-4 show the transient behaviour for the uncontrolled RCCA bank withdrawal from subcritical incident. The accident is terminated by reactor trip at 35 percent of nominal power. The reactivity insertion rate used is greater than that calculated for the two highest-worth sequential rod cluster control banks, both assumed to be in their highest incremental worth region.

Figure 9.4.1-1 shows the average neutron flux transient. The energy release and the fuel temperature increases are relatively small. The heat flux response (of interest for DNB considerations) is also shown in Figure 9.4.1-2. The beneficial effect of the inherent thermal lag in the fuel is evidenced by a peak heat flux much less than the full-power nominal value. There is margin to DNB during the transient because the rod surface heat flux remains below the critical heat flux value, and there is a high degree of subcooling at all times in the core. Figures 9.4.1-3 and 9.4.1-4 show the response of the average fuel temperature and the inner cladding temperature, respectively. The minimum DNBR at all times remains above the design limit value (see Section 22.7.1.1).

The calculated sequence of events for this accident is shown in Table 9.4-1. With the reactor tripped, the plant returns to a stable condition. Subsequently, the plant may be cooled down further by following normal plant shutdown procedures.

9.4.1.3 Diverse Mitigation

The available diverse mitigation for this event is the same as for the RCCA misalignment faults (Section 9.4.3.3).

9.4.1.3.1 Diverse Mitigation for ATWT

As explained in section 9.4.2.3.1.3 considering an ATWT event, this fault is bounded by that of the uncontrolled RCCA withdrawal at-power fault. The bounding ATWT analysis for the at-power fault is in Section 9.4.2.3.1.

9.4.1.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.4.1.4 Radiological Consequences

The initiating event does not result in fuel damage and the primary and secondary circuits remain intact. Because offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

9.4.1.5 As Low as Reasonably Practicable Assessment

The ALARP evaluation for this event is the same as for the RCCA misalignment fault (Section 9.4.3.5).

9.4.1.6 Conclusions

In the event of an RCCA withdrawal accident from the subcritical condition, the core and the reactor coolant system are not adversely affected because the combination of thermal power

and the coolant temperature results in a DNBR greater than the safety analysis limit value. Thus, no fuel or cladding damage is predicted as a result of DNB.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.4.2 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal at Power (Fault 1.15.4)

9.4.2.1 Identification of Causes and Accident Description

An uncontrolled RCCA bank withdrawal at power results in an increase in the core heat flux. Because the heat extraction from the steam generator lags behind the core power generation until the steam generator pressure reaches the relief or safety valve setpoint, there is a net increase in the reactor coolant temperature. Unless terminated by manual or automatic action, the power mismatch and resultant coolant temperature rise could eventually result in a violation of the DNB design basis or excessive linear power. Therefore, to avert damage to the fuel cladding, the PMS is designed to terminate any such transient before the DNBR falls below the design limit (see Section 22.7.1.1) or the overpower limit is exceeded.

9.4.2.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

It is noted that this event is bounded by the Section 9.2.3 analysis with respect MSS pressure criteria, therefore, these limits are not explicitly confirmed for this event. Pressuriser filling is only a concern after reactor trip for this event of the high pressuriser water level reactor trip. For post-trip pressuriser filling, this event is bounded by Section 9.2.7 analysis.

9.4.2.2.1 DBA Method of Analysis

This transient is analysed using the LOFTRAN (References 9.4-3 and 9.4-11) code. This code simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generators, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level. The core limits as illustrated in Figure 9.0-1 are used to define the inputs to LOFTRAN that determine the minimum DNBR during the transient.

Plant characteristics and initial conditions are discussed in Section 9.0.2. In performing a conservative analysis for an uncontrolled RCCA bank withdrawal at-power accident, the following assumptions are made:

- The nominal initial conditions are assumed in accordance with the revised thermal design procedure. Uncertainties in the initial conditions are included in the DNBR limit as described in WCAP-11397-P-A (Reference 9.4-9).

- Two sets of reactivity coefficients are considered:

Minimum reactivity feedback — A least-negative moderator temperature coefficient of reactivity is assumed, corresponding to the beginning of core life. A variable Doppler power coefficient with core power is used in the analysis. A conservatively small (in absolute magnitude) value is assumed (see Figure 9.0-3).

Maximum reactivity feedback — A conservatively large positive moderator density coefficient corresponding to the end of core life and a large (in absolute magnitude) negative Doppler power coefficient are assumed (see Figure 9.0-3).

- The high positive flux rate trip is assumed to be actuated when the power range neutron flux changes at a rate higher than 15% per second with a 60 second rate-lag time constant. The overpower ΔT and overtemperature ΔT trips include adverse instrumentation and setpoint uncertainties. The delays for trip actuation assumed are given in Table 9.0-8.

- The RCCA trip insertion characteristic is based on the assumption that the highest-worth assembly is stuck in its fully withdrawn position.

- A range of reactivity insertion rates is examined. The maximum positive reactivity insertion rate is greater than that for the simultaneous withdrawal of the combination of the two control banks having the maximum combined worth at maximum speed.

If RCCA movement were to cause an adverse effect on the axial core power distribution the overtemperature ΔT trip setpoint would be decreased as necessary to maintain margin to the DNBR design limit, and the overpower ΔT trip setpoint would be decreased as necessary to maintain margin to the overpower limit.

Plant systems and equipment available to mitigate the effects of the accident are discussed in Section 9.0.4 and listed in Table 9.0-10. No single active failure in these systems or equipment adversely affects the consequences of the accident.

9.4.2.2.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The credited Class 1 systems are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and steam generator SVs. The PMS provides the following:

- RT on (dependent on reactivity insertion rate):
  - Power range high positive flux rate
  - Overtemperature ΔT
  - Overpower ΔT
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.4.2.2.3 DBA Results

Three reactor trip functions were credited in the analyses to provide protection over the entire range of reactivity insertion rates. These are the high positive flux rate, overtemperature ΔT, and overpower ΔT trips.

Figures 9.4.2-1 through 9.4.2-6 show the transient response for a representative rapid (80 pcm/s) RCCA withdrawal incident starting from full power. Reactor trip on high positive flux rate occurs shortly after the start of the transient. Because this is rapid with respect to the thermal time constants of the fuel, small changes in temperature and pressure result, and the DNB design basis described in Section 22.7.1.1 is met.

The transient response for a representative intermediate (34 pcm/s) RCCA withdrawal from full power is shown in Figures 9.4.2-7 through 9.4.2-12. Reactor trip on overpower ΔT occurs preventing the peak heat flux from exceeding 118%. The minimum DNBR is greater than the design limit described in Section 22.7.1.1

The transient response for a representative slow (5 pcm/s) RCCA withdrawal from full power is shown in Figures 9.4.2-13 through 9.4.2-18. Reactor trip on overtemperature ΔT occurs after a longer period. The rise in temperature and pressure is consequently larger than for rapid RCCA withdrawal. The DNB design basis described in Section 22.7.1.1 is met.

Figure 9.4.2-19 shows the minimum DNBR as a function of reactivity insertion rate from initial full-power operation for minimum and maximum reactivity feedback. Minimum DNBR occurs immediately after rod motion. The minimum DNBR is greater than the design limit value described in Section 22.7.1.1.

Figures 9.4.2-20 and 9.4.2-21 show the minimum DNBR as a function of reactivity insertion rate for RCCA withdrawal incidents for minimum and maximum reactivity feedback, starting at 60-percent and 10-percent power, respectively. Minimum DNBR occurs immediately after rod motion. In all cases, the DNBR is greater than the design limit value described in Section 22.7.1.1.

The shape of the curves of minimum DNBR versus reactivity insertion rate in the referenced figures is due both to reactor core and coolant system transient response and to PMS action in initiating a reactor trip.

Referring to Figure 9.4.2-19, for transients initiated from full power, it is noted that:

A. Three reactor trip functions provide the DNB and overpower protection over the range of reactivity insertion rates analysed. The overtemperature ΔT reactor trip provides DNB protection except for rapid power excursions. The overpower ΔT reactor trip provides protection for the slow to moderate power excursions. The high positive flux rate trip prevents both overpower and low DNBR for rapid power excursions.

B. For minimum reactivity feedback cases, the high positive flux rate trip provides protection for reactivity insertion rates between 110 pcm/s and 10 pcm/s. The overpower ΔT reactor trip provides protection for reactivity insertion rates between 5.0 pcm/s and 1.2 pcm/s and the overtemperature ΔT reactor trip provides protection for the reactivity insertion rates between 1.0 pcm/s and 0.5 pcm/s.

C. For maximum reactivity feedback cases, the high positive flux rate trip provides protection for reactivity insertion rates between 110 pcm/s and 50 pcm/s. The overpower

ΔT reactor trip provides for reactivity insertion rates between 40 pcm/s and 30 pcm/s and the overtemperature ΔT reactor trip provides protection for the reactivity insertion rates between 25 pcm/s and 0.6 pcm/s.

Steam generator safety valves never open before the reactor trip for transients initiated at full power.

Because the RCCA bank withdrawal at-power incident is an overpower transient, the fuel temperatures rise during the transient until after reactor trip occurs. For rapid power excursions, the overpower transient is fast with respect to the fuel rod thermal time constant and the core heat flux lags behind the neutron flux response. Taking into account the effect of the RCCA withdrawal on the axial core power distribution, the peak fuel centreline temperature still remains below the fuel melting temperature.

For slow to moderate power excursions, the core heat flux remains more nearly in equilibrium with the neutron flux. The overpower transient is terminated by either the overpower ΔT or overtemperature ΔT reactor trip before the DNB design basis is violated. Taking into account the effect of the RCCA withdrawal on the axial core power distribution, the peak centreline temperature remains below the fuel melting temperature.

The reactor is tripped during the RCCA bank withdrawal at-power transient such that the ability of the primary coolant to remove heat from the fuel rods is not reduced. Thus, the fuel cladding temperature does not rise significantly above its initial value during the transient.

The calculated sequence of events for this accident is shown in Table 9.4-1. With the reactor tripped, the plant returns to a stable condition. The plant may be cooled down further by following normal plant shutdown procedures.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

Overpressure Evaluation Results

In addition to the DNB cases discussed above, several cases are analysed to ensure that the maximum RCS pressure does not exceed 110% of the design pressure. The cases cover a range of reactivity insertion rates from less than 1 pcm/s to 110 pcm/s and power levels from 10% to 100% power. Initial condition uncertainties on power, pressure, and average temperature are conservatively included, and the thermal design flow rate is assumed. The most limiting case was for a reactivity insertion rate of 10 pcm/s and an initial power level of 65% power. The peak pressure calculated is 18.139 MPa abs (2630.8 psia), which is well below the limit of 18.950 MPa abs (2748.5 psia).

9.4.2.3 Diverse Mitigation

The available diverse protection for this event is the same as for the RCCA misalignment faults (Section 9.4.3.3).

9.4.2.3.1 Diverse Mitigation for ATWT

The AP1000 plant is designed with mechanical shim (control rod motion used for small burnup effects rather than boron changes), as well as automatic axial power control. These require deeper control rod insertion than operating Westinghouse pressurised water reactors (PWRs). In this assessment, an inserted worth of 1 percent (1000 pcm) is assumed at full

power for the M bank, and higher worth at lower power to compensate for the power defect. The Axial Offset bank has comparable reactivity (but does not increase at reduced power).

For the M bank, a realistic upper limit for incremental reactivity worth at hot zero power is 12 pcm per step (about 15 pcm/second at the maximum reactivity withdrawal rate of 72 steps/minute). During power operation, the comparable value is 3 pcm/second near full power and 12 pcm/second at low power. The axial offset bank has a higher maximum incremental worth (30 pcm/step) but is limited to 8 steps/minute (4 pcm/sec). The high rates at zero and low power occur over a short range of control rod travel (i.e., they cannot be sustained.) For the purpose of investigating limits, a preliminary hypothetical case was analysed assuming a sustained 15 pcm/second starting from full power. Results of more realistic cases with 4 pcm/second from full power are also shown.

Power distribution tends to improve with increasing power, and all inadvertent control rod withdrawal events of significance go to power levels above full power, so full-power design power distribution was used in the assessment. Thus, low initial power (or even initial sub-critical) events may be treated in the same way as an uncontrolled RCCA bank withdrawal from full power.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

9.4.2.3.1.1 Diverse ATWT Method of Analysis

For this ATWT scenario, mechanical failure of the control rods to fall when de-energised is not considered. It is assumed that RCCAs that are able to step out during an uncontrolled withdrawal are not restricted from falling into the reactor on receipt of a trip signal. Therefore, only a PMS failure (including scram breaker failure) needs be addressed. The transient is terminated either when: (1) DAS reactor trip occurs on high T-hot; or (2) The control rods are fully withdraw (1 percent reactivity added for 100 percent initial power cases). The second case would be more likely later in core life with a strong reactivity feedback.

In addition to the preceding protective actions, the following rod control system interlocks are available to block RCCA withdrawal but are not credited for this analysis:

- High neutron flux (two out of four power range)
- Overpower ΔT (two out of four)
- Overtemperature ΔT (two out of four)

Analysis Assumptions

a. Plant initial conditions are assumed to be those of the nominal values consistent with Table 9.0-15.

b. Modelled reactivity coefficients are based on the reactivity coefficients discussed in Reference 9.4-20 for near the BOC.

c. Except for pressuriser sprays, the pressuriser pressure and level control system is not credited in the analyses.

d. The pressuriser safety valves are conservatively modelled to open at the maximum safety analysis setpoint 17.75 MPa abs (2575 psia).

e. The turbine bypass function is assumed to be operable and in pressure control mode. After a reactor trip signal is generated in PMS or DAS, the turbine bypass switches to pressure control automatically. Pressure setpoint for the turbine bypass system in pressure control mode is assumed to be the nominal no load secondary pressure (7.63 MPa abs [1106 psia]).

f. The turbine trip on reactor trip function is not modelled. However, the SG relief system is modelled consistent with the turbine bypass system following reactor trip. Therefore, turbine trip impact is included in the model.

g. The turbine control system is assumed to maintain initial steam flow throughout the transient.

h. Following protection functions are assumed available for this event:

- PMS Reactor Trip – None, all trip functions are set aside.

- DAS Reactor Trip – High Hot Leg Temperature in both hot legs.

Discussion of Cases Analysed

Cases modelling 100 percent, 60 percent, and 0 percent RTP were analysed. For 100 percent RTP, cases were run at the maximum hypothetical reactivity insertion (15 pcm/sec) and for a realistic reactivity insertion (4 pcm/sec). All reduced power analyses conservatively assumed the maximum hypothetical reactivity insertion (15 pcm/sec). For each case, the RCS pressure and DNBR margin have been assessed.

To determine the DNBR limit, a curve was developed based on the WRB-2M correlation which corresponds to the 95/95 DNBR limit for PWRs. This curve defines the DNBR limited core inlet temperature versus power for 100 percent of normal flow and an RCS pressure of [ ]. Next, the limiting core outlet temperature was calculated based on this inlet temperature limit and the specified core power (3400 MWt). Accordingly, the critical transient results for the core exit temperature (hot-leg inlet temperature) as a function nuclear power can be compared to determine whether the minimum DNBR exceeds the limit.

As expected, the setpoint temperature for the DAS high hot-leg trip is a significant parameter for this analysis. As this trip setpoint is increased, the peak reactor power (i.e., nuclear power just after the DAS rod insertion starts) increases. For this initial power, a sensitivity study was

run for three high hot-leg trip setpoints: 332.2°C (630°F), 335°C (635°F), and 337.8°C (640°F), as shown in Figure 9.4.2-22. As the trip setpoint was increased, the DNBR margin was reduced.

All transient results documented herein assume the high hot-leg trip setpoint is 335°C (635°F).

This event is less limiting for RCS overpressure than the loss of feedwater event as analysed in Section 9.2.7.5, is less limiting for core damage than the complete loss of RCS flow as analysed in Section 9.3.2.5. This event was explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.4-12. The evaluation conducted to closeout FS-03 (Reference 9.4-13) demonstrated that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the change in design reference point would not invalidate the conclusions presented for this event.

9.4.2.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT no Class 1 SSCs are claimed. The available SSCs are listed in Table 9.0-14. The DAS provides the following:

- RT on High hot leg temperature

9.4.2.3.1.3 Diverse ATWT Results

RCCA Withdrawal at Power from 100 Percent Power at Maximum Hypothetical Reactivity Insertion

For the 100-percent-power cases of RCCA withdrawal at power (RWAP), the event starts at nominal initial conditions with reactivity insertion at the start of the transient. Nuclear power increases initially and both the primary and secondary systems heat up. However, the rate of increase is limited by moderator temperature and power defect feedback. As the core power and RCS pressure increases, PMS trip setpoints for high neutron flux and high pressuriser pressure are reached; however, due to PMS CCF, no action is taken by the control system. PCS rod control system interlock setpoints for C-2 (high neutron flux) and C-3 (margin to overpower delta temperature (OPΔT) limit) would be reached, which would block further rod withdrawal and limit peak nuclear power. However, these interlocks are not modelled in the analyses presented.

Eventually, the high hot-leg temperature is reached, causing the DAS to shut down power to the diesel generator (DG), thereby releasing the latches on the trip scram control rods. After a 7 second delay, the control rods begin to move and insert negative reactivity into the core. Total reactivity turns negative almost immediately reducing core power. The steam generator continues to remove heat from the RCS, and the RCS coolant temperature gradually drops. Peak RCS pressure and DNBR margin are at a minimum at the peak power point.

If the turbine trip were to occur on reactor trip, the turbine bypass would switch to pressure control mode and maintain the heat sink as discussed previously.

Table 9.4.2-1 shows the sequence of events for the 100 percent initial power case with the high hot-leg trip setpoint of 335°C (635°F). Figures 9.4.2-22 to 9.4.2-26 show critical parameters for this transient.

RWAP from 100 Percent Power at Realistic Reactivity Insertion

The rod withdrawal from 100 percent power at realistic but bounding insertion rate (4 pcm/sec.) conditions produces results similar to the 100 percent power, maximum insertion case; however, the lower insertion rate produces a power excursion that is less severe. This results in higher loop temperature versus nuclear power; therefore, the DAS hot-leg trip occurs at much lower power. Since core peak heat flux is lower, DNB margin is improved as demonstrated in Figure 9.4.2-27.

RWAP from a Partial Power Condition

The cases modelling a rod withdrawal occurring from a partial power conditions produce results similar to the 100-percent-power case; however, these cases were found to be less limiting with respect to minimum DNBR. This is due to the DAS high hot-leg temperature trip of 335°C (635°F) being reached when the reactor has reached a lower core heat flux. While the cases initialised from a partial power condition result in a lower core heat flux, the partial power cases result in a higher secondary system pressure.

Figure 9.4.2-40 shows the margin to DNBR resulting from RWAP at reduced power.

Peak reactor power is significantly lower than for the 100 percent initial power case while peak hot-leg temperatures are similar for all cases. Based on the DNBR limits of Figure 9.4.2-22, it is clear that DNBR margin is greater for these cases than the 100-percent-power case.

Based on the previous discussion, uncontrolled RCCA withdrawal from lower sub-critical power would not result in a substantial risk provided the event starts from hot zero power loop temperature conditions.

9.4.2.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.4.2.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.4.2.5 As Low as Reasonably Practicable Assessment

The ALARP evaluation for this event is the same as for the RCCA misalignment fault (Section 9.4.3.5).

9.4.2.6 Conclusions

The overpower ΔT, overtemperature ΔT, and high positive flux rate trip functions provide adequate protection over the entire range of possible reactivity insertion rates. The DNB and fuel melt design basis, as defined in Section 22.7.1.1, is met for all cases. The maximum reactor coolant system pressure remains below 110% of design.

This event has also been adequately assessed with respect to ATWT considerations.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of the Class 1 SSCs as protective functions is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.4.3 Rod Cluster Control Assembly Misalignment (System Malfunction or Operator Error) (Fault 1.15.5)

9.4.3.1 Identification of Causes and Accident Description

RCCA misoperation accidents include:

- One or more dropped RCCAs within the same group (Fault 1.15.5a)
- Statically misaligned RCCA (Fault 1.15.5)
- Withdrawal of a single RCCA (Fault 1.15.5b)

Each RCCA has a position indicator channel which displays the position of the assembly. The displays of assembly positions are grouped for the operator's convenience. Fully inserted assemblies are further indicated by a rod-at-bottom signal, which actuates a local alarm and a main control room annunciator. Group demand position is also indicated.

RCCAs are moved in preselected banks, and the banks are moved in a preselected sequence. Each bank of RCCAs is divided into one or two groups of four or five RCCAs each. The rods comprising a group operate in parallel. The two groups in a bank move sequentially such that the first group is always within one step of the second group in the bank. A definite schedule of actuation (or deactuation) of the stationary gripper, movable gripper, and lift coils of a mechanism is required to withdraw the RCCA attached to the mechanism. Because the stationary gripper, movable gripper, and lift coils associated with the RCCAs of a rod group are driven in parallel, any single failure which causes rod withdrawal affects the entire group. A single electrical or mechanical failure in the plant control system could, at most, result in dropping one or more RCCAs within the same group. Mechanical failures can cause either RCCA insertion or immobility, but not RCCA withdrawal.

No single electrical or mechanical failure in the rod control system could cause the accidental withdrawal of a single RCCA from the inserted bank at full-power operation. The operator could withdraw a single RCCA in the control bank because this feature is necessary to retrieve an assembly should one be accidentally dropped. The event analysed results from multiple wiring failures or multiple significant operator errors and subsequent and repeated operator disregard of event indication. The probability of such a combination of conditions is considered low such that the limiting consequences may include slight fuel damage.

It has been shown that single failures resulting in RCCA bank withdrawals do not violate specified fuel design limits. Moreover, no single malfunction can result in the withdrawal of a single RCCA. Thus, it is concluded that criterion established for the single rod withdrawal at power is appropriate.

A dropped RCCA or RCCA bank may be detected by one or more of the following:

- Sudden drop in the core power level as seen by the nuclear instrumentation system
- Asymmetric power distribution as seen by the incore or excore neutron detectors or core exit thermocouples, through online core monitoring
- Rod at bottom signal
- Rod deviation alarm
- Rod position indication

Misaligned RCCAs are detected by one or more of the following:

- Asymmetric power distribution as seen by the incore or excore neutron detectors or core exit thermocouples, through online core monitoring
- Rod deviation alarm
- Rod position indicators

The resolution of the rod position indicator channel is $\pm$5 percent span ($\pm$0.19 m [7.5 inches]). A deviation of any RCCA from its group by twice this distance (10 percent of span or 0.38 m [15 inches]) does not cause power distributions worse than the design limits. The deviation alarm alerts the operator to rod deviation with respect to the group position in excess of 5 percent of span.

If one or more of the rod position indicator channels is out of service, operating instructions are followed to verify the alignment of the nonindicated RCCAs. The operator also takes action as required by the Technical Specifications.

In the extremely unlikely event of multiple electrical failures that result in single RCCA withdrawal, rod deviation and rod control urgent failure are both displayed to the operator, and the rod position indicators indicate the relative positions of the assemblies in the bank. The urgent failure alarm also inhibits automatic rod motion in the group in which it occurs. Withdrawal of a single RCCA by operator action, whether deliberate or by a combination of errors, results in activation of the same alarm and the same visual indication. Withdrawal of a single RCCA results in both positive reactivity insertion tending to increase core power and an increase in local power density in the core area associated with the RCCA. Automatic protection for this event is provided by the overtemperature ΔT reactor trip. The evaluation criteria are met; however, due to the increase in local power density, the limits in Figure 9.0-1 may be exceeded.

Plant systems and equipment available to mitigate the effects of the various control rod misoperations are discussed in Section 9.0.4 and listed in Table 9.0-10. No single active failure in any of these systems or equipment adversely affects the consequences of the accident.

9.4.3.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

With respect to the RCS and MSS pressure criteria, the Dropped Rod event is bounded by the analysis presented in Section 9.2.3, and is not explicitly verified. In addition, pressuriser filling is not challenged in this event.

9.4.3.2.1 Dropped RCCAs, Dropped RCCA Bank, and Statically Misaligned RCCA

9.4.3.2.1.1 DBA Method of Analysis

- One or more dropped RCCAs from the same group

  A drop of one or more RCCAs from the same group results in an initial reduction in the core power and a perturbation in the core radial power distribution. Depending on the worth and position of the dropped rods, this may cause the allowable design power peaking factors to be exceeded. Following the drop, the reduced core power and continued steam demand to the turbine causes the reactor coolant temperature to decrease. In the manual control mode, the plant will establish a new equilibrium condition. The new equilibrium condition is reached through reactivity feedback. In the presence of a negative moderator temperature coefficient, the reactor power rises monotonically back to the initial power level at a reduced inlet temperature with no power overshoot. The absence of

any power overshoot establishes the automatic operating mode as a limiting case. If the reactor coolant system temperature reduction is very large, the turbine power may not be able to be maintained due to the reduction in the secondary-side steam pressure and the volumetric flow limit of the turbine system. In this case, the equilibrium power level is less than the initial power. In the automatic control mode, the plant control system detects the drop in core power and initiates withdrawal of a control bank. Power overshoot may occur, after which the control system will insert the control bank and return the plant to the initial power level. The magnitude of the power overshoot is a function of the plant control system characteristics, core reactivity coefficients, the dropped rod worth, and the available control bank worth.

For evaluation of the dropped RCCA event, the transient system response is calculated using the LOFTRAN code (References 9.4-3 and 9.4-11). The code simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generator and steam generator safety valves. The code computes pertinent plant variables, including temperatures, pressures and power level.

Steady-state nuclear models using the computer codes described in Section 22.7 are used to obtain a hot channel factor consistent with the primary system transient conditions and reactor power. By combining the transient primary conditions with the hot channel factor from the nuclear analysis, the departure from nucleate boiling design basis is shown to be met using the VIPRE-01 code (Reference 9.4-18).

- Statically misaligned RCCA

  Steady-state power distributions are analysed using the computer codes as described in Section 22.7. The peaking factors are then used as input to the VIPRE-01 code to calculate the DNBR.

9.4.3.2.1.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The credited Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, and pressuriser SVs. For dropped RCCAs from the same group DB, the PMS provides the following:

- RT on Low-2 pressuriser pressure; however, the limiting dropped RCCA cases do not result in a reactor trip. Instead, the reactor will reach a new equilibrium power (see Section 9.4.3.2.1.3).

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow

- CMTs and containment isolation on Low-2 CL temperature

- PCS on High-2 containment pressure

9.4.3.2.1.3 DBA Results

- One or more dropped RCCAs

  Figures 9.4.3-1 through 9.4.3-4 show the transient response of the reactor to a dropped rod (or rods) in automatic control. The nuclear power and heat flux drop to a minimum value and recover under the influence of both rod withdrawal and thermal feedback. The prompt decrease in power is governed by the dropped rod worth because the plant control system does not respond during the short rod drop time period. The plant control system detects the reduction in core power and initiates control bank withdrawal to restore the primary side power. Power overshoot occurs after which the core power is restored to the initial power level.

  The primary system conditions are combined with the hot channel factors from the nuclear analysis for the DNB evaluation. Uncertainties in the initial conditions are included in the DNB evaluation as discussed in Section 9.0.2.3. The calculated minimum DNBR for any single or multiple rod drop from the same group is greater than the design limit value described in Section 22.7.1.1. The sequence of events for a representative case is shown in Table 9.4-1.

  The analysis described previously includes consideration of drops of the RCCA groups which can be selected for insertion as part of the rapid power reduction system. This system is provided to allow the reactor to ride out a complete loss of load from full power without a reactor trip. If these RCCAs are inadvertently dropped (in the absence of a loss-of-load signal), the transient behaviour is the same as for the RCCA drop described. The evaluation showed that the DNBR remains above the design limit value as a result of the inadvertent actuation of the rapid power reduction system.

  The consequential loss of offsite power described in Section 9.0.12 is not limiting for the dropped RCCA event. Due to the delay from reactor trip until turbine trip and the rapid power reduction produced by the reactor trip, the minimum DNBR occurs before the reactor coolant pumps begin to coast down.

- Statically misaligned RCCA

  The most severe misalignment situations with respect to DNBR arise from cases in which one RCCA is fully inserted, or where the mechanical shim or axial offset rod banks are inserted up to their insertion limit with one RCCA fully withdrawn while the reactor is at full power. Multiple independent alarms, including a bank insertion limit or rod deviation alarm, alert the operator well before the postulated conditions are approached.

  For RCCA misalignments in which the mechanical shim or axial offset banks are inserted to their respective insertion limits, with any one RCCA fully withdrawn, the DNBR remains above the safety analysis limit value. This case is analysed assuming the initial reactor power, pressure, and reactor coolant system temperature are at their nominal values, but with the increased radial peaking factor associated with the misaligned RCCA. Uncertainties in the initial conditions are included in the DNB evaluation as described in Section 9.0.2.3.

  DNB does not occur for the RCCA misalignment incident, and thus the ability of the primary coolant to remove heat from the fuel rod is not reduced. The peak fuel temperature is that corresponding to a linear heat generation rate based on the radial peaking factor penalty associated with the misaligned RCCA and the design axial power

distribution. The resulting linear heat generation is well below that which causes fuel melting.

Following the identification of an RCCA group misalignment condition by the operator, the operator takes action as required by the plant Technical Specifications and operating instructions.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.4.3.2.2 Single Rod Cluster Control Assembly Withdrawal

9.4.3.2.2.1 DBA Method of Analysis

Power distributions within the core are calculated using the computer codes described in Section 22.7. The peaking factors are then used by VIPRE-01 to calculate the DNBR for the event. The case of the worst rod withdrawn from the mechanical shim or axial offset bank inserted at the insertion limit, with the reactor initially at full power, is analysed. This incident is assumed to occur at beginning of life because this results in the minimum value of moderator temperature coefficient. This assumption maximises the power rise and minimizes the tendency of increased moderator temperature to flatten the power distribution.

9.4.3.2.2.2 DBA Credited SSCs

The credited Class 1 SSCs are the same as those in Section 9.4.3.2.1.2 for Dropped RCCAs, Dropped RCCA bank, and Statically Misaligned RCCA faults. In addition, one PMS reactor trip is credited for the manual rod withdrawal case:

- RT on overtemperature ΔT

9.4.3.2.2.3 DBA Results

For the single rod withdrawal event, two cases are considered as follows:

A. If the reactor is in the manual control mode, continuous withdrawal of a single RCCA results in both an increase in core power and coolant temperature and an increase in the local hot channel factor in the area of the withdrawing RCCA. In the overall system response, this case is similar to those presented in Section 9.4.2. The increased local power peaking in the area of the withdrawn RCCA results in lower minimum DNBRs than for the withdrawn bank cases. Depending on initial bank insertion and location of the withdrawn RCCA, automatic reactor trip may not occur sufficiently fast to prevent the minimum DNBR from falling below the safety analysis limit value. Evaluation of this case at the power and coolant conditions at which the overtemperature ΔT trip is expected to trip the plant shows that an upper limit for the number of rods with a DNBR less than the safety analysis limit value is 5 percent.

B. If the reactor is in the automatic control mode, the multiple failures that result in the withdrawal of a single RCCA result in the immobility of the other RCCAs in the controlling bank. The transient then proceeds in the same manner as case A.

For such cases, a reactor trip ultimately occurs although not sufficiently fast in all cases to prevent a minimum DNBR in the core of less than the safety analysis limit value. Following reactor trip, normal shutdown procedures are followed.

The consequential loss of offsite power described in Section 9.0.12 is not limiting for the single RCCA withdrawal event. Due to the delay from reactor trip until turbine trip and the rapid power reduction produced by the reactor trip, the minimum DNBR, for rods where the DNBR did not fall below the design limit value (see Section 22.7.1.1) in the cases described, occurs before the reactor coolant pumps begin to coast down.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.4.3.3 Diverse Mitigation

In addition to the passive systems credited in the DBA, the plant also has a diverse mitigation capability that is able to supply the Category A safety functions for frequent faults. For this event the diverse features are also Class 1 except for the C&I, which is Class 2.

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

In this fault, the containment function is provided by the fuel cladding and by the RCS, neither of which is threatened in the DBA. The containment building provides diverse containment and is identified as a Class 1 system on that basis for this fault.

Table 9.4.3-1 summarizes the SSCs from this fault assessment. As this is a frequent fault, a diverse means of providing the Category A safety functions is provided. The information provided in Table 9.4.3-1 is from Reference 9.4-10, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions. Table 9.4.3-2 provides the operator actions utilized in the diverse safety case.

9.4.3.3.1 Diverse Mitigation for ATWT

The primary protection for the dropped RCCA event is normally provided by the PMS low pressuriser pressure reactor trip function. This function provides a reactor trip for many of the larger dropped rod worth cases analysed due to the RCS pressure reduction caused by the drop of the RCCA(s). Cases that do not reach this reactor trip setpoint will reach a new equilibrium power level, with the possibility of a power overshoot. Some cases may actuate the P-17 permissive rod withdrawal block component of the rod control system. The P-17 is actuated as a result of a rapid reduction in neutron flux based on signals directly from the nuclear instrumentation system (NIS) and is independent of PMS comparators or logic. The P-17 function was included in the rod control system design in order to support operation of the Rapid Power Reduction System (RPRS), which allows the plant to sustain a full load rejection from full power without a reactor trip. The RPRS drops selected rod banks to reduce core power when steam dumps and normal rod control insertion cannot mitigate large load rejections. The P-17 function prevents the rod control system from unnecessarily increasing power following an RPRS actuation by blocking automatic rod withdrawal.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).

- There is no significant fuel damage.

- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

With respect to peak RCS overpressure criterion, this event is bounded by the Turbine Trip DB event (Section 9.2.3).

9.4.3.3.1.1 Diverse ATWT Method of Analysis

A bounding failure scenario was analysed for the dropped RCCA event ATWT diversity case. The scenario assumes simultaneous failures in both the PMS and the rod control system. It is assumed that the PMS low pressuriser pressure reactor trip function fails. As noted above, this trip provides protection for some large dropped rod worth cases, and was therefore assumed to fail. Also assumed to fail is the P-17 rod withdrawal block component of the rod control system. All other parts of the rod control system are assumed to function as designed. Since the P-17 function and the rod control system circuitry reside in a common logic cabinet, this type of failure is considered to be not credible. A credible failure would be the failure of all logic in a given cabinet, which in this case would disable both the P-17 function and the rod control system. This would eliminate the possibility of power overshoot from control rod withdrawal during a dropped rod event, and result in a less limiting scenario, as in the manual rod control scenario. However, for the purpose of demonstrating diversity the bounding case was analysed, in which only the P-17 portion of the rod control system is disabled.

The thermal-hydraulic conditions during the transient, namely core heat flux, RCS temperature, RCS pressure, and inserted reactivity were calculated using the LOFTRAN code for approximately 1100 cases (combinations of dropped rod worth, control bank worth, and MTC). These transient conditions were then used in the ANC and VIPRE-01 codes to calculate a maximum hot channel peaking factor ($F_{\Delta H}$) for each case for comparison to the $F_{\Delta H}$ corresponding to the DNBR limit. The WRB-2 DNBR correlation was used, consistent with the DBA analysis. Initial condition uncertainties on power, pressure, temperature, and flow were accounted for in the DNBR limit. For the frequent fault diversity analysis, some excess reserve margin was removed from the DNBR limit. The AP1000 plant is designed to have at least [ ] DNBR margin at startup for frequent fault analyses. For the purposes of defining a DNBR limit for use in the frequent fault diversity analysis, some of this reserve margin was used. However, the limit remains conservative relative to the correlation limit. The analysis confirmed that the limits are met for all cases.

9.4.3.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT no SSCs are credited.

9.4.3.3.1.3 Diverse ATWT Results

Figures 9.4.3-5 through 9.4.3-8 show the transient response for several of the zero MTC 400 pcm control bank worth cases. The transient behaviour presented in these figures is typical of the results for other values of MTC, control bank worth, and dropped rod worth. The nuclear power and heat flux drop to a minimum value and recover under the influence of both rod withdrawal and thermal feedback. The prompt decrease in power is governed by the dropped rod worth because the plant control system does not respond during the short rod drop time period. The plant control system detects the reduction in core power and initiates control

bank withdrawal to restore the primary side power. Power overshoot occurs after which the core power is restored to the initial power level.

The analysis showed that the frequent fault DNBR limit was met, when a portion of the DNB margin typically reserved within the safety analysis limit for frequent faults was credited in the analysis. This is conservative compared to the correlation limit that is typically used for frequent fault diversity analyses. In addition, no fuel melting is predicted.

The analysis and results demonstrate that the AP1000 plant will remain safe with respect to the Dropped RCCA event if the reactor trip and P-17 rod withdrawal block functions are inoperable.

9.4.3.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.4.3.4 Radiological Consequences

9.4.3.4.1 Dropped RCCAs, Dropped RCCA Bank, and Statically Misaligned RCCA

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.4.3.4.2 Single Rod Cluster Control Assembly Withdrawal

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. The analysis results presented in Section 9.4.3.2.2.3 show that for this event, an upper bound of the number of fuel rods experiencing DNB is 5 percent of the total fuel rods in the core. The radiological consequences of the locked rotor accident presented in Section 9.3.3.4 assumed 10 percent of the fuel rods are damaged. Therefore, the locked rotor doses bound those of the single rod withdrawal event. The locked rotor doses from Section 9.3.3.4.5 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 2.8 mSv worker dose: 11 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

Thus, the identification of the Class 1 SSCs credited for protection is adequate to meet DB requirements.

9.4.3.5 As Low As Reasonably Practicable Assessment

For the this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

The diverse mitigation functions, including other Class 1 safety functions and the DAS function, which is Class 2, is also shown by analysis to meet the corresponding requirements for this event. See Reference 9.4-10 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy provided by the DiD systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- SFW with steam dump for short-term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the CCS and SWS cooling water systems.
- Pressuriser spray and auxiliary spray for RCS pressure control
- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment and acuation automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (See Section 9.1.4.5).

However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

As discussed in Section 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000 development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.4.3.6 Conclusions

For cases of dropped RCCAs or dropped banks, including inadvertent drops of the RCCAs in those groups selected to be inserted as part of the rapid power reduction system, it is shown that the DNBR remains greater than the safety analysis limit value and, therefore, the DNB design basis is met.

For cases of any one RCCA fully inserted, or the mechanical shim or axial offset banks inserted to their rod insertion limits with any single RCCA in one of those banks fully withdrawn (static misalignment), the DNBR remains greater than the safety analysis limit value (see Section 22.7.1.1).

For the case of the accidental withdrawal of a single RCCA, with the reactor in the automatic or manual control mode and initially operating at full power with the mechanical shim or axial offset banks at their insertion limits, an upper bound of the number of fuel rods experiencing DNB is 5 percent of the total fuel rods in the core.

This event has also been adequately assessed with respect to ATWT considerations.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences for the dropped RCCAs or the statically misaligned RCCA are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of the Class 1 SSCs for event mitigation is adequate to meet DB requirements.

DBA radiological consequences for a single rod cluster control assembly withdrawal are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of the Class 1 SSCs credited for protection is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.4.4 Startup of an Inactive Reactor Coolant Pump at an Incorrect Temperature (Fault 1.15.6)

The Technical Specifications require all RCPs to be operating while in Modes 1 and 2. The maximum initial core power level for the startup of an inactive loop transient is approximately

zero MWt. Furthermore, the reactor will initially be subcritical by the Technical Specification requirement. There will be no increase in core power, and no automatic or manual protective action is required.

9.4.5 Not Used

9.4.6 Chemical and Volume Control System Malfunction that Results in a Decrease in the Boron Concentration in the Reactor Coolant (Fault 1.15.7)

9.4.6.1 Identification of Causes and Accident Description

Other than control rod withdrawal, the principal means of positive reactivity insertion to the core is the addition of unborated, primary-grade water from the demineralized water transfer and storage system into the reactor coolant system through the reactor makeup portion of the chemical and volume control system. Normal boron dilution with these systems is manually initiated under strict administrative controls requiring close operator surveillance. Procedures limit the rate and duration of the dilution. A boric acid blend system is available to allow the operator to match the makeup water boron concentration to that of the reactor coolant system during normal charging.

An inadvertent boron dilution is caused by the failure of the demineralized water transfer and storage system or chemical and volume control system, either by controller, operator or mechanical failure. The chemical and volume control system and demineralized water transfer and storage system are designed to limit, even under various postulated failure modes, the potential rate of dilution to values that, with indication by alarms and instrumentation, allow sufficient time for automatic or operator response to terminate the dilution.

An inadvertent dilution from the demineralized water transfer and storage system through the chemical and volume control system may be terminated by isolating the makeup flow to the reactor coolant system, by isolating the makeup pump suction line to the demineralized water transfer and storage system storage tank, or by tripping the makeup pumps. Lost shutdown margin may be regained by adding borated water to the reactor coolant system from the boric acid tank.

Generally, to dilute, the operator would need to perform two actions:

- Switch control of the makeup from the automatic makeup mode to the dilute mode.
- Start the chemical and volume control system makeup pumps.

Failure to carry out either of those actions prevents initiation of dilution. Because the AP1000 chemical and volume control system makeup pumps do not run continuously (they are expected to be operated once per day to make up for reactor coolant system leakage), a makeup pump is started when the volume control system is placed into dilute mode.

The status of the reactor coolant system makeup is available to the operator by the following:

- Indication of the boric acid and blended flow rates
- Chemical and volume control system makeup pumps status
- Deviation alarms, if the boric acid or blended flow rates deviate by more than the specified tolerance from the preset values

- When reactor is subcritical:
  - High flux at shutdown alarm
  - Indicated source range neutron flux count rate
  - Audible source range neutron flux count rate
  - Source range neutron flux-multiplication alarm
- When the reactor is critical:
  - Axial flux difference alarm (reactor power ≥ 50 percent rated thermal power)
  - Control rod insertion limit low and low-low alarms
  - Overtemperature ΔT alarm (at power)
  - Overtemperature ΔT reactor trip
  - Power range neutron flux-high, both high and low setpoint reactor trips.

In addition, this section addresses concerns related to transient reactivity excursions associated with Xenon decay following a reactor trip from power, which was fully evaluated in Reference 9.4.27. The Xenon-induced reactivity excursion is relatively slow, and the CVS would normally maintain the required shutdown margin and reactivity control in this situation. In the event of CVS failure following reactor trip but before the Xenon level stabilizes, Reference 9.4.27 demonstrates that adequate diverse protection systems are available to control reactivity through RCS boration. Of particular concern for this scenario would be an uncontrolled return-to-power from Mode 2 or 3 due to Xenon decay. For this scenario, the CVS failure does not result in a reduction in boron; however, the Xenon-induced reactivity excursion produces a similar reactivity anomaly concern.

9.4.6.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA)

Analysis is performed to demonstrate the adequacy of the protection and safety monitoring system to detect and mitigate the fault and show no return to criticality (no complete loss of shutdown margin following a boron dilution).

Provided that the reactor core will not reach criticality, and the boron dilution transient is bounded by the other transients with respect to DNB, peak primary or secondary pressure, and pressuriser fill concerns.

9.4.6.2.1 DBA Method of Analysis

Boron dilutions during refuelling, cold shutdown, hot shutdown, hot standby, startup, and power modes of operation are considered in this analysis. Conservative values for critical/key parameters are used (high reactor coolant system critical boron concentrations, high boron worths, minimum shutdown margins, and lower-than-actual reactor coolant system volumes).

These assumptions (see Table 9.4-2) result in conservative determinations of the time available for operator or automatic system response after detection of a dilution transient in progress.

A loss of offsite power is considered for the boron dilution case initiated from the power mode of operation (Mode 1) with the reactor in manual control. This is the analysed Mode 1 boron dilution case that produces a reactor and turbine trip (Section 9.4.6.2.6). The loss of offsite power is assumed to occur as a direct result of a turbine trip that would disrupt the grid and produce a consequential loss of offsite ac power. As discussed in Section 9.0.12, that scenario can occur only with the plant at power and connected to the grid. Therefore, only a boron dilution case initiated from full power will be addressed with respect to the consequential loss of offsite power.

9.4.6.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1. The credited Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, and pressuriser SVs. The PMS provides the following:

- RT on:
  - Overtemperature ΔT
  - Source range high flux
- Automatic isolation of dilution sources on:
  - Source range neutron flux-multiplication alarm prior to losing all shutdown margin when reactor is subcritical
  - Any reactor trip when reactor is critical
- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.4.6.2.3 DBA Results

9.4.6.2.3.1 Dilution During Refuelling (Mode 6)

An uncontrolled boron dilution transient cannot occur during this mode of operation. Inadvertent dilution is prevented by administrative controls, which isolate the reactor coolant system from the potential source of unborated water by locking closed specified valves in the chemical and volume control system during refuelling operations. These valves block the flow paths that allow unborated makeup water to reach the reactor coolant system. Makeup which is required during refuelling uses water supplied from the boric acid tank (which contains borated water). This information is consistent with the boron dilution discussion provided in Section 9.8.4.4.5.

9.4.6.2.3.2 Dilution During Cold Shutdown (Mode 5)

The following conditions are assumed for inadvertent boron dilution while in this operating mode:

- A dilution flow of 39.75 m^3/hr (175 gpm) of unborated water exists. The dilution flow is assumed to be at 4.4°C and 0.101 MPa abs (40°F and 14.7 psia). The fluid conditions of the RCS are assumed to be 93.33°C and 0.101 MPa abs (200°F and 14.7 psia).

- The reactor coolant system volume is 73.86 m^3 (2608.2 ft^3). This is a conservative estimate of the minimum active volume of the reactor coolant system corresponding to the water level at mid-loop in the vessel while on normal residual heat removal. The assumed active volume does not include the volume of the reactor vessel upper head region.

- Control rods are fully inserted, which is the normal condition in cold shutdown, and the critical boron concentration is 1483 ppm. This is a conservative boron concentration with control rods inserted and accounts for the most reactive rod stuck in the fully withdrawn position.

- The shutdown margin is equal to 1.6-percent Δk/k, the minimum value identified by the Technical Specifications for the cold shutdown mode. Combined with the critical boron concentration identified above, this gives an initial boron concentration of 1675 ppm.

- At least one reactor coolant pump will be normally operating during plant operation in Mode 5. It may be possible under some conditions, however, to operate the plant in Mode 5 with no reactor coolant pumps operating. For this reason, the mixing volume assumed for the analysis in Mode 5 will include the reactor coolant loop and normal residual heat removal system volumes that are being actively mixed by the residual heat removal system pumps.

- A boron dilution protection system (BDPS) Safety Analysis Limit (SAL) flux multiplier setpoint of 3.0 is assumed.

In the event of an inadvertent boron dilution transient during cold shutdown, the source range nuclear instrumentation detects an increase in the neutron flux by comparing the current source range flux to that of about 50 minutes earlier. Upon detecting a sufficiently large flux increase, an alarm is sounded for the operator, and valves are actuated to terminate the dilution automatically.

Upon the actuation of a source range flux multiplier signal, the makeup flow to the reactor coolant system and the makeup pump suction line to the demineralized water transfer and storage system storage tank are isolated. This thereby terminates the dilution. In addition, the makeup pumps are tripped for equipment protection purposes.

No operator action is required to terminate this transient. The analysis demonstrates that the flux multiplier SAL will be reached 11.2 minutes after the dilution transient begins and that there is sufficient time at this point for the automatic protective features to terminate the dilution prior to losing all shutdown margin. After the automatic protection functions take place, the operator may take action to restore the Technical Specification shutdown margin.

9.4.6.2.3.3 Dilution During Safe Shutdown (Mode 4)

The following conditions are assumed for an inadvertent boron dilution while in this mode:

- A dilution flow of 39.75 m^3/hr (175 gpm) of unborated water exists. The dilution flow is assumed to be at 4.4°C and 0.101 MPa abs (40°F and 14.7 psia). The fluid conditions of the RCS are assumed to be 215.56°C and 2.765 MPa abs (420°F and 401 psia).

- The reactor coolant system volume is 215.38 m^3 (7605.9 ft^3). This is a conservative estimate of the minimum active volume of the reactor coolant system with the reactor coolant system filled and vented and one reactor coolant pump running. The assumed active volume does not include the volume of the reactor vessel upper head region.

- All control rods are fully inserted except the most reactive rod, which is assumed stuck in the fully withdrawn position. The critical boron concentration is 1449 ppm.

- The shutdown margin is equal to 1.6-percent $\Delta k/k$, the minimum value required by the Technical Specifications for the hot shutdown mode. Combined with the critical boron concentration given above, this gives an initial boron concentration of 1649 ppm.

- The reactor coolant system dilution volume is considered well-mixed. The Technical Specification 3.4.8 requires that at least one reactor coolant pump shall be operating with a flow of at least 3000 gpm (681.37 m^3/hr) when in Mode 4. This provides sufficient flow through the system to maintain the system well-mixed. If a reactor coolant pump is not operating, the demineralized water isolation valves are closed and an uncontrolled boron dilution transient cannot occur, as discussed in Section 9.4.6.2.1.

- A BDPS SAL setpoint of 3.0 is assumed.

In the event of an inadvertent boron dilution transient during safe shutdown, the source range nuclear instrumentation detects a sufficiently large increase in the neutron flux by comparing the current source range flux to that of about 50 minutes earlier, automatically initiates valve movement to terminate the dilution, and sounds an alarm.

Upon the actuation of a source range flux multiplier signal, the makeup flow to the reactor coolant system and the makeup pump suction line to the demineralized water transfer and storage system storage tank are isolated. This thereby terminates the dilution. Also, the makeup pumps are tripped for equipment protection purposes.

No operator action is required to terminate this transient. The analysis demonstrates that the flux multiplier SAL will be reached 28.83 minutes after the dilution transient begins and that there is sufficient time at this point for the automatic protective features to terminate the dilution prior to losing all shutdown margin. After the automatic protection functions take place, the operator may take action to restore the Technical Specification shutdown margin.

9.4.6.2.3.4 Dilution During Hot Standby (Mode 3)

The following conditions are assumed for an inadvertent boron dilution while in this mode:

- A dilution flow of 39.75 m^3/hr (175 gpm) of unborated water exists. The dilution flow is assumed to be at 4.4°C and 0.101 MPa abs (40°F and 14.7 psia). The fluid conditions of

the reactor coolant system are assumed to be 291.67°C and 15.513 MPa abs (557°F and 2250 psia).

- The reactor coolant system volume is 215.38 m^3 (7605.9 ft^3). This is a conservative estimate of the minimum active volume of the reactor coolant system with the reactor coolant system filled and vented and one reactor coolant pump running. The assumed active volume does not include the volume of the reactor vessel upper head region.

- Critical boron concentration is 1281 ppm. This is a conservative boron concentration assuming control rods are fully inserted minus the most reactive rod, which is assumed stuck in the fully withdrawn position.

- The shutdown margin is equal to 1.6-percent Δk/k, the minimum value required by the Technical Specifications for the hot standby mode. Combined with the critical boron concentration given above, this gives an initial boron concentration of 1509 ppm.

- The reactor coolant system dilution volume is considered well-mixed. The Technical Specification 3.4.8 requires that at least one reactor coolant pump shall be operating with a flow of at least 681.37 m^3/hr (3000 gpm) when in Mode 3. This provides sufficient flow through the system to maintain the system well mixed. If a reactor coolant pump is not operating, the demineralized water isolation valves are closed and an uncontrolled boron dilution transient cannot occur, as discussed in section 9.4.6.2.1.

In the event of an inadvertent boron dilution transient in hot standby, the source range nuclear instrumentation detects a sufficiently large increase in the neutron flux by comparing the current source range flux to that of about 50 minutes earlier, automatically initiates valve movement to terminate the dilution, and sounds an alarm. Upon the actuation of a source range flux multiplier signal, the makeup flow to the reactor coolant system and the makeup pump suction line to the demineralized water transfer and storage system storage tank are isolated. This thereby terminates the dilution. Also, the makeup pumps are tripped for equipment protection purposes.

No operator action is required to terminate this transient. The analysis demonstrates that the flux multiplier SAL will be reached 32.07 minutes after the dilution transient begins and that there is sufficient time at this point for the automatic protective features to terminate the dilution prior to losing all shutdown margin. After the automatic protection functions take place, the operator may take action to restore the Technical Specification shutdown margin.

9.4.6.2.3.5 Dilution During Startup (Mode 2)

The plant is in the startup mode only for startup testing at the beginning of each cycle. During this mode of operation, rod control is in manual. Normal actions taken to change power level, either up or down, require operator actuation. The Technical Specifications require an available shutdown margin of 1.6-percent Δk/k and four reactor coolant pumps operating. Other conditions assumed are the following:

- A dilution flow of 39.75 m^3/hr (175 gpm) of unborated water exists. The dilution flow is assumed to be at 4.4°C and 0.101 MPa abs (40°F and 14.7 psia). The fluid conditions of the reactor coolant system are assumed to be at the 5-percent power, 296.57°C and 15.513 MPa abs (565.83°F and 2250 psia).

- Minimum reactor coolant system water volume is 238.58 m^3 (8425.5 ft^3). This is a very conservative estimate of the active reactor coolant system volume, minus the pressuriser volume.

- The initial maximum critical boron concentration, corresponding to the rods inserted to the insertion limits, is 2031 ppm. The minimum change in boron concentration from this initial condition to a hot zero power critical condition with all rods inserted is 1097 ppm, which gives a critical boron concentration of 934 ppm.

This mode of operation is a transitory operational mode in which the operator intentionally dilutes and withdraws control rods to take the plant critical. During this mode, the plant is in manual control. For a normal approach to criticality, the operator manually withdraws control rods and dilutes the reactor coolant with unborated water at controlled rates until criticality is achieved. Once critical, the power escalation is slow enough to allow the operator to manually block the source range reactor trip after receiving the P-6 permissive signal from the intermediate range detectors (nominally at 10^5 cps). Too fast a power escalation (due to an unknown dilution) would result in reaching P-6 unexpectedly, leaving insufficient time to manually block the source range reactor trip. Failure to perform this manual action results in a reactor trip and immediate shutdown of the reactor.

Upon any reactor trip signal, or low input voltage to the Class 1E DC and uninterruptable power supply system battery chargers, a Class 1 function automatically isolates the potentially unborated water from the demineralized water transfer and storage system and thereby terminates the dilution. Additionally, the suction lines for the chemical and volume control system pumps are automatically realigned to draw borated water from the chemical and volume control system boric acid tank.

After reactor trip, the dilution would have to continue for approximately 205 minutes to overcome the available shutdown margin.

9.4.6.2.3.6 Dilution During Full Power Operation (Mode 1)

The plant may be operated at power two ways: automatic T_{avg}/rod control and under operator control. The Technical Specifications require an available shutdown margin of 1.6-percent $\Delta k/k$ and four reactor coolant pumps operating. With the plant at power and the reactor coolant system at pressure, the dilution rate is limited by the capacity of the chemical and volume control system makeup pumps. The analysis is performed assuming two chemical and volume control system pumps are in operation, even though normal operation is with one pump. Conditions assumed for a dilution in this mode are the following:

- A dilution flow of 39.75 m^3/hr (175 gpm) of unborated water exists. The dilution flow is assumed to be at 4.4°C and 0.101 MPa abs (40°F and 14.7 psia). The fluid conditions of the RCS are assumed to be at full power, 305.33°C and 15.513 MPa abs (581.6°F and 2250 psia).

- Minimum reactor coolant system water volume is 238.58 m^3 (8425.5 ft^3). This is a very conservative estimate of the active reactor coolant system volume, minus the pressuriser volume.

- An initial maximum boron concentration, corresponding to the rods inserted to the insertion limits, is 1811 ppm. The minimum change in boron concentration from this initial condition to a hot zero power critical condition with all rods inserted is 877 ppm,

which gives a critical boron concentration of 934 ppm. Full rod insertion, minus the most reactive stuck rod, occurs due to reactor trip.

With the reactor in automatic rod control, the pressuriser level controller limits the dilution flow rate to the maximum letdown rate. If a dilution rate in excess of the letdown rate is present, the pressuriser level controller throttles charging flow down to match letdown rate. For the safety analysis, a conservative dilution flow rate of 39.75 m^3/hr (175 gpm) is assumed. With the reactor in automatic rod control, a boron dilution results in a power and temperature increase in such a way that the rod controller attempts to compensate by slow insertion of the control rods. This action by the controller results in at least three alarms to the operator:

A. Rod insertion limit – low level alarm
B. Rod insertion limit – low-low level alarm if insertion continues
C. Axial flux difference alarm (ΔI outside of the target band)

Given the many alarms, indications, and inherent slow process of dilution at power, the operator has sufficient time for action. The operator has at least 170.6 minutes from the rod insertion limit low-low alarm until shutdown margin is lost at beginning of cycle. The time is significantly longer at the end of the cycle because of the lower initial and critical boron concentrations.

Because the analysis for the boron dilution event with the reactor in automatic rod control does not predict a reactor and turbine trip, considering the consequential loss of offsite power for this case is not needed.

With the reactor in manual control and no operator action taken to terminate the transient, the power and temperature would rise and cause the reactor to reach the overtemperature ΔT trip setpoint resulting in a reactor trip. Upon any reactor trip signal, a Class 1 function automatically isolates the unborated water from the demineralized water transfer and storage system and thereby terminates the dilution. Additionally, the suction lines for the chemical and volume control system pumps are automatically realigned to draw borated water from the chemical and volume control system boric acid tank.

The boron dilution transient in this case is essentially equivalent to an uncontrolled rod withdrawal at power (see Section 9.4.2). The maximum reactivity insertion rate for a boron dilution transient is conservatively estimated to be approximately 0.5 pcm/s and is within the range of insertion rates analysed for uncontrolled rod withdrawal at power. Before reaching the overtemperature ΔT reactor trip, the operator receives an alarm overtemperature ΔT and an overtemperature ΔT turbine runback.

Should a consequential loss of offsite power occur after reactor and turbine trip, it does not alter the fact that the dilution event has been terminated by automatic protection features. As indicated previously, the reactor trip signal that occurs in parallel with the turbine trip will actuate a Class 1 function that automatically isolates the unborated water from the demineralized water system and thereby terminates the dilution. A subsequent loss of offsite power will cause the chemical and volume control system pumps to shut down.

After reactor trip, the automatic termination of the dilution flow from the demineralized water transfer and storage system precludes a post-trip return to criticality.

9.4.6.3 Diverse Mitigation

The available diverse protection for the Mode 1 and Mode 2 scenarios of this event is the same as for the RCCA misalignment faults (Section 9.4.3.3).

Section 9.4.6.3.1 provides a discussion of the ATWT evaluation for this event that is divided into two parts. The first evaluation addresses ATWT initiated from Mode 1 and Mode 2. The second evaluation addresses inadvertent boron dilution event initiated from the lower modes of operation with control rods already inserted. As such, this second evaluation is not technically an ATWT event. The second evaluation relies on a DAS signal as follows.

The boron dilution event at shutdown conditions is characterized by a slow increase in nuclear power from very low power levels. As a result of the increase in nuclear power the source range alarm would be generated; however this alarm is assumed to not be created in the PMS due to the common cause failure and is not credited in the analysis. The slow nuclear power increase eventually results in criticality.

As the source range nuclear instrumentation is considered the primary protection for the inadvertent boron dilution event at lower modes, a new DAS actuation based on the intermediate range nuclear instrumentation (IRNI) is credited for boron dilution at shutdown conditions. The DAS actuation logic is "ARMED" when the reactor trip breakers are open and IRNI indicates < [ ] FON power. The arming signal is retained even if the IRNI signal goes above the nominal setpoint of [ ] fraction of nominal (FON) power. The arming signal is removed if either the reactor trip breakers are "NOT" open or a demineralised water storage tank (DWST) isolation signal has been generated.

The DAS IRNI actuation signal results in trip of the RCPs and RNS pumps, isolation of the boron dilution sources (i.e., makeup flow to the RCS and the makeup pump suction line to the DWST), and CMT actuation. Boron addition to the core following the CMT actuation results in a negative reactivity addition and terminates the event. The rate of increase in the nuclear power level on the intermediate range detector scale from the DAS actuation setpoint of [ ] FON to the point of adding heat ([ ] FON) is slow enough that the required DAS functionality can be carried out in a timely manner to automatically terminate the event.

9.4.6.3.1 Diverse Mitigation for ATWT

One of the two principal means of positive reactivity insertion to the core is the addition of unborated, primary-grade water from the demineralised water into the RCS through the reactor makeup portion of the CVS. Normal boron dilution with these systems is manually initiated under strict administrative controls requiring close operator surveillance.

An inadvertent boron dilution is postulated to be caused by the failure of the CVS by the controller, mechanical failure, or operator. Two diversity scenarios are evaluated: inadvertent boron dilution from Modes 1 or 2 (ATWT) and inadvertent boron dilution from lower modes.

An inadvertent boron dilution results in a slow addition of positive reactivity. If the reactor is in Mode 1 or Mode 2, an uncontrolled boron dilution causes a slow increase in core power.

If the event is initiated at lower modes, multiple alarms are available to alert the operator of a dilution event including displayed / audible source range neutron flux count rates, and the source range neutron flux-multiplication alarm. The probability that a problem occurs in the source range neutron flux monitoring system with a simultaneous independent failure would cause a boron dilution event is extremely remote. However, boron dilution diversity analysis

at lower modes is completed to demonstrate that the DAS IRNI function would protect the plant in this scenario.

This analysis is performed to demonstrate the adequacy of the operable portions of the PMS (considering the impact of the CCF) as well as the DAS to detect and actuate mechanical SSCs to mitigate the fault. The following ATWT acceptance criteria are applicable to this event:

- The RCS does not overpressurise due to reactor coolant heatup. The ATWT pressure limit is 22.06 MPa-rel (3200 psig).
- There is no significant fuel damage.
- The rate and duration of energy release to containment is much less than for the design basis LOCA. This demonstrates that the containment does not overpressurise due to the energy release to the containment.

For the lower modes of operation, a conservative acceptance criterion is used that the point of adding heat is not reached, which ensures that the previous ATWT criteria are met.

9.4.6.3.1.1 Diverse ATWT Method of Analysis

Analysis Assumptions

The assumptions used for the ATWT Boron Dilution in Mode 1 and 2 are discussed below. No measurement/instrumentation errors are assumed.

a. Initial conditions are assumed at the nominal full power values. If the event is initiated at a lower power level, the first part of event will be dominated by a power increase. After reaching full power, the rest of the event will be essentially the same as a boron dilution event initiated at full power.

b. The initial boron concentration and core kinetics parameters are assumed to be at their BOC values. Refer to Reference 9.4-20 for core neutronics discussion.

c. Modelled reactivity coefficients are more conservative than the reactivity coefficients discussed in Reference 9.4-20. Also, to model power increase due to boron dilution, boron coefficient was set equal to -9.7, -9.3, -8.9 pcm/ppm for boron concentrations 600, 900, 1200 ppm.

d. The pressuriser pressure control system, including heaters and sprays, are assumed to be operable and function normally.

e. It is assumed that the pressuriser level control system maintains pressuriser level. The normal makeup flow when one pump is running is 0.0063 m^3/s (100 gpm) is assumed because no single failure could cause inadvertent makeup and simultaneous inadvertent wrong blending.

f. The minimum reactor coolant system water volume used for the boron concentration calculation was assumed to be 230 m^3 (8126 ft^3). The fluid density was calculated assuming an RCS pressure of 15.513 MPa abs (2250 psia) and a temperature of 316°C (600°F). The initial boron concentration is assumed to be 1050 ppm, and the dilution flow rate is assumed to be 8.6 kg/s (19 lbm/s) with a boron concentration of 0 ppm.

g. The turbine trip on reactor trip function is assumed to be operable. Turbine trip is assumed to occur 7 seconds after reaching the reactor trip setpoint. This delay includes 2 seconds for PMS/DAS logic to evaluate the setpoint and a 5 second programmed turbine trip delay from the expected time of reactor trip, which is specified in PMS and DAS.

h. The SG PORVs are assumed to be operable for all cases in which offsite power is available. A set pressure of 7.85 MPa abs (1138 psia) is assumed.

i. The turbine bypass system is assumed to be operable and the turbine is assumed to operate such that the initial steam flow is maintained.

j. The following protection functions are available for this event:

- PMS reactor trip and turbine trip and demineralised water tank line isolation on OTΔT, OPΔT or high neutron flux
- DAS reactor trip and turbine trip – High Hot Leg Temperature in both hot legs
- DAS ESF – PRHR on High Hot Leg Temperature in both hot legs (High Hot Leg Temperature Setpoint is assumed to be 343.3°C (650°F))

k. Prior to reaching PMS reactor trip setpoints, some of the PLS low margin to setpoints alarms may be actuated. The high flux power range above setpoint (C-2), the Low Margin to OTΔT (C-3) and OPΔT (C-4) rod control system power control subsystem interlocks will actuate an alarm, along with blocking automatic and manual withdrawal of control rods, and will actuate turbine runback. The deviation (above or below) of the TAVG/TREF mismatch error signal and deviation of the QN/PTU mismatch error signal will also generate an alarm. Although it is expected that these alarms would alert the operator to manually terminate the dilution and trip the reactor (for cases without RCCA CCF), these alarms are not credited in these analyses.

l. Only cases with continuing ac power supply to plant are presented due to following reasons:

- Assuming a loss of offsite power would mean assuming another independent failure.
- On a loss of ac power signal, the CVS makeup pumps are not automatically sequenced onto the diesel generator. They must be sequenced manually, and DWST must be isolated when the makeup pumps are started. Additionally, the DWST pumps (which provide demineralised water to the makeup pump suction) are not sequenced onto the diesel, providing additional protection against unwanted dilution.
- For the cases with PMS operable, the DWST is automatically isolated on low input voltage to the Class 1 IDS battery chargers.

The assumptions used in the boron dilution diversity analysis from the lower modes of operation are discussed below.

a. Modes of Operation: The lower mode boron dilution events are only considered for Mode 3 (Hot Standby), Mode 4 (Hot Shutdown) and Mode 5 (Cold Shutdown). As discussed in Section 9.4.6.2.3.1, an uncontrolled boron dilution transient cannot occur during Mode 6; therefore, no evaluation was required for this mode.

b. Minimum Dilution Volume: The active RCS volume determines the minimum dilution volume, which is a critical parameter for a dilution event. Cases both with and without RCPs operating are considered, as this assumption significantly changes the active RCS volume. For these shutdown mode analyses, three general conditions were considered:

- Cases where at least one RCP is operating and providing core cooling (Mode 3, 4, or 5). For these cases, the minimum dilution volume is 215.4 m^3 (7605.9 ft^3).
- A Mode 5 case with the RCS drained to the mid-plane of the hot legs and the RNS pumps operating and providing core cooling. For this case, the minimum dilution volume is 73.9 m^3 (2608.2 ft^3).
- Cases where both the RCPs and RNS pumps are operating. For these cases, the minimum dilution volume would be larger than either of the cases described above, and therefore would not be limiting from a boron dilution standpoint.

c. Credible Dilution Flow Rate:

- A dilution flow rate of 22.71 m^3/hr (100 gallons per minute (gpm)) is used, corresponding to a nominal CVS makeup flow from one makeup pump (normal operation). Two makeup pumps would not be operating under normal conditions.
- For conditions where the normal makeup dilution path is isolated, e.g., per Technical Specifications, a dilution path from the CVS chemical mixing tank is still possible, but the flow from this tank is limited to a maximum of 0.45 m^3/hr (2 gpm) by the chemical mixing tank demineralised water inlet flow orifice. A bounding flow of 0.68 m^3/hr (3 gpm) is conservatively considered in the analysis.

d. Initial RCS Temperature: Maximum RCS temperatures are conservatively modelled for each mode. Minimum RCS temperatures are not expected to be limiting for the boron dilution event since the increased density of the water limits the effectiveness of the dilution process. However, the effects of the higher density water on the IRNI indication (limiting the transport of fission neutrons to the detector) must be considered for the DAS actuations that are required.

- For RCP operation in Mode 3, the modelled RCS temperature is 291.7°C (557°F).
- For RCP operation in Mode 4, the modelled RCS temperature is 215.6°C (420°F).
- For Mode 4 RNS pump operation, the modelled RCS temperature is 176.7°C (350°F).
- For Mode 5 RNS pump operation, the modelled RCS temperature is 93.3°C (200°F).

e. Credible Cases: Based on the descriptions of the conditions and limitations of the analysis, the following two credible boron dilution scenarios exist:

- Dilution flow of 22.71 m^3/hr (100 gpm) with at least one RCP in operation (Modes 3 and 4).
- Dilution flow of 22.71 m^3/hr (100 gpm) for one hour with only RNS pumps in operation followed by a maximum dilution rate of 0.68 m^3/hr (3 gpm) (Modes 4 and 5).

f. Accident Scenario: For the credible cases, accident scenario evaluated in the analysis is as follows.

- Initial subcritical conditions with all control rods inserted and the core borated to the minimum shutdown margin or maintain the hot full power (HFP) critical boron concentration prior to trip.
- Simple boron concentration vs. time for dilution until the IRNI setpoint is reached. A conservative safety analysis setpoint power level for the DAS activation is [ ] FON.
- Upon DAS IRNI signal, the following actions are credited:
  - Isolate dilution sources
  - Trip RNS pumps and RCPs
  - Actuate CMTs (with a conservative [ ] second delay)
- To ensure that the ATWT criteria are met, a conservative acceptance criterion used, requiring that the point of adding heat is not reached. For practical purposes, the point of adding heat is assumed to be [ ] RTP.

9.4.6.3.1.2 Diverse ATWT Credited SSCs

For the diverse ATWT all of the claimed SSCs are Class 1 except for the DAS. The available Class 1 SSCs are listed in Table 9.0-14.

For Modes 1 2, the following actuations are provided:

- PMS Automatic isolation of dilution sources on OTΔT reactor trip signal (not credited for PMS CCF case)
- DAS PRHR on High hot leg temperature in both loops

For Modes 3-5, the DAS provides the following:

- Isolation of dilution sources, RCP trip, CMTs, and containment isolation on High intermediate range nuclear power
- Termination of RNS flow on High intermediate range nuclear power (either by RNS pump trip or RNS isolation)

9.4.6.3.1.3 Diverse ATWT Results

9.4.6.3.1.3.1 Mode 1 and Mode 2 Diverse ATWT Boron Dilution

ATWT analyses evaluated scenarios for PMS CCF, Reactor Trip Breaker CCF, and RCCA mechanical CCF. Two limiting cases are presented for this accident group: boron dilution with a PMS CCF in manual rod control and boron dilution with a RCCA mechanical CCF dilution in manual rod control. Although both automatic and manual rod control case were considered, the manual rod control cases are presented. The automatic rod control cases would compensate for a boron dilution by inserting the RCCAs during the initial portion of the transient. This would result in additional indications to alert the operator to the dilution event.

Eventually, the rod control limits would be reached and the remainder of the transient would look the same as the manual rod control scenario.

Boron Dilution with PMS CCF in Manual Rod Control

Table 9.4.6-1 shows the sequence of events for a boron dilution with a CCF of the PMS in manual rod control.

This event is characterised by a slow increase in nuclear power, which results in a primary to secondary side power mismatch due to the fact that turbine is assumed to keep initial steam flow. Secondary pressure increases, which results in an increase in RCS temperature, resulting in a negative reactivity feedback. The increase in nuclear power is slow enough that the core power reaches equilibrium with steam load. As the secondary pressure reaches the SG PORV opening pressure, the opening of SG PORV provides additional steam load. The additional load results in a further increase in the nuclear power. As a result in the increase in nuclear power, the PMS OTΔT reactor trip setpoint is reached; however, a reactor trip signal is not created in the PMS due to the CCF.

Power continues to increase until the DAS High Hot Leg Temperature setpoint of 343.3°C (650°F) is reached.

The DAS High Hot Leg Temperature signal results in a reactor trip, turbine trip, and PRHR actuation. The core power reaches maximum power of 107.5 percent at the time that the High Hot Leg Temperature signal is reached. The PMS OTΔT reactor trip typically results in an isolation of dilution paths; however, due to the failure of the PMS, the automatic isolation of the dilutions does not occur (the DAS High Hot Leg Temperature signal does not result in an automatic isolation of the dilution sources). A manual operator action is required to terminate the dilution and initiate boration of RCS.

As stated in Section 9.4.6.2.3.6, the conservatively minimised boron concentration difference between full power with rods inserted to the insertion limits and hot zero power critical condition with all rods inserted is 877 ppm. If the boron dilution continues from the beginning of the event, such dilution will be require up to approximately 500 minutes of dilution time.

Assuming that operator is not alerted to the transient until after the DAS reactor trip has occurred at 1094 seconds (18 minutes), and assuming 30 minutes for operator action, the operator would be able to act around 2894 seconds (48 minutes) after the beginning of dilution. At that time, the boron concentration will be diluted by 150 ppm from the initial boron concentration.

Boron Dilution with a RCCA Mechanical CCF in Manual Rod Control

Table 9.4.6-2 shows the sequence of events for a boron dilution with a CCF that prevents the RCCAs from inserting in manual rod control. Transient response of this event is shown in Figures 9.4.6-1 to 9.4.6-3.

This event is characterised by a slow increase in nuclear power, which results in a primary to secondary side power mismatch due to the fact that turbine is assumed to keep initial steam flow. Secondary pressure increases, which results in an increase in RCS temperature, resulting in a negative reactivity feedback. The increase in nuclear power is slow enough that the core power reaches equilibrium with steam load. As the secondary pressure reaches the SG PORV opening pressure, the opening of SG PORV provides additional steam load. The additional load results in a further increase in the nuclear power. As a result in the increase in nuclear

power, the PMS OTΔT reactor trip setpoint is reached; however, RCCAs are not inserted into the core due to a reactor trip breaker CCF. Due to the generation of the reactor trip signal in the PMS, the following actions will be taken by the PMS:

- The DWST will be isolated, and blend valve will be aligned to the boric acid storage tank only. This would result in the injection of a highly borated solution at 4375 ppm. If the blending valve is assumed to fail, the dilution will still be terminated.

- The turbine will trip.

- The turbine bypass system will be unblocked, and turbine bypass operation will be initiated in pressure control mode.

After the turbine trips, secondary pressure starts to increase sharply as SG PORVs and the turbine bypass will not be able to take the entire steam load. The secondary side pressure will continue to increase until the steam generator safety valve opening pressure is reached. This increase in secondary pressure will also results in the increase of primary temperature. The DAS High Hot Leg Temperature setpoint of 343.3°C (650°F) will eventually be reached, which actuates the PRHR system.

The core power reaches equilibrium conditions at 102 percent power level.

After that, manual operator action will be necessary to shut down reactor via boration of the RCS.

Boron Dilution with a Reactor Trip Breaker CCF in Manual Rod Control

This scenario is identical to the manual rod control RCCA CCF scenario, until the time when the first reactor trip setpoint in DAS is reached. At that time, RCCA will be dropped from DAS reactor trip signal and terminate the event (the dilution flow will be already terminated from PMS reactor trip signal on OTΔT).

9.4.6.3.1.3.2 Diverse Boron Dilution in Lower Modes

For the credible cases, simplified boron dilution calculations have shown that the second scenario, the cases with only RNS pumps operating, is not as challenging as the first scenario with the RCPs running. For the second scenario, the boron concentration decreases rapidly for the first hour (60 minutes) because of a lower active dilution volume compared to the cases with at least one RCP operating. Thereafter, the boron dilution is attenuated significantly as a result of the dilution flow change to only 0.68 m^3/hr (3 gpm). In the first hour, the boron concentration for all of the RNS-only cases does not decrease below the critical boron concentration. As the boron dilution rate significantly reduces after the CVS isolation within one hour it provides a slower transition through the neutron flux levels for the DAS actuation compared to the first scenario with the RCP(s) operating. Therefore, the scenario with RCP(s) operating is the limiting credible scenario for this event. The results and discussions provided below are based on this limiting scenario.

For the dilution event, the reactor was initially assumed to be critical at HFP with all control rods withdrawn and at equilibrium xenon conditions, followed by a reactor trip and an extended shutdown such that all xenon has decayed. The HFP critical boron concentration at the initial condition is more than sufficient to meet the shutdown margin requirements after reactor trip. Therefore, the initial condition for the transient simulation is HZP temperature

with all control rods inserted and the initial HFP boron concentration. As the dilution progresses, the core becomes nearly critical. The calculations after this point were carried out using both a static solution in ANC and a kinetic solution in SPNOVA.

The dilution event was first simulated for a typical reload cycle without the DAS activation (no boron injection from the CMTs and isolation of the dilution sources) to calculate the time it takes to increase the nuclear power from the IRNI safety analysis setpoint of [ ] FON to the point of adding detectable nuclear heat (assumed to be [ ] FON). A sensitivity study was performed and all cases demonstrated that CMT injection would terminate the transient before the point of adding heat is reached. The most conservative sensitivity is discussed in the following.

The beginning of Cycle 1 was also examined since it is the special case of a "clean" core with the only neutron source being the installed primary source rods. However, it was found that the Cycle 1 core has sufficient control rod worth at BOC such that the core remains subcritical at no-load temperature conditions with all control rods inserted and no soluble boron in the core. To create a more limiting case, it was assumed that the operation staff was in the process of bringing the reactor critical for the first time, and then paused with all shutdown banks withdrawn. An undetected boron dilution is then assumed to start from this condition. For this very conservative case, without any boron injection from the CMTs, the time from [ ] FON to [ ] FON is approximately [ ] from the static solution and [ ] from the kinetic solution. This conservatively calculated time [ ] is greater than the time from the IRNI safety analysis setpoint reached to the conservative time for the CMT injection start [ ]. Therefore, CMT injection will terminate the transient before the generation of detectable nuclear heat occurs.

To demonstrate this assertion, the nuclear power transients for the boron dilution cases with and without CMT injection are shown in Figure 9.4.6-4. As can be seen in these results, the injection of boron into the core terminates the power increase very rapidly. The peak nuclear power of approximately [ ] FON is reached [ ] after the initiation of CMT injection, after which power decreases rapidly as more boron is injected into the core. Therefore, demonstrating that the CMT injection will terminate the transient before the generation of detectable nuclear heat occurs.

9.4.6.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.4.6.3.3 Diverse Mitigation for Post-Reactor Trip Xenon-Induced Reactivity Excursion

Reference 9.4.27 provides ALARP and diversity studies to address a potential post-reactor trip Xenon-induced reactivity excursion assuming failure of CVS. Key results of Reference 9.4.27 are:

- For all frequent fault scenarios (determined to be those events that could occur when the reactor trip breakers are open) two diverse means of protection to mitigate effects of the xenon transient. The primary protection would come from PMS – Source Range High Neutron Flux signal, which would alert operators to the reactivity excursion. Based on this alarm, operators would manually open the ADS stage 1 valves to reduce RCS pressure, which would allow borated water to inject from the accumulators. The diverse protection would be provided by DAS – High Intermediate Range Power signal. Upon reaching the DAS setpoint ([ ] fraction of nominal power), DAS will

automatically actuate the CMTs. Both of these mitigation options are sufficient to protect against the effects of the Xenon induced reactivity excursion.

- For all infrequent fault scenarios (determined to be those events that could occur when the reactor trip breakers are closed), the diverse protection is provided by PMS indications from the ex-core source range detectors that reactivity in the core is increasing. In this scenario, operators will have ample time to manually actuate the CMTs to borate the core. Although not required, a second diverse system is available to provide boration should CMTs be unavailable. Specifically, operators could initiate passive feed and bleed using ADS, Accumulators, and the IRWST to provide RCS boration.

- The ALARP assessment concludes that providing automatic actuation of existing Class 1 components for boration provides the best alternative for this concern. Specifically, the intermediate range excore detector input has been added to the DAS to provide the diverse frequent fault protection.

9.4.6.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.4.6.5 As Low as Reasonably Practicable Assessment

The ALARP evaluation for this event is the same as for the RCCA misalignment fault (Section 9.4.3.5).

It is noted that the recently-implemented DAS function that monitors the IRNI signal and, upon actuation, trips the RCPs and RNS pumps (or RNS isolation), isolates the boron dilution sources, and actuates CMT, follows the ALARP principles. This function provides the diverse protection for boron dilution events initiated from subcritical conditions (Section 9.4.6.3). Additional information is provided in Reference 9.4-23.

9.4.6.6 Conclusions

Inadvertent boron dilution events are administratively prevented by the Technical Specifications during refuelling (Mode 6) and automatically terminated during cold shutdown (Mode 5), safe shutdown (Mode 4), and hot standby (Mode 3) modes. Inadvertent boron dilution events during startup (Mode 2) or power operation (Mode 1), if not detected and terminated by the operators, result in an automatic reactor trip. Following reactor trip, automatic termination of the dilution occurs and post-trip return to criticality is prevented.

The preceding results demonstrate that in all modes of operation, an inadvertent boron dilution is prevented or responded to by automatic functions, or sufficient time is available for operator action to terminate the transient. Following termination of the dilution flow and initiation of boration, the reactor is in a stable condition.

This event has also been adequately assessed with respect to ATWT considerations. Additionally, diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of the Class 1 SSCs credited for protection is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.4.7 Inadvertent Loading and Operation of a Fuel Assembly in an Improper Position (Fault 1.15.10)

9.4.7.1 Identification of Causes and Accident Description

The Inadvertent Loading Event comprises core misloading scenarios such as the loading of:

- one or more fuel assemblies into improper positions
- a fuel rod during manufacture with one or more pellets of the wrong enrichment
- a full fuel assembly during manufacture with pellets of the wrong enrichment

In addition to these scenarios, misloading events involving burnable absorbers and control rods are theoretically possible. For example, scenarios such as the placement of a cluster of 8 discrete burnable absorbers into a core location intended to have 12 discrete burnable absorbers are feasible. Also, a swap of grey rod control assembly (GRCA) and an RCCA is possible for the AP1000 plant. All of these misloading scenarios potentially result in a core reactivity distribution that differs from the intended core reactivity distribution. As a result, the core power distribution and peaking factors may differ from predictions. Specifically, misloading errors can lead to increased local power peaking at the location of the misloading if the misloading results in a local reactivity increase relative to the intended pattern. Sufficiently large local power increases can lead to fuel failure at normal operation conditions

if the power distribution increase is undetected. If the misloading results in a local reactivity decrease, power peaking increases far away from the location of the misloading are possible due to unintended power tilts. These kinds of increases, however, are generally distributed over a large core volume and are small relative to those where the local reactivity is increased. In such cases, fuel failure is unlikely even if the anomaly goes undetected.

Fuel misloads are prevented by the manufacturing controls employed to build the fuel and the core loading controls used to assemble the core. The manufacturing controls include checks on fuel rod weight to confirm the uranium loading in the fuel rod, active and passive gamma scans of individual fuel rods to confirm fuel enrichments, pellet stack lengths, pellet types, and the absence of pellet gaps during fuel manufacturing, and bar coding of each fuel rod to confirm its proper placement in the fuel assembly.

To reduce the probability of core loading errors during fuel loading, each fuel assembly and core component is marked with an identification number and loaded in accordance with a core loading diagram. During core loading, the identification numbers are checked before each assembly is moved into the core. Identification numbers read during fuel movement are subsequently recorded on the loading diagram as a further check on proper placement after the loading is completed. These procedures make the likelihood of core misloadings very small.

The severity and detectability of fuel misloads are influenced by several factors: the local reactivity perturbation relative to the intended core loading pattern, the core position of the misload, the local environment of the misloaded fuel assembly, and the number of operable fixed incore detector locations and their proximity to the misload location. Should misloadings occur, the system of fixed incore detectors, which is used to verify power distributions during startup and throughout the operating cycle, is capable of revealing enrichment errors or misloadings which would cause the kind of substantial power distribution perturbation that would be necessary to induce large numbers of fuel rod failures. In addition, thermocouples and excore detectors can provide additional indications of power distribution anomalies. This instrumentation, along with the startup testing performed each cycle, make the detection of severe misloadings highly likely.

Fuel misloads involving a single fuel rod or fuel pellet were not evaluated as part of this analysis. Such misloads, in general, will not be detectable using the fixed incore detector system due to their localized power distribution perturbations. In terms of increased peaking factors and reduced DNBR values, however, the consequences of such misloads will be very small and limited to the affected fuel rod and the immediately adjacent fuel rods.

9.4.7.2 Design Basis Mitigation

Plant operating procedures should include a provision requiring that reactor instrumentation be used to search for potential fuel loading errors after fueling operations. In the event the error is not detectable by the instrumentation system and fuel rod failure limits could be exceeded during normal operation, the acceptability of any fuel damage is judged by the radiological consequences.

9.4.7.2.1 DBA Method of Analysis

The fuel misload event is different than most other analysed events in several respects. First, the fuel misload event is not a transient; it is not the result of a system failure that causes a

dynamic reactor response. The context of the event is normal operation, i.e., there is no overpower condition. Second, it is unlike most other accident scenarios in that a bounding scenario is not obvious. For a fuel misload, the bounding scenario is not necessarily the fuel misload that results in the largest perturbation. Fuel misloads with very large power distribution perturbations tend to be very easy to detect. Rather, a bounding scenario would be an "undetectable" fuel misload case that causes the largest possible census of fuel rods to exceed the limit for fuel failure. Third, while most accident analyses can be limited to a small number of scenarios, the number of ways in theory to misload a reactor core is virtually infinite. In any analysis of fuel misload scenarios, therefore, one has to choose a limited set of specific scenarios for analysis which must then be used to make judgments concerning the general ability of the core monitoring system to resolve the misload power distributions and detect those cases that could lead to fuel failure.

The general method employed in this analysis involved modelling a range of fuel misload scenarios and then determining whether or not those misload scenarios would be detectable during the startup power distribution measurements given the resulting power distribution perturbations and defined detectability criteria. The misload scenarios specifically modelled comprised a wide range of reactivity perturbations leading to a wide range of power distribution perturbations. Misload scenarios were modelled in various core positions relative to the detector pattern. The objective of the analysis was to ascertain the ability of the fixed incore detector (FID) system to resolve the power distributions for these scenarios. In this way, the threshold for detectability was determined. If the FID system can detect misloads that could fail fuel during normal operation with high confidence, then no fuel failure would be expected for this event since the core power distribution is monitored continuously once the minimum power level for the [ ] detectors is reached (~25% power). .

The fuel failure limit for this event is the $F_{\Delta H}$ limit for DNB at normal operation conditions. The $F_{\Delta H}$ limit for DNB is approached before any fuel melt limits are reached in any non-overpower event. This is the same effective limit used in analysing the static rod cluster control assembly misalignment event. The static rod misalignment event is very analogous to the fuel misload event in that both are conditions of normal operation, both are static as opposed to dynamic events, and both are caused by deviations with respect to the intended core reactivity distribution. In the case of the static rod misalignment, the reactivity deviation is caused by the mispositioning of a control rod. In the case of a fuel misload, the reactivity deviation is caused by the mispositioning or mismanufacture of one or more fuel assemblies. For the AP1000 reactor, the $F_{\Delta H}$ limit for DNB at normal operation conditions is 1.99 on a best estimate basis. This is the largest $F_{\Delta H}$ value that could occur at normal operation conditions without exceeding the DNBR limit. (Note that this value is larger than the Technical Specification $F_{\Delta H}$ limit because the Technical Specification limit protects against overpower transient events.) Therefore, misloads which could cause the HFP hot rod relative power to exceed 1.99 on a best estimate basis have the potential for fuel failure during normal operation if they remain undetected.

In the analysis presented here, misload cases were modelled for the first cycle core design. Analysis was also performed for a representative equilibrium cycle reload core design, and the results were comparable to the results presented here for the first core. The misload scenarios comprised a range of reactivity perturbations, core positions, and misload positions relative to the detector pattern. The majority of these scenarios had power distribution perturbations which were not quite severe enough to fail fuel at normal operation conditions. If the FID system can detect these scenarios, then scenarios with larger perturbations that could cause fuel failure are even more likely to be detected. The scenarios chosen were a combination of

assembly swaps and single assembly misloads. As mentioned above, it is not feasible to model all possible misload scenarios. Rather, the objective was to model a range of scenarios of various reactivity perturbations to characterize the threshold for detectability relative to the fuel failure limit.

The AP1000 FID pattern has quarter-core reflective symmetry and a highly regular pattern of detectors such that each fuel assembly is either in a detector location or very close to a detector location. For this detector pattern, a misloaded assembly has one of three possible orientations with respect to the detector pattern. These orientations are described as Types A, B, and C:

Type A: Misloaded assembly is in a detector location

Type B: Misloaded assembly is face adjacent to one or more detector locations

Type C: Misloaded assembly is diagonally adjacent to one or more detector locations

A number of misloads of each of these types were modelled in this analysis using the first cycle core model. A total of 25 misload scenarios were modelled. Cycle depletions at hot full power were performed for each scenario, and the depletion maximum $F_{\Delta H}$ was determined. This depletion maximum $F_{\Delta H}$ value was used to characterize the severity of the misload scenario relative to the 1.99 best estimate $F_{\Delta H}$ fuel failure limit.

For each misload scenario, the "measured" power distribution at the 30% power startup condition was simulated using the same algorithm employed by the online power distribution monitoring system. Simulated detector signals were generated using the misload core model and used as inputs to the algorithm. For each misload scenario, a total of 400 simulated measured power distributions were generated reflecting different patterns of operable fixed incore detectors. For the initial power distribution assessment at the start of the operating cycle, at least 75% of the detectors must be operable. Each of the 400 simulated measured power distributions, therefore, assumed 75% of the detectors to be operable. In addition, a detector signal variability of 1% on a 1σ basis was assumed.

Detectability assessments were then performed for each measured power distribution of each misload scenario. Since 25 misload scenarios were modelled and 400 measured power distributions were simulated for each misload scenario, a total 10,000 detectability assessments were performed. Two different detectability criteria were employed in these assessments.

The first criterion was the measured versus predicted assembly average power criterion. For this criterion, the simulated measured misload startup power distributions (at 30% power) were compared to the reference startup power distribution (i.e., the predicted or expected startup power distribution). Each measured assembly power was compared to its reference power distribution counterpart. Detection of a particular misload scenario was assumed if, on a 95/95 basis, deviations of 10% or greater between the measured and predicted assembly powers in a core location were observed over the 400 simulated measured power distributions. The measured versus predicted detectability assessment was limited to core locations where the reference relative power was 0.8 or greater.

The second detectability criterion was a symmetry criterion for the measured power distributions. For this criterion, the measured relative power of each assembly was compared to the relative powers of each of its three symmetric counterparts (assuming quarter-core, cyclic symmetry) for a given simulated measured power distribution. The symmetry percent difference value was determined by taking the maximum difference between the symmetric

assembly powers and then dividing it by the average power of the four assemblies in the symmetry group. The result was then multiplied by 100%. Detection of a particular misload scenario was assumed if, on a 95/95 basis, a symmetry difference of 10% or greater was observed for a core location over the 400 simulated measured power distributions. The symmetry detectability assessment was limited to core locations where the relative power was 0.8 or greater.

For each core loading error case analysed, the percent deviations from detector readings for a normally loaded core are shown in the incore detector locations. (See Figures 9.4.7-1 through 9.4.7-4.)

9.4.7.2.2 DBA Credited SSCs

The available Class 1 systems for this fault are the same as those in Section 9.4.3.2.1.2 for Dropped RCCAs, Dropped RCCA bank, and Statically Misaligned RCCA faults.

9.4.7.2.3 DBA Results

The fixed incore detector system is used to search for potential fuel misloads at the start of each operating cycle. Following fuel loading and low power physics testing, an initial core power distribution measurement is made. The core power level of this initial measurement is ~30% of rated thermal power. The [ ] fixed incore detectors used in the AP1000 become effective for power distribution measurements at approximately [ ] power. This initial power distribution measurement is used to confirm that the measured power distribution is consistent with the predicted power distribution. At least [ ] of the fixed incore detectors are required to be operable for this initial measurement. Observed power distribution deviations in excess of the review criteria (see Table 9.4.7-1) would prompt an investigation of a possible core anomaly.

The detectability assessments performed in this analysis confirm that the fixed incore detector system can reliably detect fuel misloads that could fail fuel during normal operation when the Table 9.4.7-1 review criteria are employed for the initial power distribution assessment (≥ [ ] of detectors operable). Figure 9.4.7-1 gives the 95/95 detectability assessment value as a function of the best estimate misload depletion maximum $F_{\Delta H}$ value. The maximum difference of the measured versus predicted or symmetry assessments was plotted. This figure demonstrates that detection is expected for fuel misloads with power distribution perturbations severe enough to cause fuel failure at normal operation conditions. All of the misload cases that exceeded the fuel failure limit were easily detectable, i.e., the measured versus predicted or symmetry assessments showed differences far in excess of the 10% review criterion. Misload cases with much smaller perturbations were detectable as well. Figure 9.4.7-1 suggests that the threshold for misload detectability is in the range of a maximum depletion $F_{\Delta H}$ value of approximately 1.80 to 1.85. In other words, misloads that could lead to depletion $F_{\Delta H}$ values above this threshold are very likely to be detected. This threshold is well below the failure limit of 1.99. Consequently, detection of any misload that could fail fuel at normal operation conditions is expected with high confidence. Therefore, no fuel failure would be expected for this event.

Figures 9.4.7-2 through 9.4.7-4 provide examples of the three types of misload cases for the first core. Figure 9.4.7-2 illustrates a Type A swap misload where two fuel assemblies, Region D and E assemblies, have been interchanged. In this case, each of the swapped assemblies is in a FID location. The core diagram gives the difference between the mean measured power distribution and the expected power distribution for the 30% power startup condition. The mean measured power distribution represents the average power distribution

over the 400 simulated measured power distributions. As the figure shows, the mean measured versus predicted differences are quite large even though the power distribution perturbation was not severe enough to cause fuel failure; the depletion maximum $F_{\Delta H}$ for this case was 1.882, less than the limit for fuel failure at normal operation conditions. Consequently, this particular misload is easily detectable. Figure 9.4.7-2 also provides the maximum 95/95 measured versus predicted and symmetry differences. The 95/95 measured versus predicted difference was 25.2%, much larger than the 10% review criterion. This difference occurred in location G-8. Note that the mean difference in this location is 28.7%. The 25.2% 95/95 difference means that there is 95% confidence that at least 95% of the operable detector patterns would result in a measured versus predicted difference of ≥25.2% in location G-8. Similarly, the 95/95 symmetry difference was 26.0%, which came from the symmetry group G-14, B-7, J-2, and P-9. These large differences indicate that there is high confidence that this misload is detectable.

Figure 9.4.7-3 illustrates another swap misload. In this case, however, the misload locations are Type B, i.e., face adjacent to FID positions. For this scenario, Region B and E assemblies were interchanged. As in the previous case, the 95/95 measured versus predicted and symmetry errors are quite large, 22.7% and 25.0%, respectively, indicating that this misload would be readily detectable despite the fact that this misload is not quite severe enough to fail. The depletion maximum $F_{\Delta H}$ for this case was 1.987, which is just under the fuel failure limit.

Figure 9.4.7-4 illustrates a single assembly misload of Type C, where the misloaded assembly is diagonally adjacent to FID positions. In this scenario, a Region E assembly was loaded into position H-9 where a Region D assembly was intended. As the measured versus predicted percent difference distribution shows, this misload resulted in a much smaller power distribution perturbation than the other two cases. However, the 95/95 measured versus predicted difference was 10.3%; thus, this misload was detectable even though the depletion maximum $F_{\Delta H}$ was 1.865, well below the limit for fuel failure. The 95/95 symmetry difference was only 6.5%. Misload cases where the power distribution perturbation is at or near the center of the core do not cause large symmetry differences since the quadrant tilts in such cases are minimal. This and the fact that this misload is not in a FID location make it somewhat more difficult to detect.

Figures 9.4.7-1 through 9.4.7-4 indicate that misloads of Types A, B, or C that can lead to fuel failure will be detectable with high confidence at the 30% power startup condition when ≥ [ ] of the FIDs are operable and the 10% review criteria for symmetry and measured versus predicted are used. Given that detection of misloads severe enough to fail fuel is expected using these review criteria, a radiological consequences analysis is deemed unnecessary. In the unlikely event, however, that a misload that could fail fuel remains undetected, the radiological consequences would be acceptable as presented in Section 9.4.7.4.

Following startup, at least [ ] of the FIDs must be operable. If the number of operable detectors decreases to less than [ ] of the total number of detectors, then Table 9.4.7-1 recommends slightly tighter review criteria, [ ] for both the measured versus predicted and symmetry assessments. This is judged to be a prudent measure to ensure that any significant core anomalies that develop following startup are investigated in light of the reduced incore detector instrumentation.

The primary consideration with respect to misload detection is detector density, not the core loading pattern. Since the FID locations are fixed from cycle to cycle, one would expect power distribution perturbations of comparable magnitudes to be detectable from cycle to cycle. Furthermore, reload loading patterns tend to be designed with similar power distributions and margins to peaking factor limits. Reload core designs would be expected to

have similar peaking factor values and, therefore, comparable margins to fuel failure limits. In other words, the required perturbation to reach fuel failure limits will be similar from cycle to cycle and the ability to detect that perturbation will be similar from cycle to cycle since it is primarily dependent on the FID pattern. Furthermore, the above detectability analysis indicates that the FID system is capable of detecting power distribution perturbations which are significantly smaller than the perturbations required for fuel failure. Consequently, the ability to detect misloads that could fail fuel during normal operation should be insensitive to the details of individual reload cycle loading patterns. As such, it is judged that cycle specific misload analyses are unnecessary.

With respect to misloads of control rods, misloads of GRCAs and RCCAs are prevented by the core loading controls used to assemble the core. Each RCCA and GRCA component will have a unique engraved identification number. The identification (ID) number can be compared to the core loading diagram to confirm proper loading.

A [ ] will also provide visual differentiation between a GRCA and an RCCA. This identifying feature, along with the engraved ID, will make a GRCA/RCCA misload very unlikely to occur.

In the unlikely event of a misload of an RCCA in a GRCA position, detection of the misload is expected. Rod worth measurements and power distribution monitoring during startup and subsequent operation can detect scenarios where an RCCA is inadvertently loaded into a grey bank position.

If a GRCA is inadvertently placed in an RCCA position, the primary consequence is potentially larger peaking factors during normal operation if the black bank is deeply inserted (e.g., the axial offset (AO) bank). This scenario, however, is bounded by analyses of static rod misalignments routinely performed for each operating cycle, which assume complete withdrawal of a single RCCA. This represents a larger local reactivity perturbation than a misload of a GRCA in an RCCA position. Consequently, the current safety evaluation ensures fuel integrity during normal operation for this kind of event.

9.4.7.3 Diverse Mitigation

As this is an infrequent fault, diverse mitigation is not required.

9.4.7.4 Radiological Consequences

An undetected misload is unlikely to lead to fuel damage. With no fuel damage, the primary and secondary circuits intact, and with offsite power remaining available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the unlikely event that a misload that could fail fuel remains undetected, the Target 4 BSOs will still be met. In such a case, fuel failures in fresh fuel during startup would have negligible radiological consequences since there would be only a small fission product inventory. Following startup, any fuel rod failures would occur gradually and would be detected by coolant activity monitoring. Since the number of potential fuel rod failures due to a core misload would be small and such failures would occur gradually, any coolant activity releases would initially be well within the cleanup capacity of the plant and operations would be maintained within Technical Specification coolant activity guidelines. Any trend in increased coolant activity would warrant further investigation and evaluation.

9.4.7.5 As Low as Reasonably Practicable Assessment

The ALARP evaluation for this event is the same as for the RCCA misalignment fault (Section 9.4.3.5), with the exception of this being an infrequent fault. Therefore, although diverse mitigation is not required, it is still available.

9.4.7.6 Conclusions

Fuel assembly enrichment errors are prevented by administrative procedures implemented in fabrication.

In the event that a single pin or pellet has a higher enrichment than the nominal value, the consequences in terms of reduced DNBR and increased fuel and cladding temperatures are limited to the incorrectly loaded pin or pins and perhaps the immediately adjacent pins.

Fuel misloads are prevented by manufacturing controls and core loading controls. In the unlikely event that a fuel misload should occur, the fixed incore detector system is capable of reliably detecting misloads that could fail fuel at normal operation conditions. Exceeding the review criteria herein would initiate an investigation to identify potential core anomalies. It is expected that any misload with the potential to fail fuel would be detected. However, any fuel failures associated with an undetected fuel misload would be gradual and detectable. Consequently, plant operations would always be maintained within Technical Specification coolant activity guidelines.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.4.8 Spectrum of Rod Cluster Control Assembly Ejection Accidents (Fault 1.15.11)

9.4.8.1 Identification of Causes and Accident Description

This accident is defined as the mechanical failure of a control rod mechanism pressure housing, resulting in the ejection of an RCCA and drive shaft. The consequence of this mechanical failure is a rapid positive reactivity insertion together with an adverse core power distribution, possibly leading to localized fuel rod damage.

9.4.8.1.1 Design Precautions and Protection

9.4.8.1.1.1 Mechanical Design

The mechanical design is discussed in Section 22.8. Mechanical design and quality control procedures intended to prevent the possibility of an RCCA drive mechanism housing failure are listed below:

- Each control rod drive mechanism housing is completely assembled and shop tested at a minimum of 125 percent of system design pressure.

- The mechanism housings are hydrotested after they are attached to the reactor vessel head. The hydrostatic test of the connection between the rod travel housing and the latch housing is done as part of the system hydrostatic test.

- The allowable stress levels in the mechanism are not exceeded due to system thermal transients at power or by the thermal movement of the coolant loops. Moments induced by the safe shutdown earthquake can be accepted within the allowable primary working stress range specified for Class 1 components.

- The latch mechanism housing and rod travel housing are each a single length of forged stainless steel. This material exhibits excellent notch toughness at temperatures that are encountered.

A significant margin of strength in the elastic range together with the large energy absorption capability in the plastic range gives additional confidence that gross failure of the housing does not occur. The joint between the latch housing and latch housing nozzle is a full penetration bi-metallic weld, and the joint between the latch housing and rod travel housing is a threaded joint with a canopy seal weld.

9.4.8.1.1.2 Nuclear Design

If a rupture of an RCCA drive mechanism housing is postulated, the operation using chemical shim is such that the severity of an ejected RCCA is inherently limited. In general, the reactor is operated with the power control (or mechanical shim) RCCAs inserted only far enough to permit load follow. The axial offset RCCAs are positioned so that the targeted axial offset can be met throughout core life. Reactivity changes caused by core depletion and xenon transients are normally compensated for by boron changes and the mechanical shim banks, respectively. Further, the location and grouping of the power control and axial offset RCCAs are selected with consideration for an RCCA ejection accident. Therefore, should an RCCA be ejected from its normal position during full-power operation, a less severe reactivity excursion than analysed is expected.

It may occasionally be desirable to operate with larger than normal insertions. For this reason, a power control and axial offset rod insertion limit is defined as a function of power level. Operation with the RCCAs above this limit provides adequate shutdown capability and an acceptable power distribution. The position of the RCCAs is continuously indicated in the main control room. An alarm occurs if a bank of RCCAs approaches its insertion limit or if one RCCA deviates from its bank. Operating instructions require boration at the low level alarm and emergency boration at the low-low level alarm.

9.4.8.1.1.3 Reactor Protection

The reactor protection in the event of a rod ejection accident is described in WCAP-15806-P-A (Reference 9.4-4). The protection for this accident is provided by the high neutron flux trip (high and low setting) and the high rate of neutron flux increase trip. These protection functions are described in Section 19.2.

9.4.8.1.1.4 Effects on Adjacent Housings

Failures of an RCCA mechanism housing, due to either longitudinal or circumferential cracking, does not cause damage to adjacent housings. The control rod drive mechanism is described in Section 6.2.1.6.

9.4.8.1.1.5 Consequences

The probability of damage to an adjacent housing is considered remote. If damage is postulated, it is not expected to lead to a more severe transient because RCCAs are inserted in

the core in symmetric patterns and control rods immediately adjacent to worst ejected rods are not in the core when the reactor is critical. Damage to an adjacent housing could, at worst, cause that RCCA not to fall on receiving a trip signal. This is already taken into account in the analysis by assuming a stuck rod adjacent to the ejected rod.

9.4.8.1.1.6 Summary

Failure of a control rod housing does not cause damage to adjacent housings that increase the severity of the initial accident.

9.4.8.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the protection and safety monitoring system to detect and mitigate the fault and show that the applicable safety criteria are satisfied.

Because of the extremely low probability of an RCCA ejection accident, some fuel damage is considered an acceptable consequence.

Criteria are applied to provide confidence that there is little or no possibility of fuel dispersal in the coolant, gross lattice distortion, or severe shock waves. These criteria are the following:

- The pellet clad mechanical interaction (PCMI) failure criteria is a change in radial average fuel enthalpy greater than the corrosion-dependent limit depicted in Figure B-1 of SRP 4.2, Revision 3, Appendix B (Reference 9.4-24).

- The high cladding temperature failure criteria for zero-power conditions is a peak radial average fuel enthalpy greater than 170 cal/g (300 Btu/lb) for fuel rods with an internal rod pressure at or below system pressure and 150 cal/g (270 Btu/lb) for fuel rods with an internal rod pressure exceeding system pressure.

- For intermediate (greater than 5% rated thermal power) and full-power conditions, fuel cladding is presumed to fail if local heat flux exceeds thermal design limits (e.g., DNBR).

- For core coolability, it is conservatively assumed that the average fuel pellet enthalpy at the hot spot remains below 200 cal/g (360 Btu/lb) for irradiated fuel. This bounds non-irradiated fuel, which has a slightly higher enthalpy limit.

- For core coolability, the peak fuel temperature must remain below incipient fuel melting conditions.

- Mechanical energy generated as a result of (1) non-molten fuel-to-coolant interaction and (2) fuel rod burst must be addressed with respect to reactor pressure boundary, reactor internals, and fuel assembly structural integrity.

- No loss of coolable geometry due to (1) fuel pellet and cladding fragmentation and dispersal and (2) fuel rod ballooning.

- Peak reactor coolant system pressure is less than that which could cause stresses to exceed the “Service Limit C” as defined in the ASME code.

9.4.8.2.1 DBA Method of Analysis

The calculation of the RCCA ejection transients is performed in two stages: first, an average core calculation and then, a hot rod calculation. The average core calculation is performed using spatial neutron kinetics methods to determine the average power generation with time, including the various total core feedback effects (Doppler reactivity and moderator reactivity). Enthalpy, fuel temperature, and DNB transients are then determined by performing a conservative fuel rod transient heat transfer calculation.

A discussion of the method of analysis appears in WCAP-15806-P-A (Reference 9.4-4).

Average Core Analysis

The three-dimensional nodal code ANC (References 9.4-7, 9.4-14, 9.4-15, 9.4-16, 9.4-17, 9.4-21, 9.4-22, and 9.4-8) is used for the average core transient analysis. This code solves the two-group neutron diffusion theory kinetic equation in three spatial dimensions (rectangular coordinates) for six delayed neutron groups. The core moderator and fuel temperature feedbacks are based on the U.S. Nuclear Regulatory Commission (NRC)-approved Westinghouse version of the VIPRE-01 code and methods (References 9.4-18 and 9.4-19).

Hot Rod Analysis

The hot fuel rod models are based on the Westinghouse VIPRE models described in WCAP-15806-P-A (Reference 9.4-4). The hot rod model represents the hottest fuel rod from any channel in the core. VIPRE performs the hot rod transients for fuel enthalpy, temperature, and DNBR using as input the time-dependent nuclear core power and power distribution from the core average analysis. A description of the VIPRE code is provided in Reference 9.4-18.

System Overpressure Analysis

If the fuel coolability limits are not exceeded, the fuel dispersal into the coolant or a sudden pressure increase from thermal to kinetic energy conversion is not needed to be considered in the overpressure analysis. Therefore, the overpressure condition may be calculated on the basis of conventional fuel rod to coolant heat transfer and the prompt heat generation in the coolant. The system overpressure analysis is conducted by first performing the core power response analysis to obtain the nuclear power transient (versus time) data. The nuclear power data is then used as input to a plant transient computer code to calculate the peak reactor coolant system pressure. This code calculates the pressure transient, taking into account fluid transport in the reactor coolant system and heat transfer to the steam generators. For conservatism, no credit is taken for the possible pressure reduction caused by the assumed failure of the control rod pressure housing.

9.4.8.2.1.1 Calculation of Basic Parameters

Input parameters for the analysis are conservatively selected as described in Reference 9.4-4.

Ejected Rod Worths and Hot Channel Factors

The values for ejected rod worths and hot channel factors are calculated using three-dimensional static methods. Standard nuclear design codes are used in the analysis. The calculation is performed for the maximum allowed bank insertion at a given power level, as determined by the rod insertion limits. Adverse xenon distributions are considered in the calculation.

Appropriate safety analysis allowances are added to the ejected rod worth and hot channel factors to account for calculational uncertainties, including an allowance for nuclear peaking due to densification as discussed in Reference 9.4-4.

Moderator and Doppler Coefficients

The critical boron concentration is adjusted in the nuclear code to obtain a moderator temperature coefficient that is conservative compared to actual design conditions for the plant consistent with Reference 9.4-4. The fuel temperature feedback in the neutronics code is reduced consistent with Reference 9.4-4 requirements.

Delayed Neutron Fraction, β_{eff}

Calculations of the effective delayed neutron fraction (β_{eff}) typically yield values no less than 0.50 percent at the end of cycle. The accident is sensitive to β_{eff} if the ejected rod worth is equal to or greater than β_{eff}. To allow for future cycles, a pessimistic estimate of β_{eff} of [ ] percent is used in the analysis.

Trip Reactivity Insertion

The trip reactivity insertion accounts for the effect of the ejected rod and one adjacent stuck rod. The trip reactivity is simulated by dropping a limited set of rods of the required worth into the core. The start of rod motion occurs [ ] second after the high neutron flux trip setpoint is reached. This delay is assumed to consist of [ ] second for the instrument channel to produce a signal, [ ]second for the trip breakers to open, and [ ] second for the coil to release the rods. A curve of trip rod insertion versus time is used, which assumes that insertion to the dashpot does not occur until 2.7 seconds after the start of fall. The choice of such a conservative insertion rate means that there is over [ ] after the trip setpoint is reached before significant shutdown reactivity is inserted into the core. This conservatism is important for the hot full power accidents.

The minimum design shutdown margin available at hot zero power may be reached only at end of life in the equilibrium cycle. This value includes an allowance for the worst stuck rod, adverse xenon distribution, conservative Doppler and moderator defects, and an allowance for calculational uncertainties. Calculations show that the effect of two stuck RCCAs (one of which is the worst ejected rod) is to reduce the shutdown by about an additional 1-percent Δk. Therefore, following a reactor trip resulting from an RCCA ejection accident, the reactor is subcritical when the core returns to hot zero power.

9.4.8.2.2 DBA Credited SSCs

Reactor protection for a rod ejection is discussed in Section 9.4.8.1.1.3. For the DB, all claimed SSCs are Class 1. The credited Class 1 SSCs are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, and pressuriser SVs. Although not credited in the limiting analysis presented, the accumulators, IRWST injection, containment recirculation, and ADS are available to mitigate the resultant LOCA (See Section 9.6 for loss of inventory events). The PMS provides the following:

- RT on power range high positive flux rate

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow
- CMTs and containment isolation on Low-2 CL temperature
- PCS on High-2 containment pressure

9.4.8.2.3 DBA Results

For all cases, the core is preconditioned by assuming a fuel cycle depletion with control rod insertion that is conservative relative to expected baseload operation. All cases assume that the mechanical shim and axial offset control RCCAs are inserted to their insertion limits before the event and xenon is skewed to yield a conservative initial axial power shape. The limiting RCCA ejection cases for a typical cycle are summarised following the criteria outlined in Section 9.4.8.2.

- PCMI and high cladding temperature (hot zero power)

  The resulting maximum fuel average enthalpy rise and maximum fuel average enthalpy are less than the criteria given in Section 9.4.8.2.

- High cladding temperature (≥ 5% rated thermal power)

  The fraction of the core calculated to have a DNBR less than the safety analysis limit is less than the amount of failed fuel assumed in the dose analysis described in Section 9.4.8.4.

- Core coolability

  The resulting maximum fuel average enthalpy is less than the criterion given in Section 9.4.8.2. Fuel melting is not predicted to occur at the hot spot.

There are no fuel failures due to the fuel enthalpy deposition, i.e., both fuel and cladding enthalpy limits were met. Additionally, the coolability criteria for peak fuel enthalpy and the fuel melting criteria were met. Therefore, the fuel dispersal into the coolant, a sudden pressure increase from thermal to kinetic energy conversion, gross lattice distortion, or severe shock waves are precluded.

The nuclear power transients for the limiting cases are presented in Figures 9.4.8-1 through 9.4.8-3.

The calculated sequence of events for the limiting cases is presented in Table 9.4-1. Reactor trip occurs early in the transients, after which the nuclear power excursion is terminated.

The ejection of an RCCA constitutes a break in the reactor coolant system, located in the reactor pressure vessel head. The effects and consequences of LOCAs are discussed in Section 9.6. Following the RCCA ejection, the plant response is the same as a LOCA.

The consequential loss of offsite power described in Section 9.0.12 is not limiting for the enthalpy and temperature transients resulting from an RCCA ejection accident. Due to the delay from reactor trip until turbine trip and the rapid power reduction produced by the reactor trip, the peak fuel and cladding temperatures occur before the reactor coolant pumps begin to coast down.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.4.8.2.3.1 Rods in DNB

In the cases considered, less than 10 percent of the rods are assumed to enter DNB based on a detailed three-dimensional kinetics and hot rod analysis.

The consequential loss of offsite power described in section 9.0.12 is not limiting for the calculation of the number of rods assumed to enter DNB for the RCCA ejection accident. Due to the delay from reactor trip until turbine trip and the rapid power reduction produced by the reactor trip, the minimum DNBR, for rods where the DNBR did not fall below the design limit (see Section 22.7.1.1) in the cases described, occurs before the reactor coolant pumps begin to coast down.

9.4.8.2.3.2 Peak RCS Pressure

Calculations of the peak reactor coolant system pressure demonstrate that the peak pressure does not exceed that which would cause the stress to exceed the Service Level C Limit as described in the ASME Code, Section III. Therefore, the accident for this plant does not result in an excessive pressure rise or further damage to the reactor coolant system.

The consequential loss of offsite power described in Section 9.0.12 is not limiting for the pressure surge transient resulting from an RCCA ejection accident. Due to the delay from reactor trip until turbine trip and the rapid power reduction produced by the reactor trip, the peak system pressure occurs before the reactor coolant pumps begin to coast down.

9.4.8.2.3.3 Lattice Deformations

A large temperature gradient exists in the region of the hot spot. Because the fuel rods are free to move in the vertical direction, differential expansion between separate rods cannot produce distortion. However, the temperature gradients across individual rods may produce a differential expansion, tending to bow the midpoint of the rods toward the hotter side of the rod.

Calculations indicate that this bowing results in a negative reactivity effect at the hot spot because the core is undermoderated, and bowing tends to increase the undermoderation at the hot spot. In practice, no significant bowing is anticipated because the structural rigidity of the core is sufficient to withstand the forces produced.

Boiling in the hot spot region would produce a net flow away from that region. However, the heat from the fuel is released to the water relatively slowly, and it is considered inconceivable that crossflow is sufficient to produce lattice deformation. Even if massive and rapid boiling, sufficient to distort the lattices, is hypothetically postulated, the large void fraction in the hot spot region produces a reduction in the total core moderator to fuel ratio and a large reduction in this ratio at the hot spot. The net effect is therefore a negative feedback.

In conclusion, no credible mechanism exists for a net positive feedback resulting from lattice deformation. In fact, a small negative feedback may result. The effect is conservatively ignored in the analysis.

9.4.8.3 Diverse Protection Systems

As this is an infrequent fault (DB1), a diverse protection assessment is not required.

9.4.8.4 Radiological Consequences

The evaluation of the radiological consequences of a postulated rod ejection accident assumes that as a result of the accident, 10 percent of the fuel rods are damaged such that the activity contained in the fuel-cladding gap is released to the reactor coolant. Activity is released to the containment via the spill from the reactor vessel head and is assumed to be available for release to the environment via containment leakage.

9.4.8.4.1 Source Term

The significant radionuclide releases from the fuel due to the rod ejection accident are the iodines, alkali metals (caesiums, rubidiums) and noble gases. All activity in the fuel rod gap of the damaged fuel is assumed to be released to the coolant. Based on Table 7.3 of Reference 9.4-5, the gap fraction is assumed to be 3 percent of the core inventory for iodines, 10 percent for noble gases, and 4 percent for alkali metals. It is also assumed that a limited amount of fuel centreline melt occurs, equivalent to 0.25% of the core.

To address the fact that the failed fuel rods may have been operating at power levels above the core average, the source term is increased by a lead rod radial peaking factor of 1.75 which bounds the COLR limit of 1.72.

All gap activity in the damaged fuel rods is assumed to be immediately released to the primary coolant. For the fuel that is modelled as melting, it is assumed that all of the noble gas, iodine, and alkali metals activity is released to the primary coolant.

Noble gas releases from the primary coolant to the containment atmosphere would occur quickly.

The iodine activity is all assumed to enter into solution with 60 percent of the iodine assumed to convert to the elemental form and then enter the containment atmosphere, consistent with Section 2.2.1 of Chapter IX of Reference 9.4-5. It is assumed that 1% of the iodine released converts to the organic form while the other 99% stays in the elemental form. In practice, the iodine activity released from the fuel would initially enter into solution and is anticipated to be gradually released to the containment atmosphere over an indefinite period of time. However, it is conservatively assumed that all of the iodine releases to the containment atmosphere occur immediately. This assumption makes the activity quickly available for release to the environment by way of containment leakage.

The alkali metals activity is assumed to be retained in the primary coolant and none of it is assumed to enter the containment atmosphere.

Initial reactor coolant activities are of secondary importance compared to the release of the gap inventory of fission products from the portion of the core assumed to fail because of the accident.

9.4.8.4.2 Release Pathways

Activity from the reactor coolant system and the core is released to the containment atmosphere and is available for leakage to the environment through the assumed design basis

containment leakage. The leakage rate is modelled at the technical specification leakage rate until 24 hours and at half that rate after 24 hours.

9.4.8.4.3 Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.4.8.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.4-3.

9.4.8.4.5 Doses

The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 5.5 mSv Worker dose: 8.4 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.4-4. The Table 9.4-4 values ensure the Target 4 BSLs are met.

9.4.8.5 As Low As Reasonably Practicable Assessment

For this fault, the identification of the primary safety functions (see Table 9.4.8-1) as Class 1 SSCs has been shown to be adequate to meet DB requirements.

Although not required, diverse mitigation for the RCCA misalignment faults (Section 9.4.3.4) is available.

Additionally, the AP1000 plant design has a third level of redundancy provided by the DiD systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- SFW with steam dump for decay heat removal
- Pressuriser spray and auxiliary spray for RCS pressure control
- CVS make-up for RCS inventory control
- RNS cooling of the IRWST and SFW with steam dump via DAS for containment cooling

Providing further means of removing decay heat or tripping the reactor in addition to these functions would not significantly reduce the PSA risk for this event.

9.4.8.6 Conclusions

The analysis shows that the criterion stated in this subsection is satisfied.

Radiological consequences are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

Table 9.4-1 (Sheet 1 of 3). DBA Time Sequence Of Events For Incidents Which Result In Reactivity And Power Distribution Anomalies

Accident	Event	Time (seconds)
Uncontrolled RCCA bank withdrawal from a subcritical or low-power startup condition	Initiation of uncontrolled rod withdrawal from 10^{-9} of nominal power	0.0
	Power range high neutron flux (low setting) setpoint reached	10.4
	Peak nuclear power occurs	10.6
	Rods begin to fall into core	11.3
	Peak heat flux occurs	12.9
	Minimum DNBR occurs	12.9
	Peak average clad temperature occurs	13.5
	Peak average fuel temperature occurs	13.7
One or more dropped RCCAs	Rods drop	0.0
	Control system initiates control bank withdrawal	0.4
	Peak nuclear power occurs	21.7
	Peak core heat flux occurs	24.2
Uncontrolled RCCA bank withdrawal at power		
1. Case A – Full power with Maximum Reactivity Feedback	Initiation of uncontrolled RCCA withdrawal at a fast reactivity insertion rate (80 pcm/s)	0.0
	High positive flux rate trip setpoint reached	5.2
	Rods begin to fall into core	6.1
	Minimum DNBR occurs	6.4
2. Case B – Full power with Maximum Reactivity Feedback	Initiation of uncontrolled RCCA withdrawal at an intermediate reactivity insertion rate (34 pcm/s)	0.0
	Overpower ΔT setpoint reached	18.0
	Rods begin to fall into core	19.9
	Minimum DNBR occurs	20.1
3. Case C – Full power with Maximum Reactivity Feedback	Initiation of uncontrolled RCCA withdrawal at a slow reactivity insertion rate (5 pcm/s)	0.0
	Overtemperature ΔT setpoint reached	568.3
	Rods begin to fall into core	570.3
	Minimum DNBR occurs	570.4

Table 9.4-1 (Sheet 2 of 3). DBA Time Sequence Of Events For Incidents Which Result In Reactivity And Power Distribution Anomalies

Accident	Event	Time (minutes)
Chemical and volume control system malfunction that results in a decrease in the boron concentration in the reactor coolant		
1. Dilution during power operation (Mode 1)		
a. Automatic reactor control	Operator receives low-low rod insertion limit alarm due to dilution	0.0
	Shutdown margin lost	170.6
b. Manual reactor control	Dilution initiated	0.0
	Reactor trip on overtemperature ΔT due to dilution	3.3
	Dilution automatically terminated by demineralized water transfer and storage system isolation	3.8
2. Dilution during startup (Mode 2)	Power range high neutron flux-low setpoint reactor trip due to dilution	0.0
	Shutdown margin lost	205.3
3. Dilution during hot standby (Mode 3)	Dilution initiated	0.0
	Boron Dilution Protection System setpoint reached, which initiates isolation of the dilution source	32.1
	Shutdown margin lost	39.6
4. Dilution during safe shutdown (Mode 4)	Dilution initiated	0.0
	Boron Dilution Protection System setpoint reached, which initiates isolation of the dilution source	28.8
	Shutdown margin lost	35.6
5. Dilution during cold shutdown (Mode 5)	Dilution initiated	0.0
	Boron Dilution Protection System setpoint reached, which initiates isolation of the dilution source	11.2
	Shutdown margin lost	13.1

Table 9.4-1 (Sheet 3 of 3). DBA Time Sequence Of Events For Incidents Which Result In Reactivity And Power Distribution Anomalies

Accident	Event	Time (seconds)
RCCA ejection accident		
1. PCMI limiting event	Initiation of rod ejection	0.00
	Peak nuclear power occurs	0.14
	Reactor trip setpoint reached	<0.30
	Peak cladding temperature occurs	0.36
	Peak enthalpy deposition occurs	0.44
	Rods begin to fall into core	1.20
2. Peak cladding temperature limiting event	Initiation of rod ejection	0.00
	Peak nuclear power occurs	0.08
	Minimum DNBR occurs	0.11
	Peak cladding temperature occurs	0.11
	Reactor trip setpoint reached	<0.30
	Rods begin to fall into core	1.20
3. Peak enthalpy/peak fuel centreline temperature event	Initiation of rod ejection	0.00
	Peak nuclear power occurs	0.06
	Reactor trip setpoint reached	<0.30
	Rods begin to fall into core	1.20
	Peak fuel centre temperature occurs	2.50
	Peak cladding temperature occurs	2.80

Table 9.4-2. DBA Key Input Parameters For Boron Dilution

Dilution Flow Rates		
Mode	**Flow Rate (gal/min)**	**Flow Rate (m^3/hr)**
1 through 5	175	39.75
Active RCS Volume		
Mode	**Volume (ft^3)**	**Volume (m^3)**
1 and 2	8425.5	238.58
3 and 4	7605.9	215.38
5	2608.2	73.86
Boron Concentration		
Mode	**Initial Concentration (ppm)**	**Critical Concentration (ppm)**
1	1811	934
2	2031	934
3	1509	1281
4	1649	1449
5	1675	1483

Table 9.4-3. DBA Parameters Used In Evaluating The Radiological Consequences Of A Rod Ejection Accident

Reactor coolant iodine activity	Equal to the operating limit for reactor coolant activity of 9.25E6 Bq/kg (0.25 µCi/g) dose equivalent I-131 (see Table 9A-1)
Reactor coolant noble gas activity	Equal to the operating limit for reactor coolant activity of 2.6E9 Bq/kg (70 µCi/g) dose equivalent Xe-133 (see Table 9A-1)
Reactor coolant alkali metal activity	Design basis activity (see Table 9A-1)
Fraction of fuel rods assumed to fail	0.10
Fraction of fuel assumed to melt	0.0025
Core activity	See Table 9A-3
Radial peaking factor (for determination of activity in failed fuel rods)	1.75
Fission product gap fractions Iodines Noble gases Alkali metals	 0.03 0.10 0.04
Fraction of activity released from fuel becoming airborne in containment Iodines Noble gases Alkali metals	 0.6 1.0 0.0
Airborne Iodine Chemical Fractions Elemental Iodine Organic Iodine	 0.99 0.01
Iodine Removal Coefficients[(a)] Elemental Iodine Organic Iodine	 1.7 (hr^{-1}) 0.0 (hr^{-1})
Containment Leakage Rate 0-24 hours 24-720 hours	 0.1 (%/day) 0.05 (%/day)
Offsite atmospheric dispersion factors	See Table 9A-5
Control room modelling	See Appendix 9A

Note:
1. Elemental iodine removal is modelled until a decontamination factor (DF) of 200 is reached.

Table 9.4-4. Rod Ejection Accident Technical Specifications Used In Dose Analysis

Limit or Condition	Tech Spec Identification and Notes
Primary Containment Leakage Rate	3.6.1 (SR 3.6.1.1) within containment leakage acceptance criteria. 5.5.8 (Containment leakage rate testing program) defines maximum allowable primary containment leak rate to be less than or equal to 0.1 weight-% per day at the calculated peak containment internal pressure for the design basis LOCA.
Primary coolant specific activity	3.4.10 dose equivalent specific activity to be < 9.25E6 Bq/kg (0.25 μCi/g) for I-131 and < 2.6E9 Bq/kg (70 μCi/g) for Xe-133

Table 9.4.2-1. ATWT Uncontrolled RCCA Withdrawal from 100 Percent Power

Event	Time (Sec)
Initiate Rod Withdrawal from 100 percent power (15 pcm/sec reactivity insertion rate)	0.0
High Neutron Flux Rod Control System Interlock C-2 reached. Rod withdrawal blocked.	not credited
High Neutron Flux trip setpoint reached (PMS trip blocked)	8.8
High Pressuriser Pressure setpoint reached (PMS trip blocked)	23.1
High Pressuriser level setpoint reached (PMS trip blocked)	28.5
Margin to OPΔT Rod Control System Interlock C-3 reached. Rod withdrawal blocked and turbine runback initiated.	not credited
High Hot Leg Temperature setpoint (335°C [635°F]) reached (DAS trip)	35.6
Control Rod Motion starts	42.6
Peak Nuclear Power (1.312 FON) reached	43.0
Peak RCS pressure (18.5 MPa [2679 psia])	43.5

Table 9.4.3-1. RCCA Misalignment Faults Mitigation Features

Category A Safety Function	Provision	SSCs	Classification
Short-term reactivity control	Primary means	Reactor trip Breakers (PMS)	1
	Diverse means	Motor-generator set field breakers (DAS)	2
Long-term reactivity control	Primary means	CMT Recirculation	1
	Diverse means	Passive feed and bleed	1
Decay heat removal	Primary means	PRHR HX	1
	Diverse means	Passive feed and bleed	1
RCS pressure control	Primary means	Pressuriser safety valve	1
	Diverse means	Pressuriser	1
RCS inventory control	Primary means	CMTs	1
	Diverse means	Passive feed and bleed	1
Containment cooling	Primary means	PCS AOVs	1
	Diverse means	PCS MOVs	1

Table 9.4.3-2. RCCA Misalignment Faults Potential Operator Actions

Operator Action	Class
On failure of automatic shutdown, initiate shutdown manually using DAS.	1
On failure of shutdown rods to insert, initiate RCP trip and actuation of CMTs to achieve shutdown by boration of the primary circuit	1
If PRHR fails, activate ADS to allow automatic actuation of recirculation RHR via the IRWST.	1

Table 9.4.6-1. ATWT Boron Dilution with a PMS CCF in Manual Rod Control

Event	Time (Sec)
Start of dilution	0
SG PORVs open in Loops 1 and 2	701
PLS Margin to OTΔT setpoint C-4 reached (alarm, blocks rod withdrawal and actuates turbine runback)	not credited
PMS OTΔT setpoint reached – no action due to PMS CCF	869
High Hot Leg Temperature = 343.3°C (650°F) in both loops reached, DAS signal generated 2 sec later	1094
RCCA starts to fall into the core (5 sec delay for M-G sets)	1101
Turbine is tripped (5 sec delay from reactor trip signal)	1101
Turbine bypass start to open in Pressure control mode	1101
SG safety valves open in Loops 1 and 2	1103
PRHR valves full flow on DAS High Hot Leg Temperature (delay 5 sec +7.5 sec)	1109

Table 9.4.6-2. ATWT Boron Dilution with a RCCA Mechanical CCF in Manual Rod Control

Event	Time (Sec)
Start of dilution	0
SG PORVs open in Loops 1 and 2	701
PLS Margin to OTΔT setpoint C-4 reached (alarm, blocks rod withdrawal and actuates turbine runback)	not credited
PMS OTΔT setpoint reached, reactor trip signal generated with 2 sec delay	869
Turbine is tripped (5 sec . delay from reactor trip signal)	876
Turbine bypass system starts to open in Pressure control mode	876
SG Safety Valves open in Loops 1 and 2	879
High Hot Leg Temperature = 343.3°C (650°F) in both loops reached, DAS signal generated 2 sec later	888
Line from the demineralised water tank is isolated (assumed 30 sec delay from PMS reactor trip signal) In this time, primary is diluted -50 ppm from initial 1050 ppm	900
PRHR valves full flow on DAS High Hot Leg Temperature (delay 5 sec + 7.5 sec)	902.5

Table 9.4.7-1. Fuel Misload Detectability Review Criteria

Available Detector Locations	Measured vs. Predicted Assembly Power*	Symmetric Assembly Measured Power Comparison+
≥ 75%	10%	10%
≥ 40% but < 75%	7%	7%

*Applicable to core locations with predicted assembly relative powers above 0.8.

+Applicable to core locations with assembly relative powers above 0.8. The review criterion is relative to the expected symmetric assembly measured power difference.

Table 9.4.8-1. Spectrum of RCCA Ejection Events Mitigation Features

Category A Safety Function	Provision	SSCs	Classification
Short-term reactivity control	Primary means	Reactor trip Breakers (PMS)	1
Long-term reactivity control	Primary means	CMT Recirculation	1
Decay heat removal	Primary means	PRHR HX	1
RCS pressure control	Primary means	Pressuriser safety valve	1
RCS inventory control	Primary means	CMTs, accumulators, IRWST	1
Containment cooling	Primary means	PCS AOVs	1

9.5 Increase in Reactor Coolant System Water Inventory Faults

A number of faults that could result in an increase in reactor coolant inventory are postulated. The events are discussed in this section. Detailed analyses are presented for the most limiting of the primary system coolant increase events.

9.5.0 Introduction and Overview of Fault

This section addresses two faults:

- Inadvertent operation of a CMT
- CVS malfunction that increases reactor coolant inventory

The inadvertent operation of a CMT and the chemical and volume control system malfunction faults both lead to increases in the reactor coolant inventory and have similar plant responses. However, they are treated separately because the inadvertent operation of one of the CMTs means that, for this fault, only one CMT is available after the reactor has tripped.

Section 9.5 considers both faults in turn. Each fault is first described; the initiating event frequency and the design basis class are provided. The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are then described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

ATWT analyses presented herein are based on Reference 9.5-3.

9.5.0.1 Inadvertent Operation of a Core Makeup Tank during Power Operation

Description

In this fault one CMT is inadvertently actuated while the reactor is operating at power.

Initiating Event Frequency[1]

The fault schedule in Appendix 8A indicates that this event is expected to have a frequency in the range of 0.1 to 0.01/yr, which makes the fault a frequent fault.

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

Design Basis Class

The unmitigated consequences of an inadvertent CMT actuation are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

9.5.0.2 Chemical and Volume Control System Malfunction That Increases Reactor Coolant Inventory

Description

In this fault a CVS malfunction causes an increase of reactor coolant inventory at power.

Initiating Event Frequency[1]

The fault schedule in Appendix 8A indicates that this event is expected to have a frequency in the range of 0.1 to 0.01/yr, which makes the fault a frequent fault.

Design Basis Class

The unmitigated consequences of inadvertent actuation of the CVS are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

9.5.1 Inadvertent Operation of a Core Makeup Tank During Power Operation (Fault 1.12.1)

9.5.1.1 Identification of the Causes and Accident Description

Spurious core makeup tank operation at power could be caused by an operator error, a false electrical actuation signal, or a valve malfunction. A spurious signal may originate from any of the safeguards ("S") actuation channels identified in Table 6-4. The AP1000 protection logic is such that a single failure cannot actuate both core makeup tanks without also actuating the PRHR heat exchanger. A scenario such as this is the spurious "S" signal event. However, if one core makeup tank is inadvertently actuated by a single failure, the event may progress with the plant at power until a reactor trip is reached. For the plant under automatic rod control, a reactor trip on High-3 pressuriser water level is expected to occur followed by the PRHR actuation and eventually by an "S" signal, which would then actuate the second core makeup tank. When a consequential loss of offsite power is assumed, this event is more conservative than the spurious "S" signal event.

The inadvertent opening of the core makeup tank discharge valves, due to operator error or valve failure, results in significant core makeup tank injection flow leading to a boration transient similar to that resulting from a chemical and volume control system malfunction event. If the automatic rod control system is operable, it will begin to withdraw rods from the core to counteract the reactivity effects of the boration. As a result, the core makeup tank will continue injection and slowly increase the pressuriser level until the High-2 pressuriser level setpoint is reached and continues until the High-3 pressuriser level reactor trip setpoint is reached. A loss of offsite power is assumed to occur as a consequence of the reactor trip. The primary effect of this assumption is the coastdown of the reactor coolant pumps. The core makeup tank injection will increase as the steam generator outlet temperature increases resulting in a lower density in the CMT balance line. This event will then proceed similarly to a spurious "S" signal or chemical and volume control system malfunction event. However, this event is more limiting primarily due to the higher pressuriser level at the time of reactor trip and to the significant heat up of the injected

fluid during the pre-trip phase of the accident. Thus, the inadvertent core makeup tank actuation event with a consequential loss of offsite power is analysed here.

Upon receipt of the High-3 pressuriser level reactor trip signal, the reactor is tripped; then the turbine is tripped after a 5-second delay and 3 seconds after turbine trip a consequential loss of offsite power is assumed. The basis for the 3-second delay is described in Section 9.0.12. The High-3 pressuriser level signal also actuates the PRHR heat exchanger and blocks the pressuriser heaters, but a 15-second delay is built in to prevent unnecessary actuation of the PRHR heat exchanger if offsite power is maintained.

Following reactor trip, the reactor power drops and the average reactor coolant system temperature decreases with subsequent coolant shrinkage, which avoids PRHR actuation immediately following the first High-3 pressuriser level trip signal. However, due to the assumed loss of offsite power, the reactor coolant cold leg temperature, in the loop without the PRHR, increases and the core makeup tank starts injecting cold water into the reactor coolant system at a much higher rate. The initial primary coolant system shrinkage is counteracted by the core makeup tank injection, and the pressuriser water volume starts to increase because of the heatup of the cold injected fluid by the decay heat. The High-3 pressuriser level setpoint is once again reached, and after a 15-second delay, the signal is sent to actuate the PRHR heat exchanger and block the pressuriser heaters.

The PRHR heat exchanger extracts heat from the reactor coolant system leading to an "S" signal on a Low-2 T_{cold} signal. The PRHR heat exchanger may inject asymmetrically into the steam generator outlet plenum such that a higher percentage of the PRHR flow is in one of two cold legs coming from the steam generator on the PRHR loop. To account for this, the analysis assumes that the Low T_{cold} setpoint is reached coincident with PRHR heat exchanger actuation. This actuates the second core makeup tank sooner in the transient, which is more limiting with respect to filling the pressuriser.

Both core makeup tanks inject mass into the reactor coolant system, and the pressuriser level continues to increase until the operators take action to end the pressuriser level increase transient. The operators are assumed to be alerted to a potential filling event on the High-2 pressuriser level signal, which occurs well before the reactor trip on the first of two High-3 pressuriser level signals. The operator action assumed in the analysis is to open the reactor vessel head vent following receipt of the second High-3 pressuriser level signal; this action is at least 30 minutes (45 minutes as analysed) after the operator has been alerted by the High-2 pressuriser level signal. When the head vent is opened, the pressuriser level increase slows and ultimately the level begins to decrease.

9.5.1.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to RCS and MSS overpressurisation and fuel failure criteria, this event is not limiting because cold, borated water is added to the RCS until the time of reactor trip, which produces a modest thermal transient without significant power excursion. Therefore, although these parameters are tracked, the primary acceptance criterion is precluding pressuriser overfill or, if

overfill would occur, to ensure that the operators have enough time to take corrective action to prevent it.

9.5.1.2.1 DBA Method of Analysis

The plant response to an inadvertent core makeup tank actuation is analysed by using a modified version of the computer program LOFTRAN (References 9.5-1 and 9.5-2) described in Section 9.0.9.2. The code simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generator, steam generator safety valves, PRHR heat exchanger, and core makeup tanks. The program computes pertinent plant variables, including temperatures, pressures, and power level.

As noted previously, with respect to RCS and main steam system overpressurisation and minimum DNBR, this event is not limiting. Therefore, the DB analysis is structured to maximize the risk of pressuriser filling. Core makeup tank and PRHR system performance is conservatively simulated. Core makeup tank enthalpies have been maximised. This is conservative because it minimizes the cooling provided by the core makeup tanks as flow recirculates and thereby increases the peak pressuriser water volume during the transient. Core makeup tank injection and balance lines pressure drop is minimized. This maximises the core makeup tank flow injected in the primary system. During this event, the core makeup tanks remain filled with water. The volume of injection flow leaving the core makeup tanks is offset by an equal volume of recirculation flow that enters the core makeup tanks via the balance lines. PRHR heat transfer capability has been minimized.

Plant characteristics and initial conditions are further discussed in Section 9.0.2.

- Initial operating conditions

  The initial reactor power is assumed to be 101 percent of nominal. The initial pressuriser pressure is assumed to be 0.345 MPa (50 psi) below nominal. The initial reactor coolant system average temperature is assumed to be 4.4°C (8°F) below nominal.

- Control systems

  The pressuriser spray system and automatic rod control system are conservatively assumed to operate. The pressuriser heaters are automatically blocked on a High-3 pressuriser level signal, so they cannot add heat to the system during the period of thermal expansion that produces the peak pressuriser water volume. Thus, the pressuriser heaters are assumed to be inoperable during this event. Other control systems are conservatively not assumed to function during the transient.

- Moderator and Doppler coefficients of reactivity

  A least-negative moderator temperature coefficient, a low (absolute value) Doppler power coefficient, and a minimum boron worth are assumed. With these minimum feedback parameters and the operability of the pressuriser spray system and automatic rod control system assumed, the reactivity effects of the boron injection from the core makeup tanks is counteracted. As a result, the High-3 pressuriser level signal is the first reactor trip signal generated during the transient.

- Boron injection

  The transient is initiated by an inadvertent opening of the discharge valves of one of the two core makeup tanks. The core makeup tank injects 3400 ppm borated water.

- Protection and safety monitoring system actuations

  The operators are assumed to be alerted to the pressuriser level increase transient by the High-2 pressuriser level signal. Reactor trip is initiated by the first of two High-3 pressuriser level signals. The second High-3 pressuriser level signal triggers the operators to open the reactor vessel head vent; this action is verified to be at least 30 minutes after the operator has been alerted by the High-2 pressuriser level signal.

  The PRHR heat exchanger is automatically actuated on second instance of the High-3 pressuriser level signal, which occurs after the reactor trip. The core decay heat is removed by the PRHR heat exchanger. The worst single failure is assumed to occur in the outlet line of the PRHR heat exchanger. One of the two parallel isolation valves is assumed to fail to open.

9.5.1.2.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and reactor vessel head vent valves. The PMS provides the following

- RT on High-3 pressuriser water level
- PRHR actuation on High-3 pressuriser water level
- 2nd CMT and containment isolation on Low-2 CL temperature
- Manual head vent valve operation on High-2 pressuriser level
- PCS on High-2 containment pressure

9.5.1.2.3 DBA Results

The calculated sequence of events is shown in Table 9.5-1.

Figures 9.5.1-1 through 9.5.1-8 show the transient response to the inadvertent operation of one of the two core makeup tanks during power operation. The inadvertent opening of the core makeup tank discharge valves occurs at 10 seconds. As the core makeup tank continues to add inventory to the primary system, the pressuriser level begins to increase until the High-2 pressuriser level setpoint is reached (at 556.1 seconds) and continues until the High-3 pressuriser level reactor trip setpoint is reached at 2,589.3 seconds. After a 2-second delay, the neutron flux starts decreasing due to the reactor trip, which is followed by turbine trip after a 5-second turbine trip delay. Following reactor trip, the reactor power drops and the average reactor coolant system temperature decreases with subsequent coolant shrinkage. Due to the assumed loss of offsite power, the reactor coolant pumps trip at 2,599.3 seconds. The cold leg temperature increases and the core makeup tank starts injecting cold water into the reactor coolant system at a higher rate due to the increased driving head resulting from the density decrease in the balance line and due to the reduced pressure drop between the cold leg and the injection line connection on the reactor vessel

following the trip of the reactor coolant pumps. The post-trip primary coolant system shrinkage is counteracted by the core makeup tank injection, and the pressuriser water volume starts to increase because of the heatup of the cold injected fluid by the decay heat. The High-3 pressuriser level setpoint is once again reached at 2,736.6 seconds, and after a 15-second delay, the signal is sent to actuate the PRHR heat exchanger and block the pressuriser heaters. Following a conservative 17-second delay, the valves are assumed to open to actuate the PRHR heat exchanger at 2,768.6 seconds.

If the PRHR heat exchanger coolant asymmetrically injects into the steam generator outlet plenum, then one cold leg could reach the Low-2 T_{cold} "S" setpoint more quickly than if the flow were split evenly. To conservatively account for this effect, the Low-2 T_{cold} "S" signal is modelled to actuate simultaneously with the actuation of the PRHR heat exchanger (at 2,768.6 seconds). The Low-2 T_{cold} "S" signal activates the second core makeup tank, which then begins injecting additional mass into the reactor coolant system. Previous analyses have demonstrated that a more limiting pressuriser fill transient is calculated the earlier the second core makeup tank is actuated.

As the second core makeup tank begins injecting, the pressuriser level continues to increase. The operators are assumed to be alerted by the High-2 pressuriser level signal (at 556.1 seconds) that a pressuriser level increase transient is underway, and it is assumed that the operators are ready to take corrective action at least 30 minutes later. In this analysis, since pressuriser level continues to increase, the High-3 pressuriser level reactor trip setpoint is reached within this time. The operator action assumed in this case is to open the reactor vessel head vent to preclude pressuriser overfill following receipt of the second High-3 pressuriser level signal (at 3,256.1 seconds); this action is at least 30 minutes (45 minutes as analysed) after the operator has been alerted by the High-2 pressuriser level signal.

The safety-related reactor vessel head vent is opened by the operators, and the pressuriser water level increase slows and eventually the level begins to decrease. This demonstrates that the capacity of the reactor vessel head vent is sufficient to preclude pressuriser overfill as a result of an inadvertent actuation of a core makeup tank.

During the event, the DNBR never drops significantly below the initial value due to the addition of highly borated water from the core makeup tanks to the reactor coolant system. At the time of reactor trip, core power and heat flux drop rapidly and the DNBR is well above the design limit value defined in Section 22.7.1.1. The analysis demonstrates that no reactor coolant system overpressurisation occurs.

As noted above, the limiting case presented here models explicit operator action 45 minutes after receipt of the High-2 pressuriser level signal and demonstrates that pressuriser filling is precluded. For pressuriser level increase events, the operator would take action to reduce the increase in coolant inventory. As the pressuriser water level would increase above the high pressuriser water level that normally isolates chemical and volume control system makeup (High-2), the normal letdown line could be placed into service to reduce the increase in coolant inventory. If letdown could not be placed into service, the operator could use the safety related reactor vessel head vent valves to reduce the increase in coolant inventory (this is explicitly modelled in the case presented here). For these events, following the procedures outlined in the Emergency Response Guidelines AFR-I.1, there is sufficient time for the operator to mitigate the consequences of this event and anticipate operator action upon receipt of the second High-3 pressuriser level signal.

Appendix 9C provides discussion and analysis of long term safe shutdown for non-LOCA events.

9.5.1.3 Diverse Mitigation

In addition to the Class 1 passive systems credited in the DBA, the plant also provides diverse mitigation capability that is able to supply the Category A safety functions for frequent faults. The diverse features are also Class 1 except for the C&I, which is Class 2.

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

Table 9.5-2 summarizes the SSCs from this fault assessment. As this is a frequent fault, a diverse means of providing the Category A safety functions is provided. The information provided in Table 9.5-2 is from Reference 9.5-4, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions. Table 9.5-3 provides the operator actions utilized in the diverse safety case.

9.5.1.3.1 Diverse Mitigation for ATWT

Inadvertent operation of a CMT involves trip of the RCPs and opening of the CMT discharge valves.

If the CMT discharge valves are opened without RCP trip, then the pressure gradients will prevent flow through the CMT. A check valve in the CMT discharge line prevents reverse flow. There will be no impact on the NSSS operating conditions. In the long term, possible valve leakage in the check valves may flush out the CMT very slowly, leading to increased boron concentration in the RCS, and the need to dilute to limit control rod motion. Since this would occur over many hours or days, there is ample time for operators to respond to the incorrect CMT discharge valve position.

If the RCPs are tripped (but the control rods are not tripped), the resulting transient is addressed as a loss of RCS flow in Section 9.3.2.3.1.

Therefore, no separate analysis or evaluation is provided in this section.

9.5.1.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.5.1.4 Radiological Consequences

Design Basis

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.5.1.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

The diverse mitigation functions, including other Class 1 safety functions and the DAS function, which is Class 2, is also shown by analysis to meet applicable requirements for the inadvertent operation of a CMT during power operation event. See Reference 9.5-4 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy provided by the DiD systems. The applicable DiD functions include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- SFW with steam dump for short-term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the CCS and SWS cooling water systems.
- Control by the PLS C&I

The characteristics of the above features were compared to improvements that were evaluated for the RNS for its mitigation of cliff edge small LOCAs. First it should be recognized that in this situation the RNS provides the second level of defence for this event and is therefore more important than the above DiD features which provide a 3rd level of defence. The RNS improvements included making the RNS alignment and actuation automatic, increasing the RNS pump head, and adding a RNS suction supply tank that is separate from the Class 1 system. None of these potential improvements were found to be ALARP (See Section 9.1.4.5). However, the SFW and CVS already include characteristics similar to these proposed improvements. Another improvement that could be made to these DiD systems is to upgrade them to Class 1. This would be very expensive especially and would have wide reaching impacts to the design of SSCs; notable would be the impact on component and building design to address hazards including seismic and storm winds/missiles. Such a change would not be ALARP because the cost would be grossly disproportional to its benefit.

As discussed in Chapter 9.0.15, the AP1000 has incorporated ALARP thinking throughout its development. In addition, the current risk of a large radioactivity release is significantly less than the SAP Target 9 BSO (1E-7 pa). Considering the ALARP thinking that went into the AP1000

development, its low risk profile and the additional level of defence discussed above (including their performance characteristics), improving the Class 2 DiD to better remove decay heat or shutdown the reactor would be grossly disproportional to the risk reduction that might be achieved. As a result, the current design is considered ALARP.

9.5.1.6 Conclusions

The DB analysis demonstrates that inadvertent operation of a core makeup tank during power operation does not adversely affect the core, the reactor coolant system, or the steam system. The pressuriser does not fill; therefore, water is not relieved from the pressuriser safety valves. DNBR always remains above the design limit values, and reactor coolant system and steam generator pressures remain below 110 percent of their design values.

This event has also been adequately assessed with respect to ATWT considerations.

Diverse core cooling capabilities have been demonstrated.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAP targets and the risks have been reduced to be ALARP.

9.5.2 Chemical and Volume Control System Malfunction That Increases Reactor Coolant Inventory (Fault 1.12.4)

9.5.2.1 Identification of Causes and Accident Description

An increase of reactor coolant inventory, which results from addition of cold unborated water to the reactor coolant system, is analysed in Section 9.4.6.

In this Section, the increase of reactor coolant system inventory due to the addition of borated water is analysed.

The increase of reactor coolant system coolant inventory may be due to the spurious operation of one or both of the chemical and volume control system pumps or by the closure of the letdown path. If the chemical and volume control system is injecting highly borated water into the reactor coolant system, the reactor experiences a negative reactivity excursion due to the injected boron, causing a decrease in reactor power and subsequent coolant shrinkage. The load decreases due to the effect of reduced steam pressure after the turbine control valve fully opens.

At high chemical and volume control system boron concentration, low reactivity feedback conditions, and reactor in manual rod control, an “S” signal will be generated by either the Low-2 T_{cold} or Low-2 steam line pressure setpoints before the chemical and volume control system can inject a significant amount of water into the reactor coolant system. In this case, the chemical and volume control system malfunction event proceeds similarly to, and is only slightly more limiting than, a spurious “S” signal event. If the automatic rod control is modelled and the pressuriser spray functions properly to prevent a high pressure reactor trip signal, no “S” signals are generated and this specific event is terminated by automatic isolation of the chemical and volume control system on the safety-related High-2 pressuriser level setpoint.

Under typical operating conditions for the AP1000, the boron concentration of the injected chemical and volume control system water is equal to that of the reactor coolant system. If the chemical and volume control system is functioning in this manner and the pressuriser spray system functions properly to prevent a high pressure reactor trip signal, no "S" signals are generated and this specific event is also terminated by automatic isolation of the chemical and volume control system on the safety-related High-2 pressuriser level setpoint.

While these scenarios are the most probable outcomes of a chemical and volume control system malfunction, several combinations of boron concentration, feedback conditions, and plant system interactions have been identified which can result in more limiting scenarios with respect to pressuriser overfill. The key factors that make this event more limiting than a spurious "S" signal event are that the reactor coolant system is at a lower average temperature, higher pressure, and a higher pressuriser level at the time an "S" signal is generated. These factors produce a greater volume of higher density water and, thus, a larger reactor coolant system mass at the time of the "S" signal. In addition, at lower reactor coolant system average temperature, the PRHR is less effective in removing decay heat, which results in greater expansion of the cold water injected by the core makeup tanks.

The limiting analysis scenario minimizes reactor coolant system average temperature, maximises reactor coolant system mass, and maximises pressuriser water volume at the time of an "S" signal. This scenario is as follows:

- Both of the chemical and volume control system pumps spuriously begin delivering flow at a boron concentration slightly higher than that of the reactor coolant system. (Assuming that a chemical and volume control system malfunction results in both chemical and volume control system pumps delivering flow is a conservative assumption. One chemical and volume control system pump is automatically controlled and one is manually controlled.)

- The non-safety-related pressuriser spray is assumed to be available, so that a High-2 pressuriser pressure reactor trip is prevented.

Due to the boron addition in the core, the plant cools down until an "S" signal is generated on Low-2 cold leg temperature. On the "S" signal, the reactor is tripped, the core makeup tank discharge valves are opened, the reactor coolant pumps are tripped, the pressuriser heaters are blocked, and the main feedwater lines, steam lines, and chemical and volume control system are isolated. After a conservative 17-second delay, the PRHR heat exchanger is actuated.

Normally, the reactor coolant pumps would be tripped 15 seconds after the receipt of the "S" signal. A loss of offsite power is assumed to occur as a consequence of reactor trip. The primary effect of this assumption is the coastdown of the reactor coolant pumps. Following reactor trip and a 5-second timer delay, the turbine is tripped. 3 seconds after a turbine trip a consequential loss of offsite power is assumed. The basis for the 3-second delay is described in Section 9.0.12. As a result, the reactor coolant pumps are conservatively assumed to trip about 10 seconds before they would otherwise trip due to the "S" signal.

9.5.2.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

With respect to RCS and MSS overpressurisation and fuel failure criteria, this event is not limiting because cold, borated water is added to the RCS until the time of reactor trip, which produces a modest thermal transient without significant power excursion. Therefore, although these parameters are tracked, the primary acceptance criterion is precluding pressuriser overfill or, if overfill would occur, to ensure that the operators have enough time to take corrective action.)

9.5.2.2.1 DBA Method of Analysis

The malfunction of the chemical and volume control system is analysed by using a modified version of the computer program LOFTRAN (Reference 9.5-1 and 9.5-2) described in Section 9.0.9.2. The code simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, pressuriser spray, steam generator, steam generator safety valves, PRHR heat exchanger, and core makeup tanks. The program computes pertinent plant variables including temperatures, pressures, and power level.

Because of the power and temperature reduction during the transient, operating conditions do not approach the core limits. The analysis demonstrates that no reactor coolant system overpressurisation occurs.

The assumptions are as follows:

- Initial operating conditions

  The initial reactor power is assumed to be 101 percent of nominal. The initial pressuriser pressure is assumed to be 0.345 MPa (50 psi) above nominal. The initial reactor coolant system average temperature is assumed to be 4.4°C (40°F) above nominal.

- Moderator and Doppler coefficients of reactivity

  A least-negative moderator temperature coefficient, a low (absolute value) Doppler power coefficient, and a minimum boron worth are assumed. For a different set of reactivity feedback parameters, a different chemical and volume control system boron concentration can result in an identical transient.

- Reactor control

  Rod control is not modelled.

- Pressuriser heaters

  The pressuriser heaters are automatically blocked on an “S” signal, and do not add heat to the system during the period of fluid thermal expansion that produces the peak pressuriser water volume. Thus, the pressuriser heaters are assumed to be inoperable during this event.

- Pressuriser spray

  The spray system controls the pressuriser pressure so that a High-2 pressuriser pressure reactor trip is prevented.

- Boron injection

  After 10 seconds at steady state, the chemical and volume control system pumps start injecting borated water, which is slightly above the reactor coolant system boron

concentration. Upon receipt of an "S" signal, the core makeup tanks begin injecting 3400 ppm borated water. The chemical and volume control system pumps are isolated on a High-2 pressuriser level signal. In this analysis, the boron concentration of the chemical and volume control system is iterated upon until the High-2 pressuriser level and the Low T_{cold} "S" setpoint are reached at the same time. This begins core makeup tank injection when the chemical and volume control system pumps are isolated, which is conservative with respect to filling the pressuriser.

- Turbine load

  The turbine load is assumed constant until the turbine digital electrohydraulic control (D-EHC) drives the control valve wide open. Then the turbine load drops as steam pressure drops.

- Protection and safety monitoring system actuations

  If the automatic rod control system is modelled and the pressuriser spray system functions properly, no reactor trip signal is expected to occur. Instead, the event is terminated by automatic isolation of the chemical and volume control system on the safety grade high-2 pressuriser level setpoint. If the automatic rod control system is not active and the pressuriser spray system is assumed to be available, reactor trip may be initiated on either Low-2 T_{cold} "S" or a Low-2 steam line pressure "S" signal.

  The core decay heat is removed by the PRHR heat exchanger. The worst single failure is assumed to occur in the outlet line of the PRHR heat exchanger. One of the two parallel isolation valves is assumed to fail to open.

9.5.2.2.2 DBA Credited SSCs

For the DB, all claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs, containment isolation, pressuriser SVs and reactor vessel head vent valves. The PMS provides the following:

- RT on Low-2 cold leg temperature (T_{cold}) "S" signal

- PRHR actuation on High-3 pressuriser water level

- CMTs and containment isolation on Low-2 CL temperature

- Manual head vent valve operation on High-2 pressuriser level

- PCS on High-2 containment pressure

9.5.2.2.3 DBA Results

The calculated sequence of events is shown in Table 9.5-1.

Figures 9.5.2-1 through 9.5.2-9 show the transient response to a chemical and volume control system malfunction that results in an increase of reactor coolant system inventory.

As the chemical and volume control system injection flow increases reactor coolant system inventory, pressuriser water volume begins increasing while the primary system is cooling down. A reactor trip is modelled to occur on the Low-2 T_{cold} "S" signal (conservatively modelled to occur simultaneously with High-2 pressuriser water level) at 2,270.8 seconds. Once the Low-2 T_{cold} setpoint is reached, the reactor trips on the resulting "S" signal, and the control rods start moving into the core. At the same time, the High-2 pressuriser level setpoint is reached and after a conservative delay, the chemical and volume control system injection is isolated.

The turbine is tripped as a result of the reactor trip following a 5-second turbine trip timer delay. After a 3-second delay following turbine trip, a consequential loss of offsite power is assumed and the reactor coolant pumps trip. The basis for the 3-second delay is described in Section 9.0.12. Soon after reactor trip, the pressuriser heaters are blocked and the main feedwater lines, steam lines, and chemical and volume control system are isolated. After a conservative 17-second delay, the PRHR heat exchanger is actuated and the core makeup tank discharge valves are opened. The core makeup tanks work in recirculation mode, meaning they are always filled with water because cold borated water injected through the injection lines is replaced by hot water coming from the cold leg balance lines.

The operation of the PRHR heat exchanger and the core makeup tanks cools down the plant. Due to the swelling of the core makeup tank water, the pressuriser level continues to increase. The operators are assumed to be alerted by the High-2 pressuriser level signal (at 2,270.8 seconds) that a pressuriser level increase transient is underway, and it is assumed that the operators are ready to take corrective action at least 30 minutes later. The specific operator action assumed in this case is to open the reactor vessel head vent to preclude pressuriser overfill following the High-3 pressuriser level signal (at 4,070.8 seconds); this action is at least 30 minutes after the operator has been alerted by the High-2 pressuriser level signal.

The safety-related reactor vessel head vent is opened by the operators, and the pressuriser water level increase slows and eventually the level begins to decrease. This demonstrates that the capacity of the reactor vessel head vent is sufficient to preclude pressuriser overfill as a result of a chemical and volume control system malfunction that causes an increase in reactor coolant inventory.

During the event, the DNBR never drops significantly below the initial value since both the chemical and volume control system and the core makeup tanks add borated water to the reactor coolant system. At the time of the reactor trip, core power and heat flux drop rapidly and the DNBR is well above the design limit value defined in Section 22.7.1.1.

The limiting case presented here models operator action to open the reactor vessel head vent following receipt of the High-3 pressuriser level signal; this action is at least 30 minutes after the operator has been alerted by the High-2 pressuriser level signal. For pressuriser level increase events, the operator could take other actions to reduce the increase in coolant inventory. As the pressuriser water level would increase above the high pressuriser water level that normally isolates chemical and volume control system makeup, the normal letdown line could be placed into service to reduce the increase in coolant inventory. If letdown could not be placed into service, the operator would use the safety-related reactor vessel head vent valves to reduce the increase in coolant inventory. For these events, following operations procedures, there is sufficient time for the operator to mitigate the consequences of this event.

Appendix 9C provides discussion and analysis of long term safe shutdown for all non-LOCA events.

9.5.2.3 Diverse Mitigation

As this is classified a frequent fault, alternative means of providing the required Category A safety functions are required. For this frequent fault event the diverse features are also Class 1 except for the C&I, which is Class 2.

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS venting (Class 1). The DAS provides diverse reactor trip and safety system actuation (Class 2).

Table 9.5-2 summarizes the SSCs from this fault assessment. As this is a frequent fault, a diverse means of providing the Category A safety functions is provided. The information provided in Table 9.5-2 is from Reference 9.5-4, which documents the diversity for the frequent faults and provides additional information on the diverse mitigation functions. Table 9.5-3 provides the operator actions utilized in the diverse safety case.

9.5.2.3.1 Diverse Mitigation for ATWT

An increase in reactor coolant inventory, which results from addition of cold unborated water to the reactor coolant system, is presented in the boron dilution discussion in Section 9.4.6.3. For purposes of this discussion, the increase of reactor coolant system inventory is due to the addition of borated water.

The increase of RCS coolant inventory may be due to the spurious operation of one or both of the CVS pumps or the closure of the letdown path. If the CVS is injecting highly borated water into the RCS, the reactor experiences a negative reactivity excursion due to the injected boron, causing a decrease in reactor power and subsequent coolant shrinkage. The load decreases due to the effect of reduced steam pressure after the turbine control valve fully opens.

At high CVS boron concentration, low reactivity feedback conditions, and reactor in manual rod control, an "S" signal will be generated by either the low T_{cold} or low steam line pressure setpoints before the CVS can inject a significant amount of water into the RCS. In this case, the CVS malfunction event proceeds similarly to, and is only slightly more limiting than, a spurious "S" signal event. If the automatic rod control is modelled and the pressuriser spray functions properly to prevent a high pressure reactor trip signal, no "S" signals are generated, and this specific event is terminated by automatic isolation of the CVS on the Class 1 High-2 pressuriser level setpoint.

Under typical operating conditions for the AP1000 reactor, the boron concentration of the injected CVS water is equal to that of the RCS. If the CVS is functioning in this manner and the pressuriser spray system functions properly to prevent a high pressure reactor trip signal, no "S" signals are generated and this specific event is also terminated by automatic isolation of the CVS on the High-2 pressuriser level setpoint.

For the above two cases, no trip signal is generated, as a trip is not necessary to protect the plant. Thus, ATWT is not applicable to this transient.

While these scenarios are the most probable outcomes of a CVS malfunction, several combinations of boron concentration, feedback conditions, and plant system interactions have been identified that can result generating an "S" signal and a reactor trip. This scenario is evaluated for ATWT and assumes the following:

- One or both of the chemical and volume control system pumps spuriously begin delivering flow at a boron concentration slightly higher than that of the reactor coolant system.

- The pressuriser spray is assumed to be available, so that a high pressuriser pressure reactor trip is prevented.

- Due to the boron addition in the core, the plant cools down until an "S" signal is generated on low cold-leg temperature. On the "S" signal, the reactor is tripped (rods do not drop, either because the rods are mechanically stuck or the trip breakers fail to open), the RCPs are tripped, the pressuriser heaters are blocked, and the main feedwater lines, steam lines, and CVS are isolated.

Because these actions occur at lower than normal reactor coolant temperatures, the loss of ac power ATWT (Section 9.2.6.3.1) is more limiting than this scenario.

If the rods fail to drop due to a failure of the PMS, the "S" signal will not be generated, RCS temperatures will continue to fall, the CVS will be isolated on a High-2 pressuriser level setpoint, and the reactor will stabilise at a lower RCS temperature. For a PMS CCF, CVS would not be isolated; however, the main result of this failure would be pressuriser filling (with pressuriser safety valve (PSV) water relief), which is not an ATWT acceptance criteria (see Reference 9.5-3). Eventually, the operators would diagnose the problem and isolate the CVS. Alternatively, manual reactor trip or CMT actuation via the DAS is available.

9.5.2.3.2 Diverse Mitigation for Core Cooling

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, was determined to be bounding of all non-LOCA events.

9.5.2.4 Radiological Consequences

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, a small release of activity may occur as a result of steam dump to the atmosphere due to unavailability of the condensers. With no fuel damage and primary and secondary circuits intact, the initiating event has no impact on the doses. The doses are a consequence of the assumed loss of offsite power. Therefore, the loss of offsite power event doses from Section 9.2.6.4 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.05 mSv Worker dose: 1.5 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

Diverse Mitigation

Both the diverse ATWT and diverse core cooling scenarios demonstrate that the RCS does not overpressurise and there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not

have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.5.2.5 As Low as Reasonably Practicable Assessment

The ALARP discussion for this event is the same as for the inadvertent operation of a core makeup tank, as described in Section 9.5.1.5.

9.5.2.6 Conclusions

The DB analysis demonstrates that a chemical and volume control system malfunction does not adversely affect the core, the reactor coolant system, or the steam system. The pressuriser does not fill; therefore, water is not relieved from the pressuriser safety valves. DNBR remains above the design limit values, and reactor coolant system and steam generator pressures remain below 110 percent of their design values.

This event has also been adequately assessed with respect to ATWT considerations.
Diverse core cooling capabilities have been demonstrated.

DBA Radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAP targets and the risks has have been reduced to be ALARP.

9.6 Decrease in Reactor Coolant Inventory

The following sections evaluate faults dealing with decreases in reactor coolant system water inventory.

9.6.1 Inadvertent Opening of a Pressuriser Safety Valve or Inadvertent Operation of the ADS

9.6.1.0 Introduction and Overview of Faults

Section 9.6.1 evaluates the short term effects on the plant as a result of two inadvertent depressurisation faults (Fault 1.5.2):

- Inadvertent operation of ADS valves leading to a medium-break loss-of-coolant accident (MBLOCA)
- Inadvertent opening of a pressuriser safety valve

The long term effects for these faults are examined in Section 9.6.5.

Spurious actuation of the ADS is defined as an inadvertent valve-opening event. Depending on the number of the ADS lines spuriously opening, the frequency of ADS spurious actuation can be classified as MBLOCA or large-break loss-of-coolant accident (LBLOCA). Spurious ADS actuation leading to an LBLOCA is addressed in Section 9.6.4.

Spurious actuation of ADS consisting of Stages 1-3 opening in sequence (equivalent to a spurious C&I actuation signal) is categorised and analysed as a medium LOCA. Spurious ADS Stage 4 is categorised as a large LOCA.

The valve stroke times assumed reflect the DB of the AP1000 plant. The accidents addressed in this section were evaluated for the effect of these assumed DB valve stroke times. The results of this evaluation have shown that there is a small impact on the analysis and the conclusions remain valid. The output provided in this section for the analyses is representative of the transient phenomenon.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

Initiating Event Frequency[1]

The fault schedule (Appendix 8A) gives a frequency of <1E-07/yr for spurious ADS operation leading to an MBLOCA and a frequency of 3.9E-04/yr for a stuck-open pressuriser valve event. These two types of inadvertent depressurisations are considered to be infrequent faults.

Design Basis Class

As noted in the MBLOCA assessment, given that the unmitigated consequences of an MBLOCA are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite) and given the IEF above, the event is in the DB1 class.

9.6.1.1 Identification of Causes and Accident Description

Two types of inadvertent depressurisations are discussed in this section. One covers the inadvertent operation of ADS valves. The other covers inadvertent opening of a pressuriser safety valve.

An inadvertent depressurisation of the reactor coolant system can occur as a result of an inadvertent opening of a pressuriser safety valve or ADS valves. Initially, the event results in a rapidly decreasing reactor coolant system pressure. The pressure decrease causes a decrease in power via the moderator density feedback. The average coolant temperature decreases slowly, but the pressuriser level increases until reactor trip.

The reactor may be tripped by the following reactor protection system signals:

- Overtemperature ΔT
- Pressuriser low pressure

The ADS system consists of four stages of depressurisation valves. The ADS stages are interlocked. For example, Stage 1 is initiated first and subsequent stages are not actuated until previous stages have completed actuation. Each stage includes two redundant parallel valve paths with two valves in series in each path such that no single failure prevents operation of the ADS stage when it is called upon to actuate and the spurious opening of a single ADS valve does not initiate ADS flow. Since each ADS path includes two valves in series, no mechanical failure could result in an inadvertent operation of an ADS stage. The ADS Stage 4 squib valves cannot be opened while the reactor coolant system is at nominal operating pressure. To actuate the ADS manually from the main control room, the operators actuate two separate controls positioned at some distance apart on the main control board. Therefore, one unintended operator action does not cause ADS actuation.

ADS Stage 1 has a minimum opening time of 20 seconds and a maximum effective flow area of 0.0045 m^2 (7 in^2). ADS Stages 2 and 3 have a minimum opening time of 60 seconds and a maximum effective flow area of 0.018 m^2 (28 in^2).

---

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

For this analysis, multiple failures and or errors are assumed which actuate both Stage 1 ADS paths. Although ADS Stages 2 and 3 have larger depressurisation valves, the opening time of the Stage 1 depressurisation valves is faster. This results in a more severe reactor coolant system depressurisation due to ADS operation with the reactor at power.

Inadvertent opening of a pressuriser safety valve can only be postulated due to a mechanical failure. Although a pressuriser safety valve is smaller than the combined two Stage 1 ADS valves, the pressuriser safety valve is postulated to open in a shorter time.

Analyses are presented in this section for the inadvertent opening of a pressuriser safety valve and the inadvertent opening of a path of Stage 2 or 3 of the ADS. These analyses are performed to demonstrate that the DNBR does not decrease below the design limit values (see Section 22.7.1.1) while the reactor is at power. Performance following reactor trip for these faults is examined in Section 9.6.5.

The effects of a possible consequential loss of ac power during an RCS depressurisation event have been evaluated to not adversely impact the analysis results. This conclusion is based on a review of the time sequence associated with a consequential loss of ac power in comparison to the reactor shutdown time for an RCS depressurisation event. The primary effect of the loss of ac power is to cause the RCPs to coast down. The protection and safety monitoring system includes a five second minimum delay between the reactor trip and the turbine trip. In addition, a three second delay between the turbine trip and the loss of offsite ac power is assumed, consistent with the discussion in Section 9.0.12. Considering these delays between the time of the reactor trip and RCP coastdown due to the loss of ac power, it is clear that the plant shutdown sequence will have passed the critical point and the control rods will have been completely inserted before the RCPs begin to coast down. Therefore, the consequential loss of ac power does not adversely impact this analysis because the plant will be shut down well before the RCPs begin to coast down.

9.6.1.2 Design Basis Mitigation

Analysis is performed to demonstrate the adequacy of the PMS to detect and mitigate the fault and show that the safety analysis criteria are satisfied including:

- No fuel failures (confirmed using minimum DNBR and fuel melt criteria),
- The RCS pressure criterion is met,
- The MSS pressure criterion is met, and
- The pressuriser does not fill (which could result in a LOCA).

RCS and MSS overpressure criteria are bounded by DB analysis of Section 9.2.3 analysis and, therefore, it is not explicitly calculated for this event. Pressuriser filling is not challenged in this event.

9.6.1.2.1 Method of Analysis

The accidental depressurisation transient is analysed by using the computer code LOFTRAN (References 9.6.1-1 and 9.6.1-2). The code simulates the neutron kinetics, reactor coolant system, pressuriser, pressuriser safety valves, main steam isolation valves, pressuriser spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level.

Plant characteristics and initial conditions are discussed in Section 9.0.2. The following assumptions are made to give conservative results in calculating the DNBR during the transient:

- Initial conditions are discussed in Section 9.0.2. Uncertainties in initial conditions are included in the DNBR limit as discussed in WCAP-11397-P-A (Reference 9.6.1-3).

- A least negative moderator temperature coefficient is assumed. The spatial effect of voids resulting from local or subcooled boiling is not considered in the analysis with respect to reactivity feedback or core power shape.

- A large (absolute value) Doppler coefficient of reactivity is used such that the resulting amount of positive feedback is conservatively high to retard any power decrease.

Plant systems and equipment necessary to mitigate the effects of reactor coolant system depressurisation are discussed in Section 9.0.4 and are listed in Table 9.0-10.

Normal reactor control systems are not required to function. The rod control system is assumed to be in the automatic mode to maintain the core at full power until the reactor trip protection function is reached. This is a worst case assumption. The reactor protection system functions to trip the reactor on the appropriate signal. No single active failure prevents the reactor protection system from functioning properly.

9.6.1.2.2 DBA Credited SSCs

For the short-term DB (until shortly after reactor trip,) all claimed SSCs are Class 1. The available Class 1 systems are listed in Table 9.0-10. The presented DBA ends shortly after reactor trip; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the CMTs and containment isolation. The PMS provides the following:

- RT on:
  - Low-2 pressuriser pressure
  - Overtemperature ΔT

- PRHR actuation on Low-2 SG NR level coincident with Low-2 SFW flow

- CMTs and containment isolation on Low-2 CL temperature

- PCS on High-2 containment pressure

For the long-term post-trip DBA of the spurious ADS activation scenarios, the Class 1 systems listed under the MBLOCA event are available, and the same performance requirements also apply.

9.6.1.2.3 Results

The system response to an inadvertent opening of a pressuriser safety valve is shown in Figures 9.6.1-1 through 9.6.1-4. The calculated sequence of events for the inadvertent opening of a pressuriser safety valve scenario is shown in Table 9.6.1-1.

A pressuriser safety valve is assumed to step open at the start of the event. The reactor coolant system then depressurises until the low pressuriser pressure reactor trip setpoint is reached. Figure 9.6.1-3 shows the pressuriser pressure transient.

Prior to tripping of the reactor, the core power remains relatively constant (Figure 9.6.1-1). The minimum DNBR during the event occurs shortly after the rods begin to be inserted into the core (Figure 9.6.1-2). The DNBR remains above the design limit values as discussed in Section 22.7.1.1 throughout the transient.

The system response for inadvertent operation of the ADS is shown in Figures 9.6.1-5 through 9.6.1-8. The sequence of events is provided in Table 9.6.1-1. The system response for inadvertent operation of the ADS is very similar to that obtained for inadvertent opening of a pressuriser safety valve.

9.6.1.3 Diverse Mitigation

Diverse mitigation for this event is not required as it is an infrequent fault classified as DB1.

9.6.1.4 Radiological Consequences

Design Basis

For the purposes of comparison of radiological dose with SAPs Target 4, the spurious activation of the ADS and opening of the pressuriser relief valve are included in the assessment for the MBLOCA scenario. This is a conservative assumption, as the analysis described above shows that there is no core heatup during these events.

The analysis results presented in Section 9.6.1.2.4 show that there is no fuel damage for this event. The radiological consequences of the MBLOCA presented in Section 9.6.5.3.6.3 assumed 10 percent of the fuel rods are damaged. Therefore, the MBLOCA doses bound those of this event. The MBLOCA doses from Section 9.6.5.3.6.3.5 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 2.6 mSv worker dose: 6.0 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

9.6.1.5 As Low As Reasonably Practicable Assessment

The spurious activation of the ADS and opening of the pressuriser relief valve are included in the ALARP assessment for the MBLOCA scenario (Section 9.6.5.3.6.5).

9.6.1.6 Conclusion

The DB results of the analysis show that the low pressuriser pressure reactor protection system signal provides adequate protection against the reactor coolant system depressurisation events. The calculated DNBR remains above the design limit defined in Section 22.7.1.1. The long-term plant responses due to a stuck-open ADS valve or pressuriser safety valve, which cannot be isolated, are bounded by the small-break LOCA analysis.

DBA radiological consequences are within the Target 4 BSL for infrequent faults (i.e., 10 mSv offsite and 200 mSv onsite).

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

Table 9.6.1-1. DBA Time Sequence Of Events For Incidents That Cause A Decrease In Reactor Coolant Inventory

Accident	Event	Time (seconds)
Inadvertent opening of a pressuriser safety valve	Pressuriser safety valve opens fully	0.00
	Low pressuriser pressure reactor trip setpoint reached	20.30
	Rods begin to drop	22.30
	Minimum DNBR occurs	23.00
Inadvertent opening of an ADS Stage 2 or 3 train	ADS valves begin to open	0.0
	Low pressuriser pressure reactor trip setpoint reached	26.30
	Rods begin to drop	28.30
	Minimum DNBR occurs	29.10
	ADS valves fully open	60.00

9.6.2 Failure of Small Lines Carrying Primary Coolant outside the Containment

9.6.2.0 Introduction and Overview of Faults

A number of small lines are associated with the primary reactor circuit, two of which carry primary coolant outside containment. These are the RCS sample line and the discharge line from the CVS to the liquid radwaste system (WLS). No instrument lines carry primary coolant outside the containment.

Although technically a break in a small line is classed as a LOCA-type event, the maximum volumetric rate of loss of coolant is well within the capacity of normal operational coolant makeup by the CVS. In the absence of another concurrent compounding fault, the loss of coolant aspects of the event would be managed without any call on the emergency coolant makeup systems. For the CVS and sample lines; however, breaks can occur outside the containment, with the potential for local discharge of primary coolant and a release of radioactivity into the environment.

The fault is first described; the initial event frequency and the design basis class is provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP assessment
- Conclusions

Description

Two faults are considered (see Appendix 8A):

- Rupture in the discharge line from the CVS to the WLS (Fault 3.4.1)
- Rupture in the RCS sample line outside containment (Fault 1.9.2)

Initiating Event Frequency[1]

Faults involving a break in a small line, or instrumentation line, are considered to be a fault of moderate frequency (i.e., in the range of 0.1 to 0.01/yr). Instrument line breaks are included with RCS leakage faults in the PSA with an IEF for the all of these faults of 1.4E-03/yr (Fault 1.9.1, Table 8A-2). The bottom end of the range (i.e., 1E-02/yr) was selected as the frequency of the fault. Therefore, the sample line break event is considered to be a frequent fault (i.e., >1E-3/yr) for the purposes of DB classification.

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

Design Basis Class

On the basis of the assessed frequency (>1E-3/y) and an unmitigated offsite radiological consequence for a member of the public of <1 mSv and unmitigated onsite radiological consequence for a worker of < 20 mSv, the bounding sample line break fault is classified as an HFLC fault, as discussed in Chapter 8.

9.6.2.0.1 Rupture in the Chemical and Volume Control System Discharge Line

When excess primary coolant is generated because of boron dilution operations, the CVS purification flow is diverted out of containment to the WLS. Before passing outside containment, the flow stream passes through the CVS heat exchangers (HXs) and mixed-bed demineraliser. The flow leaving the containment is at a temperature of less than 60.0°C (140°F) and has been cleaned by the demineraliser. The flow out of a postulated break in this line is limited to the CVS purification flow rate of 22.71 m^3/hr (100 gpm), which supports small (<3/8-inch (0.95 cm) diameter break) LOCA.

9.6.2.0.2 Rupture in the Reactor Coolant System Sample Line

The liquid sample lines that penetrate the containment convey liquid samples from their RCS sources to either the grab sample panel (GSP) or the laboratory. The GSP is situated in the sampling room in the auxiliary building, and the radiological chemistry facility is located immediately above this room. The liquid lines contain one containment isolation valve inside the containment and one containment isolation valve outside the containment. One liquid sample line set of valves are normally open only when RCS hot leg sampling is being performed. The failure of the sample line is postulated to occur between the isolation valve outside the containment and the grab sample panel. The maximum loss of coolant from the primary circuit for the RCS sample line break is calculated to be 22.71 m^3/hr (100 gpm) The nozzles where the sample lines connect to the reactor coolant piping include an orifice with a 3/8-inch (0.95 cm) hole. This hole restricts the flow so that the loss through a break in one of the sample lines can be made up by normal charging flow provided by CVS.

9.6.2.1 Failure of Small Lines Carrying Primary Coolant Outside Containment (Fault 1.9.2)

When excess primary coolant is generated because of boron dilution operations, the chemical and volume control system purification flow is diverted out of containment to the liquid radwaste system. Before passing outside containment, the flow stream passes through the chemical and volume control system heat exchangers and mixed bed demineralizer. The flow leaving the containment is at a temperature of less than 60°C (140°F) and has been cleaned by the demineralizer. The flow out a postulated break in this line is limited to the chemical and volume control system purification flow rate of 22.71 m^3/hr (100 gpm). Considering the low temperature of the flow and the reduced iodine activity because of demineralization, this event is not analysed. The postulated sample line break is more limiting.
