A continuous sample of the RCS hot legs flows through normally open isolation valves inside and outside containment when sampling. The failure of the sample line is postulated to occur between the isolation valve outside the containment and the sample panel. Because the isolation valves are open only when sampling, the loss of sample flow provides indication of the break to plant personnel. In addition, a break in a sample line results in activity release and a resulting actuation of area and air radiation monitors. The loss of coolant reduces the pressuriser level and creates a demand for makeup to the reactor coolant system. Upon indication of a sample line break, the operator would take action to isolate the break.

The sample line includes a flow restrictor at the point of sample to limit the break flow to less than 22.71 m^3/hr (100 gpm). The nozzles where the sample lines connect to the reactor coolant piping include an orifice with a 3/8-inch (0.95 cm) hole. This hole restricts the flow so that the loss through a break in one of the sample lines can be made up by normal charging flow provided by CVS.

The liquid sampling lines passing through the containment are 0.635 cm (1/4 inch) tubing which further restricts the break flow of a sampling line outside containment to much less than the flow that could pass through the 3/8-inch (0.95 cm) restrictor inside containment. Doses are based on a conservative break flow of 29.53 m^3/hr (130 gpm) with isolation after 30 minutes.

Given the fact that the leak being considered is large enough to solicit immediate operator attention and the plant abnormal operating procedures will provide direct guidance to isolate RCS sampling as part of RCS leak rate determination, the 30 minute period assumed for manual operator action to isolate a sample line leak is a valid assumption.

In common with other radiologically controlled areas in the auxiliary and annex buildings, the sampling area is serviced by the radiologically controlled area ventilation system (VAS). The VAS consists of two separate subsystems, the fuel handling area ventilation subsystem, and the auxiliary or annex building ventilation subsystem. These are combined into a single extract. Both of these subsystems are once-through-type ventilation systems.

The sample line break fault was assigned an HFLC DB classification (see Section 9.6.2.0 above), and while there is no formal requirement regarding safety measures for this class, it is considered best practice to identify one Class 2 system for each Category B safety function (see Chapter 8). With the present arrangements, the Category B functional requirement is for environmental release control that is met by manual operator action following local radiation or contamination alarm as a Class 2 system. The ALARP aspects of introducing possible additional safety measures are discussed below in Section 9.6.2.1.4.

9.6.2.1.2 Radiological Consequences

There is no fuel damage as a result of the accident. Therefore, the most significant radionuclide releases are the noble gases, alkali metals, and iodines that are present in the primary coolant, become airborne, and are released to the environment as a result of the accident.

9.6.2.1.2.1 Release Pathway

The consequence assessment conservatively considers the release of 29.53 m^3/hr (130 gpm) of primary coolant into the sample room in the auxiliary building for 30 minutes. The reactor coolant that is spilled from the break is assumed to be at high temperature and pressure. A portion of the radionuclides released are assumed to become airborne. The radionuclides are assumed to be released directly to the environment, although a large fraction of the airborne iodine and alkali metals are expected to deposit on building surfaces.

9.6.2.1.2.2 Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.6.2.1.2.3 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.6.2-1.

9.6.2.1.2.4 Doses

The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.52 mSv Worker dose: 1.6 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.6.2-2. The Table 9.6.2-2 values ensure the Target 4 BSL is met.

9.6.2.1.3 Diverse Mitigation

The primary protection for this fault category is the RMS radiation alarm, which is a Class 1 SSC (see Table 9.6.2-3). Table 9.6.2-4 provides the operator actions utilized in the design basis analysis. Diverse protection via Class 1 or Class 2 SSCs is not available for this event; however, the consequences of the unmitigated event are low and the operator has the capability of detecting the event via main control room indications. Reactor protection, both primary and diverse, is bounded by the SBLOCA fault (1.8.1 – 1.8.3).

9.6.2.1.4 As Low As Reasonably Practicable Assessment

Although the DB requirements for the sample line break fault have been met, consideration has been given to including high-efficiency particulate air (HEPA) filtration into the ventilation train as an additional safety measure. The VFS HEPA filtration could provide a dose reduction if the VAS flow was isolated and diverted to this system on a high-radiation signal. Nevertheless, the cost of implementing such a measure is considered to be grossly disproportionate to benefit, since it would take a spillage of over 28000 kg (28 m^3) of primary coolant to cause an offsite consequence >1 mSv, and so faults involving spillage of a few tens of litres of primary coolant would not represent a significant radiological hazard.

In addition to the visual flow behaviour and local radiological alarms, the CVS makeup system would also provide a general indication of RCS leakage. The CVS makeup balance inventory is performed on a regular basis and can identify a minimum detectable leak of 2.95E-2 m^3/hr (0.13 gpm). This detection limit is much lower than the flow rate considered for the bounding fault.

9.6.2.1.5 Conclusions

Radiological consequences are within the Target 4 BSL for frequent faults (i.e., 1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSC is adequate to meet DB requirements.

It has been shown that the AP1000 plant design includes adequate systems for the protection of this fault, which limit the radiological consequences such that they are compliant with the SAP targets and the risks have been reduced to be ALARP.

9.6.3 Steam Generator Tube Rupture (Fault 1.11.1)

9.6.3.0 Introduction and Overview of Fault

A steam generator tube rupture (SGTR) is defined as the sudden failure of one or more SG tubes, giving rise to a leakage with a rate that is beyond the makeup capability of the CVS. Depending upon the size of the leakage and the plant operating conditions at the initiation of the fault, SGTR can lead to significant contamination of the secondary system because of ingress of coolant from the RCS. The range of breach sizes covered by SGTR falls within the SBLOCA category.

This section analyses SGTRs at power conditions, Fault 1.11.1 (see Appendix 8A).

The AP1000 design provides automatic protective actions to mitigate the consequences of an SGTR. The automatic actions include reactor trip, actuation of the PRHR HX, initiation of CMT flow, termination of pressuriser heater operation, and isolation of CVS flow and SFW flow on High-3 SG level coincident with reactor trip (P-4). These protective actions result in automatic cooldown and depressurisation of the RCS, termination of the break flow and release of steam to the atmosphere, and long-term maintenance of stable conditions in the RCS. These protection systems serve to prevent SG overfill and to maintain radiological consequences within the allowable guideline values for a DB SGTR. The operator may take actions that would provide a more rapid mitigation of the consequences of an SGTR.

Because of the series of alarms, the operator can readily determine when an SGTR occurs, identify and isolate the ruptured SG, and complete the required recovery actions to stabilise the plant and terminate the primary-to-secondary break flow. The recovery procedures are completed on a time scale that terminates break flow to the secondary system before SG overfill occurs and limits the doses to acceptable levels without actuation of the ADS. Indications and controls are provided to enable the operator to carry out these functions, but if operator intervention were to fail, automatic protective action would be initiated.

For the purposes of the DB analysis, no credit is taken for operator actions and it is assumed that offsite power is not available (e.g., because of a turbine trip). Under these pessimistic circumstances, an SGTR fault is likely to result in some release of contaminated steam from the secondary circuit through the steam release valves to the atmosphere. This release will be terminated as a result of automatic recovery actions. Therefore, the release is limited in duration, but has the potential to give a radiological dose to members of the public near the site boundary and to onsite workers, including control room staff.

The significant radionuclide releases from the SGTR are noble gases, alkali metals (caesium and rubidium), and iodines that become airborne and are released to the environment as a result of the accident. These originate from the reactor fuel, a small fraction of which is tolerated by the Tech Specs to have defective cladding. A small amount of activity leaks out through these defects into the primary coolant (RCS).

During normal, steady operation, the concentration of activity in the RCS reaches an equilibrium value when the release rate from the fuel equals the rate of removal by decay and cleanup. During a transient such as an SGTR, the release rate of iodine and other radionuclides increases. This phenomenon is known as spiking and can result in much higher concentrations of activity in the RCS than the equilibrium value for a short time (some hours). The spiking phenomenon is taken into account in the assessment of radiological release from the fault.

In the sections below, the fault is first described in more detail; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP assessment
- Conclusions

9.6.3.0.1 Steam Generator Tube Rupture Fault Description

Description

This fault has the potential to release radioactivity to the environment through the secondary circuit steam release valves. Therefore, it represents a loss of containment by the primary circuit through leakage to the secondary circuit.

The more severe fault is considered to be a single tube rupture, since the plant response to a multiple SGTR is substantially the same as, or more favourable than, the response to a single SGTR. A larger break introduces mass into the ruptured SG at a faster rate. However, the larger flow rate also results in earlier actuation of the passive safety systems CMT and PRHR, which terminates the event earlier. Using transient analysis, runs were performed to investigate the impact of multiple SGTRs on the AP1000 reactor (Reference 9.6.3-1). The impact of these competing effects was investigated for 0.5 tube, one tube, two tubes, and five tubes and it was found that the limiting case is one ruptured tube.

The fault is further subdivided into two cases. In one case, referred to as the accident-initiated iodine spike case, an iodine spike is assumed to be initiated by the accident, with the spike causing an increasing level of iodine in the reactor coolant. In the second case, referred to as the pre-accident spike case, the iodine spike is assumed to have occurred before the tube ruptures, with the reactor coolant iodine concentration reaching a maximum at the time the accident occurs. The probability of this second case occurring is small.

Initiating Event Frequency[1]

The fault schedule (Appendix 8A) gives the IEF for SGTR as 3.3E-03/yr (Table 8A-2), which makes the fault a frequent fault in the UK definition. The fault is assessed as a frequent fault (DB2).

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorization of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

9.6.3.1 Identification of Cause and Accident Description

9.6.3.1.1 Introduction

The accident examined is the complete severance of a single steam generator tube. The accident is assumed to take place at power with the reactor coolant contaminated with fission products corresponding to continuous operation with a limited number of defective fuel rods within the allowance of the Technical Specifications. The accident leads to an increase in contamination of the secondary system due to leakage of radioactive coolant from the reactor coolant system. In the event of a coincident loss of offsite power, or a failure of the condenser steam dump, discharge of radioactivity to the atmosphere takes place via the steam generator power-operated relief valves or the safety valves.

The assumption of a complete tube severance is conservative because the steam generator tube material is a corrosion-resistant and ductile material. The more probable mode of tube failure is one or more smaller leaks of undetermined origin. Activity in the secondary side is subject to continual surveillance, and an accumulation of such leaks, which exceeds the limits established in the Technical Specifications, is not permitted during operation.

The AP1000 design provides automatic protective actions to mitigate the consequences of an SGTR. The automatic actions include reactor trip, actuation of the PRHR heat exchanger, initiation of core makeup tank flow, termination of pressuriser heater operation, and isolation of chemical and volume control system flow and startup feedwater flow on High-3 steam generator level coincident with reactor trip (P-4). These protective actions result in automatic cooldown and depressurisation of the reactor coolant system, termination of the break flow and release of steam to the atmosphere, and long-term maintenance of stable conditions in the reactor coolant system. These protection systems serve to prevent steam generator overfill (see discussion in Sections 9.6.3.1.2 and 9.6.3.1.3) and to maintain offsite radiological consequences within the allowable guideline values for a design basis SGTR.

Although not required, the operator may take actions that would provide a more rapid mitigation of the consequences of an SGTR. Because of the series of alarms described next, the operator can readily determine when an SGTR occurs, identify and isolate the ruptured steam generator, and complete the required recovery actions to stabilize the plant and terminate the primary-to-secondary break flow. The recovery procedures are completed on a time scale that terminates break flow to the secondary system before steam generator overfill occurs and limits the offsite doses to acceptable levels without actuation of the ADS. Indications and controls are provided to enable the operator to carry out these functions.

9.6.3.1.2 Sequence of Events for a Steam Generator Tube Rupture, Primary

The following sequence of events occurs following an SGTR:

- Pressuriser low pressure and low level alarms are actuated and chemical and volume control system makeup flow and pressuriser heater heat addition starts or increases in an attempt to maintain pressuriser level and pressure. On the secondary side, main feedwater flow to the affected steam generator is reduced because the primary-to-secondary break flow increases steam generator level.

- The condenser air removal discharge radiation monitor, steam generator blowdown radiation monitor, and/or main steam line radiation monitor alarm indicate an increase in radioactivity in the secondary system.

- Continued loss of reactor coolant inventory leads to a reactor trip generated by a Low-2 pressuriser pressure or over-temperature ΔT signal. Following reactor trip, the SGTR leads to a decrease in reactor coolant pressure and pressuriser level, counteracted by chemical and volume control system flow and pressuriser heater operation. A safeguards ("S") signal from low pressuriser pressure actuates the core makeup tanks. The "S" signal automatically terminates the normal feedwater supply and trips the reactor coolant pumps. The core makeup tank actuation signal will actuate the PRHR heat exchanger and trip pressuriser heaters. Startup feedwater flow is initiated on a Low-2 steam generator narrow range level signal and controls the steam generator levels to the programmed level.

- The reactor trip automatically trips the turbine, and if offsite power is available, the steam dump valves open permitting steam dump to the condenser. In the event of a loss of offsite power or loss of the condenser, the steam dump valves automatically close to protect the condenser. The steam generator pressure rapidly increases resulting in steam discharge to the atmosphere through the steam generator power-operated relief valves and/or the safety valves.

- Following reactor trip and core makeup tank and PRHR actuation, the PRHR heat exchanger operation – combined with startup feedwater flow, borated core makeup tank flow, and chemical and volume control system flow – provides a heat sink that absorbs the decay heat. This reduces the amount of steam generated in the steam generators and steam bypass to the condenser. In the case of loss of offsite power, this reduces steam relief to the atmosphere.

- Injection of the chemical and volume control system and core makeup tank flow stabilizes reactor coolant system pressure and pressuriser water level, and the reactor coolant system pressure trends toward an equilibrium value, where the total injected flow rate equals the break flow rate.

9.6.3.1.3 Steam Generator Tube Rupture Automatic Recovery Actions

The AP1000 incorporates several protection system and passive design features that automatically terminate a steam generator tube leak and stabilize the reactor coolant system. Following an SGTR, the injecting chemical and volume control system flow (and pressuriser heater heat addition if the pressure control system is operating) maintains the primary-to-secondary break flow and the ruptured steam generator secondary level increases as break flow accumulates in the steam generator. Eventually, the ruptured steam generator secondary level reaches the high and High-3 steam generator narrow range level setpoint, which is near the top of the narrow range level span.

The AP1000 protection system automatically provides several Class 1 actions to cool down and depressurise the reactor coolant system, terminate the break flow and steam release to the atmosphere, and stabilize the reactor coolant system in a safe condition. The Class 1 actions include initiation of the PRHR system heat exchanger, isolation of the chemical and volume control system pumps and pressuriser heaters, and isolation of the startup feedwater pumps. In addition, the protection and safety monitoring system provides a Class 1 signal to trip the redundant, Class 2 related pressuriser heater breakers.

Actuating the PRHR heat exchanger transfers core decay heat to the IRWST and initiates a cooldown (and a consequential depressurisation) of the reactor coolant system.

Isolation of the chemical and volume control system pumps and pressuriser heaters

minimizes the repressurisation of the primary system. This allows primary pressure to equilibrate with the secondary pressure, which effectively terminates the primary-to-secondary break flow. Because the core makeup tank continues to inject when needed to provide boration following isolation of the chemical and volume control system pumps, isolating the chemical and volume control system pumps does not present a safety concern.

Isolation of the startup feedwater provides protection against a failure of the startup feedwater control system, which could potentially result in the ruptured steam generator being overfilled.

With decay heat removal by the PRHR heat exchanger, steam generator steaming through the power-operated relief valves ceases and steam generator secondary level is maintained.

9.6.3.1.4 Steam Generator Tube Rupture Assuming Operator Recovery Actions

Operator actions are not required for the primary safety case of the SGTR event; however, likely operator actions are explained below.

In the event of an SGTR, the operators can diagnose the accident and perform recovery actions to stabilize the plant, terminate the primary-to-secondary leakage, and proceed with orderly shutdown of the reactor before actuation of the automatic protection systems. The operator actions for SGTR recovery are provided in the plant emergency operating procedures. The major operator actions include the following:

- Identify the ruptured steam generator – The ruptured steam generator can be identified by an unexpected increase in steam generator narrow range level or a high radiation indication from any main steam line monitor, steam generator blowdown line monitor, or steam generator sample.

- Isolate the ruptured steam generator – Once the steam generator with the ruptured tube is identified, recovery actions begin by isolating steam flow from and stopping feedwater flow to the ruptured steam generator.

- Cooldown of the reactor coolant system using the intact steam generator or the PRHR system – After isolation of the ruptured steam generator, the reactor coolant system is cooled as rapidly as possible to less than the saturation temperature corresponding to the ruptured steam generator pressure. This provides adequate subcooling in the reactor coolant system after depressurisation of the reactor coolant system to the ruptured steam generator pressure in subsequent actions.

- Depressurise the reactor coolant system to restore reactor coolant inventory – When the cooldown is completed, the chemical and volume control system and core makeup tank injection flow increases the reactor coolant system pressure until break flow matches the total injection flow. Consequently, these flows must be terminated or controlled to stop primary-to-secondary leakage. However, adequate reactor coolant inventory must first be provided. This includes both sufficient reactor coolant subcooling and pressuriser inventory to maintain a reliable pressuriser level indication after the injection flow is stopped.

Because leakage from the primary side continues after the injection flow is stopped, until reactor coolant system and ruptured steam generator pressures equalise, the reactor coolant system is depressurised to provide sufficient inventory to verify that the pressuriser level remains on span after the pressures equalise.

- Termination of the injection flow to stop primary to secondary leakage – The previous actions establish adequate reactor coolant system subcooling, a secondary side heat sink, and sufficient reactor coolant inventory to verify that injection flow is no longer needed. When these actions are completed, core makeup tank and chemical and volume control system flow is stopped to terminate primary-to-secondary leakage. Primary-to-secondary leakage continues after the injection flow is stopped until the reactor coolant system and ruptured steam generator pressures equalise. Chemical and volume control system makeup flow, letdown, pressuriser heaters, and decay heat removal via the intact steam generator or the PRHR heat exchanger are then controlled to prevent repressurisation of the reactor coolant system and reinitiation of leakage into the ruptured steam generator.

Following the injection flow termination, the plant conditions stabilize and the primary-to-secondary break flow terminates. At this time, a series of operator actions is performed to prepare the plant for cooldown to cold shutdown conditions. The actions taken depend on the available plant systems and the plan for further plant repair and operation.

9.6.3.2 Design Basis Mitigation

An SGTR results in the leakage of contaminated reactor coolant into the secondary system and subsequent release of a portion of the activity to the atmosphere. An analysis is performed to demonstrate that the offsite radiological consequences resulting from an SGTR are within the allowable guidelines.

One of the concerns for an SGTR is the possibility of steam generator overfill because this can potentially result in a significant increase in the offsite radiological consequences. Automatic protection and passive design features are incorporated into the AP1000 design to automatically terminate the break flow to prevent overfill during an SGTR. These features include actuation of the PRHR system, isolation of chemical and volume control system flow, and isolation of startup feedwater.

An analysis is performed, without modelling expected operator actions to isolate the ruptured steam generator and cool down and depressurise the reactor coolant system, to demonstrate the role that the AP1000 design features have in preventing steam generator overfill. The limiting single failure for the overfill analysis is assumed to be the failure of the startup feedwater control valve to throttle flow when nominal steam generator level is reached. Other conservative assumptions that maximize steam generator secondary volume (such as high initial steam generator level, minimum initial reactor coolant system pressure, loss of offsite power, maximum chemical and volume control system injection flow, maximum pressuriser heater addition, maximum startup feedwater flow, and minimum startup feedwater delay time) are also assumed.

The results of this analysis demonstrate the effectiveness of the AP1000 protection system and passive system design features and support the conclusion that an SGTR event would not result in steam generator overfill.

For determining the offsite radiological consequences, an SGTR analysis is performed assuming the limiting single failure and limiting initial conditions relative to offsite doses. Because steam generator overfill is prevented for the AP1000, the results of this analysis

represent the limiting radiological consequences for an SGTR.

A thermal-hydraulic analysis is performed to determine the plant response for a design basis SGTR, the integrated primary-to-secondary break flow, and the mass releases from the ruptured and intact steam generators to the condenser and to the atmosphere. This information is then used to calculate the radioactivity release to the environment and the resulting radiological consequences.

9.6.3.2.1 DBA Method of Analysis

9.6.3.2.1.1 Computer Program

The plant response following an SGTR until the primary-to-secondary break flow is terminated is analysed with the LOFTTR2 program (Reference 9.6.3-2). The LOFTTR2 program is modified to model the PRHR system, core makeup tanks, and protection system actions appropriate for the AP1000. These modifications to LOFTTR2 are described in WCAP-14234, Revision 1 (Reference 9.6.3-3).

9.6.3.2.1.2 Analysis Assumptions

The accident modelled is a double-ended break of one steam generator tube located at the top of the tube sheet on the outlet (cold leg) side of the steam generator. The location of the break on the cold leg side of the steam generator results in higher initial primary-to-secondary leakage than a break on the hot side of the steam generator.

The reactor is assumed to be operating at full power at the time of the accident, and the initial secondary mass is assumed to correspond to operation at nominal steam generator mass minus an allowance for uncertainties. Offsite power is assumed to be lost and the rods are assumed to be inserted at the start of the event because continued operation of the reactor coolant pumps has been determined to reduce flashing of primary-to-secondary break flow and, consequently, lower offsite radiological doses. Maximum chemical and volume control system flows and pressuriser heater heat addition are assumed immediately (even though offsite power is not available) to conservatively maximize primary-to-secondary leakage. The steam dump system is assumed to be inoperable, consistent with the loss of offsite power assumption, because this results in steam release from the steam generator power-operated relief valves to the atmosphere following reactor trip. The chemical and volume control system and pressuriser heater modelling is conservatively chosen to delay the Low-3 pressuriser pressure “S” and the low-2 pressuriser level signal and associated protection system actions.

The limiting single failure is assumed to be the failure of the ruptured steam generator power-operated relief valve. Failure of this valve in the open position causes an uncontrolled depressurisation of the ruptured steam generator, which increases primary-to-secondary leakage and the mass release to the atmosphere.

It is assumed that the ruptured steam generator power-operated relief valve fails open when the low-2 pressuriser level signal is generated. This results in the maximum integrated flashed primary-to-secondary break flow.

The valve is subsequently isolated when the associated block valve is automatically closed on a low steam line pressure protection system signal.

No operator actions are modelled in this limiting analysis, and the plant protection system provides the protection for the plant. Not modelling operator actions is conservative because

the operators are expected to have sufficient time to recover from the accident and supplement the automatic protection system. In particular, the operator would take action to reduce the primary pressure before the High-3 steam generator level coincident with reactor trip (P-4) chemical and volume control and startup feedwater system shutoff signals are generated. It is also expected that the operator can close the block valve to the ruptured steam generator power-operated relief valve in much shorter time than the automatic protection signal. The operators can quickly diagnose a power-operated relief valve failure based on the rapid depressurisation of the steam generator and increase in steam flow. They can then close the block valve from the control panel.

Consistent with the assumed loss of offsite power, the main feedwater pumps coast down and no startup feedwater is assumed to conservatively minimize steam generator secondary inventory and thus maximize secondary activity concentration and steam release.

9.6.3.2.2 DBA Credited SSCs

For the DB, all of the claimed SSCs are Class 1, and are listed in Table 9.0-10. The presented DBA ends when break flow is terminated; however, essential safety functions for the long term safe shutdown analysis (Appendix 9C) bound safe shutdown response for this event. The primary core cooling is provided by the PRHR and passive containment cooling. Other SSCs include the steam generator safety and/or relief valves. The PMS provides the following:

- RT on Low-2 pressuriser level (analysed at event initiation)
- CMTs on Low-2 pressuriser level
- PRHR on Low-2 pressuriser level (via CMT actuation signal)
- Containment isolation on Low-2 steamline pressure
- PCS on High-2 containment pressure

9.6.3.2.3 DBA Results

The sequence of events for this transient is presented in Table 9.6.3-1. The system responses to the SGTR accident are shown in Figures 9.6.3-1 to 9.6.3-9.

Offsite power is lost concurrent with the rupture of the tube. The reactor trips due to the loss of offsite power. The main feedwater pumps are assumed to coast down following reactor trip. The startup feedwater pumps are conservatively assumed not to start. Following the tube rupture, reactor coolant flows from the primary into the secondary side of the ruptured steam generator. In response to this loss of reactor coolant, pressuriser level and reactor coolant system pressure decreases as shown in Figures 9.6.3-1 and 9.6.3-2. As a result of the decreasing pressuriser level and pressure, two chemical and volume control system pumps are automatically initiated to provide makeup flow and the pressuriser heaters turn on.

After reactor trip, core power rapidly decreases to decay heat levels and the core inlet to outlet temperature differential decreases. The turbine stop valves close, and steam flow to the turbine is terminated. The steam dump system is conservatively assumed to be inoperable. The secondary side pressure increases rapidly after reactor trip until the steam generator power-operated relief valves (and safety valves, if their setpoints are reached) lift to dissipate the energy, as shown in Figure 9.6.3-3.

Maximum heat addition to the pressuriser from the pressuriser heaters increases the primary pressure.

As the leak flow continues to deplete primary inventory, low pressuriser level "S" and core makeup tank and PRHR actuation signals are reached. Power to the pressuriser heaters is shut off so that they will not provide additional heat to the primary should the pressuriser level return. The ruptured steam generator power-operated relief valve is assumed to fail open at this time.

The failure causes the intact and ruptured steam generators to rapidly depressurise (Figure 9.6.3-3). This results in an initial increase in primary-to-secondary leakage and a decrease in the reactor coolant system temperatures. Both the intact and ruptured steam generators depressurise because the steam generators communicate through the open steam line isolation valves.

The decrease in the reactor coolant system temperature results in a decrease in the pressuriser level and reactor coolant system pressure (Figures 9.6.3-1 and 9.6.3-2). Depressurisation of the primary and secondary systems continues until the Low-2 steam line pressure setpoint is reached. As a result, the steam line isolation valves and intact and ruptured steam generator power-operated relief block valves are closed.

Following closure of the block valves, the primary and secondary pressures and the ruptured steam generator secondary water volume and mass increase as break flow accumulates. This increase continues until the steam generator secondary level reaches the High-3 narrow range level when the chemical and volume control and startup feedwater systems are isolated.

With continued reactor coolant system cooldown, depressurisation provided by the PRHR heat exchanger, and with the chemical and volume control system isolated, primary system pressure eventually falls to match the secondary pressure. The break flow terminates as shown in Figure 9.6.3-5, and the system is stabilized in a safe condition. As shown in Figure 9.6.3-8, steam release through the intact loop, unfaulted power-operated relief valve does not occur following PRHR initiation because the PRHR is capable of removing the core decay heat.

As shown in Figure 9.6.3-9, the core makeup tank flow trends toward zero because the gravity head diminishes as the core makeup tank temperature approaches the reactor coolant system temperature due to the continued balance line flow. The core makeup tank remains full, and ADS actuation does not occur.

The ruptured steam generator water volume is shown in Figure 9.6.3-6. The water volume in the ruptured steam generator when the break flow is terminated is significantly less than the total steam generator volume of greater than 255 m^3 (9000 ft^3).

Appendix 9C provides the means for safe shutdown.

9.6.3.2.3.1 Fuel Damage

The design basis SGTR event does not result in fuel failures. In the event of an SGTR, the reactor coolant system depressurises due to the primary-to-secondary leakage through the ruptured steam generator tube. This depressurisation reduces the calculated DNBR. The depressurisation prior to reactor trip for the SGTR has been compared to the depressurisation for the reactor coolant system pressurisation accidents analysed in Section 9.6.1. The rate of depressurisation is much slower for the SGTR than for the reactor coolant system

depressurisation accidents. Following reactor trip, the DNBR increases rapidly. Thus, the conclusion of Section 9.6.1, that the calculated DNBR remains above the limit, is extended to the SGTR analysis, justifying the assumption of no failed fuel.

9.6.3.2.3.2 Steam Generator Overfill

One of the concerns for an SGTR is the possibility of SG overfill because it can potentially result in a significant increase in the offsite radiological consequences. Automatic protection and passive design features are incorporated into the AP1000 design to automatically terminate the break flow to prevent overfill during an SGTR. These features include actuation of the PRHR system, isolation of CVS flow, and isolation of SFW.

An essential step in the SGTR DB justification is to demonstrate that margin to SG overfill is maintained for an appropriate, fully conservative, bounding case. A thermal-hydraulic analysis has been performed for such a case (referred to as the margin to overfill (MTO) case). As for the associated thermal-hydraulic modelling to support the radiological consequences assessment for SGTR, this has been done without modelling expected operator actions to isolate the ruptured SG, and to cool down and depressurise the RCS. For this case, SFW is modelled with a maximum flow rate and minimum start delay time. The limiting single failure for the overfill analysis is assumed to be the failure of the SFW control valve to throttle flow when nominal SG level is reached. The remaining assumptions identified previously for the analysis of the DB fault apply in this case.

The sequence of events is listed in Table 9.6.3-2. The calculated ruptured SG water volume is shown as a function of time in Figure 9.6.3-10. The peak water volume, prior to primary to secondary break flow termination at 19,767 sec, is determined to be 252 m^3 (8898 ft^3), corresponding to a margin to overfill of 3.7 m^3 (129 ft^3).

The results of this analysis therefore support the conclusion that an SGTR event would not result in SG overfill.

9.6.3.3 Diverse Mitigation

9.6.3.3.1 Diverse Mitigation for ATWT

As this is a DB2 frequent fault, a diverse means of providing the Category A safety functions is provided. For this event the diverse features are also Class 1 except for the C&I, which is Class 2. Table 9.6.3-5 summarizes the SSCs from this fault assessment, and this information is supported by Reference 9.6.3-4. Table 9.6.3-6 provides the operator actions utilized in the diverse safety case. DAS provides the following:

- Rods are assumed to not insert due to a mechanical CCF
- PRHR and CMTs on Low pressuriser level
- PCS and containment isolation on High containment temperature

An analysis evaluating diverse mitigation has not been explicitly performed; however, this will be addressed during site licensing. This is considered acceptable for GDA as the consequences of this fault are bounded by other those of a SBLOCA (See Section 9.6.5).

9.6.3.3.2 Diverse Mitigation for Core Cooling

The diverse core cooling is provided by passive feed and bleed using PXS injection and ADS

venting (all Class 1) via DAS (Class 2). The DAS provides the following:

- RT on Low SG WR level
- Manual ADS, IRWST injection, and containment recirculation
- PCS and containment isolation on High containment temperature

The loss of normal feedwater diverse core cooling, as analysed in Section 9.2.7.3.2, is bounding of this event.

9.6.3.4 Radiological Consequences

9.6.3.4.1 DBA Source Term

There is no fuel damage as a result of the accident. Therefore, the most significant radionuclide releases from the SGTR are the noble gases, alkali metals, and iodines that are present in the primary and secondary coolants, become airborne, and are released to the environment as a result of the accident.

The evaluation assumes that the reactor has been operating with a limited number of fuel rods containing cladding defects and that leaking steam generator tubes have resulted in a build-up of activity in the secondary coolant.

The methodology assesses two different reactor coolant iodine source terms, both of which consider the iodine-spiking phenomenon. In one case, the initial iodine concentrations are assumed to be those associated with the equilibrium operating limit for primary coolant iodine activity. The iodine spike is assumed to be initiated by the accident, with the spike causing an increasing level of iodine in the reactor coolant.

The second case assumes that the iodine spike occurs prior to the accident and that the maximum resulting reactor coolant iodine concentration exists at the time the accident occurs.

The secondary coolant iodine and alkali metal concentrations are assumed to be 10 percent of the primary concentrations. Noble gases are not assumed to accumulate in the secondary coolant

9.6.3.4.2 DBA Release Pathways

Activity release for an SGTR occurs through two pathways.

- Activity is transferred to the secondary system via primary-to-secondary leakage and break flow, and is then released to the environment through steaming from the intact and ruptured steam generators. Iodine, alkali metal, and noble gas activity is released via this transfer.
- Activity that is present in the secondary coolant prior to the accident is released to the environment via steaming from the intact and ruptured steam generators. Iodine and alkali metal activity is released via this transfer.

9.6.3.4.3 DBA Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.6.3.4.4 DBA Analytical Assumptions and Parameters

The sequence of events in listed in Table 9.6.3-1. The assumptions and parameters used in the analysis are listed in Table 9.6.3-3.

9.6.3.4.5 DBA Doses

In the case where offsite power remains available, there is no release of activity to the environment and the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite) are met.

In the case where offsite power is lost, the highest doses are found to be for the accident-initiated iodine spike. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

Offsite dose: 0.91 mSv Worker dose: 4.8 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.6.3-4. The Table 9.6.3-4 values ensure the Target 4 BSLs are met.

9.6.3.4.6 Diverse Mitigation

Both diverse ATWT and diverse core cooling scenarios discussed in Section 9.6.3.3 demonstrate that there is no significant fuel damage expected. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment and in the steam generators. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse ATWT scenario would be less than those reported for the non-LOCA DBAs and doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults.

9.6.3.5 As Low As Reasonably Practicable Assessment

For the SGTR event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements. Diverse mitigation functions are also available for mitigation of the event for this cliff edge frequent fault. See Reference 9.6.3-4 for additional discussions on these diverse mitigation features.

Additionally, the AP1000 plant design has a third level of redundancy provided by the DiD systems. The DiD functions applicable to the SGTR include:

- CVS boration for long-term reactivity control
- CVS make-up for RCS inventory control
- CVS auxiliary spray to reduce the RCS pressure, equalize it with the SG pressure and terminate the RCS inventory loss into the SG

- Isolation of the faulted SG by closing its MSIV
- SFW with steam dump for short–term decay heat removal
- RNS cooling of the RCS for long-term decay heat removal. The RNS requires support from the CCS and SWS cooling water systems.
- Control by the PLS C&I

Some of the above functions require operators to take actions and they have sufficient time to take these actions to mitigate this event independent of the protections discussed above.

Providing further means of removing decay heat or tripping the reactor in addition to these functions would not significantly reduce the PSA risk for this event.

9.6.3.6 SGTR Conclusions

The results of the SGTR analysis show that the overfill protection logic and the passive system design features provide protection to prevent steam generator overfill. The AP1000 protection system and passive design features initiate automatic actions that can terminate a steam generator tube leak and stabilize the reactor coolant system in a safe condition while preventing steam generator overfill and ADS actuation.

No operator actions are required to bring the AP1000 to a safe, stable state following an SGTR. However, the operators can identify and isolate the ruptured steam generator and complete the actions to terminate the primary-to-secondary break flow before steam generator overfill or ADS actuation occurs.

Radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 design includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.4 Large Break Loss of Coolant Accident (Fault 1.2.1)

A number of faults that could result in a loss of RCS inventory are postulated. This section discusses the largest postulated loss. Detailed analysis is presented for this most limiting of the RCS inventory loss events.

9.6.4.0 Introduction and Overview of Faults

A LOCA is the result of a pipe rupture of the RCS pressure boundary. The LBLOCA event is defined in the AP1000 design as all RCS ruptures with break sizes sufficient to produce a depressurisation of the RCS that allows gravity injection from the IRWST. The break size corresponding to this category is a 229 mm (9 inch) equivalent diameter or larger break, up to the size of a double-ended break of a cold or hot leg.

In the sections below, the fault is first described; the initial event frequency and the design basis class are provided. The analysed faults are presented in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment
- Conclusions

9.6.4.0.1 Large Break Loss of Coolant Accident Fault

Description

The fault includes the rupture of any RCS pressure boundary pipe sufficient to produce a depressurisation of the RCS that allows gravity injection from the IRWST, that is, with an equivalent diameter equal to or greater than 229 mm (9 inches). Because these faults involve a leak path to the containment and may lead to core uncovery and heatup, they are considered to have the potential to release radioactivity to the environment.

Initiating Event Frequency[1]

The AP1000 plant PSA gives the IEF for a LBLOCA event as 8.4E-07/yr. This places the fault just outside the DB in the UK definition but in practice the LBLOCA fault is evaluated within the DB as an infrequent fault. Spurious actuation of ADS stage 4 is classified as a LBLOCA but has a low IEF of <1.0E-08/yr.

1 As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

Design Basis Class

The unmitigated consequences of a LBLOCA are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Although the assessed IEF is just less than 1.0E-05/yr, the event is considered to be in the low probability design basis event DBL class, in line with its evaluation as an infrequent fault with significant potential consequences.

This classification is due to historical LOCA experience, the AP1000 design approach of reduced quantity of piping, fewer welds, use of bent pipe rather than fittings, better materials, etc., and the special leak before break piping analysis approach used for the AP1000 design. The core cooling response is conservatively analysed with DB assumptions (best estimate plus full uncertainty evaluation). The dose and reactor internal structures are analysed with assumptions that are conservative, but not necessarily bounding. The structural and dose acceptance criteria are also relaxed consistent with their low probability.

9.6.4.1 Large Break LOCA Analysis Methodology and Results

Westinghouse applies the WCOBRA/TRAC computer code to perform best-estimate large-break LOCA analyses in compliance with the following criteria:

- The calculated maximum fuel element cladding temperature will not exceed 1204.4°C (2200°F).
- Localised cladding oxidation will not exceed 17 percent of the total cladding thickness before oxidation.
- The amount of hydrogen generated from fuel element cladding reacting chemically with water or steam will not exceed 1 percent of the total amount if all metal cladding were to react.
- The core remains amenable to cooling for any calculated change in core geometry.
- The core temperature is maintained at a low value, and decay heat is removed for the extended period of time required by the long-lived radioactivity remaining in the core.

These criteria are established to provide significant margin in emergency core cooling system (ECCS) performance following a LOCA.

Demonstration that the loads resulting from an LBLOCA event do not threaten the integrity of the containment is presented in Appendix 9D.

WCOBRA/TRAC is a thermal- hydraulic computer code that calculates realistic fluid conditions in a PWR during the blowdown and reflood of a postulated large-break LOCA. The methodology used for the AP1000 analysis is documented in WCAP-12945-P-A, WCAP-14171, Revision 2, WCAP-16009-P-A (References 9.6.4-2, 9.6.4-3, and 9.6.4-6), and Reference 9.6.4-5.

The automated statistical treatment of uncertainty method (ASTRUM) best-estimate LOCA methodology (ASTRUM methodology) is utilised for estimating the 95th percentile peak clad temperature (PCT) for two-loop, three-loop and four-loop Westinghouse PWRs and the AP600 plant. An AP1000 design specific application of the ASTRUM methodology was developed (Reference 9.6.4-8) for estimating the 95th percentile PCT for the AP1000 plant. In the ASTRUM methodology, the WCOBRA/TRAC code is used to calculate the effects of initial conditions, power distributions, and global models, and the HOTSPOT code is used to calculate the effects of local models.

In the ASTRUM uncertainty methodology (Reference 9.6.4-6), as used in the AP1000 LBLOCA analysis, global models and initial-condition, power-distribution, and local uncertainties are sampled independently for each of 124 runs over the same ranges of uncertainty and distributions as in References 9.6.4-2, 9.6.4-6, and 9.6.4-7, as described in References 9.6.4-5 and 9.6.4-8. The sampled global models, initial conditions, and power-distribution uncertainties become inputs to each of the WCOBRA/ TRAC calculations. The thermal-hydraulic boundary conditions for the hot rod are input to the local uncertainties calculation performed by the HOTSPOT code.

Results from the calculations are ranked by PCT from highest to lowest. A similar procedure is repeated for maximum local oxidation (MLO) and core-wide oxidation (CWO). In order statistics as applied in the ASTRUM methodology, the limiting case for a parameter, such as PCT, is a conservative estimate of the 95th percentile with 95 percent confidence. The limiting PCT, limiting MLO, and CWO may come from the same case or as many as three different cases because each parameter is assumed to be independent of the other two. The assumption of independence of the calculated licensing parameters is a conservative assumption because there is a dependence of MLO and CWO on cladding temperature.

For the AP1000 large-break LOCA analysis, a plant-specific adaptation of the ASTRUM methodology is applied as described in Reference 9.6.4-5. The plant-specific adaptation explicitly models the effects of thermal conductivity degradation and peaking factor burndown. The post-LOCA long-term core cooling and core boron concentration analyses discussed in Section 9.6.6 are applicable to the large-break LOCA transient.

9.6.4.1.1 General Description of WCOBRA/TRAC Modelling

WCOBRA/TRAC is the best-estimate thermal-hydraulic computer code used to calculate realistic fluid conditions in the PWR during blowdown and reflood of a postulated large-break LOCA.

The WCOBRA/TRAC Code Qualification Document (Reference 9.6.4-2) contains a complete description of the code models and justifies their applicability to PWR large-break LOCA analysis.

Table 9.6.4-1 lists AP1000-specific parameters identified for use in the large-break LOCA analysis. WCOBRA/TRAC studies were performed to establish sensitivities to parameter variations. These studies included effects of ranging steam generator tube plugging, ranging the relative power in the low-power assemblies, loss of offsite power coincident with the break initiation, and break location. The calculated results were used to identify bounding conditions, which are then used in the uncertainty calculations.

The WCOBRA/TRAC vessel nodalization is developed from plant design drawings to divide the vessel into 10 vertical sections. The bottom of section 1 is the inside vessel bottom, and the top of section 10 is the inside top of the vessel upper head. In addition to the major downcomer and core flow paths, the modelled bypass flow paths are the upper head cooling spray, guide thimbles, and core bypass. After defining the elevations for each section, a noding scheme is defined for the WCOBRA/TRAC model as shown in Reference 9.6.4-8. WCOBRA/TRAC assumes a vertical flow path for vertically stacked channels, unless specified otherwise in the input. Positive flow for the vertically connected channels (and cells) is upward. Several of the 10 sections are divided vertically into 2 or more levels; these levels are referred to as cells within a channel.

The WCOBRA/TRAC loop model represents the major primary, secondary, and passive safety systems components. Both loops are explicitly modelled, including the hot leg, the steam generator, and the two cold legs and associated pumps. The loop designated “1” has the pressuriser and the PRHR system connections, and loop “2” cold legs have the core makeup tank

pressure balance line connections. The reactor coolant pump models contain the homologous curves together with appropriate two-phase head and torque multipliers and degradation data. AP1000 design values for pump coastdown characteristics are also applied. The passive safety features are modelled using design data for elevations, liquid volumes, and line losses. Because the ADS is not actuated until long after the time of PCT in large-break LOCA events, it is not modelled in detail.

9.6.4.1.2 Steady-State Calculation

A WCOBRA/TRAC LOCA calculation is initiated from a point at which the flows, temperatures, powers, and pressures are at their approximate steady-state values before the postulated break occurs. Steady-state WCOBRA/TRAC calculations are run for a brief time period to verify that the calculated conditions are steady and that the desired reactor conditions are achieved.

The values used to set the steady-state plant conditions reflect the AP1000 plant parameters for reactor coolant pump flows, core power, and steam generator tube plugging levels. The fuel parameters provide the steady-state fuel temperatures, pressures, and gap conductances as a function of fuel burnup and linear power, accounting for the effects of the thermal conductivity degradation as described in Reference 9.6.4-5. The calculated fuel temperatures from WCOBRA/TRAC are adjusted to match the specified fuel data by adjusting the gap heat transfer coefficient between the pellet and the cladding. Once the vessel fluid temperatures, flows, pressures, loop pressure drop, and core parameters are in agreement with the desired values and are steady, a suitable initial condition is achieved.

9.6.4.1.3 Signal Logic for Large Break LOCA

The reactor trip signal occurs due to compensated pressuriser pressure within the first seconds of the large-break transient; however, control rod insertion is not modelled in WCOBRA/TRAC and no effects of control rod insertion on reactivity ensue. A safeguards “S” signal occurs due to containment high pressure of 0.046 MPa (6.7 psig) at 2.2 seconds of large-break LOCA transients.

As a consequence of this signal, after appropriate delays, the PRHR and core makeup tank isolation valves open, containment isolation occurs, and the reactor coolant automatic trip timer begins. The rapid depressurisation of the primary system during a large-break LOCA leads to the initiation of accumulator injection early in the large-break transient. The accumulator flow diminishes core makeup tank delivery to such an extent that the core makeup tank level does not approach the ADS Stage 1 valve actuation point until after the accumulator tank is empty. The accumulator empties long after the blowdown portion of the large-break LOCA transient is complete. Actuation of the ADS on CMT water level does not occur until long after the PCT is calculated to occur.

9.6.4.1.4 Transient Calculation

Once the steady-state calculation is found to be acceptable, the transient calculation is initiated. The semi-implicit pipe break model is added to the desired break location. Cold-leg breaks are analysed because the hot-leg break location is nonlimiting in the large-break LOCA best-estimate methodology. The break size and type are sampled consistent with the WCAP-16009-P-A (Reference 9.6.4-6) methodology. The containment backpressure is specified consistent with WCAP-16009-P-A (Reference 9.6.4-6) methodology. The steady-state calculation is restarted with the above changes to begin the transient.

Table 9.6.4-2 shows a general sequence of events following a large cold-leg break LOCA and the relationship of these events to the blowdown and reflood portion of the transient.

9.6.4.1.5 DBA Credited SSCs

For the LBLOCA fault, all of the claimed SSCs are Class 1. The claimed Class 1 SSCs are listed in Table 9.0-10. The primary core cooling is provided by the CMTs, IRWST and passive containment cooling. Other SSCs include the accumulators, steam generator safety and/or relief valves. The PMS provides the following:

- RT on Low-2 pressuriser pressure
- CMTs and containment isolation on Low pressuriser pressure
- ADS and IRWST injection on Low CMT level
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

9.6.4.2 Analysis Results

For the AP1000 large-break LOCA analysis, a plant-specific adaptation of the ASTRUM best-estimate LOCA analysis methodology is applied as described in Reference 9.6.4-5. The AP1000 large-break LOCA analysis complies with the criteria listed in Section 9.6.4.1. Sensitivity calculations evaluated the sensitivity to the modelling of the CMT and PRHR relative to the reference transient configuration. A case in which the CMT was isolated from the rest of the plant was analysed, and the calculated PCT was lower than the PCT of the reference transient configuration. Also, a case in which the PRHR was isolated from the rest of the plant was analysed, and the calculated PCT was 1.1°C (2°F) higher than the PCT of the reference transient configuration. The ASTRUM methodology samples the parameters ranged in the global model matrix of calculations, and the final 95 percent uncertainty calculations have been performed for the AP1000 design. Further, local and core-wide cladding oxidation values have been determined using the plant-specific adaptation of the approved Reference 9.6.4-6 methodology as described in Reference 9.6.4-5.

In the AP1000 ASTRUM analysis, the limiting PCT and limiting MLO results were from two different uncertainty calculations. Both the limiting PCT case and the limiting MLO case were double-ended guillotine breaks. Figures 9.6.4-1 through 9.6.4-12 present the parameters of principal interest for the limiting PCT case. Values of the following parameters are presented:

- Highest calculated cladding temperature at any elevation for the five fuel rods modelled
- Hot rod cladding temperature transient at the limiting elevation for PCT
- Core fluid mass flows at the top of the core for the fuel assemblies modelled in WCOBRA/TRAC
- Pressuriser pressure
- Break flow rates
- Core and downcomer collapsed liquid levels
- Accumulator water flow rates
- Core makeup tank flow rates

9.6.4.2,1 Description of AP1000 Large Break LOCA Transient

A description of the limiting PCT case from the AP1000 ASTRUM analysis follows. The limiting PCT case is a double-ended guillotine break. The sequence of events is presented in Table 9.6.4-3.

The break was modelled to occur in one of the cold legs in the loop containing the core makeup tanks. After the break opens, the vessel rapidly depressurises and the core flow quickly reverses. The hot assembly fuel rods dry out and begin to heat up (Figures 9.6.4-1 and 9.6.4-2) after the initial flow reversal (Figure 9.6.4-3).

In Figure 9.6.4-1, "Hot Rod" refers to the hot fuel rod at the maximum linear heat rate for the run, "Hot Assembly" refers to the average fuel rod in the hot assembly that contains the hot rod, "Support Column/Open Hole" refers to the fuel rod in average assemblies under support columns or open holes, "Guide Tubes" refers to the fuel rod in average assemblies under guide tubes, and "Low Power" refers to the fuel rod in the low power peripheral fuel assemblies.

The steam generator secondaries are assumed to be isolated immediately at the inception of the break, which maximizes their stored energy. The massive size of the break causes an immediate, rapid pressurisation of the containment. At 2.2 seconds, an "S" signal is generated due to High-2 containment pressure. Applying the pertinent signal processing delay means that the valves isolating the core makeup tanks from the direct vessel injection line and the PRHR begin to open at 4.2 seconds into the transient. The reactor coolant pumps automatically trip after a 5.3-second delay from the actuation of the core makeup tank isolation valves, which is 9.5 seconds into the transient. Core shutdown occurs due to voiding; no credit is taken for the control rod insertion effect.

The system depressurises rapidly (Figure 9.6.4-4) as the initial mass inventory is depleted due to break flow. The pressuriser drains completely approximately 30 seconds into the transient, and accumulator injection commences 13 seconds into the transient (Figure 9.6.4-5). Accumulator actuation shuts off core makeup tank flow (Figure 9.6.4-6), which has been occurring since the isolation valve opened. The CMT liquid level remains well above the ADS Stage 1 actuation setpoint throughout the LBLOCA cladding temperature excursion, even though CMT injection begins again around 200 seconds.

The dynamics of the 95th percentile estimator PCT case are shown in terms of the flow rates of liquid, vapour, and entrained liquid at the top of the core (Figures 9.6.4-7 through 9.6.4-9) for the peripheral, open hole/support column average power interior, and guide tube average power interior assemblies (the corresponding figure for the hot assembly is Figure 9.6.4-3).

Figure 9.6.4-7 demonstrates that liquid downflow exists through the top of the peripheral core assemblies from approximately 1 to 3 seconds and again from 9 to 20 seconds in the 95th percentile estimator PCT case. The power of the fuel in this region is significantly lower than that of the fuel in the open hole/support column and guide tube locations (Table 9.6.4-1), so liquid downflow occurs earlier on the periphery than in the average power assemblies. Once the upper head begins to flash, liquid drains directly down the guide tubes and that fraction able to penetrate into the core does so, at a maximum flow rate exceeding 453.6 kg/sec (1000 lbm/sec) of total liquid flow between 5 to 23 seconds (Figure 9.6.4-8).

Figure 9.6.4-9 presents the open hole/support column assembly top of core flow behaviour. In this case, liquid downflow into the support column/open hole assemblies is delayed relative to downflow into the guide tubes; there is a continuous liquid flow from approximately 10 seconds until 22 seconds; the entrained liquid flow continues to be significant until 28 seconds as fluid drains through the upper core plate holes into the upper plenum.

The timing of the initial downflow into the hot assembly is similar to that of the downflow into the open hole/support column average assemblies. Around 10 seconds into the transient, liquid that has built up in the global region above the hot assembly begins to flow into the hot assembly (Figure 9.6.4-3). Significant flow of continuous liquid into the hot assembly exists between

10 to 20 seconds. The liquid flow is not enough to quench the hot rod and hot assembly rod or the average rods at all elevations (Figure 9.6.4-1) although some cooling is achieved.

After 13 seconds into the transient, the accumulator begins to inject water into the upper downcomer region, most of which is initially bypassed to the break. The break flow rate diminishes as the transient progresses (Figure 9.6.4-10). At 27.5 seconds, the accumulator injection begins to refill the lower plenum. At approximately 40.0 seconds, the lower plenum fills to the point that water begins to reflood the core from below (Figure 9.6.4-11). The void fraction at the core bottom begins to decrease, and as time passes, core cooling increases substantially. Figure 9.6.4-11 presents the collapsed liquid levels in the core; Figure 9.6.4-12 presents the collapsed liquid levels in the downcomer. The cladding temperature begins to decrease once the core water level has risen high enough in the core.

9.6.4.2.2 Global Model Sensitivity Studies and Uncertainty Evaluation

Section 9.6.4.1 discusses the treatment of the global model parameters and the uncertainty evaluation in the ASTRUM methodology.

9.6.4.3 Diverse Mitigation

Diverse mitigation for this event is not required as it is a low probability design basis fault classified as DBL.

9.6.4.4 Radiological Consequences

The evaluation of the radiological consequences of a postulated large break LOCA assumes that as a result of the accident, 33 percent of the fuel rods are damaged such that the activity contained in the fuel-cladding gap is released to the reactor coolant. This is consistent with the recommendation in Chapter X of Reference 9.6.4-1. Activity is released to the containment via the break. The dose calculations take into account the release of activity by way of the containment purge line prior to its isolation near the beginning of the accident and the release of activity resulting from containment leakage. Purge of the containment for hydrogen control is not an intended mode of operation and is not considered in the dose analysis. While the normal residual heat removal system is capable of post-LOCA cooling, it is not a safety-related system and may not be available following the accident. If it is operable, it would be used only if the source term is not far above the normal shutdown primary coolant source term. It is assumed that core cooling is accomplished by the passive core cooling system, which does not pass coolant outside of containment. Thus, there is no recirculation leakage release path to be modelled.

This section describes the fault study analysis performed for a large break loss of coolant accident. Since this analysis is a design basis accident analysis, and is not an analysis describing the severe accident beyond design basis source term that is generated as a result of the GI-AP1000-RC-01 issue, this section is concluded to not be impacted.

9.6.4.4.1 Source Term

The most significant radionuclide releases are the noble gases, alkali metals, and iodines. The release of activity to the containment consists of two parts. The initial release is the activity contained in the reactor coolant system. This is followed by the release of core activity.

All activity in the fuel rod gap of the damaged fuel is assumed to be released to the coolant. Based on Table 7.3 of Reference 9.6.4-1, the gap fraction is assumed to be 3 percent of the core inventory for iodines, 10 percent for noble gases, and 4 percent for alkali metals. To address the

fact that the failed fuel rods may have been operating at power levels above the core average, the source term is increased by a lead rod radial peaking factor of 1.75 which bounds the COLR limit of 1.72.

From Chapter X of Reference 9.6.4-1, the activity releases from the damaged fuel rods can be modelled as occurring in two phases: the dry phase (when the core is uncovered) and the wet phase (when reflood of the core has been accomplished).

The dry phase is assumed to begin at 30 seconds into the accident. The dry phase is assumed to end at 120 seconds. The fraction of gap activity released during the dry phase is 1.0 for noble gases, 0.1 for iodines, and 0.1 for alkali metals. It is assumed that 0.2% of the iodine released is in the organic form, 2% of the iodine is in the elemental form, and the remainder is in the particulate form.

The wet phase is assumed to begin at the end of the dry phase (120 seconds). The fraction of gap activity released during the wet phase is 0.0 for noble gases, 0.9 for iodines, and 0.9 for alkali metals. The water covering the core is assumed to retain some of the radionuclides released from the core. The iodine activity is all assumed to enter into solution with 60 percent of the iodine assumed to convert to the elemental form and then enter the containment atmosphere, consistent with Section 2.2.1 of Chapter IX of Reference 9.6.4-1. It is assumed that 1% of the iodine released converts to the organic form while the other 99% stays in the elemental form. In practice, the iodine activity released from the fuel would initially enter into solution and is anticipated to be gradually released to the containment atmosphere over an indefinite period of time. However, it is conservatively assumed that all of the iodine releases to the containment atmosphere occur over 60 seconds. This assumption makes the activity quickly available for release to the environment by way of containment leakage. The alkali metals activity is assumed to be retained in the primary coolant and none of it is assumed to enter the containment atmosphere

The AP1000 does not include active systems for the removal of activity from the containment atmosphere. The containment atmosphere is depleted of elemental iodine and of particulates as a result of natural processes within the containment.

Elemental iodine is removed by deposition onto surfaces. Particulates are removed by sedimentation, diffusiophoresis (deposition driven by steam condensation), and thermophoresis (deposition driven by heat transfer). No removal of organic iodine is assumed.

If the post-LOCA cooling solution has a pH of less than 6.0, part of the cesium iodide may be converted to the elemental iodine form. The passive core cooling system provides sufficient trisodium phosphate to the post-LOCA cooling solution to maintain the solution pH at 7.0 or greater following a LOCA.

9.6.4.4.2 Release Pathways

The release pathways are the containment purge line and containment leakage. The activity releases are assumed to be ground level releases.

During the initial part of the accident, before the containment is isolated, it is assumed that containment purge is in operation and that activity is released through this pathway until the purge valves are closed. No credit is taken for the filters in the purge exhaust line.

The majority of the releases due to the LOCA are the result of containment leakage. The containment is assumed to leak at its design leak rate for the first 24 hours and at half that rate for the remainder of the analysis period.

9.6.4.4.3 Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.6.4.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.6.4-8.

9.6.4.4.5 Doses

The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 10.2 mSv Worker dose: 14.8 mSv

These doses are within the Target 4 BSL for infrequent faults with IEF<1E-04 (100 mSv offsite and 500 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.6.4-9. The Table 9.6.4-9 values ensure the Target 4 BSLs are met.

9.6.4.5 As Low As Reasonably Practicable Assessment

For the LBLOCA event, the identification of the primary safety functions as Class 1 SSCs (CMTs, the accumulators, full ADS, PCS, and reactor containment) has been shown to be adequate to meet DB requirements.

LBLOCAs are low probability design basis events (DBLs) and have core a low probability of causing a large radioactivity release that is less than the SAP Target 9 BSO (1.0E-7 pa).

In order to provide improved reliability (diversity) the following features would have to be provided:

- Two additional Accumulators with diverse actuation check valves
- Auto start of the RNS pumps; note that ADS 1/2/3 is adequate to support RNS injection and recirculation whereas the diverse ADS 4 is adequate to support PXS IRWST injection / recirculation.

The impact of the addition of two more Accumulators would have a very large impact on the containment design, possibly requiring a larger diameter containment. The additional Accumulators would also increase the radiation exposure to operational personnel for inservice testing and inspection and also to deal with the increased chance of RCS leakage into the new Accumulators. The impact of providing automatic RNS start would not be so costly but would complicate the design and probably make it less reliable for SBLOCAs. As a result, such changes are not considered ALARP because the significant cost increase would be grossly disproportional to the small improvement in safety, especially since the SAP Target 9 BSO is already met.

9.6.4.6 Large Break LOCA Conclusions

The conclusions of the best-estimate large-break LOCA analysis are that there is a high level probability that the following criteria are met.

1. The calculated maximum fuel element cladding temperature (i.e., PCT) will not exceed 1204.4°C (2200°F).

2. The calculated total oxidation of the cladding (i.e., maximum cladding oxidation) will nowhere exceed 0.17 times the total cladding thickness before oxidation.

3. The calculated total amount of hydrogen generated from the chemical reaction of the cladding with water or steam (i.e., maximum hydrogen generation) will not exceed 0.01 times the hypothetical amount that would be generated if all of the metal in the cladding cylinders surrounding the fuel, excluding the cladding surrounding the plenum volume, were to react.

4. The calculated changes in core geometry are such that the core remains amenable to cooling.

   Note that criterion 4 has historically been satisfied by adherence to criteria 1 and 2, and by assuring that fuel deformation due to combined LOCA and seismic loads is specifically addressed. Criteria 1 and 2 are satisfied for best-estimate large-break LOCA applications. The approved methodology specifies that effects of LOCA and seismic loads on core geometry do not need to be considered unless grid crushing extends beyond the assemblies in the low power channel as defined in the WCOBRA/TRAC model. This situation has not been calculated to occur for the AP1000 plant in the standard LOCA analysis. Therefore, acceptance criterion 4 is satisfied.

   An additional assessment was carried out to assess the potential for grid crush to extend beyond the assemblies in the low power channel as a result of a depressurisation of the primary circuit due to a double-ended guillotine (DEG) break of the RCS cold leg. This assessment, documented in Reference 9.6.4-4, analysed the DEG break at the reactor vessel inlet using the standard LOCA methodology and tools. Due to the low IEF of such a break, realistic but conservative operating assumptions were used as described in Reference 9.6.4-4. This assessment concluded that no grid crushing will occur outside of the low power assemblies due to the depressurisation and therefore coolable geometry will be maintained.

5. After successful initial operation of the ECCS, the core temperature will be maintained at an acceptably low value and decay heat will be removed for the extended period of time required by the long-lived radioactivity remaining in the core.

   Criterion 5 is satisfied if a coolable core geometry is maintained and the core is cooled continuously following the LOCA. The AP1000 passive core cooling system provides effective core cooling following a large-break LOCA event, even assuming the limiting single failure of a core makeup tank delivery line isolation valve. The large-break LOCA transient has been extended beyond fuel rod quench to the time at which the CMT liquid level has decreased to the Low-6 setpoint that actuates the fourth-stage ADS valves and IRWST injection. A significant increase in safety injection flow rate occurs when the IRWST becomes active. The analysis performed demonstrates that CMT injection is sufficient to maintain the mass inventory in the core and downcomer, from the period of fuel rod quench until IRWST injection. The PXS provides effective post-LOCA long-term core cooling (Section 9.6.6).

Table 9.6.4-5 presents the calculated 95th percentile PCT, maximum cladding oxidation, maximum hydrogen generation, and core cooling results.

Based on the analysis, the Westinghouse Best-Estimate Large-Break LOCA methodology has shown that the applicable acceptance are satisfied when the burnup-related effects of thermal conductivity degradation and peaking factor burndown are considered.

Radiological consequences are within the Target 4 BSL for infrequent faults with IEF < 1E-04 (100 mSv offsite and 500 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

An assessment of the large break loss of coolant accident has been completed concluding that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAP targets and the risks have been reduced to be ALARP.

Table 9.6.4-1. Major Plant Parameter Assumptions Used in the Best-Estimate Large-Break LOCA Analysis

Parameter	Value
Plant Physical Configuration	
Steam generator tube plugging level	≤ 10% (10% tube plugging bounds 0%)
Hot assembly location	Under support column (Bounds under open hole or guide tube)
Pressuriser location	In intact loop (Bounds location in broken loop)
Initial Operating Conditions	
Reactor power	Core power < 1.01*3400 MWt
Peak linear heat rate	See Table 9.6.4-4
Hot rod assembly power	See Table 9.6.4-4
Hot assembly power	$P_{HA} \leq 1.654$
Axial power distribution(1)	See Figure 9.6.4-13
Peripheral assembly power	$0.2 \leq P_{LOW} \leq 0.8$
Fluid Conditions	
Reactor coolant system average temperature	$300.9 - 4.4°C \leq T_{AVG} \leq 300.9 + 4.4°C$ $(573.6 - 8.0°F \leq T_{AVG} \leq 573.6 + 8.0°F)$
Pressuriser pressure	15.51 ± 0.34 MPa abs (2250 ± 50 psia)
Pressuriser level (water volume)	28.3 m^3 (1000 ft^3) (nominal)
Accumulator temperature	$10°C \leq T_{ACC} \leq 48.9°C$ ($50°F \leq T_{ACC} \leq 120°F$)
Accumulator pressure	4.5 MPa abs $\leq P_{ACC} \leq$ 5.4 MPa abs (652 psia $\leq P_{ACC} \leq$ 784 psia)
Accumulator water volume	47.2 $m^3 \leq V_{ACC} \leq$ 49.1 m^3 (1666.8 $ft^3 \leq V_{ACC} \leq$ 1732.3 ft^3)
Reactor Coolant System Boundary Conditions	
Single failure assumption	Failure of one CMT isolation valve to open
Offsite power availability	Available (Bounds loss of offsite power at time zero)
RCP automatic trip delay time after receiving S-signal	5.3 s
Containment pressure	Bounded (minimum)

Note:
1. Treatment of axial power distribution consistent with WCAP-16009-P-A (Reference 9.6.4-6) methodology.

Table 9.6.4-2. AP1000 LOCA Chronology

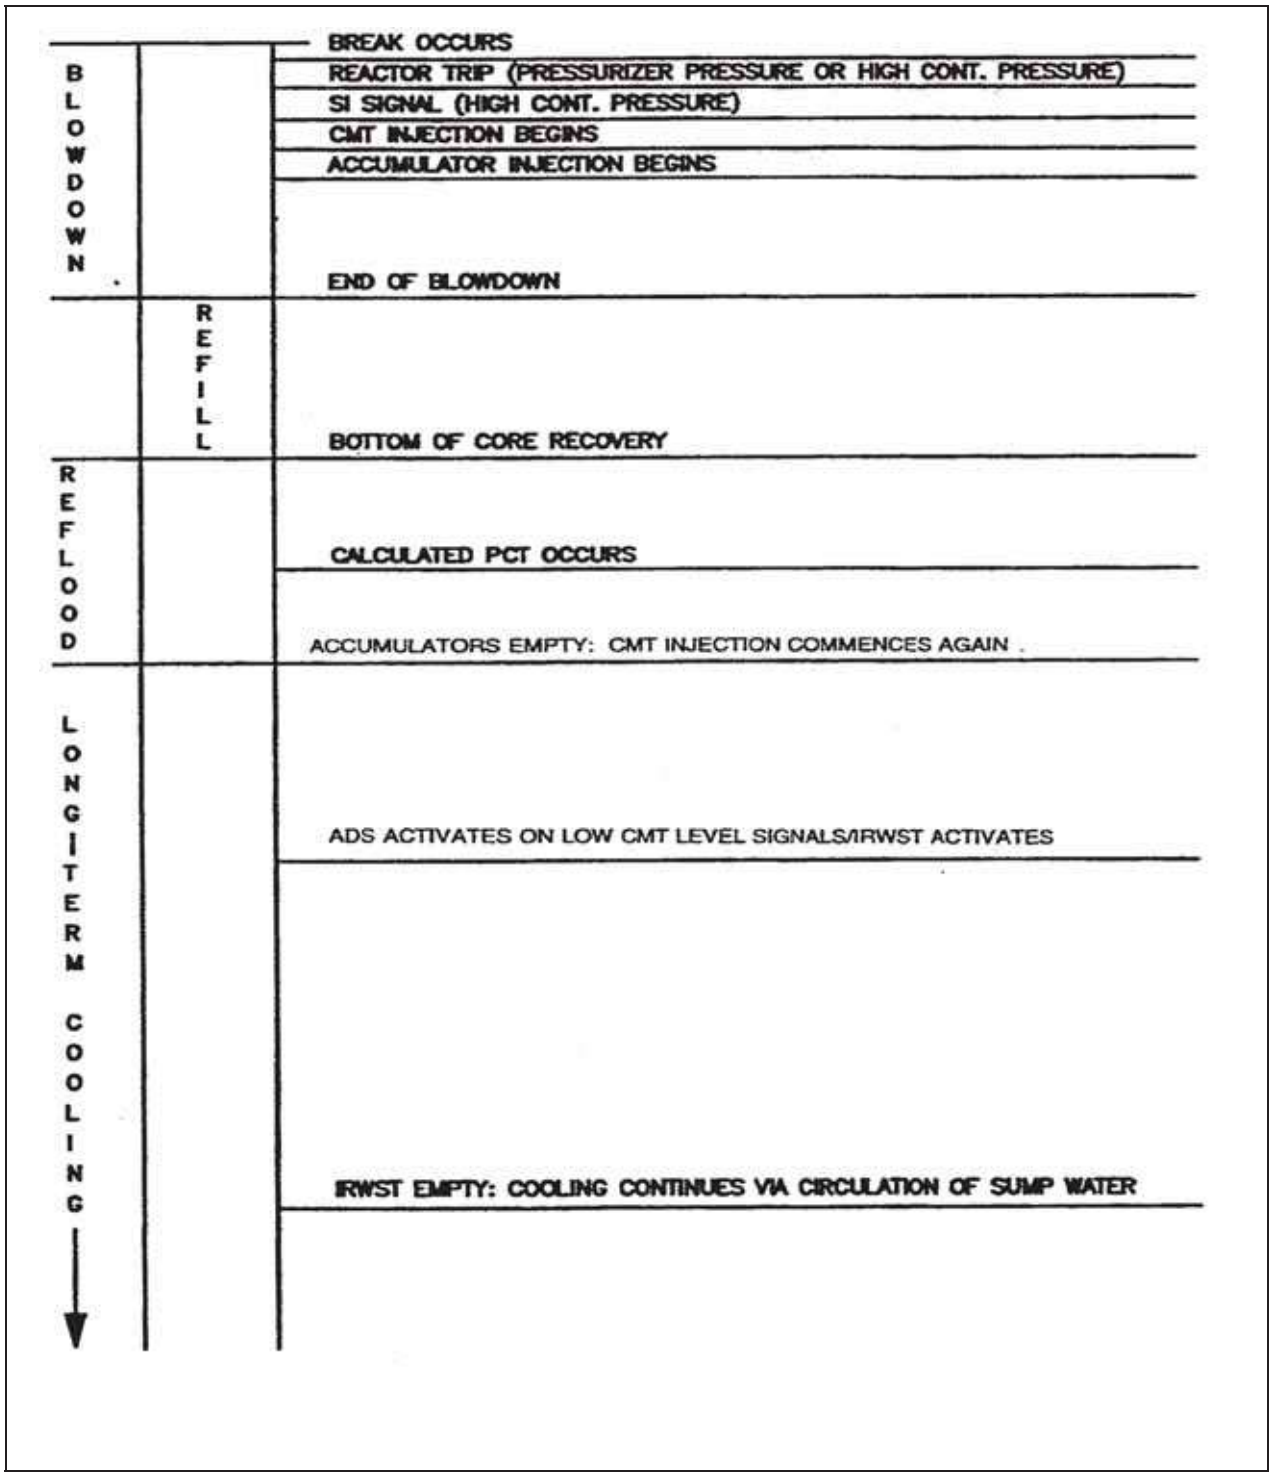

Table 9.6.4-3. Best-Estimate Large-Break Sequence Of Events For The Limiting PCT Case

Event	Time (seconds)
Break initiation	0.0
Safeguards signal	2.2
CMT isolation valves begin to open	4.2
Reactor coolant pumps trip	9.5
Accumulator injection begins	~13
End of blowdown	27.5
Bottom of core recovery	39.5
Calculated PCT occurs	~58
Core quench occurs	~240
CMT injection resumes	~200
End of transient	265

Table 9.6.4-4. Summary Of Peaking Factor Burndown Supported By Best-Estimate Large-Break LOCA

Hot Rod Burnup (GWd/MTU)	FdH (includes uncertainties)[1]	FQ Transient (maximum FQ, includes uncertainties)	FQ SS Baseload (without uncertainties)
0	1.72	2.60	2.10
30	1.72	2.60	2.10
49	1.55	2.30	1.85
55	1.55	2.30	1.85
62	1.40	1.90	1.45

Note:
1. Hot assembly power follows the same burndown since it is a function of FdH.

Table 9.6.4-5. Best-Estimate Large-Break LOCA Results

Requirement	Value	Criteria
Calculated 95th percentile PCT (°C [°F])	1058 [1936][(1)]	≤ 1204.4 [2200]
Maximum local cladding oxidation (%)	4.2	≤ 17
Maximum core-wide cladding oxidation (%)	0.30	≤ 1
Coolable geometry	Core remains coolable	Core remains coolable
Long-term cooling	Core remains cool in long term	Core remains cool in long term

Note:
1. Value contains 1.1°C [2°F] bias for PCT sensitivity to PRHR isolation.

9.6.5 Medium and Small Break Loss-of-Coolant Accident Faults

A number of faults that could result in a decrease in reactor coolant inventory are postulated. The events smaller than a large break LOCA are discussed in this section. Detailed analyses are presented for the most limiting of the primary system coolant decrease events.

9.6.5.0 Introduction and Overview of Faults

A LOCA is the result of a rupture of the RCS pressure boundary. For the sake of convenience, this section addresses most LOCAs except LBLOCAs, since the phenomenology and methods of analysis are similar. The faults considered here, all of which result in leak paths to the containment, are as follows:

- MBLOCA, (Faults 1.4.1 – see Appendix 8A) including inadvertent opening of a pressuriser safety valve and inadvertent operation of ADS stages 1 to 3 (Fault 1.5.2 – see Appendix 8A)
- Safety injection (direct vessel injection [DVI]) line break (SI-LB) (Fault 1.7.1 – see Appendix 8A)
- CMT line break (CMTLB) (Fault 1.6.1 – see Appendix 8A)
- SBLOCA (Faults 1.8.1 and 1.8.2 – see Appendix 8A)
- PRHR system tube rupture (Fault 1.10.1 – see Appendix 8A)
- Reactor coolant leakage (Fault 1.9.1 – see Appendix 8A)

SGTR and leakage through sample and instrumentation lines are addressed separately because they may yield leak paths from the RCS that bypass the containment.

The AP1000 plant design includes passive safety features to prevent or minimise core uncovery during MBLOCAs and SBLOCAs (see the fault schedule in Appendix 8A). The passive safety design approach of the AP1000 plant is to depressurise the RCS if the break or leak is greater than the capability of the makeup system or if the normal makeup system fails to perform. By depressurising the reactor system, large volumes of borated water in the accumulators and IRWST become available for cooling the core. The CMT injection is available at any RCS pressure and its level is used to actuate the depressurisation system. The analysis presented herein demonstrates that, with a single failure, the passive systems are capable of depressurising the RCS while maintaining acceptable core conditions and establishing stable delivery of cooling water from the IRWST.

The spectrum of breaks analysed for the AP1000 design represents a range of expected break sizes in the RCS and PXS, and expected system response. It should be noted that a pipe break can consist of the following types:

1. Full or partial breaks across the diameter of a pipe
2. Split breaks of various orientations and configurations
3. Non-breaks consisting of the inadvertent opening of valves that form the pressure boundary.

A double-ended pipe break depends on the pipe diameter. For example, a double-ended break of a primary loop piping is a large LOCA, while a double-ended break of an instrument line is a small LOCA. Split breaks can be any size depending on the length and width of the crack. In general, if a split break is larger than the pipe flow area, the break flow will choke at the pipe diameter. Choked flow dominates the flow through the break until the upstream pressure is roughly twice the containment pressure. After the upstream pressure falls below this level, the flow is no longer choked and the size of the break has a large influence on the break flow.

A DBA of the bounding fault is presented, aspects of the fault progression are described, the methods and assumptions adopted for the DB analysis are reviewed, and the Class 1 systems assumed to be available for that analysis are summarised. The DB analyses are summarised, and the radiological consequences are compared with the relevant SAPs targets.

The discussion of each fault concludes with an ALARP assessment and a summary of the safety designations that follow from the assessment.

Design Basis Requirements

The acceptance criteria for all of the DB analyses for MBLOCAs and SBLOCAs are consistent, and are described below:

- The calculated maximum fuel element cladding temperature shall not exceed 1204.4°C (2200°F).
- Localised cladding oxidation shall not exceed 17 percent of the total cladding thickness before oxidation.
- The amount of hydrogen generated from fuel element cladding reacting chemically with water or steam shall not exceed 1 percent of the total amount if all metal cladding were to react.
- The core remains amenable to cooling for any calculated change in core geometry.
- The core temperature is maintained at a low value, and decay heat is removed for the extended period of time required by the long-lived radioactivity remaining in the core.

Each individual fault analysis shows that these criteria are met. These criteria are established to provide significant margin in ECCS performance following a LOCA.

The faults listed below are considered in turn in the sections below. Each fault is first described; the initial event frequency and the design basis class are provided and the bounding fault or faults are identified (if needed). The analysed faults are presented individually in Table 8A-2.

The analysed fault(s) are described in additional detail in the subsequent sections to complete the safety case for each fault, including:

- Identification of Causes and Accident Description
- Design Basis Analysis of Effects and Consequences
- Assessment of the Radiological Consequences for the DBA
- Diverse Mitigation and ATWT for Frequent Faults
- ALARP Assessment

- Conclusions

9.6.5.0.1 Medium Break Loss-of-Coolant Accident (Fault 1.4.1)

Description

The MBLOCA events are defined as all RCS ruptures with break sizes insufficient to depressurise the RCS to the RNS operating pressure without operation of the ADS, but sufficient to allow the automatic actuation of the ADS stage 4 without operation of the ADS stages 1, 2, and 3. This includes RCS pressure boundary breaks of less than 229 mm (9 inches) and greater than or equal to 101.6 mm (4 inches) equivalent diameter. Because these faults involve a leak path to the containment and may lead to core uncovery and heat-up, they are considered to have the potential to release radioactivity to the environment.

Stuck-open pressuriser safety valves and ADS spurious actuation events, which result in a consequential MBLOCA event, are included in the MBLOCA fault, since the pathways to the containment lie in the MBLOCA size range, but are discussed in a separate section.

On the basis of piping size, the range of this category includes SI-LBs and CMTLBs. However, because the mitigating systems response for these break categories is different than for an MBLOCA, they are evaluated separately.

Initiating Event Frequency[1]

The AP1000 design PSA gives the summed IEF for an MBLOCA resulting from a pipe break as 6.8E-06/yr (Table 8A-2). The summed frequency for the fault, which includes spurious operation of ADS stages 1 to 3 and stuck-open pressuriser valve events, is 3.9E-04/yr (Table 8A-2), which makes the fault an infrequent fault. See also a discussion under the SBLOCA section on IEF for further clarification of the correct interpretation of this frequency.

Design Basis Class

The unmitigated consequences of an MBLOCA are assumed to be greater than Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). These LOCAs (152 mm [6 inch] equivalent piping diameter and larger) are DBL due to historical LOCA experience, the AP1000 design approach (reduced amount of piping, use of bent pipe to reduce number of welds, and better materials), and the piping analysis approach used for the AP1000 (i.e., leak before break). The core cooling response is conservatively analysed with DB1 assumptions (bounding analysis). The reactor internals/fuel structural analysis for these medium LOCAs is bounded by the large break LOCA analysis.

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.

9.6.5.0.2 Spurious Actuation of Automatic Depressurisation System or Opening of a Pressure Relief Valve (Fault 1.5.2)

Description

Two types of inadvertent depressurisation are discussed in this section: inadvertent operation of ADS valves leading to an MBLOCA, and inadvertent opening of a pressuriser safety valve. These faults are included in the MBLOCA fault; however, their analysis is described separately here for completeness.

Spurious actuation of the ADS is defined as an inadvertent valve-opening event. Depending on the number of the ADS lines spuriously opening, the frequency of ADS spurious actuation can be classified as MBLOCA or LBLOCA. Spurious ADS actuation leading to an LBLOCA is addressed in Section 9.6.4.

Spurious actuation of ADS consisting of one line of the ADS stage 1, 2, 3, or 4 opening is categorised and analysed as a medium LOCA. Spurious ADS consisting of the opening two lines of the ADS stage 4 or one line of the ADS stage 4 with all lines of the ADS stages 1, 2, and 3 may be categorised as a large LOCA.

The ADS system consists of four stages of depressurisation valves. The ADS stages are interlocked; for example, stage 1 is initiated first, and subsequent stages are not actuated until previous stages have been actuated. Each stage includes two redundant parallel valve paths, so that no single failure prevents operation of the ADS stage when it is called upon to actuate, and the spurious opening of a single ADS valve does not initiate ADS flow. To actuate the ADS manually from the MCR, the operators actuate two separate controls positioned at some distance apart on the main control board. Therefore, one unintended operator action does not cause ADS actuation (Section 9.6.1.1).

Initiating Event Frequency

The fault schedule (Appendix 8A) gives a frequency of <1E-08/yr for spurious ADS operation leading to an MBLOCA and a frequency of 3.9E-04/yr for a stuck-open pressuriser valve event. The latter is the dominant contributor to the overall MBLOCA frequency of 6.8E-06/yr. Given the frequency, the fault is an infrequent fault (DB1) in the UK definition.

Design Basis Class

As noted in the MBLOCA assessment, given that the unmitigated consequences of an MBLOCA are assumed to be greater than 1 mSv offsite and 20 mSv onsite and given the IEF, the event is in the DB1 class.

9.6.5.0.3 Small Break Loss-of-Coolant Accident (Faults 1.8.1 and 1.8.2)

Description

The SBLOCA is defined as all RCS ruptures with break sizes less than 102-mm (4-inch) equivalent diameter and greater than those producing leakage that can be made up by the CVS (about 9.5-mm (3/8-inch) equivalent diameter, which corresponds to a break flow rate within the capability of CVS makeup). Note that this fault is divided into two different faults, fault 1.8.1 includes larger breaks that are infrequent and fault 1.8.2 includes smaller breaks that are frequent.

The SBLOCA event differs from the MBLOCA event in that the operation of the PRHR system or the ADS stages 1, 2, and 3 is required to allow the actuation of the ADS stage 4 within its design basis RCS pressure.

Initiating Event Frequency

The more frequent small LOCAs are listed in the fault schedule (appendix 8A) as less than 102 mm (2 inch) with a frequency that is greater than 1E-4 pa. Since this frequency is greater than the cliff edge frequent fault, they are classified as DB2 events.

The less frequent small LOCAs are listed in the fault schedule (appendix 8A) as greater than 102 mm (2 inch) with a frequency that is less than 1E-4 pa. As a result, these faults are classified as DB1 events.

Design Basis Class

The unmitigated consequences of an SBLOCA are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEFs listed above, the event classification is DB1 for small LOCAs ≥102 mm (2 inch) and DB2 for small LOCAs <102 mm (2 inch).

9.6.5.0.4 Direct Vessel Injection (DVI) Line Break (Fault 1.7.1)

Description

The DVI line break event is defined as any rupture occurring in one of the safety injection (SI) lines (including the DVI and the line that connects the CMT, accumulator, or IRWST to the DVI).

On the basis of break size, these faults are classified as medium LOCAs, but they differ from the MBLOCA because one CMT, one accumulator, one gravity injection line, and one recirculation line are unavailable.

Initiating Event Frequency

The AP1000 design PSA gives the IEF for a DVI line pipe break of 1.4E-06/yr (Table 8A-2), which makes the fault an infrequent fault in the UK definition. It is noted that, depending on the size of the break, this fault is already included in the MBLOCA or SBLOCA faults discussed in previous sections.

Design Basis Class

The unmitigated consequences of an SI-LB are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.6.5.0.5 Core Makeup Tank Line Break (Fault 1.6.1)

Description

The CMTLB event is defined as all ruptures occurring in one of the lines connecting the CMTs to the reactor coolant cold legs.

On the basis of break size, this category is classified as an MBLOCA but is different from the MBLOCA because one of the CMTs is unavailable, with no other systems being impacted.

Initiating Event Frequency

The AP1000 design PSA gives the IEF for a CMTLB of 5.4E-07/yr (Table 8A-2), which makes the fault an infrequent fault. It is noted that, depending on the size of the break, this fault is already included in the MBLOCA or SBLOCA faults discussed in previous sections.

Design Basis Class

The unmitigated consequences of a CMTLB are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.6.5.0.6 Passive Residual Heat Removal Tube Rupture (Fault 1.10.1)

Description

This fault includes events in which a complete, circumferential tube rupture occurs in the PRHR HX. Note that this break could be isolated if the operators close the inlet MOV and the outlet AOVs. For the purposes of this evaluation, it is assumed that isolation of the PRHR does not occur. In this case, the progression of a PRHR tube rupture event is similar to that of an SBLOCA.

Initiating Event Frequency

The probability of this event is listed as 1.1E-04/yr in Table 8A-2, which makes the fault an infrequent fault. The size of the break is bounded by the SBLOCA faults discussed in previous sections.

Design Basis Class

The unmitigated consequences of a PRHR system tube rupture are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB1 class.

9.6.5.0.7 Reactor Coolant Leakage (Fault 1.9.1)

Description

For the purpose of this analysis, the RCS leakage category is defined as primary coolant leakage with a leak rate between 0.0631 (1 gpm) and 6.31 L/s (100 gpm). The break size corresponding to a 6.31 L/s flow rate is approximately a 9.5-mm (3/8-inch) break.

The CVS is designed to provide makeup for RCS leaks of 6.31 L/s or less. As long as the RCS inventory is replenished by the CVS, the plant will remain at power and in a safe condition. If the CVS fails, the pressuriser water level will decrease and the event will proceed as an SBLOCA. Thus, the initiating event for this fault is loss of CVS.

For the 0 to 0.0631 L/s leak range with failure of the CVS, it takes more than 60 hours to empty the pressuriser and more than 190 hours to drain each CMT to the ADS actuation water level setpoint. That is, with both CMTs operating, it would take more than 18 days to get to the ADS actuation setpoint.

This event is bounded by the small LOCA and analysis is not presented in this section.

Initiating Event Frequency

The AP1000 design PSA gives the IEF for reactor coolant leakage fault of 1.4E-03/yr (Table 8A-2), which makes the fault a frequent fault.

Design Basis Class

The unmitigated consequences of a reactor coolant leak are assumed to be greater than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB2 class.

9.6.5.1 Medium and Small Break LOCA Analyses

Should a medium or small-break LOCA occur, depressurisation of the reactor coolant system results in a pressure decrease in the pressuriser. The reactor trip signal occurs when the pressuriser low-pressure trip setpoint is reached. An "S" signal is generated when the appropriate setpoint is reached. These measures limit the consequences of the accident in two ways:

- Reactor trip leads to a rapid reduction of power to a residual level corresponding to fission product decay heat by the insertion of control rods to shut down the reactor.
- Injection of borated water provides core cooling and prevents excessive cladding temperatures.

9.6.5.1.1 Description of MBLOCA and SBLOCA Transients

The AP1000 plant design includes passive safety features to prevent or minimize core uncovery during small-break LOCAs. The passive safety design approach is to depressurise the reactor coolant system if the break or leak is greater than the capability of the makeup system or if the non-Class 1 makeup system fails to perform. By depressurising the reactor coolant system, large volumes of borated water in the accumulators and in the IRWST become available for cooling the core. The small-break analyses demonstrate that with a single failure of one of the ADS Stage 4 valves located off the non-pressuriser loop, the passive systems are capable of depressurising the reactor coolant system while maintaining acceptable core conditions and establishing stable delivery of cooling water from the IRWST.

During MBLOCAs and SBLOCAs, the reactor coolant system depressurises to the pressuriser low-pressure setpoint, actuating a reactor trip signal. The passive core cooling system is aligned for delivery following the generation of an "S" signal when the pressuriser low-pressure setpoint is reached. The passive core cooling system includes two core makeup tanks, two accumulators, a large IRWST, and the PRHR heat exchanger.

The core makeup tanks operate at reactor coolant system pressure. They provide high-pressure safety injection in the event of an MBLOCA or SBLOCA and are filled with borated water to provide core shutdown margin. The core makeup tanks share a common discharge line with the accumulators and IRWST. Gravity head of the colder water in the core makeup tanks provides the injection of the core makeup tanks. The core makeup tanks are located above the reactor coolant loops, and each is equipped with a pressure balancing line from a cold leg to the top of the tank.

The pressurised accumulators provide additional borated water to the reactor coolant system in the event of a LOCA. Nominally, these 57.2 m^3 (2020 ft^3) tanks are filled with 48.1 m^3 (1700 ft^3) of water and nitrogen cover gas at an initial gauge pressure of 4.83 MPa (700 psig). Once sufficient reactor coolant system depressurisation occurs, either as a result of a LOCA or the actuation of the ADS, accumulator injection begins.

The IRWST provides an additional source of water for core cooling. To attain injection from the IRWST, the reactor coolant system pressure must be lowered to approximately 0.0896 MPa (13 psi) above containment pressure. For this pressure to be achieved during a small-break LOCA, the actuation of the ADS valves is required.

The ADS consists of a series of valves, connected to the pressuriser and hot legs, which provide a phased depressurisation of the reactor coolant system. As the reactor coolant system loses inventory through the break, the core makeup tanks provide flow to the reactor vessel. When the inventory level in one core makeup tank drops to 67.5-percent volume, the ADS valves begin opening to accelerate the reactor coolant system depressurisation rate. The ADS Stage 1 valves open at the 67.5-percent volume setpoint; the Stage 2 and the Stage 3 valves open in a timed sequence thereafter. The flow from the first three stages of the ADS is discharged into the IRWST through a sparger system. The fourth stages of the ADS are connected to the reactor coolant system hot legs and discharge to containment atmosphere. The ADS Stage 4 valves are activated when one core makeup tank reaches 20-percent volume and a delay has elapsed after ADS Stage 3 actuation. A list of the ADS parameters is given in Table 9.6.5-10.

As the reactor system depressurises and mass is lost out of the break, mass is added to the reactor vessel from the core makeup tanks and the accumulators. When the system is depressurised below the IRWST delivery pressure, flow from the IRWST continues to maintain the core in a coolable state. Calculations described in this section indicate that acceptable core cooling is provided for the medium and small-break LOCA transients.

9.6.5.2 Medium and Small Break LOCA Analysis Methodology

Medium and Small-break LOCA responses are evaluated for the AP1000 plant with a deterministic evaluation model. The elements of the AP1000 plant small-break LOCA evaluation model are the following:

- NOTRUMP computer code
- NOTRUMP homogeneous sensitivity model
- Critical heat flux assessment during accumulator injection
- SBLOCTA computer code

Note that the cliff edge small-break LOCA diversity analyses are evaluated using the RELAP computer code. In the site specific phase, this analysis will be repeated using the NOTRUMP computer code. For this cliff edge small-break LOCA diversity analsyes, the use of the NOTRUMP computer code will use realistic inputs and assumptions and with acceptance criteria that are appropriate for such events (cliff edge faults with a common cause failure); refer to Section 8.2.3.

9.6.5.2.1 NOTRUMP Computer Code

The NOTRUMP computer code is used in the analysis of LOCAs due to medium and small-breaks in the reactor coolant system. The NOTRUMP computer code is a one-dimensional, general network code, which includes a number of advanced features. Among these features

are the calculation of thermal non-equilibrium in all fluid volumes, flow regime-dependent drift flux calculations with counter-current flooding limitations, mixture level tracking logic in multiple-stacked fluid nodes, and regime-dependent heat transfer correlations. The version of NOTRUMP used in AP1000 medium and small-break LOCA calculations has been validated against applicable passive plant test data (References 9.6.5-8 and 9.6.5-9). The code has limited capability in modelling upper plenum and hot leg entrainment and did not predict the core collapsed level during the accumulator injection phase adequately. The NOTRUMP homogeneous sensitivity model (discussed in Section 9.6.5.2.2) and the critical heat flux assessment during the accumulator injection phase (discussed in Section 9.6.5.2.3) supplement the base NOTRUMP analysis to demonstrate the adequacy of the design.

In NOTRUMP, the reactor coolant system is nodalised into volumes interconnected by flow paths. The transient behaviour of the system is determined from the governing conservation equations of mass, energy, and momentum applied throughout the system. A description of NOTRUMP is given in References 9.6.5-5 and 9.6.5-6. The AP600 modelling approach, described in Reference 9.6.5-7, is also used to develop the AP1000 model; NOTRUMP's applicability to the AP1000 design is documented in Reference 9.6.5-9.

The use of NOTRUMP in the analysis involves the representation of the reactor core as heated control volumes with an associated bubble rise model to permit a transient mixture height calculation. The multi-node capability of the program enables an explicit and detailed spatial representation of various system components. Table 9.6.5-9 lists important initial conditions of the analysis.

A steady-state input deck was set up to comply, where appropriate, with the standard small-break LOCA Evaluation Model methodology. Major features of the modelling of the AP1000 plant follow:

- Accumulators are modelled at an initial pressure of 4.9 MPa (715 psia).

- The flow through the ADS links is modelled using the Henry-Fauske and the homogeneous equilibrium (HEM) critical flow models. The Henry-Fauske subcooled correlation is used for subcooled flow, and the HEM correlation is used for superheated flow. For saturated donor conditions above the transition static quality of 10 percent, the HEM correlation is used. Below the transition quality, the flow is transitioned between the HEM correlation and the Henry-Fauske saturated correlation.

- Isolation and check valves used in the passive safety systems are modelled.

- The IRWST is modelled as two connected fluid nodes. The lower node is connected to the direct vessel injection line and is the source of injection water to the DVI lines driven by gravity head. The upper node acts as a sink for the ADS flow from the pressuriser and as a heat sink for the PRHR heat exchanger. These nodes are modelled as having an initial temperature of 48.9°C (120°F), a pressure reflective of containment conditions, and the minimum full-power operation level of 8.72 m (28.6 feet). Therefore, the minimum head for IRWST injection is assumed. For the double-ended, direct vessel injection (DEDVI) line break simulations, a conservatively low 0.138-MPa (20 psia) containment pressure was used based on containment pressurisation calculations performed with the WGOTHIC containment model. In addition, the inadvertent ADS actuation and the 50.8 mm (2-inch) cold leg break simulations each used a conservatively low, time-dependent containment pressure response also based on containment pressurisation calculations performed with the WGOTHIC minimum

containment pressure model as described in Section 13.8 of WCAP-15846 (Reference 9.6.5-3).

- The PRHR system is modelled in accordance with the guidance provided in References 9.6.5-8 and 9.6.5-9. The PRHR isolation valve is modelled as opening with the maximum delay after the generation of an "S" signal to conservatively deny the cooling capability of the heat exchanger to the reactor coolant system for an extended period.

- The core power is initially set to 101 percent of the nominal core power. The reactor trip signal occurs when the pressuriser pressure falls below 12.41 MPa (1800 psia). A conservative delay time is modelled between the reactor trip signal and reactor trip. Decay heat is modelled according to the ANS 5.1-1971 (Reference 9.6.5-1) standard, with 20-percent uncertainty added.

- The "S" signal is generated when the pressuriser pressure falls below 11.72 MPa (1700 psia). The isolation valves on the core makeup tank injection lines begin to open after the signal setpoint is reached; the valves are then assumed to open linearly. The main feedwater isolation valves are ramped closed between 2 and 7 seconds after the "S" signal. The reactor coolant pumps are tripped 7 seconds after the "S" signal.

- The ADS actuation signals are generated on low core makeup tank levels and the ADS timer delays. A list of the ADS parameters is given in Table 9.6.5-10. Note that the medium and small-break LOCA transients model the minimum valve flow area given in Table 9.6.5-10. ADS Stages 1, 2, and 3 are modelled as discharging through spargers submerged in the IRWST at the appropriate depth.

- The inadvertent ADS actuation and 50.8 mm (2-inch) cold leg break NOTRUMP simulations use a time-dependent containment pressure in the boundary node modelling containment. These containment conditions were generated by providing mass and energy releases from these breaks to the AP1000 plant WGOTHIC minimum containment pressure model (described in Section 13.8 of Reference 9.6.5-3). The WGOTHIC code calculates the containment pressure response. The inadvertent ADS actuation and 50.8 mm (2-inch) cold leg break NOTRUMP simulations then used the time-dependent pressure history curves as generated by WGOTHIC. The 254 mm (10-inch) cold leg break case models a constant containment pressure of 0.101 MPa (14.7 psia) and the DEDVI line break models a constant containment pressure of 0.138 MPa (20 psia).

- The steam generator secondary is isolated immediately after the reactor trip signal, due to closure of the turbine stop valves. The main steam safety valves actuate and remove energy from the steam generator secondary when pressure reaches approximately 8.34 MPa (1210 psia).

A single failure of the passive ESF systems is considered. The limiting failure is one out of four ADS Stage 4 valves failing to open on demand, which is the failure that most severely impacts depressurisation capability. The safety design approach of the AP1000 plant is to depressurise the reactor coolant system to the containment pressure in an orderly fashion such that the large reservoir of water stored in the IRWST is available for core cooling. The mass inventory plots provided for the breaks show the minimum inventory condition generally occurs at the start of IRWST injection. Penalizing the depressurisation is the most conservative approach in postulating the single failure for such breaks.

The analysed medium and small-break LOCA break spectrum includes breaks that exhibit a minimum reactor vessel inventory early in the transient, before the ADS Stage 4 depressurisation phase: the DEDVI line break at 0.138-MPa (20 psia) containment backpressure and 254 mm (10 inch) cold leg break transients. In these transients, the early mass inventory decrease is terminated by injection flow from the accumulators. For consistency, and because the transition to IRWST injection is still a tenuous period of the transients, the conservative failure of one of the ADS Stage 4 valves located off of the non-pressuriser loop is assumed in all cases.

9.6.5.2.1.1 AP1000 Model-Detailed Noding

The AP1000 plant NOTRUMP model was developed in the same fashion as the AP600 NORTUMP model (details of the AP600 NOTRUMP model are provided in Reference 9.6.5-7). Modifications to the AP600 model to create the AP1000 plant model include the following:

- The addition of two core nodes, one foot each in length, to reflect the added active fuel length of this design.
- The ADS-4 flow path resistances were increased to accommodate shortcomings in NOTRUMP identified during the integral test facility simulations, namely, the lack of a detailed momentum flux model in the ADS-4 discharge paths. A detailed calculation of the energy and momentum equations is performed for the ADS-4 piping over a range of flow and pressure conditions to provide a benchmark for the NOTRUMP ADS-4 flow path resistance. The methodology used to determine the resistance increase is described in Reference 9.6.5-9. By increasing the ADS-4 resistances, the onset of IRWST injection is more appropriately calculated. This methodology directly addresses the effect of momentum flux in ADS-4. The ADS-4 resistance increase utilized is computed for the NOTRUMP analyses in this section to be a 79-percent ADS-4 flow path resistance increase.

The AP1000 plant NOTRUMP model noding diagram is provided as Figure F-10 of Reference 9.6.5-9.

9.6.5.2.1.2 Plant Initial Conditions/Steady-State

Steady-state calculations are performed prior to initiating the transient portion of the calculations.

Table 9.6.5-9 contains the most important initial conditions for the transient calculations. The behaviours of the primary pressure and pressuriser level, steam generator pressures, and the core flow rate are stable at the end of the 100-second steady-state calculation.

9.6.5.2.2 NOTRUMP Homogeneous Sensitivity Model

In order to address the uncertainties associated with entrainment in the upper plenum and hot leg following ADS-4 operation, a sensitivity study is performed with the limiting break with respect to these phenomena, effectively maximizing the amount of entrainment downstream of the core. This methodology is described and the original results are presented for the DEDVI line break in detail in Reference 9.6.5-9.

In order to maximize the entrainment downstream of the core for the limiting break with respect to entrainment, NOTRUMP is run with the regions of the upper plenum, hot leg, and ADS-4 lines in a homogeneous fluid condition, with slip = 1, to demonstrate that even with maximum entrainment, the design basis requirements are met.

9.6.5.2.3 Critical Heat Flux Assessment During Accumulator Injection

An assessment is performed of the peak core heat flux with respect to the critical heat flux during the later ADS depressurisation time period for a double-ended rupture of the direct vessel injection line. This time period corresponds to the accumulator injection phase of the transient. The predicted average mass flux at the core inlet and the reactor pressure from the NOTRUMP computer code base model analysis are used as input parameters to critical heat flux correlation as described in Reference 9.6.5-10. The design basis requirements are met provided the maximum heat flux is less than the critical heat flux calculated by the correlation. NOTRUMP has been shown (Reference 9.6.5-9) to adequately predict mass flux and pressure for integral systems tests. The predicted mass flux at the core inlet is on the average constant and corresponds to 35 kg m^{-2} s^{-1} (7.2 lbm ft^{-2} s^{-1}). The key thermal-hydraulic parameters at different times during the ADS depressurisation time period are summarized in the following table.

Time (sec)	UP Pressure (kPa)	UP Pressure (psia)	Mass Flux (kg/m^2s)	Hot Channel Heat Flux (kW/m^2)
400	1196	173.4	35	48.6
450	903	131.0	35	47.2
500	581	84.3	35	46.0
570	314	45.5	35	44.5

For the critical heat flux assessment, the peak core heat flux is applied to simulate the hot channel condition in a conservative manner. No credit is taken for increased flow in the hot channel that is known to occur in rod bundles.

The correlation applied for this assessment is from vertical tube data (Reference 9.6.5-10) and recognizes two regimes depending on the mass flux. The main difference between the two is the mass flux dependence. The equations for the two regimes are as follows:

$$q^*_{CL} = q^*_{CF} + 0.01351\left(D^*\right)^{-0.473}\left(L/D\right)^{-0.533}\left|G^*\right|^{1.45} \quad \text{for low G*}$$

and,

$$q^*_{CH} = q^*_{CF} + 0.05664\left(D^*\right)^{-0.247}\left(L/D\right)^{-0.501}\left|G^*\right|^{0.77} \quad \text{for high G*}$$

The first term of above correlations is,

$$q^*_{CF} = 1.61\left(\frac{A}{Ah}\right)\frac{\left(D^*\right)^{0.5}}{\left[1+\left(\frac{\rho_g}{\rho_l}\right)^{0.25}\right]^2}$$

where A is the flow area and Ah is the heated area.

The dimensionless CHF is calculated as,

$$q^*_{CHF} = \min(q^*_{CL}, q^*_{CH})$$

Dimensionless CHF, G, and D are defined as,

$$q^*_{CHF} = \frac{q''_{CHF}}{h_{fg}\sqrt{\lambda \rho_g g \Delta\rho}}$$

$$G^* = \frac{G}{\sqrt{\lambda \rho_g g \Delta\rho}}$$

$$D^* = \frac{D}{\lambda}$$

where λ is the length scale of the Taylor instability:

$$\lambda = \sqrt{\frac{\sigma}{g\Delta\rho}}$$

Conservative application of this correlation with the AP1000 parameters indicates that the peak AP1000 heat flux during this period is approximately 30 percent or more below the predicted critical heat flux.

This CHF assessment addresses core cooling during a time period where the NOTRUMP computer code may not conservatively predict the core average void fraction. The design basis requirements are met during this period since this CHF assessment indicates peak core heat flux is less than critical heat flux. Cladding temperatures will remain near the coolant saturation temperature, well below the peak cladding temperature limit.

9.6.5.2.4 SBLOCTA Computer Code

The LOCTA-IV computer code (Reference 9.6.5-2) was modified as described in WCAP-10054-P-A (Reference 9.6.5-6) to form SBLOCTA, a small-break LOCA specific version of the LOCTA-IV code. The SBLOCTA code calculates the cladding temperature and oxidation transients for the hot rod and hot assembly average rod, which represent the highest power rod and the average of the highest power fuel assembly in the core. PCT calculations are performed with the SBLOCTA code using boundary conditions from the NOTRUMP calculation. In addition to PCT, SBLOCTA also calculates the maximum local and axial average zirconium-water oxidation reaction based on the Baker-Just oxidation model. In the event that the NOTRUMP code predicts core uncovery in the core average channel, the NOTRUMP boundary conditions will be transferred to the SBLOCTA code to perform fuel rod heatup calculations.

9.6.5.3 Medium and Small Break LOCA Analysis Results

Several medium and small break LOCA transients are analysed using NOTRUMP, and the results of these calculations are presented. The transients documented herein analyse a single failure of one ADS Stage 4 valve on the non-pressuriser side. The results demonstrate that the minimum reactor vessel mixture mass inventory condition occurs for the relatively small system pipe breaks. Larger breaks exhibit a greater margin-to-core uncovery.

9.6.5.3.1 Introduction

The small-break LOCA safety design approach for the AP1000 design is to provide for a controlled depressurisation of the primary system if the break cannot be terminated, or if the non-Class 1 CVS makeup system is postulated to be lost or cannot maintain acceptable plant conditions. Non-Class 1 systems are not modelled in this design basis analysis; the testing conducted in the SPES-2 facility has indicated that the mass inventory condition during small LOCAs is significantly improved when these non-Class 1 systems operate. The core makeup tank level activates primary system depressurisation through the actuation of the ADS. The core makeup tank provides makeup to help compensate for the postulated break in the reactor coolant system. As the core makeup tank level drops, Stages 1 through 4 of the ADS valves are ramped open in sequence. The ADS valve parameters used in the small-break analysis are presented in Table 9.6.5-10. Note that the small-break LOCA transients model the minimum valve flow area. The reactor coolant system depressurises due to the break and the ADS valves, while subcooled water from the core makeup tanks and accumulators enters the reactor vessel downcomer to maintain system inventory. Design basis maximum values of passive core cooling system resistances are applied to obtain a conservative prediction of system behaviour during the small LOCA events.

During controlled depressurisation via the ADS, the accumulators and core makeup tanks maintain system inventory for small-break LOCAs. Once the reactor coolant system depressurises, injection from the IRWST maintains core cooling. For continued injection from the IRWST, the reactor coolant system must remain depressurised. To conservatively model this condition, design maximum resistance values are specified for the IRWST delivery lines.

A series of small-break LOCA calculations are performed to assess the passive core cooling system design performance. In the DBA calculations, the decay heat used is the ANS 5.1-1971 standard (Reference 9.6.5-1) plus 20 percent for uncertainty. This maximizes the core steam generation to be vented. Note that for diverse mitigation analysis, margin is not added to the decay heat because of the low probability of the event combined with a CCF.

Additional detail about some of the breaks analysed in this section are provided as follows:

Inadvertent ADS Actuation

A “no-break” small-break LOCA calculation that uses an inadvertent opening of the 101.6 mm (4 inch) nominal size ADS Stage 1 valves is a situation that minimizes the venting capability of the reactor coolant system. Only the ADS valve vent area is available; no additional vent area exists due to a break. This case demonstrates that sufficient ADS vent area is available to completely depressurise the reactor coolant system and achieve adequate injection from the IRWST as well as long term core cooling by natural circulation containment cooling. The worst single failure for this situation is a failure of one of two ADS Stage 4 valves connected to the non-pressuriser side hot leg. The ADS Stage 4 valves are the largest ADS valves, and they vent directly to the containment with no additional backpressure from the spargers being submerged in the IRWST. The containment pressure is a

conservative, time-dependent containment pressure response. This pressure response is based on iterative execution of the NOTRUMP and WGOTHIC codes. The NOTRUMP code generates the mass and energy releases from the inadvertent ADS actuation simulation, which are then input into the WGOTHIC minimum containment pressure model, which calculates the containment pressure response.

50.8 mm (2 inch) Break in a Cold Leg

A 50.8 mm (2 inch) equivalent diameter break is analysed as a representative break, not specific to a particular pipe connection. The small size of the break leads to a long period of recirculatory flow from the cold leg into the core makeup tanks. This delays the formation of a vapour space in the core makeup tank and therefore the actuation of the ADS. The containment pressure is a conservative, time-dependent containment pressure response. This pressure response is based on iterative execution of the NOTRUMP and WGOTHIC codes. The NOTRUMP code generates the mass and energy releases from the 50.8mm (2-inch) cold leg break simulation, which are then input into the WGOTHIC minimum containment pressure model, which calculates the containment pressure response. Note that both DBA and diverse analyses are presented for this break size. In addition, the diverse analysis assumes nominal initial RCS conditions, PXS performance, and decay heat; these assumptions are appropriate for these events because of the probability of the event and a CCF is low.

Double-Ended Rupture of the Direct Vessel Injection Line

The DEDVI line break evaluates the ability of the plant to recover from a moderately sized break with only half of the total passive core cooling system capacity available. The vessel side of the break of the DEDVI line break is 101.6 mm (4 inches) in equivalent diameter. The double-ended nature of this break means that there are effectively two breaks modelled:

- Downcomer to containment. The direct vessel injection nozzle includes a venturi, which limits the available break area.

- Direct vessel injection line into containment from the cold leg balance line and the broken line core makeup tank.

The containment pressure is conservatively assumed to be 0.138 MPa (20 psia) based on iterative execution of the NOTRUMP and WGOTHIC codes. The NOTRUMP code generates the mass and energy releases from the DEDVI line break, which are input into the WGOTHIC minimum containment pressure model, which calculates the containment pressure response used to confirm the NOTRUMP containment pressure assumption remains conservative.

The peak core heat flux during the accumulator injection period is assessed relative to the predicted critical heat flux as discussed in Section 9.6.5.2.3.

Double-Ended Rupture of the Direct Vessel Injection Line Entrainment Sensitivity

The sensitivity case is performed to assess the effect of higher than expected entrainment in the upper plenum and hot legs on the overall system response and core cooling.

254 mm (10 inch) Break in a Cold Leg

The 254 mm (10 inch) equivalent diameter break models a break size at the upper limit for MBLOCAs.

9.6.5.3.2 Not Used

9.6.5.3.3 DBA Spurious Actuation of Automatic Depressurisation System or Opening of a Pressure Relief Valve Results

This section evaluates the consequences of a spurious ADS or spurious opening of a pressuriser safety valve fault. This evaluation focuses on the ability of the plant safety systems to cope with the associated depressurisation due to a loss of coolant event. The evaluation of short term effects of this fault, such as DNB criteria, is presented in Section 9.6.1.

9.6.5.3.3.1 DBA Credited SSCs

For the DBA LOCA for spurious ADS actuation scenarios, only the Class 1 systems listed in Table 9.6.5-3 are credited, and the same performance requirements discussed in Section 9.6.5.2.1 apply. In addition to the accumulators, the PMS provides the following:

- RT on:
  - Low-2 pressuriser pressure
  - Overtemperature ΔT
- PRHR on Low-2 steam generator narrow range level coincident with Low-2 startup feedwater flow
- CMTs and containment isolation on Low-2 cold leg temperature
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

9.6.5.3.3.2 DBA Results

An ADS actuation signal is spuriously generated and the ADS Stage 1 valves open. The plant is depressurised via the ADS alone. Only safety-related systems are assumed to operate in this and other small-break LOCA cases. The ADS Stage 2 and 3 valves open in sequence after the ADS Stage 1 valves open (Table 9.6.5-11 (sheet 1)). At the 20-percent core makeup tank volume, the operating ADS Stage 4A valve, which is connected to the PRHR inlet pipe, receives a signal to open. After a 60-second delay, both Stage 4B valves (one connected to the non-pressuriser hot leg and the other connected to the PRHR inlet pipe) open. The path that fails to open as the assumed single active failure is the Stage 4A valve connected to the hot leg. The assumed reactor steady-state initial conditions can be found in Table 9.6.5-9. The sequence of events for the transient is given in Table 9.6.5-11.

This case uses a containment backpressure based on the containment pressure history that occurs as a result of the inadvertent ADS actuation. It represents a conservatively low estimate of the expected containment pressure response during the transient. The containment pressurises for an inadvertent ADS actuation as a result of the ADS Stage 4 discharge paths that vent directly to the containment atmosphere. The time-dependent containment pressure curve (Figure 9.6.5-1(c)) was calculated using the mass and energy releases from the NOTRUMP small-break LOCA code, which were used as inputs in the WGOTHIC containment model.

Transient results are shown in Figures 9.6.5-1(a) through 9.6.5-16(b).The transient is initiated by the opening of the two ADS Stage 1 paths. Reactor trip, reactor coolant pump trip, and safety injection signals are generated via pressuriser low-pressure signals with appropriate delays. After generation of the reactor trip signal, the turbine stop valves close. The main feedwater isolation valves begin to close 2 seconds after the "S" signal pressure setpoint is reached. The opening of the ADS valves and the reduction in core power due to reactor trip causes the primary pressure to fall rapidly (Figure 9.6.5-1(a)). Flow of fluid toward the open ADS paths causes the pressuriser to fill rapidly (Figure 9.6.5-2), and the ADS flow becomes two-phase (Figures 9.6.5-3 and 9.6.5-4(a)). The safety injection signal opens the valves isolating the core makeup tanks and circulation of cold water begins (Figures 9.6.5-5 and 9.6.5-6). The core makeup tanks begin to drain (Figures 9.6.5-7 and 9.6.5-8) during the accumulators injection period (Figures 9.6.5-10 and 9.6.5-11). The reactor coolant pumps begin to coast down due to an automatic trip signal following a 7-second delay from the "S" signal.

Continued mass flow through the ADS Stage 1, 2, and 3 valves drains the upper parts of the reactor coolant system (Figure 9.6.5-4(b)). The cold leg sides of the steam generator tubes start to drain, followed by the drop in mixture levels in the hot leg sides. As the ADS Stage 2 and 3 paths begin to open, increased ADS flow causes the primary pressure to continue falling rapidly (Figures 9.6.5-1(a)). As the cold leg sides of the steam generator tubes empty, the cold legs drain and a mixture level forms in the downcomer (Figure 9.6.5-9).

The primary pressure falls below the pressure in the accumulators thus causing the accumulator check valves to open and accumulator delivery to begin (Figures 9.6.5-10 and 9.6.5-11). The accumulators, and then the core makeup tanks inject until they empty. The ADS flow falls off (Figures 9.6.5-3, 9.6.5-4(a), and 9.6.5-4(b)) as the primary pressure decreases. The flow from the accumulators raise the mixture levels in the upper plenum and downcomer (Figures 9.6.5-16(a) and 9.6.5-9).

As the levels in the core makeup tanks reach the ADS Stage 4 actuation setpoint, the ADS Stage 4 valves open as described earlier. Activating the Stage 4 paths (Figures 9.6.5-12(a), 9.6.5-12(b), and 9.6.5-12(c)) leads to reduced flow through ADS Stages 1, 2, and 3 (Figures 9.6.5-3, 9.6.5-4(a), and 9.6.5-4(b)). The reduced flow allows the pressuriser mixture level to fall (Figure 9.6.5-2), and these stages begin to discharge only steam. After the CMTs are empty (Figures 9.6.5-7 and 9.6.5-8), IRWST injection (Figures 9.6.5-13 and 9.6.5-14) does not begin until the pressure in the DVI line drops below the IRWST injection pressure, creating an injection gap (Table 9.6.5-11 and Figures 9.6.5-5, 9.6.5-6, 9.6.5-13, and 9.6.5-14). The overall decrease in reactor vessel mixture inventory (Figure 9.6.5-15(b)) is large enough to result in a core uncovery (Figure 9.6.5-16(a)). At 4000 seconds, the calculation is considered complete; IRWST delivery exceeds the ADS flows (which are removing the decay heat), and the reactor coolant system inventory and reactor vessel mixture inventory are slowly rising (Figure 9.6.5-15(a) and 9.6.5-15(b))

The inadvertent opening of the ADS Stage 1 transient confirms the capability of the minimum venting area to depressurise the reactor coolant system to the IRWST pressure. The analysis indicates that the ADS sizing is sufficient to depressurise the reactor coolant system assuming the worst single failure as the failure of a Stage 4 ADS path to open and the decay heat based on the ANS 5.1-1971 Standard (Reference 9.6.5-1) plus 20 percent, which leads to over estimation of the core steam generation rate. Even under these limiting conditions, IRWST injection is obtained, and the core mixture level recovers, which terminates the cladding heatup transient (Figure 9.6.5-16(b)).

9.6.5.3.3.3 Radiological Consequences

For the purposes of comparison of radiological dose with SAPs Target 4, the spurious activation of the ADS and opening of the pressuriser relief valve are included in the assessment for the MBLOCA scenario presented in Section 9.6.5.3.6.3. This is a conservative assumption, as the analysis described above shows that there is no core heatup during these events.

9.6.5.3.3.4 As Low As Reasonably Practicable Assessment

First of all extensive efforts have been applied to the AP1000 to prevent spurious ADS stage 1, 2, 3 actuation and as a result its probability of occurrence is so low that it is a DBD event. These features and the event classification are summarized in Table 8A-2.

The spurious activation of the ADS and opening of the pressuriser relief valve are included in the ALARP assessment for the MBLOCA scenario, as discussed in Section 9.6.5.3.6.5.

9.6.5.3.3.5 Spurious ADS or Pressuriser Relief Valve Conclusions

The conclusion from the MBLOCA fault applies (Section 9.6.5.3.6.5).

9.6.5.3.4 SBLOCA – 50.8 mm (2-inch) Cold Leg Break Results

This size small LOCA represents the maximum small LOCA that is considered a cliff edge frequent fault. As a result, diverse mitigation needs to be demonstrated.

Two different types of diverse mitigation analysis are provided in the following sections. One demonstrates the reactor can be shut down when considering a CCF that prevents control rod insertion. Such an event is defined as an ATWT. The other demonstrates that adequate core cooling can be provided when analysis considers a CCF the affects the core cooling credited in the DBA. In the diverse core cooling case rod insertion via RT is assumed to occur.

This section contains analysis results for:

- DBA case, where all installed Class 1 SSCs are credited (Section 9.6.5.3.4.1)
- Diverse core cooling cases, where several different sets of SSCs are credited (Section 9.6.5.3.4.2)
- Diverse reactor shutdown cases (ATWT), where a diverse set of SSCs is credited (Section 9.6.5.3.4.3)

9.6.5.3.4.1 DBA Small LOCA Results

9.6.5.3.4.1.1 DBA Credited SSCs

For the DBA of the SBLOCA, only the Class 1 systems listed in Table 9.6.5-3 are credited, and the performance parameters described in Section 9.6.5.2.1 apply. In addition to the accumulators, the PMS provides the following:

- RT, PRHR, CMTs and containment isolation on Low-2 pressuriser pressure
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

9.6.5.3.4.1.2 DBA Analysis Results

This case models a 50.8 mm (2 inch) break occurring in a cold leg on the pressuriser side of the RCS. The reactor steady-state initial conditions assumed for this transient can be found in Table 9.6.5-9. The event times for this transient are given in Table 9.6.5-11 (sheet 2).

This case uses a containment backpressure based on the containment pressure history that occurs as a result of the 50.8 mm (2 inch) cold leg break. It represents a conservatively low estimate of the expected containment pressure response during the transient. The containment pressurises for a 50.8 mm (2 inch) cold leg break as a result of the break and the ADS Stage 4 discharge paths that vent directly to the containment atmosphere. The time-dependent containment pressure curve (Figure 9.6.5-17(c)) was calculated using the mass and energy releases from the NOTRUMP small-break LOCA code, which were used as inputs in the WGOTHIC containment model.

The transient results are shown in Figures 9.6.5-17(a) through 9.6.5-35. The break opens at time zero, and the pressuriser pressure begins to fall as shown in Figure 9.6.5-17(a) as mass is lost out the break. The pressuriser mixture level initially decreases as given in Figure 9.6.5-18. The liquid and vapour flow out of the break is shown in Figures 9.6.5-32 and 9.6.5-33. The pressuriser pressure falls below the reactor trip set point, causing the reactor to trip (after the appropriate time delay) and causing isolation of the steam generator main steam lines. The core makeup tank discharge isolation valves for both core makeup tanks and the PRHR delivery line isolation valve open after an “S” signal occurs (with appropriate delays); the reactor coolant pumps trip after an “S” signal with a 7-second delay. The reactor coolant system is cooled by natural circulation with decay heat being removed by the steam generators through their safety valves, through the break, and via the PRHR. The PRHR heat removal and integrated heat removal are shown in Figure 9.6.5-34 and Figure 9.6.5-35. Once the core makeup tank isolation valves open, the core makeup tanks begin to inject borated water into the reactor coolant system as shown in Figures 9.6.5-22 and 9.6.5-23.

As time proceeds, the loops drain to the reactor vessel. The mixture level in the downcomer begins to drop as seen in Figure 9.6.5-21. The core makeup tank reaches the 67.5-percent volume, and after an appropriate delay, the ADS Stage 1 valves open. When the ADS is actuated, the mixture level increases in the pressuriser (Figure 9.6.5-18) because an opening has been created at the top of the pressuriser. After these valves open, a rapid depressurisation occurs as seen in Figure 9.6.5-17(a); the accumulator gas cover pressure is reached and the

accumulators begin to inject. The injection flow from the core makeup tanks are shown in Figures 9.6.5-22 and 9.6.5-23, and from the accumulators, in Figures 9.6.5-24 and 9.6.5-25.

As Figures 9.6.5-22 and 9.6.5-23 indicate, when the accumulators begin to inject, the flow from both core makeup tanks is reduced, and the flow is temporarily reversed due to the pressurisation of the DVI line and core makeup tanks injection lines by the accumulators.

The ADS Stage 2 valves open, continuing the RCS depressurisation as shown in Figure 9.6.5-17(a). ADS Stage 3 valves open, thereby increasing the system venting capability. Figures 9.6.5-31(a), 9.6.5-31(b), and 9.6.5-31(c) indicate the instantaneous liquid, instantaneous vapour, and integrated total mass discharged from the ADS Stage 1-3 valves. The ADS Stage 4 valves open when the core makeup tank water volume is reduced to 20 percent. Figures 9.6.5-28(a), 9.6.5-28(b), and 9.6.5-28(c) indicate the instantaneous liquid, instantaneous vapour, and integrated total mass discharged from the ADS Stage 4 valves. After the ADS Stage 4 paths open, the pressuriser begins to drain mixture into the hot legs as seen in Figure 9.6.5-18. After the CMTs are empty, IRWST injection does not begin until the pressure in the DVI line drops below the IRWST injection pressure, creating an injection gap (Table 9.6.5-11 and Figures 9.6.5-22, 9.6.5-23, 9.6.5-26, and 9.6.5-27). The mass inventory shown in Figure 9.6.5-29(a) considers the primary inventory to be the reactor coolant system proper, including the pressuriser; the mass present in the passive safety system components is not included. The mass inventory shown in Figure 9.6.5-29(b) considers the reactor vessel mixture inventory, including the downcomer, lower plenum, core fluid channel, upper plenum, and upper head, and clearly shows the decrease in the inventory during the injection gap period. Once the pressures in the DVI lines drop below the IRWST injection pressure, flow enters the reactor vessel from the IRWST. The mixture level in the reactor vessel is approximately at the hot leg elevation as shown in Figure 9.6.5-30(a) for the majority of the transient; however, the upper plenum mixture level drops during the injection gap period and the core uncovers as the mixture level drops below the top of the active fuel. The 50.8 mm (2-inch) break case exhibits a cladding heatup transient as a result of the core uncovery as shown in Figure 9.6.5-30(b).

Section 9.6.6 describes the analysis that has been performed to demonstrate long-term safe shutdown is achieved following LOCAs.

9.6.5.3.4.1.3 Radiological Consequences

The consequences of an SBLOCA are conservatively estimated based on the consequences of an MBLOCA. With limited fuel damage (less than 1 percent predicted for SBLOCA) and a concurrent release to containment, the releases are less than 10 percent of those considered in the MBLOCA doses presented in Section 9.6.5.3.6.3 which considered up to 10 percent fuel damage. Therefore, doses that are ten percent of the MBLOCA doses listed in Section 9.6.5.3.6.3 are presented herein. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

Offsite dose: 0.26 mSv Worker dose: 0.60 mSv

These doses are within the Target 4 BSL for these frequent faults (1 mSv offsite and 20 mSv onsite).

9.6.5.3.4.2 Diverse Core Cooling SBLOCA Mitigation

This section describes the diverse mitigation of this cliff edge frequent fault small LOCA (Reference 9.6.5-13). This diverse analysis focuses on the cliff-edge SBLOCA size of up to a

50.8 mm (2-inch) equivalent break diameter. Above this size is considered DB1 and does not require diverse mitigation.

The primary design basis analysis presented in Section 9.6.5.3.4.1 for the SBLOCA assumes the full suite of Class 1 equipment is available for mitigation including a worst-case single failure. In order to show diverse core cooling mitigation, three additional cases are presented. Three diversity cases are analysed using different combinations of Class 1 SSCs, and in some cases Class 2 SSCs. The SSCs credited in these cases are listed in Table 9.6.5-4.

For diverse core cooling the following 3 diverse cases are provided. Diversity Case 1 utilises a subset of the Class 1 SSCs noted for the primary DB case, including the PMS, PRHR, CMTs, ADS 4 and IRWST. Diversity Case 2 utilises a different set of Class 1 SSCs, including the PMS, CMTs, ADS 1, 2, 3, and 4 and IRWST. Diversity Case 3 utilises both Class 1 and Class 2 SSCs, including DAS, PRHR, Accumulator, ADS 1, 2, and 3, RNS. For Diversity Cases 1 and 2, core cooling is provided by Class 1 SSCs including actuation from the Class 1 PMS. For Diversity Case 3, core cooling is also provided by Class 1 SSCs except pumped injection by the Class 2 RNS, and actuation by the Class 2 DAS.

Table 9.6.5-4 lists the SSCs credited in these different cases. As this is a frequent fault, diverse means of providing the Category A safety functions is provided.

The next three sections discuss core cooling analysis of an SBLOCA using diverse mitigation.

For Diversity Cases 1 and 2, Section 9.6.6 describes the analysis that has been performed to demonstrate long-term safe shutdown is achieved following LOCAs. For Diversity Case 3, long-term safe shutdown is achieved by switching suction sources (RNS and IRWST).

9.6.5.3.4.2.1 Diverse Core Cooling Mitigation SBLOCA Event, Case 1

The Diversity Case 1 credited SSCs include the PMS, PRHR, CMTs, ADS 4, IRWST injection, and containment recirculation. Table 9.6.5-11 (sheet 3) shows the sequence of events. Figures 9.6.5-95 through 98 show the plant behaviour. The PMS provides the following:

- RT on Low-2 pressuriser pressure
- PRHR, CMTs, and containment isolation on Low-2 pressuriser pressure
- ADS stage 4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

The PRHR HX and the break cause the RCS pressure to decrease, such that even without credit for ADS stages 1, 2, and 3, the RCS pressure has dropped to 2.15 MPa (313 psig) when ADS stage 4 is actuated at about 3400 sec. Note that the ADS stage 4 valves and piping are designed to actuate with an RCS pressure of 1.4 MPa (200 psig) and have been shown to remain operable up to pressures of 4.14 MPa (600 psig) for use in PSA sequences. This analysis shows that the RCS pressure at the time of ADS stage 4 actuation is 2.15 MPa (313

psia) which is somewhat above the design actuation pressure but is significantly below the pressure assumed in the PSA.

This analysis shows that adequate core cooling is provided with no core uncovery.

9.6.5.3.4.2.2 Diverse Core Cooling Mitigation SBLOCA Event, Case 2

The Diversity Case 2 credited SSCs include the PMS, CMTs, ADS 1-4, IRWST injection, and containment recirculation. Table 9.6.5-11 (sheet 4) shows the sequence of events. Figures 9.6.5-99 through 101 show the plant behaviour. The PMS provides the following:

- RT on Low-2 pressuriser pressure
- CMTs and containment isolation on Low-2 pressuriser pressure
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

This case shows that the initial SG secondary side inventory is sufficient to limit the RCS pressure and allow for adequate ADS performance even though without the PRHR the RCS pressure is somewhat higher.

This analysis shows that adequate core cooling is provided with no core uncovery. In addition, it shows that the ADS stage 1 actuation at an elevated pressure due to PRHR being out of service still leads to successful event mitigation.

9.6.5.3.4.2.3 Diverse Core Cooling Mitigation SBLOCA Event, Case 3

The Diversity Case 3 credited SSCs include the DAS, PRHR, accumulators, ADS 1-3, RNS pumped injection, and containment recirculation. Table 9.6.5-11 (sheet 5) shows the sequence of events. Figures 9.6.5-102 through 105 show the plant behaviour. Manual RNS injection is credited via the plant control system (PLS). DAS provides:

- RT and PRHR on Low-2 pressuriser level
- Manual ADS 1-3 and containment recirculation
- PCS and containment isolation on High containment temperature

In this case, the PRHR and the accumulators keep the core cooled and covered until the operator take action to align and start the RNS pumps and actuate ADS stages 1, 2, and 3. The PRHR assists by condensing steam and draining the condensate into the RV through the CLs. The break location is placed on the bottom of one of the CLs on the PRHR side to minimize this benefit. If the break were on the other loop or on the top of the CL it would extend the time available for operator action.

This analysis shows that adequate core cooling is provided with no core uncovery. In addition, it shows that the operators have ample time to perform the required manual actions, more than 1 hour.

Note that Reference 9.6.5-13 contains a sensitivity case from Case 3 which credits the same SSCs except for ADS stages 1, 2, and 3. This case shows that a limited amount of nitrogen gas is injected from the accumulators because the RCS pressure only drops slightly below the accumulator empty pressure. This nitrogen is expected to result in a small degradation of the PRHR HX performance however the PRHR HX is predicted to maintain this RCS pressure and allow for adequate RNS pumped injection. This case credits operator action at one hour. An additional sensitivity case was also performed assuming operator action at two hours. For this case, the core would still be adequately cooled however there would be a core uncovery resulting in a heat-up significantly below the peak cladding temperature limit.

9.6.5.3.4.3 Diverse ATWT for SBLOCA

Two additional cases are provided to demonstrate diverse ATWT mitigation for SBLOCAs in Table 9.6.5-4.

For diversity Case 4, an SBLOCA with a PMS CCF, the credited SSCs include both Class 1 and Class 2 SSCs; DAS, RCCAs, PRHR, CMTs, ADS 1-4, IRWST injection, and containment recirculation are all utilised. The DAS provides:

- RT on High hot leg temperature
- PRHR and CMTs on Low-2 pressuriser level
- Manual ADS 1-4, IRWST injection, and containment recirculation
- PCS and containment isolation on High containment temperature

For Case 4, the RCS will lose coolant which will cause the pressuriser level to decrease. Assuming that the PMS does not respond, DAS will sense the low pressuriser level and generate signals to automatically trip the reactor, turbine, RCPs, and start the PRHR and CMTs. Actuation of those features will shut down the reactor core and provide short-term core cooling. Later on, due to the LOCA causing continued loss of coolant, the operators would manually actuate ADS, IRWST injection, and containment recirculation through DAS to maintain core cooling.

For diversity Case 5, an SBLOCA with a mechanical CCF of the control rods, the Class 1 credited SSCs include PMS, PRHR, CMTs, ADS 1-4, IRWST injection, and containment recirculation. The PMS provides:

- No reactor trip due to mechanical failure
- PRHR, CMTs, and containment isolation on Low-2 pressuriser pressure
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS isolation on High-2 containment pressure

For Case 5, the rods fail to insert due to a CCF mechanical failure. The PMS trip of the RCPs together with the loss of coolant causes voiding in the core which results in a rapid power

reduction. With PMS also actuating the CMTs the core would be completely shut down by the boron addition. Such an ATWT case is less limiting than others because main feedwater is not lost as the initiating event and the LOCA drains the pressuriser which increases its steam space; both of these factors reduce the peak RCS pressure. In this case, PMS also automatically starts the PRHR, which would provide short-term decay heat removal. Later on, due to the LOCA causing continued loss of coolant, the PMS would automatically actuate ADS, IRWST injection and containment recirculation to maintain core cooling.

9.6.5.3.4.4 Diverse Radiological Consequences

The diverse core cooling scenarios demonstrate that there is no significant fuel damage. For a diverse mitigation radiological consequences analysis better estimate assumptions would be credited. This would include reactor coolant system activity levels significantly lower than those modelled for the DBA and better activity retention in containment. In addition better estimate atmospheric dispersion factors would be used. Therefore, a diverse mitigation radiological consequences analysis would show that the doses for the diverse core cooling scenario would be much less than for the design basis LOCA. The diverse mitigation analyses would not have to meet the Target 4 BSL for frequent faults and would meet the Target 4 BSL for infrequent faults. Further, while consideration of a containment isolation failure (if required) would result in higher doses, the results would be much less than those presented in Section 9.8.5.2.3.3 for a design basis RNS break outside containment, which are within the Target 4 BSL for infrequent faults with IEF < 1E-04 (100 mSv offsite and 500 mSv onsite).

9.6.5.3.4.5 As Low As Reasonably Practicable Assessment

For this event, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

In addition, since smaller SBLOCAs are frequent faults, diverse core cooling has been demonstrated in three cases using different sets of SSCs. For the small-break loss of coolant accident, the two diversity cases that credit the Class 1 SSCs were shown to be adequate to meet DB requirements.

The third diversity case which includes other Class 1 safety functions as well as RNS and the DAS functions, which are Class 2, are also shown by analysis to meet the corresponding requirements for this event. See Reference 9.6.5-12 for additional discussions on these diverse mitigation features.

It was determined that an increase in the RNS pump head would not significantly increase the plant safety for this event.

A detailed ALARP assessment is documented in Reference 9.6.5-13. The following information developed in this assessment supports the justification of the use of the RNS for RCS injection as the diverse mitigation of frequent SBLOCA faults:

- The upper range ‘cliff edge’ small break LOCA was analysed only crediting the equipment identified for the diverse mitigation, including the PRHR HX, accumulators, ADS Stage 1, 2, and 3, and the RNS pumps. The accident was successfully mitigated even with delayed operator actions times (up to 2 hours) to align the RNS for injection and manually actuate ADS. This analysis shows large margin to the operator action time expected when the emergency operating procedures are followed.

- The benefit of increasing the RNS pump injection pressure for the diverse mitigation case is insignificant because the PRHR and ADS Stage 1, 2 and 3 are able to reduce the RCS pressure to the RNS pump cut-in pressure. Note that the increased RNS pump pressure does not change / eliminate the need for the operator to take manual action (to align and start the RNS pumps). Changing the RNS pump injection and the related system impacts would result in potential reductions in RNS pump reliability without a significant increase in safety benefits.
- The benefit of adding a new water storage tank to replace the cask loading pit (CLP) option has essentially no safety benefit. Adding a new tank results in significant cost impacts without a meaningful increase in safety benefits.
- The benefit of automatically aligning and starting injection from the RNS has essentially no safety benefit and may even reduce safety because of the potential of failures for such a complex interlock. The number of different RNS operating alignments as well as the use of two different suction supplies (IRWST or CLP) results in the complexity of automatic control. Given the long-time available for operator action, the reliability of the operator actions will only contribute a small amount to the RNS unreliability. The cost of adding and maintaining the automatic controls would not be so large; however, the safety benefit is negligible.
- The benefit of automatically actuating PRHR on a low pressuriser level DAS signal does have some safety benefit to prevent PCT excursions and to provide some additional time for operator actions. The impact to the plant would be minor, since DAS already has pressuriser level sensors as well as PRHR valve controls. However, as the effort to implement is not considered to be overly arduous; this DAS function is incorporated into the AP1000 design.

Providing further means of removing decay heat or tripping the reactor in addition to these functions would not be significantly reduce the PSA risk for this event.

9.6.5.3.4.6 SBLOCA Conclusions

The DB analysis shows that for the SBLOCA fault, the acceptance criteria defined in Section 9.6.5.0 are met. Two diversity cases were analysed to show that different combinations of Class 1 SSCs result in successful mitigation, and a third case showed that a combination of Class 1 and Class 2 SSCs also meet the LOCA acceptance criteria.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.5.3.5 Direct Vessel Injection Line Break Results

9.6.5.3.5.1 DBA Credited SSCs

For the DBA of the DVI scenarios, only the Class 1 systems listed under the MBLOCA event are available (See Section 9.6.5.3.6.1) with the exception of only one accumulator, one CMT,

and one IRWST direct injection line being available since the others spill as a result of the initiating fault. The same performance requirements discussed in Section 9.6.5.2.1 apply.

9.6.5.3.5.2 Results of Design Basis Analysis

This case models the double-ended rupture of the DVI line at the nozzle into the downcomer. The broken loop injection system (consisting of an accumulator, a core makeup tank, and an IRWST delivery line) is modelled to spill completely out of the DVI line side of the break into containment. The steady-state reactor coolant system conditions for this transient are shown in Table 9.6.5-11 (sheet 6). Minimum resistances are applied to the broken loop IRWST injection line to maximize the spill to containment, thus minimizing the reactor coolant system mass inventory. The containment pressurisation is calculated using the mass and energy releases from the NOTRUMP small-break LOCA code in the WGOTHIC minimum containment pressure model and demonstrates that the 0.138 MPa abs (20 psia) containment backpressure assumption is conservative.

This case uses a containment backpressure defined to be a constant 0.138 MPa abs (20 psia). While not exactly reflecting the containment pressure history that occurs as a result of the DVI line break, it represents a conservatively low estimate of the expected containment pressure response during a DEDVI transient. The containment pressurises for a DEDVI line break as a result of the break mass and energy releases in addition to the ADS-4 discharge paths that vent directly to the containment atmosphere.

The event times for this transient are shown in Table 9.6.5-11 (sheet 6). Transient results are shown in Figures 9.6.5-36 through 9.6.5-55. The break is assumed to open instantaneously at 0 seconds. The accumulator on the broken loop starts to discharge via the DVI line to the containment. Figure 9.6.5-36 shows the subcooled discharge from the downcomer nozzle, which causes a rapid RCS depressurisation (Figure 9.6.5-38(a)). A reactor trip signal is generated, followed by generation of the “S” signal. Following a delay, the isolation valves on the core makeup tank and PRHR delivery lines begin to open. The PRHR heat removal and integrated heat removal are shown in Figure 9.6.5-54 and Figure 9.6.5-55. The “S” signal also causes closure of the main feedwater isolation valves after a 2-second delay and trips the reactor coolant pumps after a 7-second delay. The opening of the core makeup tank isolation valves allows the broken loop core makeup tank to discharge directly to the containment (Figure 9.6.5-39), and a small circulatory flow develops through the intact loop core makeup tank (Figure 9.6.5-40).

As the pressure falls, the reactor coolant system fluid saturates, and a mixture level forms in the upper plenum and then falls to the hot leg elevation (Figure 9.6.5-41). The upper parts of the reactor coolant system start to drain, and a mixture level forms in the downcomer (Figure 9.6.5-42) and falls below the elevation of the break. Two-phase discharge, then vapour flow occurs from the downcomer side of the break (Figure 9.6.5-37).

In the core makeup tank connected to the broken loop, a level forms and starts to fall. The ADS Stage 1 setpoint is reached, and the ADS Stage 1 valves open after the signal delay time elapses. The ensuing steam discharge from the top of the pressuriser (through the ADS valves; Figures 9.6.5-43(a), 9.6.5-43(b), and 9.6.5-43(c)) increases the reactor coolant system depressurisation rate. The depressurisation rate is also increased due to the steam discharge from the downcomer to the containment (Figure 9.6.5-37) as the downcomer mixture level falls below the DVI nozzle (Figure 9.6.5-42).

During the initial portion of the DEDVI line break, only liquid flows out the top of the core (Figure 9.6.5-45). Soon, steam flow follows (Figure 9.6.5-46) correlating with the void fraction increase in the core (Figure 9.6.5-44). The break in the downcomer stalls fluid flow

into the bottom of the core (Figure 9.6.5-47) leaving insufficient liquid in the upper plenum. The mixture level, therefore, starts to decrease (Figure 9.6.5-41). The mixture level falls early in the transient and then recovers slightly as flow slowly re-enters the core from the downcomer (Figure 9.6.5-41 compared to Figure 9.6.5-47).

The ADS Stage 2 valves open after the appropriate time delay following the actuation of ADS Stage 1. The intact loop accumulator starts to inject into the downcomer (Figure 9.6.5-50) causing the mixture level in the downcomer to slowly rise (Figure 9.6.5-42). The mixture level also increases slightly within the upper plenum.

The ADS Stage 3 valves open upon completion of the time delay of 120 seconds following the actuation of ADS Stage 2. The broken loop core makeup tank level reaches the ADS Stage 4 setpoint, but the ADS Stage 4 valves do not open until the minimum time delay between the actuation of ADS Stages 3 and 4 occurs. Two-phase discharge ensues through three of the four Stage 4 paths (Figures 9.6.5-48(a), 9.6.5-48(b), and 9.6.5-49). During the same time frame, the broken loop core makeup tank and accumulator empty rapidly.

The fluid level at the top of the intact loop core makeup tank starts to decrease slowly (Figure 9.6.5-52) because injection from the tank has begun (Figure 9.6.5-40). The intact loop core makeup tank injection is temporarily reduced and then reversed as the intact loop accumulator injects (Figure 9.6.5-50). Following accumulator injection, the core makeup tank injects continuously until empty.

During the period of accumulator injection, the downcomer mixture level rises slowly (Figure 9.6.5-42). Figure 9.6.5-53(a) presents the RCS mass inventory, and Figure 9.6.5-53(b) presents the reactor vessel mixture inventory, which includes the downcomer, lower plenum, core fluid channel, upper plenum, and upper head. Both figures also show the increase in inventory due to the accumulator injection. With injection available only from the intact loop core makeup tank, the downcomer level remains fairly constant; however, reactor vessel mixture coolant system inventory depletion continues until sufficient IRWST injection flow can be introduced. The level in the upper plenum is maintained near the hot leg elevation (Figure 9.6.5-41) throughout the remainder of the transient.

Once the pressure in the broken DVI line falls below that in the IRWST discharge piping, the water from the tank begins spilling to containment.

Stable, but decreasing, injection continues from the intact loop core makeup tank as the inventory slowly depletes; the reactor coolant system pressure declines slowly. The reactor coolant system pressure continues to fall until it drops below that of the IRWST and injection begins (Figure 9.6.5-51). With the reduced initial RCS inventory recovery from a single accumulator, CMT, and IRWST injection path available for the DEDVI line break, the minimum RCS inventory occurs after the initiation of continuous IRWST injection flow. After injection flow greater than the sum of the break and ADS flows exists, a slow rise in the reactor vessel mixture inventory (Figure 9.6.5-53(b)) occurs. Since no core uncovery is predicted for this scenario, no cladding heatup occurs.

The critical heat flux (CHF) assessment described in Section 9.6.5.2.3 addresses core cooling during a time period where the NOTRUMP computer code may not conservatively predict the core average void fraction. The design basis requirements are met during this period since this CHF assessment indicates peak core heat flux is less than critical heat flux. Cladding temperatures will remain near the coolant saturation temperature, well below the peak cladding temperature limit.

Section 9.6.6 describes the analysis that has been performed to demonstrate long-term safe shutdown is achieved following LOCAs.

9.6.5.3.5.2.1 Direct Vessel Injection Line Break (Entrainment Sensitivity) Results

In order to assess the potential impact of higher than expected entrainment in the upper plenum and hot legs on the overall system response and core cooling, an AP1000 plant sensitivity run was performed. The simulation utilizes the same initial conditions as the base DEDVI line break case presented in Section 9.6.5.3.5. The transient response is essentially identical until ADS-4 actuation, at which time the bounding entrainment conditions are included in the analysis by assuming homogenous conditions in the regions downstream of the core (upper plenum, hot leg, and PRHR inlet). In addition, since homogenous treatment of these regions will eliminate the pressure drop effect of the accumulated mass stored in the upper plenum, the NOTRUMP model was conservatively adjusted to account for this effect following the transition of the ADS-4 flow paths to noncritical conditions.

The event times for this transient are shown in Table 9.6.5-11 (Sheet 8). Transient results are shown in Figures 9.6.5-79(a) through 9.6.5-90. Figures 9.6.5-79(a) and 9.6.5-79(b) present comparisons of the pressure in the upper portion of the downcomer between the base and sensitivity cases. The sensitivity case results in higher pressure in the upper portion of the downcomer and subsequently results in delayed IRWST injection (Figure 9.6.5-80). This can also be observed in the intact DVI line flow, which comprises all intact injection flow components (accumulator, CMT, and IRWST) per Figure 9.6.5-81, and the pressuriser mixture level response (Figure 9.6.5-90), which follows the change in pressure response. As expected, the initial ADS-4 liquid discharge is much higher (Figure 9.6.5-82) until the upper plenum and hot leg region inventory is depleted (Figure 9.6.5-83). The net effect is a decrease in the ADS-4 vapour discharge rate (Figure 9.6.5-84) and subsequently higher RCS pressure.

Due to the elimination of the inventory stored in the upper plenum, the downcomer mass is also reduced (Figure 9.6.5-85). Since the static head that existed in the upper plenum is eliminated when the model is made homogenous, the downcomer mixture is subsequently driven into the core as the static heads equilibrate. This results in the core region mass increasing initially due to the introduction of cold downcomer fluid to the core region (Figure 9.6.5-86(a) and 9.6.5-86(b)). The net effect of the sensitivity case is that the vessel inventory is substantially decreased over the base model simulation (Figure 9.6.5-87); however, this inventory is sufficient to provide adequate core cooling because the ADS-4 continually draws liquid flow through the core (Figure 9.6.5-82). Even though there is no liquid storage in the upper plenum for the homogenous case (Figure 9.6.5-88), the core collapsed liquid level (Figure 9.6.5-89(a) and 9.6.5-89(b)) is not impacted significantly.

This sensitivity demonstrates that the AP1000 plant response is relatively insensitive to upper plenum and hot leg entrainment. Even with the assumption of homogenous fluid nodes above the core, adequate core cooling is demonstrated. No significant core uncovery/heatup is predicted for this scenario.

9.6.5.3.5.3 Radiological Consequences

The consequences of a DVI line break are bounded by those of an MBLOCA. With limited fuel damage and a concurrent release to containment, the releases are the same as those considered in the medium break LOCA doses presented in Section 9.6.5.3.6.3. Therefore, the medium break LOCA doses from Section 9.6.5.3.6.3 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

Offsite dose: 2.6 mSv Worker dose: 6.0 mSv

These doses are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite).

9.6.5.3.5.4 Diverse Mitigation

Diverse mitigation for this event is not required as it is an infrequent fault classified as DB1.

9.6.5.3.5.5 As Low As Reasonably Practicable Assessment

The ALARP assessment for the MBLOCA fault applies with the exception that only one accumulator and one CMT are available. Refer to Section 9.6.5.3.6.5.

9.6.5.3.5.6 DVI Line Break Conclusions

The DB analysis shows that for the DVI line break fault, the acceptance criteria defined in Section 9.6.5.0 are met.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.5.3.6 MBLOCA – 254 mm (10-inch) Cold Leg Break Results

9.6.5.3.6.1 DBA Credited SSCs

As the MBLOCA event is classified as an infrequent fault (DB1), a diverse means of providing the required Category A safety functions are not required. For the MBLOCA fault, the available Class 1 SSCs are shown below.

In addition to the accumulators, the PMS provides the following:

- RT, PRHR, CMTs and containment isolation on Low-2 pressuriser pressure
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS stage 4 signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

9.6.5.3.6.2 Results of Design Basis Analysis

This case models a 254 mm (10-inch) break occurring in the cold leg connected to the balance line of CMT-1. The reactor steady-state initial conditions assumed for this transient are found in Table 9.6.5-9. The event times for this transient are given in Table 9.6.5-11 (Sheet 7).

Transient results are shown in Figures 9.6.5-56(a) through 9.6.5-78. The break opens at time zero, and the pressuriser pressure begins to fall, as shown in Figures 9.6.5-56(a), as mass is lost out the break. The pressuriser mixture level initially decreases as given in Figure 9.6.5-57. The break fluid flow is shown in Figures 9.6.5-75 and 9.6.5-76 for the liquid and vapour components respectively. The pressuriser pressure falls below the reactor trip set point, which causes the reactor to trip (after the appropriate time delay) and isolation of the steam generator main steam lines. The core makeup tank discharge isolation valves for both CMTs and the PRHR delivery line isolation valves open after an "S" signal occurs (with appropriate delays); the reactor coolant pumps trip after an "S" signal with a 7-second delay. The reactor coolant system is cooled by natural circulation with energy being removed by the steam generator safety valves, the core makeup tanks, and the PRHR heat exchanger. The PRHR heat removal rate and integrated heat removal are shown in Figure 9.6.5-77 and Figure 9.6.5-78. Once the core makeup tank isolation valves open, the core makeup tanks begin to inject borated water into the reactor coolant system as shown in Figures 9.6.5-61 and 9.6.5-62.

As time proceeds, the loops drain to the reactor vessel. The mixture level in the downcomer begins to drop as seen in Figure 9.6.5-60, and the core remains completely covered with the exception of a few short oscillatory time intervals in which the mixture level drops below the active fuel (Figure 9.6.5-69). Due to the size and location of the break involved, the accumulator setpoint is reached prior to the core makeup tanks transitioning from recirculation to injection mode. The flows from the core makeup tanks are shown in Figures 9.6.5-61 and 9.6.5-62, and from the accumulators, in Figures 9.6.5-63 and 9.6.5-64. Core makeup tank 2 reaches the 67.5-percent volume first, and after an appropriate delay, the ADS Stage 1 valves open. When the ADS is actuated, the mixture level increases in the pressuriser (Figure 9.6.5-57) because an opening has been created at the top of the pressuriser. After these valves open, a more rapid depressurisation occurs as seen in Figure 9.6.5-56(a).

During the initial portion of the 254 mm (10-inch) break, both liquid and steam flow out the top of the core (Figures 9.6.5-71 and 9.6.5-72) as the void fraction in the core increases (Figure 9.6.5-73). The break in the cold leg draws fluid from the bottom of the core, leaving insufficient liquid in the upper plenum. The mixture level, therefore, starts to decrease (Figure 9.6.5-69). The mixture level falls until accumulator flows enter the downcomer (Figures 9.6.5-63 and 9.6.5-64).

As Figures 9.6.5-61 and 9.6.5-62 indicate, when the accumulators begin to inject, the flow from both core makeup tanks is reduced and briefly reversed due to the pressurisation of the CMT injection lines by the accumulators. The opening of ADS Stage 2 valves maintains the depressurisation rate as shown in Figure 9.6.5-56(a). ADS Stage 3 valves subsequently open. This increases the system venting capability. Figures 9.6.5-70(a), 9.6.5-70(b), and 9.6.5-70(c) indicate the instantaneous liquid, instantaneous vapour, and integrated total mass discharge from the ADS Stage 1-3 valves respectively. The ADS Stage 4 valves open when the core makeup tank water volume is reduced to 20 percent. Figures 9.6.5-67(a), 9.6.5-67(b), and 9.6.5-74 indicate the instantaneous liquid, instantaneous vapour, and integrated total mass discharged from the ADS Stage 4 valves. After the ADS Stage 4 path opens, the pressuriser begins to drain mixture into the hot legs as seen in Figure 9.6.5-57. The Figure 9.6.5-68(a) mass inventory plot considers the primary inventory to be the reactor coolant system proper, including the pressuriser; the mass present in the passive safety system components is not included. The Figure 9.6.5-68(b) mass inventory plot considers the reactor vessel mixture inventory, including the downcomer, lower plenum, core fluid channels, upper plenum, and upper head. Once the downcomer pressure drops below the IRWST injection pressure, flow enters the reactor vessel from the IRWST. The mixture level in the reactor vessel is

approximately at the hot leg elevation as shown in Figure 9.6.5-69 throughout this transient; core uncovery does not occur for any prolonged period of time and may be deemed negligible. As such, the 254 mm (10-inch) break case exhibits large margins to the peak cladding temperature acceptance criteria of 1204.4°C (2200°F).

9.6.5.3.6.3 Radiological Consequences

The evaluation of the radiological consequences of a postulated MBLOCA assumes that as a result of the accident, 10 percent of the fuel rods are damaged such that the activity contained in the fuel-cladding gap is released to the reactor coolant. Activity is released to the containment via the break. The dose calculations take into account the release of activity by way of the containment purge line prior to its isolation near the beginning of the accident and the release of activity resulting from containment leakage. Purge of the containment for hydrogen control is not an intended mode of operation and is not considered in the dose analysis. While the normal residual heat removal system is capable of post-LOCA cooling, it is not a safety-related system and may not be available following the accident. If it is operable, it would be used only if the source term is not far above the normal shutdown primary coolant source term. It is assumed that core cooling is accomplished by the passive core cooling system, which does not pass coolant outside of containment. Thus, there is no recirculation leakage release path to be modelled.

9.6.5.3.6.3.1 Source Term

The most significant radionuclide releases are the noble gases, alkali metals, and iodines. The release of activity to the containment consists of two parts. The initial release is the activity contained in the reactor coolant system. This is followed by the release of core activity.

All activity in the fuel rod gap of the damaged fuel is assumed to be released to the coolant. Based on Table 7.3 of Reference 9.6.5-4, the gap fraction is assumed to be 3 percent of the core inventory for iodines, 10 percent for noble gases, and 4 percent for alkali metals. To address the fact that the failed fuel rods may have been operating at power levels above the core average, the source term is increased by a lead rod radial peaking factor of 1.75 which bounds the COLR limit of 1.72.

The core is assumed to remain covered by water post-accident. Therefore, the modelling is consistent with the wet phase described in Reference 9.6.5-4.

The release from the fuel is assumed to begin at 120 seconds. The fraction of gap activity released is 1.0 for noble gases, 1.0 for iodines, and 1.0 for alkali metals. The water covering the core is assumed to retain some of the radionuclides released from the core. The iodine activity is all assumed to enter into solution with 60 percent of the iodine assumed to convert to the elemental form and then enter the containment atmosphere, consistent with Section 2.2.1 of Chapter IX of Reference 9.6.5-4. It is assumed that 1% of the iodine released converts to the organic form while the other 99% stays in the elemental form. In practice, the iodine activity released from the fuel would initially enter into solution and is anticipated to be gradually released to the containment atmosphere over an indefinite period of time. However, it is conservatively assumed that all of the iodine releases to the containment atmosphere occur over 60 seconds. This assumption makes the activity quickly available for release to the environment by way of containment leakage. The alkali metals activity is assumed to be retained in the primary coolant and none of it is assumed to enter the containment atmosphere

The AP1000 does not include active systems for the removal of activity from the containment atmosphere. The containment atmosphere is depleted of elemental iodine and of particulates as a result of natural processes within the containment.

Elemental iodine is removed by deposition onto surfaces. Particulates are removed by sedimentation, diffusiophoresis (deposition driven by steam condensation), and thermophoresis (deposition driven by heat transfer). No removal of organic iodine is assumed.

If the post-LOCA cooling solution has a pH of less than 6.0, part of the caesium iodide may be converted to the elemental iodine form. The passive core cooling system provides sufficient trisodium phosphate to the post-LOCA cooling solution to maintain the solution pH at 7.0 or greater following a LOCA.

9.6.5.3.6.3.2 Release Pathways

The release pathways are the containment purge line and containment leakage. The activity releases are assumed to be ground level releases.

During the initial part of the accident, before the containment is isolated, it is assumed that containment purge is in operation and that activity is released through this pathway until the purge valves are closed. No credit is taken for the filters in the purge exhaust line.

The majority of the releases due to the LOCA are the result of containment leakage. The containment is assumed to leak at its design leak rate for the first 24 hours and at half that rate for the remainder of the analysis period.

9.6.5.3.6.3.3 Dose Calculation Models

The models used to calculate doses are provided in Appendix 9A.

9.6.5.3.6.3.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.6.5-1.

9.6.5.3.6.3.5 Doses

The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 2.6 mSv Worker dose: 6.0 mSv

These doses are within the Target 4 BSL for these infrequent faults (100 mSv offsite and 500 mSv onsite).

The limiting conditions for operation of the Technical Specifications used in the dose assessment are provided in Table 9.6.5-2. The Table 9.6.5-2 values ensure the Target 4 BSL is met.

9.6.5.3.6.4 Diverse Mitigation

Diverse mitigation for this event is not required as it is an infrequent fault classified as DB1.

9.6.5.3.6.5 As Low As Reasonably Practicable Assessment

For the medium-break loss of coolant accident, the identification of the primary safety functions as Class 1 SSCs has been shown to be adequate to meet DB requirements.

As shown in the PSA (Chapter 10), the AP1000 has diverse MBLOCA features including:

- CMTs or Accumulator provide high pressure injection
- ADS Stage 4 with IRWST gravity injection and recirculation or ADS Stage 1, 2, and 3 with RNS pumps providing IRWST injection and containment recirculation.
- PMS or DAS provide C&I. There is sufficient time available for the operators to manually actuate ADS and align the RNS if PMS is unavailable and DAS is credited.

Providing further means of removing decay heat or tripping the reactor in addition to these functions would not be significantly reduce the PSA risk for this event.

9.6.5.3.6.6 MBLOCA Conclusions

The DB analysis shows that for the MBLOCA fault, the acceptance criteria defined in Section 9.6.5.0 are met.

DBA radiological consequences are within the Target 4 BSL for infrequent faults (10 mSv offsite and 200 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.5.3.7 Not Used

9.6.5.3.8 Core Makeup Tank Line Break Results

The general description of MBLOCA fault applies (See Section 9.6.5.3.6). However, with the break located in one of the lines between the CMT and the cold leg, only one of the CMTs is available.

For the DBA of the DVI line break scenarios, only the Class 1 systems listed under the MBLOCA event are available, but additionally, only one CMT is available. The same performance requirements apply.

A break in a balance line between a CMT and a cold leg is bounded by both of the following:

- The DVI line break scenario, which involves a similar break size but in which not only one CMT but also one accumulator and one IRWST injection line are unavailable, so that less emergency cooling water is available to replenish that lost from the break

- The limiting MBLOCA, which involves a larger-size break in the cold leg so that more water is lost from the break, placing greater demands on the emergency cooling water systems

Therefore, no additional analyses have been performed for the CMTLB; for the purpose of the DB analyses, the consequences have been assumed to be those associated with the DVI line break.

9.6.5.3.8.1 As Low As Reasonably Practicable Assessment

The ALARP assessment for the MBLOCA fault applies with the exception that only one CMT is available. Refer to Section 9.6.5.3.6.5.

9.6.5.3.8.2 CMT Line Break Conclusions

A separate analysis for this fault is not required as it is bounded by the DVI line break and MBLOCA faults as described above.

It has been shown that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.5.3.9 Passive Residual Heat Removal Tube Rupture Results

The general descriptions of SBLOCAs apply (See Section 9.6.5.3.4). However, with the break located in one of the PRHR system tubes, the PRHR performance would be degraded.

For the DBA of the PRHR system tube rupture, only the Class 1 systems listed for SBLOCA events would be credited, except that the PRHR system is conservatively assumed to be unavailable. In reality, the PRHR heat exchanger would be expected to be functional, albeit at a reduced capacity. A rupture of one of the PRHR tubes (inner diameter 15.7 mm (0.62 inch) results in a LOCA that is smaller than the limiting frequent fault SBLOCA, which has an equivalent break diameter of 50.8 mm (2 inch). The PRHR performance for SBLOCAs is not very important because the initial SG secondary side inventory is capable of removing heat for an extended time. During this time the RCS pressure would be reduced to the SG secondary side pressure of 8.34 MPa (1210 psia) due to steam relief from the SGs and the break. The RCS pressure at the time of ADS 1, 2, and 3 actuation would be higher if the PRHR was assumed unavailable. However, the spurious ADS actuation case discussed in this section bounds this case with respect to RCS pressure at the time of ADS 1, 2, and 3 actuation (normal RCS pressure, 15.9 MPa (2300 psig)) and has much higher decay heat levels since the ADS actuation time is much earlier.

Also note that in the DBA SBLOCA analysis, the PRHR is assumed to stop functioning when the accumulators empty and nitrogen enters the RCS. Therefore, no additional analyses have been performed for the PRHR system tube rupture; for the purpose of the DB analyses, the consequences have been assumed to be those associated with the limiting infrequent SBLOCA.

9.6.5.3.9.1 As Low As Reasonably Practicable Assessment

The ALARP assessment for the SBLOCA fault applies with the exception that the PRHR system is not available. Refer to Section 9.6.5.3.4.4.

9.6.5.3.10 Reactor Coolant Leakage Results

The general descriptions of SBLOCAs apply to the reactor coolant leakage fault, noting that time scales are extended.

The analysis methods and assumptions described for the SBLOCA apply for the analysis of reactor leaks. The plant conditions from transient analysis of the SBLOCA scenario are assumed to be bounding.

9.6.5.3.10.1 DBA Credited SSCs

For the DBA of the reactor coolant leakage, only the Class 1 systems listed under the SBLOCA event are available (See Section 9.6.5.3.4.1.1), and the same performance requirements discussed in Section 9.6.5.2.1 also apply. As the RCS Leak event is classified as a high frequency, low consequence fault, a diverse means of providing the required Category A safety functions is also required.

9.6.5.3.10.2 Results of Design Basis Analysis

Since the behaviour associated with the reactor coolant leakage fault is bounded by the limiting SBLOCA, only sensitivity transient analyses have been performed for the RCS leakage fault in order to demonstrate diverse mitigation for this frequent fault.

9.6.5.3.10.3 Radiological Consequences

The consequences of a reactor coolant leakage fault are bounded by the consequences from an SBLOCA. The consequences of an SBLOCA are conservatively estimated based on those of an MBLOCA (see Section 9.6.5.3.4.3). With limited fuel damage (less than 1 percent predicted for SBLOCA) and a concurrent release to containment, the releases are less than 10 percent of those considered in the MBLOCA doses (see Section 9.6.5.3.6.3) which considered up to 10 percent fuel damage. Therefore, doses that are ten percent of the MBLOCA doses from Section 9.6.5.3.6.3 are presented. The calculated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

Offsite dose: 0.26 mSv Worker dose: 0.60 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

9.6.5.3.10.4 Diverse Mitigation

The available diverse mitigation for the SBLOCA fault applies to the RCS leak event.

9.6.5.3.10.5 Diverse Mitigation Analysis

Depressurisation of Reactor Coolant System

This section deals with inadvertent pressuriser spray, even though it is not a loss of RCS coolant inventory. Pressuriser spray draws subcooled water from a scope in the RCS cold leg and sprays it into the top of the pressuriser (the steam space). The subcooled spray condenses steam, thereby lowering the RCS pressure. The spray valve is controlled by the PLS pressure control system.

Inadvertent spray could result from either a spray valve failure causing it to go open when not needed, or by a failure in the pressure control system demanding spray when it is not needed.

The PMS will protect the core DNB design limits with reactor trip on low pressuriser pressure and overtemperature ΔT. The PLS will initiate alarms and control withdrawal blocks based on low margin to the overtemperature ΔT reactor trip.

For ATWS assessment of this event, the pressuriser spray valves was assumed to go wide open and stay there, and the pressuriser heaters were not energised (as they would be on low pressure).

Figures 9.6.5-91 to 9.6.5-94 illustrate the transient with no action by either reactor trip or ESF actuation from the PMS (i.e., it applies to assumed PMS CCF.)

Initially, the spray will reduce pressure and increase pressuriser water level as steam is condensed. The reduction in pressure will tend to cause a small decrease in core power. The automatic reactor power control system will withdraw control rods as needed to maintain RCS average temperature.

In this calculation, the PLS overtemperature ΔT rod stop (on low margin to overtemperature ΔT reactor trip) was arbitrarily assumed to be reached 5 minutes after start of spray. (It makes little difference in the course of events when that event occurs. Five minutes was an arbitrary selection and is not intended to represent an actual setpoint.) Its effect is so small that there is no noticeable change at that time in the figures.

In this illustration, saturation of the average core outlet fluid is reached at approximately 375 seconds. At that time, core power begins to decrease noticeably, causing reduction in RCS temperatures and steam pressure. The turbine control valves will open automatically to maintain constant turbine power until they reach their full open position. (A 5 percent margin is assumed in the turbine control valves, such that they are able to maintain flow turbine load until pressure drops to 5.45 MPa-abs (790 psia). At that point, turbine steam flow begins to decrease.

As the pressuriser pressure and saturation temperature decrease, the liquid region cools and becomes more dense, causing a slow decrease in pressuriser water volume. This water volume decrease accelerates as temperature decreases in the cold leg (and its density increases).

RCS pressure continues to decrease as pressuriser steam continues to be condenses by the continually cooling cold-leg fluid. The core reactivity balance dictates that the core exit conditions stay near boiling, with low void content in the top of the core. Lower RCS temperatures and steam pressures cause a decrease in turbine steam flow. Basically, the reactor core continues to meet the steam load demand, with the reactivity balance forcing the power to stay near the saturation line in the hot leg.

For simplicity, these calculations neglected the decrease in feedwater temperature that would accompany a reduction in turbine steam flow. Cooler feedwater would cause a somewhat higher steam thermal load, causing core power to decrease somewhat more slowly than is shown in the figures. The inherent behaviour and sequence of events would not be significantly affected.

These calculations were based on BOC reactivity feedback described in Section 9D.6.1.1. There would be little difference with EOC feedback. In either case, the core reactivity will force low void content in the upper part of the core.

Unless a PMS CCF is assumed, the PMS reactor trip signal will trip the turbine. In that case, the transient is dominated by the loss of steam load and the course of events would be similar to those shown for turbine trip. Whatever voids were formed as a result of depressurisation would aid in reducing core power.

Loss of Reactor Coolant System Inventory – Reactor Coolant System Leaks

This section deals with RCS leaks that are greater than the capacity of the makeup system or when the makeup system is unavailable. Therefore, they represent a loss of RCS inventory that eventually requires automatic or manual action to maintain effective core cooling.

A leak will drain the pressuriser. Assuming no PMS reactor trip or actuations of ESFs, the system response will be similar to that shown for inadvertent pressuriser spray, with one important difference: Since fluid inventory is being lost from the RCS, the pressuriser level will decrease much more than is shown in Figure 9.6.5-94. The rate of depressurisation will depend upon the size of the leak.

In the absence of manual or automatic PMS action, the pressuriser will drain, leading to DAS low pressuriser level actuation of reactor trip, turbine trip, RCP trips, CMT, and PRHR. Actuation of those features will shut down the reactor core and maintain core cooling.

If mechanical failure of control rods to insert is postulated, then the PMS would still actuate turbine trip, RCP trips, CMT, and PRHR. Trip of RCPs will cause a rapid core power reduction, and boration by the CMT will provide shutdown reactivity.

9.6.5.3.10.6 As Low As Reasonably Practicable Assessment

The ALARP assessment for this event is the same as for small LOCAs as discussed in Section 9.6.5.3.4.4.

9.6.5.3.10.7 RCS Leak Conclusions

The DB analysis shows that for the SBLOCA fault, which bounds the RCS leak fault, the acceptance criteria defined in Section 9.6.5.0 are met.

This event has also been adequately assessed with respect to ATWT considerations. This event was explicitly analysed for the change in the current design reference point in the UK as described in Reference 9.6.5-14. Reference 9.6.5-11 demonstrated that there is little impact on the key analysis trends, results, and margin to the applicable acceptance criteria. Therefore, the change in design reference point would not invalidate the conclusions presented for this event.

DBA radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Thus, the identification of necessary Class 1 SSCs is adequate to meet DB requirements for this fault.

It has been shown that the AP1000 plant includes adequate systems for the protection of the fault, which limit the radiological consequences such that they are compliant with the SAPs targets and the risks have been reduced to be ALARP.

9.6.5.4 MBLOCA and SBLOCA Overall Conclusions

The small-break and medium-break LOCA analyses performed show that the passive safeguards systems are sufficient to mitigate small-break and medium-break LOCAs. Specifically, it is concluded that:

- The primary side can be depressurised by the ADS to allow stable injection into the core.
- Injection from the core makeup tanks, accumulators, and IRWST prevents excessive cladding heatup for small-break and medium-break LOCAs analysed, including double-ended ruptures in the passive safeguards system lines. The peak heat flux during the DEDVI line break accumulator injection period is below the predicted critical heat flux.
- The effect of increasing upper plenum/hot leg entrainment does not significantly affect plant safety margins.

The analyses performed demonstrate that the acceptance criteria provided in the design basis requirements are met. Summarizing the small-break and medium-break LOCA spectrum:

Break Location/Diameter	Minimum Reactor Vessel Mixture Inventory	Peak Cladding Temperature
DBA Inadvertent ADS	24,717 kg (54,491 lbm)	504°C (938.5°F)
DBA 50.8 mm (2-inch) cold leg break	24,557 kg (54,139 lbm)	434°C (813.5°F)
DBA 254 mm (10-inch) cold leg break	35,978 kg (79,319 lbm)	(1)
DBA DEDVI	33,234 kg (73,268 lbm)	(1)
DBA DEDVI (Entrainment Study)	25,817 kg (56,916 lbm)	(1)

(1) There is no core heatup as a result of these transients; PCT occurs at transient initiation.

The 50.8 mm (2-inch) cold leg break exhibits the limiting minimum reactor vessel mixture inventory conditions, and the inadvertent ADS actuation transient has the limiting peak cladding temperature. The AP1000 design is such that the minimum reactor vessel mixture inventory occurs around the time of IRWST injection for the limiting breaks. All breaks simulated in the break spectrum produce results that demonstrate significant margin to the design basis requirements.

In addition, a selection of appropriate diversity cases is presented to demonstrate the diverse capabilities for all frequent fault small-break LOCAs (those up to 2" in diameter).

As noted in Section 9.6.4.6, an additional assessment was carried out to assess the potential for grid crush to extend beyond the assemblies in the low power channel as a result of a depressurisation of the primary circuit due to a double-ended guillotine (DEG) break of the RCS cold leg. This assessment concluded that no grid crushing will occur outside of the low power assemblies due to the depressurisation and therefore coolable geometry will be maintained. These limited impacts for LBLOCAs are further reduced when considering smaller breaks; therefore, the analysis results presented in this section are not impacted.

(Page 2 of 2)

Removal Coefficients(1) Elemental Iodine Organic Iodine Particulates	 1.7 (hr^{-1}) 0.0 (hr^{-1}) 0.5 (hr^{-1})
Containment Leakage Rate 0-24 hours 24-720 hours	 0.1 (%/day) 0.05 (%/day)
Offsite atmospheric dispersion factors	See Table 9A-5
Control room modelling	See Appendix 9A

Note:

1. Elemental iodine removal is modelled until a DF of 200 is reached. Particulate removal is modelled until a DF of 1.0E4 is reached.

Table 9.6.5-2. Medium Break LOCA Technical Specifications Used In Dose Analysis

Limit or Condition	Tech Spec Identification and Notes
Primary Containment Leakage Rate	3.6.1 (SR 3.6.1.1) within containment leakage acceptance criteria. 5.5.8 (Containment leakage rate testing program) defines maximum allowable primary containment leak rate to be less than or equal to 0.1 weight-% per day at the calculated peak containment internal pressure for the design basis LOCA.
Primary coolant specific activity	3.4.10 dose equivalent specific activity to be < 9.25E6 Bq/kg (0.25 μCi/g) for I-131 and < 2.6E9 Bq/kg (70 μCi/g) for Xe-133

Table 9.6.5-3 SSCs Available for DBA Mitigation of Small and Medium LOCA

Category A Safety Function	SSCs	Classification
Short-term reactivity control	Reactor trip Breakers (PMS)	1
Long-term reactivity control	Note 1	1
Decay heat removal	Note 1	1
RCS pressure control	Not required. - Small and Medium LOCAs result in RCS depressurisation	
RCS inventory control	Note 1	1
Containment cooling	PCS AOVs and MOV	1

Note: 1. Passive RCS injection and depressurisation is provided by PRHR HX, CMTs, accumulators, IRWST injection, containment recirculation, and ADS.

Table 9.6.5-4 SSCs Credited in Diverse Mitigation of Small Break LOCAs

Case	PMS	DAS	RCCA	PRHR	CMT	ACC	ADS123	ADS4	RNS	IRWST(2)	Notes
1	X	-	X	X	X	-	-	X	-	X	Core cooling
2	X	-	X	-	X	-	X	X	-	X	Core cooling
3	-	X	X	X	-	X	X(1,3)	-	X(3)	X(4)	Core cooling
4	-	X	X	X	X	-	X(3)	X(3)	-	X(3)	ATWT
5	X	-	-	X	X	-	X	X	-	X	ATWT

Notes (1) ADS 1, 2, and 3 is included in this 3rd diverse case to address potential concerns with non-condensable gas (nitrogen) entering the RCS from the accumulators and degrading the PRHR performance. Reference 9.6.5-12 provides analysis that shows that such degradation would not be severe and would allow for RNS injection without ADS 1, 2, and 3 actuation.

(2) "IRWST" means passive IRWST injection and Containment Recirculation capability.

(3) Manually actuated via DAS.

(4) Containment recirculation function only.

Tables 9.6.5-5 through 9.6.5-8 Not Used.

Table 9.6.5-9. Initial Conditions For AP1000 Small-Break And Medium-Break LOCA Analysis

Condition	Calculation	Nominal Steady-state
Pressuriser pressure (MPa [psia])	15.859 [2300.1]	15.858 [2300]
Vessel inlet temperature (°C [°F])	278.91 [534.03]	279.22 [534.59]
Vessel outlet temperature (°C [°F])	322.31 [612.16]	322.56 [612.61]
Vessel flow rate (kg/sec [lbm/sec])	14115 [31118]	14115 [31118]
Steam generator pressure (MPa [psia])	5.480 [794.76]	5.478 [794.59]

Table 9.6.5-10. ADS Parameters Utilised In LOCA Analyses

ADS Valve Actuation Signal (percentage of core makeup tank volume)		Actuation Time (seconds)	Minimum Valve Flow Area (for each path, in^2)	Maximum Valve Flow Area (for each path, in^2)	Number of Paths	Valve Opening Time (seconds)
Stage 1 – Control CMT Level – Low 3	67.5	32 after CMT Level-Low 3	4.6(4)	7(4)	2 out of 2	≤ 40
Stage 2 – Control		48 after Stage 1	21(4)	26(4)	2 out of 2	≤ 100
Stage 3 – Control		120 after Stage 2	21(4)	26(4)	2 out of 2	≤ 100
Stage 4A CMT Level – Low 6	20	128 after Stage 3(2)	67	NA	1 out of 2	≤ 4(3)
Stage 4B		60 after Stage 4A	67	NA	2 out of 2	≤ 4(3)

Notes:

1. Not used.
2. The interlock requires coincidence of CMT Level Low-6 as well as 128 seconds after the Stage 3 actuation signal is generated.
3. This includes “arm-fire” processing delay and the assumed valve opening time.
4. The areas listed above for the ADS Stage 1, 2, and 3 valves are an effective flow area.

Table 9.6.5-11 (Sheet 1 of 8) DBA Sequence Of Events, Inadvertent ADS Depressurisation

Event	Time (seconds)
Inadvertent opening of ADS Stage 1 valves	0.0
Reactor trip signal	47.4
Steam turbine stop valves close	47.4
ADS Stage 2	48.0
"S" signal	56.4
Main feed isolation valves close	63.4

9.6.6 Post-LOCA Long-Term Cooling

9.6.6.1 Long-Term Cooling Analysis Methodology

The AP1000 plant Class 1 systems are designed to provide adequate cooling of the reactor indefinitely. Initially, this is achieved by discharging water from the IRWST into the vessel. When the low-3 level setpoint is reached in the IRWST, the containment recirculation subsystem isolation valves open and water from the containment RCS compartment can flow into the vessel through the PXS piping. The water in containment rises in temperature toward the saturation temperature. Long-term heat removal from the reactor and containment is by heat transfer through the containment shell to atmosphere.

The purpose of the post-LOCA long-term cooling analysis is to demonstrate that the passive systems provide adequate emergency core cooling system performance during the IRWST injection/containment recirculation time scale. The long-term cooling analysis is performed using the WCOBRA/TRAC computer code to verify that the passive injection system is providing sufficient flow to the reactor vessel to cool the core and to preclude boron precipitation.

The AP1000 plant long-term cooling analysis is supported by the series of tests at the Oregon State University AP600 APEX Test Facility. This test facility is designed to represent the AP600 reactor Class 1 and Class 2 systems at quarter-scale during long-term cooling. The data obtained during testing at this facility has been shown to apply to the AP1000 design (Reference 9.6.6-3). These tests were modelled using WCOBRA/TRAC with an equivalent noding scheme to that used for the AP600 design (Reference 9.6.6-1) in order to validate the code for long-term cooling analysis.

Reference 9.6.6-2 provides details of the AP1000 plant WCOBRA/TRAC modelling. The coarse reactor vessel modelling used for the AP600 design has been replaced with a detailed noding like that applied in the large-break LOCA analyses described in Section 9.6.5. The reactor vessel noding used in the AP1000 plant long-term cooling analyses in core and upper plenum regions is equivalent to that used in full-scale test simulations (see Reference 9.6.6-2).

A DEDVI line break is analysed because it is the most limiting long-term cooling case in the relationship between decay power and available liquid driving head. Because the IRWST spills directly onto the containment floor in a DEDVI break, this event has the highest core decay power when the transfer to sump injection is initiated. In postulated DEDVI break cases, the compartment water level exceeds the elevation at which the DVI line enters the reactor vessel, so water can flow from the containment into the reactor vessel through the broken DVI line; this in-flow of water through the broken DVI line assists in the heat removal from the core. The steam produced by boiling in the core vents to the containment through the ADS valves and condenses on the inner surface of the steel containment vessel. The condensate is collected and drains to the IRWST to become available for injection into the reactor coolant system. The WCOBRA/TRAC analysis presented analyses the DEDVI small-break LOCA event from a time (3000 seconds) at which IRWST injection is fully established to beyond the time of containment recirculation. During this time, the head of water to drive the flow into the vessel for IRWST injection decreases from the initial level to its lowest value at the containment recirculation switchover time. PXS Room B is the location of the break in the DVI line. At this break location, liquid level in containment at the time of recirculation is a minimum.

A continuous analysis of the post-LOCA long term cooling is provided from the time of stable IRWST injection through the time of sump recirculation for the DEDVI break. Maximum design resistances are applied in WCOBRA/TRAC for both the ADS Stage 4 flow paths and the IRWST injection and containment recirculation flow paths.

The break modelled is a double-ended guillotine rupture of one of the direct vessel injection lines. The long-term cooling phase begins after the simultaneous opening of the isolation valves in the IRWST DVI lines and the opening of ADS Stage 4 squib valves, when flow injection from the IRWST has been fully established. Initial conditions are consistent with the NOTRUMP DEDVI case at 0.14 MPa (20 psia) containment pressure reported in Section 9.6.5.

Appendix 9C provides the means for safe shutdown for all design basis faults.

9.6.6.2 DEDVI Line Break with ADS Stage 4 Single Failure, Passive Core Cooling System Only Case; Continuous Case

This section presents the results of a DEDVI line break analysis during IRWST injection phase continuing into sump recirculation. Initial conditions at the start of the case are prescribed based on the NOTRUMP DEDVI break results to allow a calculation to begin shortly after IRWST injection begins in the small break long-term cooling transient. The WCOBRA/TRAC calculation is then allowed to proceed until a quasi-steady-state is achieved. At this time, the predicted results are independent of the assumed initial conditions. This calculation uses boundary conditions taken from a WGOTHIC analysis of this event. During the calculation, which is carried out for 10,000 seconds until a quasi-steady-state sump recirculation condition has been established, the IRWST water level is decreased continuously until the sump recirculation setpoint is reached.

In the analysis, one of the two ADS Stage 4 valves in the PRHR loop is assumed to have failed. The initial reactor coolant system liquid inventory and temperatures are determined from the NOTRUMP calculation. The core makeup tanks do not contribute to the DVI injection during this phase of the transient. Steam generator secondary side conditions are taken from the NOTRUMP calculation (at the beginning of long-term cooling). The reactor coolant pumps are tripped and not rotating.

The temperatures of the liquid in the containment sump and the containment pressure are based on WGOTHIC calculations of the conservative minimum pressure during this long-term cooling transient, including operation of the containment fan coolers. Small changes in the RCS compartment level do not have a major effect on the predicted core collapsed liquid level or on the predicted flow rate through the core. The minimum compartment floodup level for this break scenario is 102.4 meters (107.8 feet) or greater.

In this transient, the IRWST provides a hydraulic head sufficient to drive water into the downcomer through the intact DVI nozzle. Also, water flows into the downcomer from the broken DVI line once the liquid level in the compartment with the broken line is adequate to support flow. The water flows down the downcomer and up through the core, into the upper plenum. Steam produced in the core and liquid flow out of the reactor coolant system via the ADS Stage 4 valves. There is little flow out of ADS Stages 1, 2, and 3 even when the IRWST liquid level falls below the sparger elevation, so they are not modelled in this calculation. The venting provided by the ADS-4 paths enables the liquid flow through the core to maintain core cooling.

Approximately 500 seconds of WCOBRA/TRAC calculation are required to establish the quasi-steady-state condition associated with IRWST injection at the start of long-term cooling and so are ignored in the following discussion. The hot leg levels are such that during the IRWST injection phase the quality of the ADS Stage 4 mass flows varies as water is carried out of the hot legs. This periodically increases the pressure drop across the ADS Stage 4 valves and the upper plenum pressure. The higher pressure in the upper plenum reduces the injection flow. This cycle of pressure variations due to changing void fractions in the flow through ADS Stage 4 is consistent with test observations and is expected to recur often during long-term cooling.

The head of water in the IRWST causes a flow of subcooled water into the downcomer at an approximate rate of 81.6 kg/s (180 lbm/s) through the intact DVI nozzle at the start of long-term cooling. The downcomer level at the end of the code initiation (the start of long-term cooling) is about 5.49 meters (18.0 feet) (Figure 9.6.6-1). Note that the time scale of this and other figures in Section 9.6.6.2 is offset by 2500 seconds; that is, a time of 500 seconds on the Figure 9.6.6-1 axis equals 3000 seconds transient time for the DEDVI break. All of the injection water flows down the downcomer and up through the core. The accumulators have been fully discharged before the start of the time window and do not contribute to the DVI flow.

Boiling in the core produces steam and a two-phase mixture, which flows into the upper plenum. The core is 4.27 meters (14 feet) high, and the core average collapsed liquid level (Figure 9.6.6-2) is shown from the start of long-term cooling. The boiling process causes a variable rate of steam production and resulting pressure changes, which in turn causes oscillations in the liquid flow rate at the bottom of the core and also variations in the core collapsed level and the flow rates of liquid and vapour out of the top of the core. In the WCOBRA/TRAC noding, the core is divided both axially and radially as described in Reference 9.6.6-2. The void fractions in the top two cells of the hot assembly are shown as Figures 9.6.6-3 and -4. The average void fraction of these upper core cells is approximately 0.8 during long-term cooling, during IRWST injection, and into the containment recirculation period. There is a continuous flow of two-phase fluid into the hot legs, and mainly vapour flow toward the ADS Stage 4 valve occurs at the top of the pipe. The collapsed liquid level in the hot leg averages around 0.46 meters (1.5 feet) (Figure 9.6.6-5). The hot legs on average are more than 50-percent full. Vapour and liquid flows at the top of the core are shown in Figures 9.6.6-6 and 9.6.6-7; the upper plenum collapsed liquid level in Figure 9.6.6-8. Figures 9.6.6-9 and 9.6.6-10 are ADS stage 4 mass flowrates.

The pressure in the upper plenum is shown in Figure 9.6.6-11. The upper plenum pressure fluctuation that occurs is due to the ADS Stage 4 water discharge. The PCT of the hot rod follows saturation temperature (Figure 9.6.6-12), which demonstrates that no uncovery and no cladding temperature excursion occurs. A small pressure drop is calculated across the reactor vessel, and injection rates through the DVI lines into the vessel are presented in Figures 9.6.6-13 and -14. Figure 9.6.6-14 shows the broken DVI line flow during the start of the long-term cooling period increases to about 34.0 kg/s (75 lbm/s) after the compartment water level has increased above the nozzle elevation to permit liquid injection into the reactor vessel. In contrast, the intact DVI line flow falls from 81.6 kg/s (180 lbm/s) with a full IRWST to about 34.9 kg/s (77 lbm/s) flow from the containment at the end of the calculation. The recirculation core liquid throughput is more than adequate to preclude any boron buildup on the fuel.

9.6.6.3 DEDVI Break and Wall-to-Wall Floodup; Containment Recirculation

This section presents a DEDVI line break analysis with wall-to-wall flooding due to leakage between compartments, using the window mode methodology. All containment free volume beneath the level of the liquid is assumed filled in this calculation to generate the minimum water level condition during containment recirculation. The time identified for this calculation is 14 days into the event, and the core power is calculated accordingly. The initial conditions at the start of the window are consistent with the analysis described in Section 9.6.6.2. Containment recirculation is simulated during the time window. The calculation is carried out over a time period long enough to establish a quasi-steady-state solution; after 500 seconds of problem time, the flow dynamics are quasi-steady-state and the predicted results are independent of the assumed initial conditions. The liquid level is simulated constant at 8.60 meters (28.2 feet) above the bottom inside surface of the reactor vessel (refer to Figure 9.0-2 for AP1000 reference plant elevations) during the time window, and the liquid temperatures in the containment sump and the PXS “B” room are both modelled at 100°C (212°F). The containment pressure is conservatively

assumed to be 0.101 MPa (14.7 psia). The single failure of an ADS Stage 4 flow path is assumed as in the Section 9.6.6.2 case.

Focusing on the post 400-second time interval of this case, the containment liquid provides a hydraulic head sufficient to drive water into the downcomer through the DVI nozzles. The water introduced into the downcomer flows down the downcomer and up through the core, into the upper plenum. Steam produced in the core entrains liquid and flows out of the reactor coolant system via the ADS Stage 4 valves. The DVI flow and the venting provided by the ADS paths provide a liquid flow through the core that enables the core to remain cool.

The downcomer collapsed liquid level (Figure 9.6.6-15) varies between 7.32 and 7.62 meters (24 and 25 feet) during the analysis. Pressure spikes produced by boiling in the core can cause the mass flow of the DVI flow rates shown in Figures 9.6.6-27 and -28 into the vessel to fluctuate upward and downward.

Boiling in the core produces steam and a two-phase mixture, which flows out of the core into the upper plenum. The core is 4.27 meters (14 feet) high, and the core collapsed liquid level (Figure 9.6.6-16) maintains a mean level close to the top of the core. The boiling process causes pressure variations, which in turn, cause variations in the core collapsed level and the flow rates of liquid and vapour out of the top of the core. In the WCOBRA/TRAC analysis, the core is nodalised as described in Reference 9.6.6-2. The void fraction in the top cell is shown in Figure 9.6.6-17 for the core hot assembly, and Figure 9.6.6-18 shows the void fraction that exists one cell further down in the hot assembly. The PCT does not rise appreciably above the saturation temperature (Figure 9.6.6.3-26). The flow through the core and out of the reactor coolant system is more than sufficient to provide adequate flushing to preclude concentration of the boric acid solution. Liquid collects above the upper core plate in the upper plenum, where the average collapsed liquid level is approximately 0.94 meters (3.1 feet) (Figure 9.6.6-22). There is no significant flow through the cold legs into either the broken or the intact loops, and there is no significant quantity of liquid residing in any of the cold legs.

The pressure in the upper plenum is shown in Figure 9.6.6-25. The upper plenum pressurisation, which occurs periodically, is due to the ADS Stage 4 water discharge. The collapsed liquid level in the hot leg of the pressuriser loop increases to greater than .046 meters (1.5 feet) by the end of the transient, as shown in Figure 9.6.6-19. Injection rates through the DVI lines into the vessel are presented in Figures 9.6.6-27 and -28.

9.6.6.4 Post Accident Core Boron Concentration

An evaluation has been performed of the potential for the boron concentration to build up in the core following a cold leg LOCA. The evaluation methodology, simplified calculations, and their results are discussed in Reference 9.6.6-2. This evaluation considers both short-term operations, before ADS is actuated, and long-term operations, after ADS is actuated. These evaluations and their results are discussed in the follow paragraphs.

Short-term – Prior to ADS actuation, it is not likely for boron to build up significantly in the core. Normally, water circulation mixes boron in the RCS and prevents buildup in the core. In order for boron to start to build up in the core region, water circulation through the steam generators and PRHR HX has to stop. In addition, significant injection of borated water is needed from the CMTs and the CVS. For this situation to happen, the hot legs need to void sufficiently to allow the steam generator tubes to drain. Once the steam generator tubes void, the cold legs will also void since they are located higher than the hot legs. When the top of the cold legs void, the CMTs will begin to drain. When the CMTs drain to the ADS stage 1 setpoint, ADS is actuated.

Short-term Results – As shown in Section 9.6.5.3.4.2, a 2-inch LOCA requires less than 16 minutes from the time that the hot legs void significantly until ADS is actuated. For larger LOCAs, this time difference is shorter, as seen for the 10-inch (254 mm) cold leg LOCA (Section 9.6.5.3.6.2). The core boron concentration will not build up significantly in this short time. If the break is smaller than 2 inches (50.8 mm), voiding of the hot legs will occur at a later time. With maximum operation of CVS makeup, it takes more than 3 hours for the core boron concentration to build up significantly. In addition, the volume of the boric acid tank limits the maximum buildup of boron in the core.

Following a small LOCA where ADS is not actuated, the operators are guided to sample the RCS boron concentration and to initiate a post-LOCA cooldown and depressurisation. The cooldown and depressurisation of the RCS reduces the leak rate and facilitates recovery of the pressuriser level. Recovery of the pressuriser level allows for re-establishment of water flow through the RCS loops, which mixes the boron. The operators are guided to take an RCS boron sample within 3 hours of the accident and several more during the plant cooldown. The purpose of the boron samples is to assess that there is adequate shutdown margin and that the RCS boron concentration has not built up to excessive levels. The maximum calculated core boron concentration 3 hours after a LOCA without ADS actuation is less than 16,000 ppm. Operator action within 3 hours maintains the maximum core boron concentration well below the boron solubility limit for the core inlet temperatures during the cooldown.

Long-term – Once ADS is actuated, water carryover out the ADS Stage 4 lines limits the potential core boron concentration buildup following a cold leg LOCA. The design of the AP1000 plant facilitates water discharge from the hot legs as follows:

- PXS recirculation flow capability tends to fill the hot legs and bring the water level up to the ADS Stage 4 inlet.

- ADS Stage 4 lines discharge at an elevation 0.91 to 1.22 meters (3 to 4 feet) above the containment water level.

With water carried out ADS Stage 4, the core boron concentration increases until the boron added to the core in the safety injection flow equals the boron removed in the water leaving the RCS through the ADS Stage 4 flow. The lower the ADS Stage 4 vent quality, the lower the core boron concentration buildup.

Long-term Results – Analyses have been performed (Reference 9.6.6-2) to bound the maximum core boron concentration buildup. These analyses demonstrate that highest ADS Stage 4 vent qualities result from the following:

- Highest decay heat levels

- Lowest PXS injection/ADS 4 vent flows, including high line resistances and low containment water levels

The long-term cooling analysis discussed in Section 9.6.6.2 is consistent with these assumptions. The ADS Stage 4 vent quality resulting from this analysis is less than 40 percent at the beginning of IRWST injection and reaches a maximum of less than 50 percent around the initiation of recirculation. It decreases after this peak, dropping to a value less than 8 percent at 14 days.

With the maximum ADS Stage 4 vent qualities, the maximum core boron concentration peaks at a value of about 7400 ppm at the time of recirculation initiation. After this time, the core boron concentration decreases as the ADS Stage 4 vent quality decreases, reaching 5000 ppm about

9 hours after the accident. The core boron solubility temperature reaches a maximum of 14.4°C (58°F) (at 7400 ppm) and quickly drops to 4.4°C (40°F) (at 5000 ppm). With these low core boron solubility temperatures, there is no concern with cold PXS injection water causing boron precipitation in the core. With the IRWST located inside containment, its water temperature is normally expected to be above these solubility temperatures. The minimum core inlet temperature is greater than the solubility temperature considering heatup of the injection by steam condensation in the downcomer and pickup of sensible heat from the reactor vessel, core barrel, and lower support plate.

The boron concentration water in the containment is initially about 2980 ppm. As the core boron concentration increases, the containment concentration decreases slightly. The minimum boron concentration in containment is greater than 2950 ppm. The solubility temperature of the containment water at its maximum boron concentration is 0°C (32°F).

With high decay heat values, the ADS Stage 4 vent flows and velocities are high. These high vent velocities result in flow regimes that are annular for more than 30 days. The annular flow regime moves water up and out the ADS Stage 4 lines. This flow regime is based on the Taitel-Dukler vertical flow regime map. Lower decay heat levels can be postulated later in time or just after a refuelling outage. Significantly lower decay heat levels result in lower ADS Stage 4 vent qualities. They also result in ADS Stage 4 vent flows/velocities that are lower. Even with low ADS Stage 4 vent flow velocities, the AP1000 plant will move water out the ADS Stage 4 operating as a manometer. Small amounts of steam generated in the core reduce the density of the steam/water mixture in the core, upper plenum, and ADS Stage 4 line as it bubbles up through the water. As a result, the injection head is sufficient to push the less dense, bubbly steam/water mix out the ADS Stage 4 line.

At the time recirculation begins, the containment level will be about 102.8 meters (109.3 feet) (for a non-DVI LOCA) and will be about 102.4 meters (108.0 feet) (for a DVI LOCA). Over a period of weeks after a LOCA, water may slowly leak from the flooded areas in containment to other areas inside containment that did not initially flood. As a result, the minimum containment water could decrease to 101.1 meters (103.5 feet). During recirculation operation following a LOCA and ADS actuation, the operators are guided to maintain the containment water level above the 102.1 meter (107 feet) elevation by adding borated water to the containment. In addition, if the plant continues to operate in the recirculation mode, the operators are guided to increase the level to 102.7 meters (109 feet) within 30 days of the accident. These actions provide additional margin in water flow through the ADS Stage 4 line. The operators are also guided to sample the hot leg boron concentration prior to initiating recovery actions that might introduce low temperature water to the reactor.

9.6.6.5 Conclusions

Calculations of AP1000 plant long-term cooling performance have been performed using the WCOBRA/TRAC model developed for the AP1000 design and described in Reference 9.6.6-2. The DEDVI case was chosen because it reaches sump recirculation at the earliest time (and highest decay heat). A window mode case at the minimum containment water level postulated to occur 2 weeks into long-term cooling was also performed.

The DEDVI small-break LOCA exhibits no core uncovery due to its adequate reactor coolant system mass inventory condition during the long-term cooling phase from initiation into containment recirculation. Adequate flow through the core is provided to maintain a low cladding temperature and to prevent any buildup of boric acid on the fuel rods. The wall-to-wall floodup case using the window mode technique demonstrates that effective core cooling is also provided at

the minimum containment water level. The results of these cases demonstrate the capability of the AP1000 plant passive systems to provide long-term cooling for a limiting LOCA event.

9.7 Spent Fuel Pool Fault Groups

9.7.1 Criticality Faults during Refuelling, Fuel Handling, and Fuel Storage

9.7.1.1 Introduction and Overview

This section assesses the criticality faults associated with refuelling, fuel handling, and fuel storage (faults 2.4.5 and 3.2.1-3.2.4 – see Appendix 8A).

9.7.1.1.1 Refuelling – Normal Operations

Refuelling is achieved by removing the integrated head package (IHP) from the RPV so that the fuel assemblies can be accessed. The reactor is deemed to be in the refuelling mode (Mode 6) once any of the head bolts are less than fully tensioned.

Both RNS pumps and heat exchangers remain operating during refuelling. As decay heat decreases and as fuel is moved to the SFP, one residual heat removal pump and heat exchanger may be taken out of service. However, the valves remain aligned should the need arise to start this pump quickly in case of a failure of the operating residual heat removal pump.

Then the refuelling cavity is flooded with borated water from the IRWST. The reactor upper internals are then removed and placed on a stand in the refuelling cavity. Fuel may now be removed from the core.

The fuel handling equipment is designed to handle the spent fuel assemblies underwater from the time they leave the reactor vessel until they are placed in a container for shipment from the site. Underwater transfer of spent fuel assemblies provides an effective and transparent radiation shield, as well as a reliable cooling medium for removal of decay heat. Boric acid in the water is a defence in depth measure to preclude criticality.

The refuelling cavity and the fuel storage area are connected by the fuel transfer tube which is fitted with a quick opening hatch on the canal end and a valve on the fuel storage area end and kept full of borated water at all times during fuel movement. The hatch is in place except during refuelling to provide containment integrity. The hatch or valve can be used to provide isolation during a refuelling outage. Fuel is carried through the tube on an underwater transfer car.

Fuel is moved between the RPV and the fuel transfer system by the refuelling machine. The fuel transfer system is used to move a fuel assembly and its associated core component between the containment building and the auxiliary building fuel handling area. After a fuel assembly is placed in the fuel container in the fuel transfer system, the lifting arm pivots the fuel assembly to the horizontal position for passage through the fuel transfer tube. After the transfer car transports the fuel assembly through the transfer tube, the lifting arm at that end of the tube pivots the assembly to a vertical position so that the assembly can be lifted out of the fuel container and placed in the spent fuel racks.

Fuel (both new and used) is moved back into the core using the reverse procedure to that for removing spent fuel from the core. Fuel is introduced into the refuelling cavity via the fuel transfer system and placed in the specified location in the core by the refuelling machine.

9.7.1.1.2 Fuel Storage – Normal Operation

The new and spent fuel storage areas are accessible to operating personnel.

New fuel assemblies received for refuelling are removed one at a time from the shipping container and moved into the new fuel assembly inspection area. After inspection, the accepted new fuel assemblies are stored dry in the new fuel storage rack. The rack is designed to store 72 fuel assemblies of the maximum design basis enrichment, and includes integral neutron absorbing material to maintain the required degree of sub-criticality. For the initial core load, some new fuel assemblies may be stored in the SFP. During fuel loading, new fuel is moved via the SFP to the reactor.

The SFP provides storage space, heat removal and shielding for spent fuel. The pool, which is constructed of reinforced concrete and concrete filled structural modules, is approximately 12.95 m (42.5 ft) deep and contains borated water with a nominal boron concentration of 2700 ppm. It has storage locations for 10 years of spent fuel storage, including 5 locations for damaged/defective fuel.

Spent fuel storage cells are composed of stainless steel boxes separated by a water gap, with fixed neutron absorber panels centred on each side. The steel walls define the storage cells, and stainless steel sheathing supports the neutron absorber panel and defines the boundary of the flux-trap water-gaps used to augment reactivity control. Stainless steel channels connect the storage cells in a rigid structure and define the flux-trap between the neutron absorber panels. Neutron absorber panels are installed on all exterior walls where a fuel assembly could be mislocated. For those areas where there is insufficient space to misplace a fuel assembly between the rack and the spent fuel pool wall, no neutron absorber is present. Radial neutron leakage compensates for the lack of exterior neutron absorber in these areas.

There are five locations to store defective fuel assemblies which are separated from each other by a water gap, similar to the rack design for normal storage locations. Additionally, they are separated from the surrounding storage cells by a large water gap. Therefore two neutron absorber panels separate the fuel assemblies in the defective storage locations from any other fuel assembly.

The full capacity of the pool is more than sufficient to hold an entire core off-load of 157 fuel assemblies.

In addition to the integral neutron absorbing material to preclude criticality the SFP contains soluble boron at a concentration controlled by Technical Specification limits (minimum 2300 ppm). This increases the margin to criticality.

9.7.1.1.3 Fuel Handling- Normal Operation

In the fuel handling area, fuel assemblies are moved about by the fuel handling machine, which is a gantry-style crane equipped with two hoists, one of which is used for lifting new fuel, the other for spent fuel. Initially, a short tool is used to handle new fuel assemblies, but the new fuel elevator must be used to lower the assembly to a depth at which the fuel handling machine can place the new fuel assemblies into or out of the spent fuel storage racks.

The fuel handling machine is used to handle new fuel assemblies in the rail car bay, new fuel rack, and new fuel elevator. The capacity of the fuel handling machine, while over the new fuel storage rack, is limited to lifting a fuel assembly, control rod assembly, and handling

tool. The new fuel storage rack is not accessed by the cask handling crane. This precludes the movement of loads greater than fuel components over stored new fuel assemblies.

During fuel handling operations, a ventilation system removes gaseous radioactivity from the atmosphere above the new fuel pit and SFP.

Spent fuel assemblies are lifted using a long (approximately 11 m (36.1 ft)) spent fuel handling tool, which ensures an adequate depth of water is maintained for radiation shielding.

The following procedure briefly outlines the typical steps of the operation to transfer spent fuel assemblies from the SFP to a shipping cask. It assumes that the cask loading pit has been previously filled with water and that the gate between the cask loading pit and the SFP has been opened:

- The transfer cask containing a clean, empty spent fuel canister is brought into the cask washdown pit. The spent fuel canister is removed as necessary and prepared for cask loading.

- The transfer cask/spent fuel canister are placed into the cask loading pit.

- The fuel handling machine is positioned over the specific fuel assembly to be shipped out of the spent fuel storage rack. The fuel assembly is picked up and transported into the cask loading pit. During the transfer process the fuel assembly is always maintained with the top of the active fuel at least 2.67 m (8.8 ft) below the water surface, to ensure adequate shielding from direct radiation.

- Once the fuel transfer process is complete, the lid is placed on top of the cask to provide the required shielding.

- The cask is then moved to the washdown pit and cleaned with demineralised water. Decontamination procedures can be started at this time.

- When the spent fuel canister closure and drying processes are complete, the transfer cask is prepared for transfer into a storage or shipping container as applicable.

The cask is lifted using the cask handling crane, which is a bridge crane mounted on two runway rails. It is typically used only when fuel movement activities associated with refuelling the reactor are not in progress. The cask handling crane's path is designed such that the cask cannot pass over the spent fuel pool, new fuel pit, or fuel transfer canal. This precludes the movement of loads greater than fuel components over stored fuel. For the unlikely event of a dropped cask on to a hard surface, consideration of integrity of fuel in the cask and consequences for criticality will be addressed in the cask safety case.

9.7.1.2 Fault Assessment

The faults are considered in two groups: those within the reactor containment and those outside the containment (i.e., in the auxiliary building). Note that the criticality safety of fuel in a new fuel cask or in a spent fuel cask (including dropped load events) will be demonstrated in the safety case for the relevant cask.

The following faults have the potential to present a criticality hazard during refuelling or fuel handling operations within the reactor containment:

Fault 2.4.1, Uncontrolled Rod Cluster Control Assembly Bank Withdrawal During Refuelling

When fuel assemblies are in the pressure vessel and the vessel head is not in place, k_{eff} will be maintained at or below 0.95 with control rods and soluble boron. Further, the fuel will be maintained sufficiently sub-critical that removal of the rod cluster control assembly bank will not result in criticality. The COLR will define the soluble boron concentration required to maintain the shutdown margin.

Fault 2.4.2, Inadvertent Loading of a Fuel Assembly in an Improper Position in Core During Refuelling

During refuelling, the boron concentration in the reactor is kept at such a level that fuel of any burnup can occupy its intended position in the core without challenging the criticality safety limits ($k_{eff} < 0.95$). If fuel were placed in an improper position in the core, it is expected that this would be noticed from monitoring the Inverse Count Rate Ratio derived from the source range detectors during fuel loading, especially if the margin to criticality were significantly reduced (k_{eff} approaching 1.0). If fuel assemblies of similar reactivity were interchanged so that it was not noticed during loading, this might create operational difficulties (e.g., with core power distribution) but there would be no safety issue. It is shown below that, for a reactor operating at power, a fuel misloading fault (Fault 3.1) is bounded by uncontrolled withdrawal of a single RCCA (discussed in Section 9.5).

Fault 2.4.3, Loss or Reduction of Boration in Refuelling Cavity due to:

- **Faulty boron concentration measurement**
- **Uncontrolled dilution/addition of unborated water (e.g., from Fire Protection System (FPS))**

Loss or reduction of boration would reduce the margin to criticality but would not cause a criticality event. In the refuelling cavity, fuel is only moved one assembly at a time in transit to the SFP; or stored in the in-containment fuel storage rack which is a 1x6 array of storage cells. Each storage location is surrounded by neutron-absorbing panels. A criticality assessment of the in-containment rack (Reference 9.7-14) shows that, when loaded with six new fuel assemblies in unborated water, the neutron multiplication factor (including biases and uncertainties) is $k_{eff} = 0.88$, i.e., it would be sub-critical with a large margin of safety below the criterion for safe operation under normal conditions ($k_{eff} < 0.95$).

The assessment referred to above (Reference 9.7-14) also includes a calculation for a single isolated fresh fuel assembly outside of the in-containment rack, in unborated water, and shows that $k_{eff} < 0.95$ for this case also. It is fully reflected but assumes no neutronic interaction with other fissile material. To ensure neutronic isolation, the in-containment storage rack has at least 254 mm (10 inches) of water separation from the sides of the rack. The design of the in-containment storage rack ensures this.

Therefore, a complete loss of boron in the refuelling cavity would not result in a criticality event.

Fault 2.4.4, Loss of Configuration of Reactor Core due to Dropped Loads (Including Integrated Head Package, or Upper Core Internals)

The heavy loads such as the vessel head would not fit inside the open reactor vessel and so could only damage at most the upper part of the fuel. The radiological consequences of this

event are dealt with as part of a separate fault group (Appendix 8A – dropped loads). Regarding the risk of criticality, all such scenarios are considered to be bounded by a dropped load onto the fuel assemblies in the SFP.

Fault 2.4.5, Dropped Fuel Assembly (Spent or New) Onto, or Into Reactor Core

The risk of a dropped fuel assembly onto the reactor core is dealt with as part of a separate fault group (dropped loads). Regarding the risk of criticality, all such scenarios are considered to be bounded by a dropped fuel assembly in the SFP, where there are potentially many more fuel assemblies stored.

Fault 2.4.6, Displacement of Control Rods

As with fault 2.11, the fuel will be maintained sufficiently sub-critical that displacement or complete removal of one or more rod cluster control assemblies will not result in criticality.

The following faults have the potential to present a criticality hazard when handling new or spent fuel outside the reactor containment:

Fault 3.1.8, Flooding of New Fuel with Unborated Water or Oil

- In new fuel assembly inspection area (with concrete reflection)
- In new fuel storage rack (dry buffer store)

The criticality assessment for the new fuel storage rack (Reference 9.7-15) shows that $k_{eff} < 0.95$ when the storage pit is fully flooded with unborated water (for the maximum load of 72 fuel assemblies with 5.0 weight percent U-235, and with full water reflection). Furthermore, if the water density is chosen for optimum moderation conditions, then $k_{eff} < 0.98$ so that the criterion for accident conditions is still met.

For a single fuel assembly in the inspection area flooded or sprayed with water, and with concrete reflection on two sides, the reactivity is expected to be less than for a fully loaded new fuel storage rack covered in water. This fault scenario is therefore screened out from further analysis.

Although oil is more moderating than water, the quantity of oil present in the fuel handling area (e.g., in lifting equipment) is not sufficient to significantly affect the margin to criticality of the new fuel, even if it leaked directly into the pit.

Fault 3.2.1, Loss or reduction of boration in SFP due to:

- Faulty boron concentration measurement
- Uncontrolled dilution/addition of unborated water (e.g., from FPS)

As an all region 1 style of fuel rack does not require the use of soluble boron or burnup credit to maintain criticality safety, the above fault is not a bounding fault.

Reference 9.7-13 calculates the maximum k_{eff} for the spent fuel racks filled with fresh fuel of maximum nominal initial enrichment of 4.95 weight percent U-235 without soluble boron. The results show that the maximum k_{eff} of the racks is less than 0.95 at a 95% probability at a 95% confidence level.

Fault 3.2.2, Loss of Configuration of Fuel in Storage Racks (e.g., Seismic or Dropped Load)

- Dropped fuel assembly lying on top of rack (toppled)
- Vertical misalignment of fuel assembly relative to fixed neutron absorber panels
- Change in rod pitch to a more reactive configuration (possibly outside rack)
- Distortion of rack geometry (e.g., bringing fuel assemblies closer together)
- Displacement of racks closer together, or with more concrete reflection

It is possible to drop a fresh fuel assembly on top of the SFP storage racks. In this case the physical separation between the fuel assemblies in the SFP storage racks is such that the dropped assembly must either enter a vacant storage location or remain lying on top of the racks.

For the case in which a fuel assembly is assumed to be dropped on top of a rack, Reference 9.7-13 shows that the fuel assembly will come to rest horizontally on top of the rack with a minimum separation distance from the active fuel region of more than 0.3 m (1 ft), which is sufficient to preclude neutron coupling (i.e., an effectively infinite separation). Consequently, the horizontal fuel assembly drop accident will not result in a significant increase in reactivity which remains below a k_{eff} of 0.95. Furthermore, the soluble boron in the spent fuel pool water increases the margin to criticality. This fault is not considered further as there are no consequences.

For a vertical drop of an assembly into a location that might be occupied by another assembly or that might be empty, Reference 9.7-13 concludes that a vertical impact onto another assembly would at most cause a small compression of the stored assembly, reducing the water-to-fuel ratio and thereby reducing reactivity. A vertical drop into an empty storage cell could result in a small deformation of the baseplate. The resultant effect would be the lowering of a single fuel assembly by the amount of the deformation. This could potentially result in a misalignment between the active fuel region and the neutron absorber. However, the amount of deformation for this drop would be small and restricted to a localised area of the rack around the storage cell where the drop occurs. Furthermore, the soluble boron in the spent fuel pool water assures that the true reactivity is always less than the limiting value for this dropped fuel accident. This fault is not considered further as there are no consequences.

Fault 3.2.3, Misplaced fuel assembly in SFP

- In space next to fuel racks
- Vertical misalignment of fuel assembly relative to fixed neutron absorber panels

The arrangement of the fuel storage racks in the pool and design of the racks physically prevents placement of an assembly outside the racks which would challenge criticality safety.

The spent fuel storage racks are qualified for the storage of fresh unburned fuel assemblies with the maximum permissible enrichment (4.95 weight percent U-235) in every location. Therefore the abnormal location of a new fuel assembly within normal cells is not an issue.

When fuel assemblies are lowered into the racks, it is conceivable that some part of an assembly could catch on the rack canister openings and not get fully lowered into position, leaving some portion of the fuel protruding above the fixed neutron absorber panels. However, if this happened to a single fuel assembly, it would not have criticality consequences because there would be no neighbouring fuel assemblies with which to couple.

It is considered incredible that this would happen to multiple adjacent fuel assemblies due to fuel handling controls. This fault is not considered further.

Fault 3.2.4, Increased Reactivity After Incomplete Repair of Fuel Assembly

- Some fuel rods removed and not replaced

If fresh fuel is found defective at delivery inspection and needs to be reconstituted it would not be handled at site. It would be sent back to the fabrication facility instead. The only other type of fuel assembly that needs to be reconstituted would be one with a leaking pin caused by in-reactor operation and would therefore have experienced burnup. It would be placed in one of the defective fuel racks on the side of the SFP. If a pin is removed it would be for the sole purpose of immediately replacing it with a steel dummy rod.

It is conceivable that fuel rods could be removed from a fuel assembly with the intention of later replacing them (e.g., with stainless steel rods), and that the fuel assembly may be left with one or more vacant positions until this is done and placed in a pool rack inadvertently. The likelihood of one of these assemblies being placed with the rest of the fuel with a pin removed is therefore very low. However, the increased reactivity effect of having removed a pin will be significantly smaller than the reduced reactivity effect due to the burnup that the assembly accrued. To get a significantly increased reactivity would require repair on low burnup fuel and multiple errors with vacant positions in the optimum locations, and this is considered very unlikely and not within the design basis. This fault is not considered further.

9.7.1.2.1 Bounding Fault for Design Basis Assessment

No fault is identified as bounding because no criticality faults increase reactivity above allowed levels. These faults are therefore screened out deterministically and no initiating event frequency, DB class, or response need be discussed.

9.7.1.2.2 ALARP Assessment

Note that while not necessary to maintain subcriticality the spent fuel pool boron concentration is measured manually, once every seven days. An automatic boron concentration monitor and alarm would provide a further indication to the operators of any dilution, at an earlier time than the manual measurements. However, it is most likely that other indications would occur first, e.g., a high SFP level. Any automatic system like this would have to be of high reliability and built to high standards, and the costs of providing such a system is considered disproportionate to the marginal improvement in risk as an additional defence in depth measure.

The rack design is such that, even if the racks were loaded with fresh fuel and/or boron concentrations assumed to be zero, the fuel would remain sub-critical. This physically safe design is considered ALARP.

9.7.2 Loss of Heat Removal Faults during Refuelling, Fuel Handling, and Fuel Storage

9.7.2.1 Introduction and Overview

This section assesses the loss of heat removal faults associated with refuelling, fuel handling and fuel storage in faults 3.2.5-3.2.9 and 3.2.10 – see Appendix 8A.

The AP1000 SFP design is based on a defence in depth approach that relies on both A-2 active systems and A-1 passive systems to provide protection against potential heat-up leading to damage of the stored fuel. In line with the AP1000 passive design philosophy, the active spent fuel pool cooling system (SFS) is a Class 2 safety system. The Class 2 cooling chain is designed not only to reliably support normal operation, but also to minimise the demand on the passive systems.

In case of multiple failures in the Class 2 cooling chain (SFS/RNS, CCS, SWS, their supporting systems, or AC power supplies), the principal means of ensuring cooling of the spent fuel is provided by the Class 1 inventory of water in the pool and additional Class 1 makeup sources that can provide passive makeup to the spent fuel pool. Following a postulated complete loss of the Class 2 cooling chain, the pool will heat up and boil off water, providing the necessary cooling to the spent fuel. The water above the fuel, even at reduced water levels, provides sufficient shielding since no operations immediately above or in the pool fuel handling area would be conducted. The Class 1 SFP water inventory is thus the principal means of fulfilling the Category A safety function of cooling and shielding the fuel in the SFP. Class 1 sources provide sufficient inventory to provide cooling for at least 72 hours (and in most cases, a much longer period of time).

When fuel is removed from the reactor after shutdown, the decay heat can be tens of kW per fuel assembly. The decay heat is removed by keeping the fuel continually immersed in water, which is typically cooled by the RNS when the fuel is inside containment or by the SFS when the fuel is in the spent fuel pool, which is in the Auxiliary Building, outside of containment. The SFP water temperature is normally limited to 49ºC (120ºF) during all plant operations. If one of the cooling trains fails during refuelling operations, this SFP temperature can be exceeded, but will be limited to 60ºC (140ºF). Furthermore, operation of any single train of SFS or RNS will prevent boiling from occurring in the SFP or in the refuelling cavity inside containment. Thus, the Class 2 SFS with the ability of the Class 2 RNS to also remove heat from the SFP minimises reliance on the operation of the Class 1 passive systems, structures, and components (SSCs). A brief description of the AP1000 spent fuel cooling methods is provided below.

Both the RNS and SFS are comprised of two redundant trains of equipment that are powered by redundant and separated power supplies. The RNS and SFS heat exchangers are cooled by the Class 2 CCS and SWS systems, which are also comprised of redundant trains that are powered by redundant and separated power supplies. Additionally, the associated supporting structures and piping that ensure fuel coverage are designed as seismic Class 1 SSCs. These SSCs include:

- The RNS pressure boundary (includes piping, valves, RNS side of heat exchangers, RNS pumps)
- SFS piping connected to the pool or other associated pits that are at elevations below the SFS pump suction and return piping connections to and from the pool
- The refuelling cavity
- The refuelling cavity seal
- The fuel transfer tube
- The fuel transfer canal

- The spent fuel pool
- The cask loading pit
- The cask washdown pit
- The spent fuel pool gates.

During normal plant operation, the SFP water is maintained at or below 49ºC (120ºF) by operation of either one of the two SFS cooling trains. The SFS train not being used for cooling is placed in standby and is available should the operating train of equipment become unavailable. Similarly, only one of the two trains of the CCS and SWS are normally required to operate. In addition, the CCS is designed such that either CCS pump can be operated and aligned to either CCS heat exchanger, and can cool either SFS heat exchanger. Likewise, the SWS is designed such that either SWS pump can be operated and aligned to either CCS heat exchanger, and the service water can be cooled by either SWS cooling tower. This flexibility in operation ensures that the failure of any active component in the SFS, CCS, and SWS will not interfere with normal SFP cooling, and that normal planned maintenance on these components can be performed without a significant loss in cooling reliability. The two CCS and SWS trains can also be segregated in the event of a passive failure such that no single piping failure can disable both trains. Additionally, either one of the two redundant, separated RNS trains can be aligned to cool the SFP should both SFS trains be unavailable, since the RNS pumps and heat exchangers are not operating during normal plant operation.

During plant cooldown operations and prior to the initiation of refuelling activities, both RNS trains are aligned to the RCS to remove the core decay heat, and both CCS and SWS trains operate to support RNS cooling. Typically, the decay heat from the fuel assemblies in the SFP is quite low at this time since the last core region removed from the core has had one whole fuel cycle for its decay heat to decrease. However, the RNS, CCS, and SWS are designed such that after RCS cooldown and preparations for refuelling, the operation of just one train of each system provides sufficient cooling to the RCS, such that one of the two RNS trains can be aligned to provide SFP cooling should both the operating train and standby train of the SFS become unavailable.

During the removal of the spent or used fuel from the reactor vessel, during the fuel transfer process, and during storage in the SFP, both the RNS trains and SFS trains are aligned to and operate to remove the core decay heat. Both CCS and SWS trains are also operated to support the RNS and SFS cooling functions. However, the RNS, SFS, CCS, and SWS are all designed such that only one of the two trains of each system is required to prevent boiling of the water in the reactor vessel and SFP. Therefore, adequate cooling to prevent boiling can be provided by aligning one RNS train to provide SFP cooling should both the operating train and standby train of the SFS become unavailable; or by one of two RNS trains providing cooling for the fuel inside the reactor containment and one of two SFS trains providing cooling for the fuel outside containment in the SFP and transfer canal.

Following a full core off-load (including an emergency core off-load), where all the fuel inside the reactor vessel is removed and placed in the SFP, any one of the four SFS and RNS cooling trains combined with any one of two CCS pumps, CCS heat exchangers, SWS pumps, and SWS cooling towers can provide sufficient SFP cooling to prevent boiling in the SFP.

Eventually (after a number of years), the decay heat is low enough to enable the spent fuel to be transferred to a spent fuel cask for ultimate disposal or storage in dry conditions. The

following sections address fault conditions in spent fuel cooling during refuelling (Mode 6) and throughout the time it is stored in the spent fuel pool.

Safety Case Overview

The AP1000 design provides sufficient inventory to ensure that the fuel assemblies located in the racks in the SFP will remain covered for at least 72 hours following all Design Basis Events, by a combination of initial inventory in the pool and available Class 1 makeup sources, assuming the un-availability of all non-Class 1 systems.

The analyses presented in Sections 9.7.2.3 and 9.7.2.4 demonstrate that adequate Class 1 inventory is provided to ensure coverage of fuel seated in the racks for at least 72 hours for all postulated breaks, even for breaks in Class 1 lines. A discussion is provided to explain how fuel being moved at the time of an event can be placed in the spent fuel racks. It is noted that for RNS breaks (Class 1), this makeup will have to be supplied via a Class 2 line, which is considered acceptable due to the frequency of the event and the significant time available (over 1 day) before any makeup is necessary. Additionally, for the vast majority of the fuel cycle, no SFP makeup is required to support having the 72 hours before the stored fuel is uncovered.

In addition to the provision of pool makeup from Class 1 sources, the AP1000 design provides a robust design of the Class 2 active cooling chain and of the Class 3 and general non-safety (GNS) systems that minimises the demands on the Class 1 passive systems

The analysis presented in Section 9.7.2.3 demonstrates that the Class 2 systems are designed such that no single failure can preclude the operation of the cooling chain, and multiple failures are necessary before the actuation of the passive systems is required. The design is such that the probability of onset of boiling is a DB1 fault (with an initiating event frequency ~1.0E-03 per year). For cases where boiling in the SFP occurs, the analysis presented in Section 9.7.2.3 shows that doses to the public and workforce would remain well below the Target 4 BSL.

Finally, Section 9.7.2.3.4 shows that the design provides additional defence in depth in that there are additional Class 2, 3, and GNS sources, with their own dedicated power supply (diverse from main AC and the standby Diesel Generators), that are available to provide makeup should there be a failure of both the Class 2 heat removal chain and the Class 1 makeup, or should makeup be required for an extended period of time beyond 72 hours.

9.7.2.2 Analysis of Faults

Two faults were identified from the fault schedule (Table 8A-2):

Fault ID	Description
3.2.5-3.2.9	Loss of Water Inventory from SFP
3.2.10	Loss of Spent Fuel Cooling Capability

Fault ID 3.2.10, the loss of spent fuel cooling capability will be addressed first in Section 9.7.2.3. Fault ID 3.2.5-3.2.9 is addressed in Section 9.7.2.4, which describes the protection against a postulated break in Class 1 and Class 2 lines.

9.7.2.3 Fault ID#3.2.10 – Loss of Spent Fuel Cooling Capability

9.7.2.3.1 Identification of Causes and Accident Description

This section provides an overview of the potential causes of a loss of SFP cooling and provides an integrated narrative to describe the interaction of the Class 1, 2 and 3 systems and the associated claims.

Section 9.7.2.3.2 discusses the normal spent fuel pool operation, including the Class 2 cooling chain and the associated train separation. Assuming an initiating event (e.g., loss of ac electrical power, or failure of a pump in the SFS/RNS/CCS/SWS systems), and assuming a series of failures in the Class 2 cooling chain (including the potential for common cause failures), a loss of pool cooling capability of the pool would result.

The unmitigated consequence of such a loss of cooling event is heatup and boil off of the water in the SFP. After a significant length of time (a day or more) fuel damage would occur resulting from fuel uncovery and the subsequent release of radioactivity. Section 9.7.2.3.3 describes how the pool inventory and other Class 1 passive systems provide protection against the potential for fuel uncovery. Section 9.7.2.3.4 provides a description of the additional lines of defence in depth, including Class 2 makeup that can be supplied to the pool. Considering that a loss of cooling would be due to the loss of the normal Class 2 cooling chain, these Class 2 sources are diverse, and rely on diverse and/or separated power supplies.

Finally, in Section 9.7.2.3.8, post fault recovery is described for a break in the Class 2 SFS suction/return piping, as well as the non-break scenario where the cooling chain is lost.

The following sections provide the analyses required to demonstrate the capability of each line of defence to achieve its objective.

9.7.2.3.2 Normal Spent Fuel Cooling and Overview of Class 2 Cooling Chain

The SFS consists of two mechanical trains of equipment. Each train includes one pump, one heat exchanger, and separate piping to and from the pool. During normal plant operation, only one of the SFS trains is needed to provide spent fuel pool cooling and purification. Therefore, if the operating train fails, the standby train can be brought into operation.

During refuelling, as fuel assemblies are unloaded from the core and moved into the pool, and for some time afterwards (based on the decay heat load), both SFS trains are in operation, but only one train is required to prevent onset of boiling conditions. Either RNS train can also be aligned to provide cooling for the SFS pool, provided it is no longer needed for normal shutdown cooling.

Both SFS and RNS reject heat to the CCS and SWS. All of these systems are normally powered by the main ac power system (ECS), but each SFS-RNS-CCS-SWS train and their supporting systems can also be powered by one of the two standby diesels (onsite standby power system (ZOS)) in the event of a loss of offsite electrical power and plant trip.

All of the systems discussed above are Class A-2, and provide a high reliability of spent fuel cooling. Multiple failures are required for a loss of heat removal to occur. The potential scenarios leading to a loss of cooling capability are:

- Loss of offsite power with plant trip (caused by failure of the rapid power reduction system) and subsequent failure of both trains of the onsite standby diesel generators

- Loss of both trains of SFS, plus the loss of both RNS trains
- Loss of both trains of CCS
- Loss of both trains of SWS
- Loss of both trains of the ECS
- Complete loss of the PLS

In the unlikely event of an extended loss of normal spent fuel pool cooling (i.e., loss of both trains of SFS and available train(s) of the RNS, or their supporting systems), it is likely that the fault can be identified and repaired before the onset of boiling in the SFP and certainly before there is any significant loss of SFP water inventory (i.e., mean time to return (MTTR) is lower than the time to onset of boiling or to significant water loss challenging fuel uncovery). Low spent fuel pool level alarms in the control room will alert the operator to initiate makeup water to the pool. If the non-seismically qualified sensor is functional, an alarm for low spent fuel pool level will alert the operators in the control room to makeup water in the SFP. In addition, alarms are provided from redundant Class 1 instrumentation to alert the operator to makeup to the pool and to alert the operator that the pool has reached the low level limit.

Loss of cooling in the refuelling cavity is bounded by the loss of spent fuel pool cooling since the amount of water in the spent fuel pool compared to the inventory of spent fuel (and decay heat) is much less than in the refuelling cavity. Also, the containment provides an additional barrier to any activity release if water is boiled in the refuelling cavity, compared with the spent fuel pool located outside the containment. In addition, the operation of the Class 1 PCS acts to condense the steam created if the refuelling cavity boils and the condensed steam is returned to the IRWST and can be re-used to remove core decay heat.

9.7.2.3.3 Class 1 Passive Cooling

During the first 72 hours after a loss of cooling event, any required makeup water is supplied from Class 1 seismically qualified sources that do not rely on ac power. If further makeup water is required after 72 hours, water from other onsite sources is made available to the spent fuel pool. The amount of makeup water to the pool required to ensure the 72 hours and 7 day cooling capability depends on the decay heat level of the fuel in the spent fuel pool and is provided as follows:

- When the calculated decay heat level in the spent fuel pool is less than or equal to 4.0 MW, no makeup is needed to achieve spent fuel pool cooling for at least 72 hours.
- When the calculated decay heat level in the spent fuel pool is greater than 4.0 MW and less than or equal to 5.0 MW, makeup from the Class 1 cask washdown pit is sufficient to achieve spent fuel pool cooling for at least 72 hours. A minimum level of 4.19 m (13.75 feet) in the cask washdown pit is provided for this purpose. Availability of this makeup source is controlled by Technical Specifications.
- When calculated decay heat level in the spent fuel pool is greater than 5.0 MW and less than or equal to 7.0 MW, makeup from the cask washdown pit and cask loading pit is sufficient to achieve spent fuel pool cooling for at least 72 hours. A minimum level of 4.19 m (13.75 feet) in the cask washdown pit is provided for this purpose. The cask

loading pit is maintained full during shutdown operations for this purpose. Availability of these water makeup sources are controlled by Technical Specifications.

- When the calculated decay heat level in the spent fuel pool is greater than 7.0 MW, makeup from the PCCWST is sufficient to achieve SFP cooling for at least 72 hours, and the combination of the PCCWST and the passive containment cooling ancillary water storage tank (PCCAWST) is sufficient to achieve spent fuel pool cooling for at least 7 days.

- When the decay heat level in the reactor is less than or equal to 7.0 MW, water is not needed for containment cooling for the first 72 hours and the PCCWST can be used for makeup to the spent fuel pool. The volume of water in this tank is sufficient to provide makeup for at least 72 hours, based on the highest heat load in the spent fuel pool. Between 72 hours and 7 days the tank can continue to provide makeup water as required until it is empty.

- When the decay heat level in the reactor is greater than 7.0 MW, the water in the PCCWST is reserved for containment cooling. Spent fuel pool makeup water is initially provided by the cask washdown pit or a combination of the cask washdown pit and cask loading pit depending on the heat load in the spent fuel pool according to Technical Specifications. After 72 hours, makeup water can be provided from the PCCAWST.

Alignment of the cask washdown pit and PCCWST is accomplished by positioning manual valves. Gravity driven flow from the cask washdown pit to the spent fuel pool is provided as the cask washdown pit water level will follow the spent fuel pool level. Gravity driven flow from the PCCWST is controlled by a manual throttle valve with local flow indication, which is set to achieve the desired flow when the makeup is initiated. The initial flow will be set based on the amount of decay heat in the SFP and the throttle valve can be adjusted to match the boiling conditions. This can be determined from the full-range level indicators displayed in the control room. The cask loading pit can be aligned to the spent fuel pool by opening the gate which separates these two pits.

After 72 hours, makeup water from the Class 2 PCCAWST can either be pumped to the PCCWST and then gravity fed to the spent fuel pool as discussed above, or the water can be pumped directly to the spent fuel pool. When the makeup water is pumped directly to the pool, the flow rate is controlled by the same manual throttle valve used to set the flow rate when providing gravity driven flow from the PCCWST.

It is expected that after 7 days other site water sources such as the fire protection system, demineralised water system, or water from offsite sources can be used to makeup SFP boiling for an extended time period. In addition, river or sea water may be used as makeup.

The following indications and alarms will alert the operator of a loss of normal spent fuel cooling:

- Spent fuel pool high temperature indication and high alarm – Safety Class B-3

- Spent fuel pool low-2 water level indication and low alarm – 3 way redundant Safety Class A-1 instrumentation

- Spent fuel pool low water level indication and low alarm – Safety Class B-3

- SFS pumps discharge flow indication and low alarm and/or SFS heat exchanger outlet temperature indication and high alarm – Safety Class B-3

- If the loss of SFP cooling was caused by failures in the CCS or SWS, there would be additional indications and alarms associated with those systems

After the operators become aware of the loss of cooling to the SFP, they would track the SFP temperature as it increased toward boiling. After boiling starts, they would track the SFP level as it decreased due to the boil-off. If the SFP is boiling, an additional indication and alarm may be generated by the spent fuel room air-activity monitor (Safety Class C-3). During this time the operators would attempt the recover Class 2 cooling. The SFP water level indication would be used to indicate when the operators would need to align an alternative makeup source.

9.7.2.3.4 Placement of Fuel in the Racks

Upon the loss of off-site power and notification from the control room or the pool visual level indicator, the operators involved with fuel movement in the fuel handling area assess the condition and the immediate actions needed to place a fuel assembly in a safe storage location.

A total time of less than one hour is assumed to perform the manual fuel move from the fuel transfer system upender to a defective fuel cell storage location. This time estimate is considered conservative and can be improved with the reduction of travel distance to place a fuel assembly fully down.

The fuel handling area will remain habitable with adequate lighting for greater than 2 hours with an averaged wet bulb global temperature (WBGT) of 35 °C (95°F) or less.

Completion of the operation would result in dose rates well below the appropriate Target 4 limits. The doses for the described event bound anticipated less limiting doses for other events, where spent fuel pool level is maintained until the onset of boiling.

Following safe placement of the fuel assembly, the fuel handling area (FHA) would be evacuated (Reference 9.7-11).

9.7.2.3.5 Post-72 Hour Cooling and Diverse Class 2/3 makeup sources

As stated in 9.7.2.3.3, the amount of makeup water needed to prevent fuel uncovery for at least 72 hours depends on the decay heat load in the SFP. This makeup is provided solely by Class 1 sources. In the unlikely event of an extended loss of cooling scenario, where post fault recovery has not occurred after 72 hours, the Class 2, 3, and GNS makeup sources are able to provide post-72 hour cooling capability. Furthermore, if there is a loss of cooling event coincident with a failure of a Class 1 passive makeup source, the sources described below provide a diverse means of ensuring adequate water level in the SFP, each with its own dedicated power supply.

Class 2 makeup water from the PCCAWST: Either one of the two Safety Class B-2 pumps powered by its corresponding ancillary diesel generator can provide makeup to the SFP. The ancillary diesels are a diverse power source separate from the standby diesel system. The pumps are located in the Seismic II portion of the Annex Building. Makeup water can be aligned to the pool through any of the following paths:

1. Directly into the SFP through the Class 1 RNS line

2. Through the Class 2 SFP Spray lines.
3. Indirectly to the SFP through the Class 1 RNS line by refilling the PCCWST

Note that the Class 2 Ancillary equipment is protected against hurricanes but is not protected from other limiting internal / external hazards. If these SSCs are not available then offsite equipment would be brought to the site and connected to Class 1 connections to provide the same functions.

Makeup from the FPS to SFP spray lines: One of the two Safety Class B-3 FPS tank packages can be used to provide at least 1893m^3 (500,000 US gallons) of makeup supply to the spray lines. The lead fire pump is electric motor-driven and the second pump, to be used if offsite power is lost, is diesel engine-driven. This is a dedicated fire protection diesel engine. This diverse source pumps water from the FPS storage tanks to the spray lines. In addition, upon actuation, up to 2366 l/min (625 gpm) of makeup water can be provided to refill the FPS tanks by the Raw Water System (RWS).

Flanged Connection to SFP spray lines: A Safety Class B-3 flanged connection, located outside of the fuel handling area, can also be used to provide makeup water to the SFP through the spray lines. This connection is powered by a dedicated, portable pump and will provide a diverse means of providing makeup to the SFP. The portable pump can be used to take suction from a fire hydrant on the southeast side of the plant or any other potable water source and discharge the water into the flange to connect to the SFP spray lines.

The above makeup sources can all be used if ac power is not available. If ac power is available, demineralised water transfer and storage system (DWS) and CVS water can also be supplied as makeup water to the SFP. The DWS water can be pumped through the SFS connection to the SFP, while the CVS makeup water can be pumped through the SFS connection or RNS connection to the SFP.

PCCAWST Flange Connection: A Class 2 flanged connection, which ties into the existing line PCS-PL-L064 between the PCCAWST and PCS-PL-V037, can also be used to provide makeug water for SFP and Containment cooling. A site-specific portable pump can be used to take suction from the PCCAWST flange connections and discharge to the PCS Class 1 flange connections to provide makeup water for SFP and Containment cooling.

9.7.2.3.6 Analysis of Effects and Consequences

There are two scenarios which may lead to a release of activity:

- Loss of all forced flow cooling leads to boiling of the pool which causes activity in the pool to be carried into the building atmosphere and the outside environment

- Boiling continues long enough and makeup is not supplied for the fuel to be uncovered, leading to fuel failure and a large release to the building and atmosphere.

This section addresses loss of cooling events due to the failures in the cooling chain, including a break in the non-seismic, non-Class 1 SFS suction/return piping. This is the only non-Class 1 piping that can lead to a loss of cooling in the event of a pipe break. Postulated breaks in Class 1 lines are discussed in Section 9.7.2.4.

9.7.2.3.7 Analysis Method

The analysis for the AP1000 spent fuel pool heatup, boiloff, and emergency makeup on loss of cooling is documented in APP-SFS-M3C-012 (Reference 9.7-10). This analysis supports the AP1000 design, but it only considers loss of cooling or a break of non-Class 1 lines. It does not assume a break in Class 1 lines and does not directly provide time to onset of boiling analysis. To support the UK safety case, additional analyses has been performed, covering a wider range of frequent and infrequent design basis conditions. These analyses are documented in UKP-SFS-M3C-012 (Reference 9.7-3).

The time to the onset of boiling and the time to fuel uncovery were calculated for a number of scenarios. The loss of cooling scenarios that have been investigated are defined below and are also described in Reference 9.7-3.

Emergency full core offload: This case assumes the maximum possible heat load in the SFP. It is assumed that a full core offload (157 assemblies) occurs just after the reactor has reached maximum power following a recent refuelling. When the full core is offloaded, all fuel storage positions are occupied.

Full core offload: Similar to the emergency full core case, this scenario assumes a full core (157 assemblies) has been recently transferred to a full SFP; however, in this scenario the offload takes place after a normal fuel cycle of 18 months.

Beginning of cycle: This case assumes that a refuelling outage has just finished and there are 69 recently offloaded assemblies in the SFP, along with the maximum number of long term fuel assemblies.

Middle of cycle: This case assumes that an event occurs during the middle of a normal fuel cycle of 18 months, with 69 recently offloaded assemblies and the maximum number of long term fuel assemblies.

The emergency full core offload is a very unlikely event, such that its occurrence coincident with loss of spent fuel cooling could be excluded on the double contingency principle. The remaining three cases conservatively evaluate different time in cycle conditions. In general, the refuelling cases considered – the emergency and full core offload – would only apply for a very small fraction of the fuel cycle (approximately 10-15 days every 18 months, or under 3%), while the cases at the beginning and middle of the cycle can be used to provide an estimate of average conditions during the vast majority of the cycle.

The calculations of the boiloff times and fuel uncovery times (Reference 9.7-3) include several conservative assumptions, designed to make the evaluation very conservative and simplify the evaluation methodology. Conservative assumptions include assuming increased core power and uncertainty in the decay heat, draindown of all connected water sources to the postulated break elevations, and event initiation at maximum normal pool temperature of 48.9° C (120°F). Further the top of fuel in the Spent Fuel Pool is assumed to be at elevation [ ][1] since that is the location of the level measurement instrumentation. The actual top of active fuel is located at elevation [ ].

1. Note that the basis for all elevations is set to 100 feet in US design and 100 m in metric design.

9.7.2.3.8 Analysis Results

Onset of Boiling Conditions Analysis

If a complete loss of cooling is assumed, there is a potential for SFP pool boiling. However, even during normal refuelling scenarios (with the whole core off loaded), it would take at least 3 hours for the pool to begin boiling. Figure 9.7.2-1 shows the results of the onset of boiling calculations for various times that the loss of cooling may occur. The available time to onset of boiling conditions is a function of when the event occurs during the fuel cycle. The boiling time is shortest during the portion of the refuelling outage where the entire recently discharged core is located in the pool. At end of the outage, only approximately 44% of the fuel assemblies removed from the reactor are left in the pool (69 assemblies are conservatively assumed to be discharged to the spent fuel pool and the remaining 88 assemblies returned to the core). During the subsequent operation of the plant, the spent fuel decay heat continues to decrease, such that at end of cycle the onset of boiling would take over 24 hours, after the complete loss of pool cooling capability occurs.

As discussed in the following section, actuation of the Class 1 passive pool makeup system will then prevent fuel uncovery in the bounding case for at least 72 hours, and a significantly longer time is provided for more credible conditions.

Fuel Uncovery Analysis

Table 9.7.2-1 shows the estimated times to fuel uncovery from the beginning of the transient for the scenarios identified above, relying solely on the initial inventory in the SFP and the associated pits. This is essentially the time available for operator action to align the makeup sources to prevent fuel uncovery. For each heat load, the time from the loss of SFP cooling to when the pool water inventory is reduced to the top of the fuel assemblies is listed. Both a loss of cooling event, with all lines intact, and a postulated break in a SFS Class 2 line are considered. Postulated breaks in Class 1 lines are discussed in Section 9.7.2.4.

Table 9.7.2-1 illustrates that for the “no break” and “Class 2 piping break” cases, abundant time is available for the operators to initiate water makeup to the SFP from Class 1 (or Class 2 and 3) water sources, and to restore the SFP cooling function. In fact, only during increased heat loads during and immediately following a refuelling scenario would any action be required to support the 72 hour safety claim.

In Case 2, a break in the SFS suction piping, the ability to cool the SFP using the normal Class 2 SFS cooling chain would be lost; however, the operator could align the SFP to an available RNS train, if either of the two trains is available. With at least 2 hours available until boiling starts, it is highly unlikely that a Class 2 SFS suction or return line piping break would lead to a boiling scenario, considering one of the two RNS trains can be used to cool the pool.

For the cases where the operator is required to provide initiate passive makeup, the Class 1 PCCWST could be aligned to achieve the 72 hour objective with abundant margin. The operator actions required to align the PCCWST consist of opening three manually operated valves. Once aligned, the PCCWST has a minimum of 2864 m^3 (756,700 US gallons) available for spent fuel pool makeup, enough to keep the fuel covered well past 72 hours.

Operator Actions

The robust design of the AP1000 ensures multiple pathways to provide Class 1 makeup from the PCCWST and additional Class 2 and 3 makeup from other diverse sources. The operator

actions required to align the various makeup sources are outlined in Table 2.4-3 of Reference 9.7-4.

9.7.2.3.9 Post Fault Recovery

The following post-accident recovery section below, along with Section 9.7.2.4.6 (Post Fault Recovery for infrequent pipe breaks), provide a general description of how the operators would deal with a loss of cooling event.

Loss of Cooling without a Pipe Break:

If a loss of cooling accident occurs without a pipe break, the recovery actions consist of maintaining sufficient level in the SFP while the cause of the loss of cooling accident is identified and fixed. Additional details on operations to restore cooling are provided in Reference 9.7-4.

Table 9.7.2-1 shows that during normal plant conditions, the operators will have at least 3 days to identify the cause of the problem and take corrective actions. During a refuelling outage, the operators will have at least 36 hours. The most likely cause of a loss of cooling is a station blackout or a loss of the CCS/SWS cooling chain. The MTTRs for these faults are significantly shorter than the 3 days and 36 hours for normal operation and refuelling, respectively.

Break of SFS Suction/Return Piping

The SFS return line to the SFP has a hole that is located below the operating deck elevation. This hole acts as a siphon break to prevent draining the pool in the event of an SFS return pipe break or equipment leak.

Because the Class 1 SFP connection to the RNS is below the SFS piping connections, even if the SFP pool level drops to the bottom of the SFS suction piping, an RNS pump and heat exchanger train can be aligned to the SFP to restore cooling capability. At least one of the two RNS trains would always normally be available as the first line of defence for an SFS pipe break. Additional detail on operations to restore cooling are provided in Reference 9.7-4.

9.7.2.3.10 Consequences Analysis for Onset of Boiling Conditions and Event Frequency

Dose Analysis

The following conservative assumptions are included in the dose analyses:

- The initial activity in the pool is based on the .025 mSv/hr (2.5 mRem/hr) dose rate limit at the pool surface. It is conservatively assumed that the entire dose is from I-131, the iodine nuclide with the greatest dose impact. It is, however, expected that most of the dose rate would actually be coming from cobalt, instead of iodine.

- It is conservatively assumed that the iodine escape rate coefficient increases by 2 orders of magnitude coincident with the loss of SFP cooling. It is however expected that the escape rate coefficient would remain approximately the same since the heat transfer from the fuel to the SFP water would not significantly increase. Additionally, the iodine that would be released over a 30-day period is assumed to be present in the pool at the onset of boiling. These conservatisms account for approximately 45% of the analysis source term.

- Iodine, when oxidised, becomes volatile and may enter the air above the SFP; other nuclides, except for noble gases, are non-volatile (i.e., particulate). It is conservatively assumed that 1% of the iodine becomes airborne. From Figure 11 of Reference 9.7-12, it can be seen that the fraction of iodine oxidised (and therefore assumed to be volatile) in a boric acid solution is less than 1% at 100 ºC (212°F). The iodine release rate is assumed to be proportional to the calculated steaming rate from the pool. Since the SFP boiling is a gradual process as opposed to flashing, the moisture carryover and resultant particulate release is assumed to be negligible and is therefore not modelled.

- The SFP iodine release is assumed to be a direct atmospheric release (e.g., everything that escapes the pool surface is assumed to be released to the environment). No credit is taken for the volume of the room in which the SFP is located. Atmospheric releases would be subject to dilution effects from the volume of the room and the exhaust rate from the room to the atmosphere

- Operation of the VAS and containment air filtration system (VFS) HVAC systems is not credited in the dose analysis. It is noted that for most expected normal operation conditions (e.g., not emergency core offload or during refuelling), even with the conservative assumptions identified herein, the VAS and VFS systems, if available, would be able to at least significantly delay, if not prevent, the actuation of the relief panels following onset of boiling conditions. This would extend the time before any postulated release to the environment occurs, and significantly reduce any such release.

While airborne crud contribution is not modelled in the evaluation of the radiological consequences of a SFP boiling event, the dose impact of crud in the SFP is expected to be very small (Reference 9.7-5).

As discussed in Section 4.1.2 of Reference 9.7-5 (Spent Fuel Pool Chemistry, UKP-GW-GL-081, Rev. 0, January 2011), a passive filtering capability is provided by the fuel handling area relief paths. This solution is considered ALARP as it resolves an uncertainty with a design change that is considered practical. The filters will be specified to ASME-AG-1, which requires a minimum efficiency of 99.97% when testing with 0.3μm particles. The conclusion is that with this additional filtration the boiling dose analysis remains bounding.

Reference 9.7-6 documents Westinghouse analyses for the doses at the site boundary and in the control room following a postulated extended pool boiling. Two cases are considered:

1. Emergency core offload case. The dose for the duration at the site boundary is reported as less than 0.3 mSv. The control room dose is calculated as less than 0.4 mSv. The assumptions considered in this case are consistent with the emergency core offload case described in Section 9.7.2.3.6 and Reference 9.7-4.

2. Normal At-Power Operation case. The dose at the site boundary is calculated as 0.04 mSv.[1] The control room dose is calculated as less than 3.0E-03 mSv (assuming main control room emergency habitability system (VES) in operation). The assumptions considered in this case are consistent with the beginning of cycle case described in Section 9.7.2.3.6 and Reference 9.7-4.

1. Note that the dose provided in Reference 9.7-6 for this case is calculated for the limiting 2 hours. The dose for the duration at the site boundary that is provided here has been conservatively estimated by multiplying the LPZ (low population zone) dose by the ratio of the EAB (exclusion area boundary) X/Q by the smallest LPZ X/Q used in the analysis, as 5.0-03 mSv * (5.1E-04/8.0E-05) = 4.0E-02 mSv. The site boundary X/Q used in Reference 9.7-6 bounds the value listed in Appendix 9A, Table 9A-5.

It is noted that even considering the emergency core offload case to conservatively bound refuelling, and for the normal at-power operation case to conservatively bound the rest of the cycle, the emergency core offload case only applies to approximately 3% of the time in cycle, while for the remaining 97% the very low doses calculated for a loss of spent fuel cooling during normal operation case would remain bounding. In all cases, the doses are below the limits of Chapter 8 for the appropriate event class.

Operators will not be allowed to re-enter fuel handling area during pool boiling after all fuel has been seated in the racks. Further, anyone attempting entry or residing in the area would notice that the building was full of steam; therefore, it is incredible that there would be any cumulative dose associated with workers in the immediate vicinity of the pool.

Event Frequency

The bounding fault as described above includes a seismic event sufficient to damage the SFS piping. This would be a rare event. More frequent events would be associated with failures leading to a loss of spent fuel cooling, due to system failures or loss of offsite power. In each of these cases, the SFS piping would remain intact and the initial water level would be higher than is conservatively assumed in the consequence assessment.

The following faults needs to be considered to establish a probability for the loss of cooling function provided by the A-2 systems:

- Loss of offsite power with plant trip and subsequent failure of both trains of the onsite standby diesel generators
- Loss of both trains of SFS, plus the loss of both RNS trains
- Loss of both trains of CCS
- Loss of both trains of SWS
- Loss of both trains of the ECS
- Complete loss of the PLS

A PSA has been conducted for loss of spent fuel pool cooling (Reference 9.7-7). The two main initiators leading to pool boiling, and eventually to fuel uncovery, are LOOP and Loss of Component Cooling/Service Water Systems (LCCW).

PSA studies conducted in Reference 9.7-7 have been revised in Reference 9.7-8 to take into account the UK specific SFP, RNS, CCS and SWS design and the latest reliability data from NUREG/CR-6928 (Reference 9.7-9). The Spent Fuel Pool boiling contribution from pipe breaks retained in the PSA study is less than 1.0E-05/yr.

The spent fuel pool boiling frequency contribution from loss of offsite power is calculated by multiplying the frequency of loss of offsite power used in Reference 9.7-8 (3.59E-02/yr. a DB2 fault) by the probability of failing to recover offsite power, and by the probability of failure of the diesels to start and run for 24 hours. The frequency calculated is less than 1.0E-05/yr.

The spent fuel pool boiling frequency contribution from loss of the SFS and RNS trains documented in Reference 9.7-8 is less than 1.0E-04/yr.

A frequency of 3.50E-04/yr. (Reference 9.7-8) has been calculated for the spent fuel pool boiling due to LCCW is calculated as a DB1 fault (Reference 9.7-8). This frequency takes into account the diverse FPS connection to the CCS that is able to provide a separate heat sink to significantly reduce the probability of SFP boiling. With at least 1230 m^3 (325,000 US gallons) of fire protection water available and 2366 l/min (625 gpm) of RWS makeup water available to the FPS, this diverse connection can sustain cooling for a heat load of approximately 8.8 MW (30 MBTU/hr) in the SFP. The RWS makeup water automatically supplies water to the FPS storage tank once a low level is reached. If FPS water is being used to cool the SFP, the PRHR HX or other Class 1 components could be activated to cool the RCS inside containment until CCW/CCS is restored.

The total frequency calculated for onset of boiling conditions, taking into account the various contributors described above, is approximately 5.0E-04/yr. classifies boiling as a DB1 fault (Reference 9.7-8).

Consequences Assessment

As discussed above, the unmitigated consequences of any event potentially leading to a loss of cooling is eventual fuel uncovery and fuel damage. The primary protection against fuel uncovery is provided by the Class 1 systems.

The analysis documented herein shows that the calculated doses (<< 1mSv) and the low probability of the event (DB1) are acceptable. The associated doses remain well below the limits of Chapter 8 for the appropriate event class.

9.7.2.3.11 Consequences Analysis for Extended Boiloff and Potential Fuel Uncovery

As the pool boils, the water inventory is slowly reduced. As shown in Table 9.7.2-1, for the majority of time in a fuel cycle (approximately 97% of the time), no operator action is needed before 72 hours. In the unlikely event that the operator has to perform an action before 72 hours, the operator has over 24 hours before additional makeup is required. The operator would align makeup from the Class 1 source to ensure water is maintained above the stored fuel for at least 72 hours. For non-refuelling scenarios, over 72 hours are available before any makeup to the SFP is needed to prevent stored fuel uncovery.

There are several diverse engineered means of making up the pool inventory and, the long timescale before fuel uncovery means that operator intervention with water being supplied from a number of alternative on-site sources or from public water source can be claimed. The non-Class 1 sources of water that do not rely on the plant ECS and therefore do not rely on offsite or on-site standby power include:

- The PCCAWST with the use of ancillary diesel generators to power the PCS recirculation pumps
- The FPS water storage tank with diesel driven FPS pump and fixed piping to add water directly to the pool
- Fire hydrant or potable water source through flanged connection to SFP spray lines
- Offsite water supplies as available

All of these sources can be initiated if there is a failure of the Class 1 sources or to maintain long term cooling of the SFP. There are also several additional sources of water that can be used, but rely on the plant ac electrical power (ECS) including:

- The FPS water storage tank with motor driven pump and fixed piping to add water directly to the pool.
- The DWS water storage tank with motor driven pumps and fixed piping to add water directly to the pool.
- The boric acid storage tank and DWS water storage tank with the CVS makeup pumps and fixed piping to add borated water directly to the pool.

Since the water loss from the SFP is due to boiling, the boron concentration in the pool would not be reduced to below normal levels by using unborated water to make up the inventory, so there is no criticality issue.

In summary, the Class 1 water inventory and makeup ensure at least 72 hours are available before fuel uncovery is challenged, even when a postulated loss of the complete A-2 cooling chain without recovery is assumed. As discussed in the next section, 'Event Frequency', this results in an extremely robust design, which is effective in achieving a very low frequency for fuel uncovery.

Additionally, it is be noted that, as a beyond design basis measure, the spent fuel pool sprays will be available to maintain fuel cooling in the event of loss of water immersion. This requires either the diesel driven FPS pump or the motor driven FPS pump and a standby diesel generator to be available and working. In addition, there is a gravity driven spray line to the pool provided from the PCCWST and a flanged connection to the spray lines for additional water sources to be supplied to the SFP. These sources of makeup can be initiated by manual operator action, but they have no flow control.

Event Frequency

The "AP1000 PRA Spent Fuel Pool Evaluation" (Reference 9.7-7) presents the initial PSA for the AP1000 SFP. Fault tree analysis was used to quantify an estimate of the SFP contribution to the AP1000 fuel damage frequency (FDF). The analysis includes development of success criteria and mitigation strategy used to provide cooling and water makeup to the SFP and fault tree quantification results. The FDF calculated for the SFP is expected to have a small effect on radionuclide releases at the plant boundary.

The AP1000 SFP FDF was calculated in Reference 9.7-7 to be less than 1.0E-9 per year. This analysis is judged to be conservative. It does not include the latest SFS, RNS, CCS and SWS design for UK (and therefore the newly calculated spent fuel pool boiling frequency contribution from the loss of CCS/SWS). This is significantly lower than the 1.0E-07/yr. cut-off for design basis events in the UK. Also no MTTRs are credited although results from Table 9.7.2-1 shows that in the worst scenario, more than 24 hours are available for the operators restore SFP cooling when SFP cooling is lost or before establishing a makeup water source.

The SFP is located outside the reactor containment building, and fuel damage in the SFP is, therefore, considered to result in a release outside containment. The comparable large release frequency (LRF) quantified in the "UK AP1000 Probabilistic Safety Assessment" is less than 1.0E-07 events per year (Section 10.4.11). The FDF value is less than 1 percent of the LRF

value. The FDF quantified for the SFP will result in a minimal increase in the source term values used for a Level 3 PSA analysis.

9.7.2.3.12 Conclusions

The AP1000 design provides robust Class 1 passive systems to backup the active Class 2 spent fuel cooling chain. As demonstrated in Section 9.7.2.3.7, not only is the initial pool inventory sufficient to provide abundant time before a potential for fuel uncovery is approached, but also several Class 1 makeup sources are available to the operator to provide makeup water to the SFP for well over the 72 hours claimed in the safety claim in Section 9.7.2.1. These multiple lines of defence are sufficient to reduce the probability of fuel damage to less than 1.0E-9/yr., which places it well beyond the design basis.

9.7.2.4 Fault ID#3.2.5-3.2.9 – Postulated Loss of Water Inventory from the SFP

9.7.2.4.1 Identification of Causes and Accident Description

The no-break and non-seismic piping break scenarios are already included in the analysis documented in Section 9.7.2.3. In this Section, other less likely, but potentially more severe, Class 1 breaks are considered.

The spent fuel storage facility is located within the seismic Category I auxiliary building fuel handling area. The walls of the spent fuel pool are an integral part of the seismic Category I auxiliary building structure and are therefore designed to withstand a design basis earthquake. The spent fuel pool racks are also seismic Category I. The fuel handling machine is a seismic Category II component and is evaluated to show that it does not collapse into the spent fuel pool as a result of a seismic event. The fuel handling machine is also designed to maintain its load carrying and structural integrity functions during a safe shutdown earthquake. The spent fuel cask handling crane is a single-failure proof, seismic Category 1 component. In addition, the cask handling crane rails are placed such that the crane cannot drop any load that would fall or topple into the spent fuel pool. Therefore, a design basis earthquake or credible dropped load would not cause serious damage to the pool wall or liner sufficient to cause a leak.

There are, however, a number of piping connections to the SFP, all of which are seismic Category I, except for the SFS pump suction lines from the pool and the SFS pump discharge lines returning to the pool. Therefore, damage to the SFS pump suction and return piping is within the design basis and could lead to a lowering of the pool water to the level of the SFS suction header, i.e., about [ ] below the normal water level. This is still [ ] above the top of the fuel stored in the pool. Note that the SFS pump discharge lines returning cooled water to the pool are each provided with a siphon break hole consistent with limiting the loss of pool water as described above. In the case of a pipe break of the SFS piping connected to the SFP caused by a seismic event, the water level would be lowered to the SFS pump suction piping connection and the SFS cooling capability would be lost, however an RNS train can be connected to the SFP to restore cooling capability. This scenario is discussed in Section 9.7.2.3.

Leakage from any of the other pipes connected to the SFP is considered to be a very low probability event. This is because, apart from the SFS pump lines, all piping connected to the pool is seismic Category I. These Class 1 lines connected to the open SFP will normally be at ~20% of their design pressure. Further, these lines are schedule 40 or greater which are capable of use in systems with higher design pressures and thereby provide significant margin against pipe rupture. Furthermore, they are not under the load path of any lifting machinery.

A break in a Class 1 pipe connected to the SFP is an infrequent event; however, these postulated breaks have been analysed to show that even under the worst possible scenarios, the AP1000 design provides a significant window of time before the fuel is uncovered: hence, considering the low probability of occurrence of these events, consequential fuel uncovery is not considered credible.

The possible postulated breaks of Class 1 piping that could lead to the pool draining are listed below:

- A break in the Class 1 RNS suction line (the return line has a siphon break to limit draindown)
- A break in the DN 150 mm (6 inch nominal) Fuel Transfer Canal (FTC) drain line (only if the FTC gate is open)
- A break in the DN 200 mm (8 inch nominal) CLP piping connection to RNS (only if the CLP gate is open)
- A break in the DN 50 mm (2 inch nominal) SFP makeup water piping connection to the common water supply/drain header

The only time the FTC gate is expected to be closed, is during maintenance, when the FTC needs to be emptied. The CLP gate is required to be open when the decay heat load in the SFP is greater than 5.0 MW. Note that a break in the DN 25 mm (1 inch nominal) SFP level instrumentation piping will not result in rapid pool draindown since these connections include a 9.5 mm (3/8 inch) diameter orifice to limit possible pool outflow. In addition, because of the low discharge flow rate and the accessibility of these instrument lines, operator action to plug the leaking line can be taken and this event is not considered further.

Figure 9.7.2-2 provides a sketch illustrating the relative position of these lines relative in the SFP.

All of the breaks considered would cause the SFP to drain to the [ ] elevation in different amounts of time. Due to the design of the Class 1 spent fuel pool piping, it can be argued that the probability of any of these breaks occurring is negligible.

A review of all the potential breaks identifies three potential limiting scenarios that need to be considered in a design basis analysis:

1. The first scenario considered is a Class 1 RNS suction line break. While the RNS suction line is connected at a relatively high elevation compared to other potential Class 1 break locations in the spent fuel pool, a break in this suction line could prevent safety class makeup from the PCCWST from being supplied to the SFP.

2. The second scenario considered is a break during refuelling outage of the DN 200 mm (8 inch nominal) Class 1 CLP piping connection. This is the largest line potentially connected to the SFP that could drain the SFP and leads to the fastest drain time to the [ ] elevation. It is noted that this break is postulated during refuelling with the CLP gate open and the entire core relocated to the spent fuel pool, thus maximizing the heat load. This is the fastest draindown scenario, but with the core in the spent fuel pool, the PCCWST is available to provide Class 1 makeup, as long as sufficient time for operator action can be shown.

3. The third scenario considered is a break during normal operation of the DN 150 mm (6 inch nominal) class 1 FTC drain line. This scenario presents a slightly slower drain time than the CLP line break discussed above and a significantly lower decay heat in the pool (since assemblies have been returned to the core), but this event is postulated during normal operation. In this mode of operation, PCCWST cannot be aligned to provide makeup to the SFP without breaking a Limiting Condition for Operation (LCO) required by Technical Specifications.

The analyses of these scenarios demonstrate that the 72 hour claim is met and that adequate time is provided for the operator to initiate Class 1 mitigation features.

9.7.2.4.2 Analyses of Consequences and Frequency of the Event

The failure of Class 1 lines is considered an infrequent event and an Incredibility of Failure (IoF) argument could be made for these lines. However, the AP1000 design is such to provide significant protection against these postulated events, with sufficient Class 1 makeup sources to ensure an extended grace period before additional actions are required. Hence, to simplify the licensing and operational impact an IoF argument is not made for these lines; instead analyses are performed to demonstrate acceptable consequences for these postulated events.

9.7.2.4.3 Analysis Method

The analysis methodology outlined in Section 9.7.2.3.6 was used for the analysis of these postulated breaks. For additional conservatism, all breaks are assumed to drain the SFP instantaneously to the postulated break level. This allows simplification of the analysis model, but it is a significant conservatism added to the analysis, as only water below the draindown elevation is credited in the transient. Furthermore, taking no credit for the steel and concrete heat sinks, the assumption of a minimum time (15 days) following shutdown, and no credit for the draindown time, all have a significant effect on the calculated time. The assumptions and analysis can be found in Reference 9.7-3.

It would be possible to develop a more realistic evaluation model and show significant additional margin, but given the extended grace periods demonstrated in the following sections, this is not considered necessary.

9.7.2.4.4 Analysis Results

The times until fuel uncovery are discussed below for the limiting cases identified in Section 9.7.2.4.1.

9.7.2.4.5 Postulated Breaks in Class 1 RNS Line

The frequency of an RNS break has been calculated at less than 1.0E-05/yr. in Reference 9.7-8, which is outside the design basis (more frequent than 1.0E-05 per year, Reference 9.7-2). This frequency was determined by measuring the length of pipe from the pool boundary to the first isolation valve and multiplying the length by the frequency of the pipe breaking per foot of pipe. This estimate ignores conservatisms that exist with respect to the operating pressure being ~1% of the design capability of the installed piping and there being very little thermal transients.

A postulated break in the Class 1 RNS suction line during an emergency full core offload will not uncover the fuel for at least 24 hours without any operator action. As expected, if the break occurs during a full core offload, during the beginning of a cycle, or during the middle of a cycle, even more time is required to boil-off the SFP water.

Table 9.7.2-2 provides the time available for the operator actions to align the Class 1 makeup sources to the Spent Fuel Pool. The break of the RNS lines means the PCCWST water cannot be supplied via the Class 1 RNS line; however, Class 1 makeup from the PCCWST can be supplied via the non-Class 1 SFP spray lines. This provides a passive means of supplying makeup to the SFP even if the Class 1 path has been broken. Although the SFP spray lines are not Class 1, given the frequency on the order of 1.0E-05 breaks/year, this capability is sufficient. In addition, with a minimum of 24 hours the operator has to align the passive Class 1 makeup source, the 72 hour requirement for Class 1 is satisfied in this case. In addition to the Class 1 passive makeup, makeup water can be provided through the spray lines by the PCCAWST (powered by ancillary diesel), FPS water tanks (powered by FPS diesel), and an outside water source through the flanged connection (powered by portable, site-specific pump). These diverse paths provide additional layers of defence against fuel uncovery and can be used to extend the 72 hours to at least 7 days.

Postulated Breaks in DN 200 mm (8 inch nominal) CLP Line During Refuelling

A postulated break in the DN 200 mm (8 inch) CLP line has the potential to drain the SFP to the bottom of the gate [ ]. In order for this to occur, the break would have to be located in a portion of the pipe between the CLP pool boundary and the first isolation valve. In addition, the CLP gate would have to be opened, which only occurs when the decay heat load in the SFP is greater than 5.0 MW. Taking into account the conditions necessary for the break to drain the pool (the amount of time in a cycle the gate is open and the length of pipe before the isolation valve), the frequency of the DN 200 mm CLP line breaking is well below the design basis cut-off.

Table 9.7.2-3 shows the time available for operator action assuming a break in the DN 200 mm CLP line that drains the pool to gate elevation occurs, Table 9.7.2-3 shows the time available for operator action.

In this break scenario, it is assumed that the break occurs at 150 hours after plant shutdown, when the full core of 157 assemblies has been offloaded from the reactor vessel and stored in the SFP. This maximises the heat load in the pool, but since the decay heat in the reactor for this scenario will be less than 7.0 MW (since the fuel is not in the reactor vessel but in the spent fuel pool), makeup water from the PCCWST is available for makeup to the faulted SFP. As shown in Table 9.7.2-3, over two hours, calculated with very conservative assumptions, are available before the operator needs to align the class 1 PCCWST water makeup, which is then sufficient to maintain the fuel covered for an extended period of time, well above 72 hours. Additional non-Class 1 makeup sources are also available, but this analysis shows that the initial inventory and the available makeup from Class 1 sources are sufficient to maintain the fuel covered for 72 hours.

Postulated Break in DN 150 mm (6 inch nominal) FTC Drain Line

The frequency of a break in the DN 150 mm FTC drain line, taking into account the length of pipe that would cause the pool to drain, is well below the design basis cut-off (Reference 9.7-8). Due to the fact that the FTC gate is normally open, the frequency of the break is greater than the DN 200 mm CLP line break; however, more time is available for the operator to initiate makeup.

The break analysed in Table 9.7.2-4 is assumed to occur during normal operation of the plant (but at the beginning of a new cycle to maximise the heat load in the pool); 360 hours after plant shutdown, while 69 freshly discharged assemblies reside in the SFP. The CLP gate is assumed to be closed, while the FTC gate is assumed to be open, as this is expected during

normal operation. In this case, the most limiting postulated break is the double ended guillotine rupture of the FTC drain line. Assuming the operator was not able to isolate the break from the SFP by closing the FTC gate, the water level would lower to the bottom of the gate [ ]. The operator would first try to align any of the non-Class 1 sources described in Section 9.7.2.3.4.

Should these steps prove unsuccessful, the Class 1 makeup from the PCCWST would be available. However, use of this makeup source would result in a violation of Technical Specification LCO 3.6.6. This LCO states that the operator would trip the reactor and bring the reactor to a safe shutdown conditions, according to the required steps.

The results in Table 9.7.2-4 show that, even for this limiting case, the initial pool inventory is sufficient to prevent fuel uncovery for over 4 hours, without reliance on any additional water source. It is noted that this case is analysed at the beginning of a cycle, and thus the calculated time to uncovery represents a minimum value during the fuel cycle.

During this time, if non-Class 1 makeup water sources are available, the operator would try to establish stable makeup from the non-Class 1 sources. However, if non-Class 1 makeup water sources are not available, the operator would proceed to shutdown the reactor and maintain it in a safe state using Class 1 and Class 2 systems, and provide makeup to the Spent Fuel Pool from the available Class 1 makeup water sources. The Class 1 makeup water sources ensure sufficient makeup water is available to protect the fuel in the Spent Fuel Pool for at least 72 hours. These sources are the normally isolated Cask Washdown Pit, Cask Loading Pit, and PCCWST. This extends the grace period provided by Class 1 sources only to over 72 hours.

Loss of Water in Refuelling Cavity due to CLP Line Break or FTC Drain Line Break

It is noted that when the fuel transfer tube is open during refuelling operations, postulated breaks in the FTC/SFP/CLP piping will result in the loss of some water from the Refuelling Cavity inside containment. The non-seismic portions of the SFS are isolated from the refuelling cavity on Low-2 Class A-1 spent fuel pool level sensors to preclude a decrease in Refuelling Cavity level below [ ]. Following such breaks, the operator has sufficient time to restore isolation of the Refuelling Cavity from the FTC/SFP/CLP by closing the manual gate valve on the FTC side of the fuel transfer tube, prior to significant heatup and subsequent boiling of the SFP water.

For postulated breaks in the Class 1 DN 150 mm (6 inch nominal) FTC drain line or the DN 200 mm (8 inch nominal) CLP line (if the CLP gate is open), the Refuelling Cavity water will transfer to the FTC as the FTC/SFP/CLP water level decreases. Since the fuel transfer tube is very large (76 cm (30 inch) in diameter) compared to the postulated breaks, the Refuelling Cavity water level will closely follow the decreasing water level in the FTC/SFP/CLP, and the rate of water loss from the entire FTC/SFP/CLP/Refuelling Cavity will be limited by the flow from the broken FTC or CLP line. The water level in the refuelling cavity decreases at a slower rate than it would for the postulated break of an RNS line outside containment described in Section 9.8.5.3. This is due to the large combined surface area of the FTC/SFP/CLP/Refuelling Cavity.

The loss of water from inside containment to the FTC, which would prolong the draindown of the SFP, is not considered in the SFP boiloff calculations. The boiloff calculations assume a more conservative scenario in which the water in the pool instantaneously drains to the gate elevation. The impact of these breaks on the ability to maintain cooling for fuel in the reactor vessel containment has not been analysed since they are bounded by the postulated break of an RNS line outside containment, described in Section 9.8.5.3.

The isolation on Low-2 spent fuel pool level automatically terminates the loss of water from the refuelling cavity; this bounds breaks in the non-seismic spent fuel pool suction line.

9.7.2.4.6 Post Fault Recovery

Recovery following these unlikely events is more complex than the recovery from more likely loss of cooling faults (as discussed in Section 9.7.2.3.7, and for which recovery is discussed in Section 9.7.2.3.8) due to the need to terminate the originating cause of the event. Once the break is isolated, the recovery is completed with the same actions described in Section 9.7.2.3.8. Additional details on operations to restore cooling are provided in Reference 9.7-4.

9.7.2.4.7 Conclusions

Even for postulated, infrequent breaks in Class 1 lines, sufficient water inventory and makeup are available to ensure at least 72 hours before any potential fuel uncovery. Refer to the additional conclusions stated in Section 9.7.2.3.12.

9.8 Shutdown Faults

9.8.1 Introduction and Overview

Table 9.8.1-1 provides a summary description of the AP1000 operating modes. The discussion in this Section is focused on Shutdown and Refuelling Modes, which are Modes 4, 5 and 6.

Westinghouse has considered shutdown operations in the design of the AP1000 nuclear power plant. The AP1000 defence-in-depth design philosophy to provide normally operating Class 2 active systems and passive Class 1 safety systems gives the AP1000 a greater degree of safety during shutdown operations as well as during normal power operation when compared to currently operating plants. This section presents and evaluates the AP1000 design features to address the issues of shutdown risk and shutdown safety. Potential faults during shutdown modes were evaluated to determine whether they are potentially limiting. The potentially limiting faults were analysed using design basis computer codes and methods, only crediting mitigation by A-1 features.

Potential faults in shutdown modes have been identified. The process of identifying potential faults in shutdown mode considers three different aspects:

1. Screening of at-power faults that are also applicable in shutdown modes
2. Potential faults that are specific to shutdown modes
3. Other faults that are generic to refuelling operation

One of the key aspects of shutdown evaluations is that, while shutdown events are typically covered by the analysis of at-power events, which are in general more limiting and designed to cover a full range of operating conditions from 0 to 100% power, different Class 1 safety systems are not available once certain shutdown conditions are reached. Therefore, an evaluation of shutdown events needs to be accompanied by a detailed assessment of the systems available and the procedures available.

To achieve this objective, the content of this section is therefore organised as follows:

- Section 9.8.2 – potential faults for each identified category are identified and organised.
- Section 9.8.3 provides a detailed description of systems designed to operate during shutdown conditions and for shutdown operations.

The following Sections are then dedicated to the documentation of the fault studies for shutdown faults:

- Section 9.8.4 is dedicated to the analysis of faults identified as at-power faults but which can also occur during shutdown.
- Section 9.8.5 covers potential faults that are specific to shutdown modes.

As is demonstrated in the following sections, for each of these groups of faults the AP1000 design provides multiple lines of defence, both through the Class 2 active systems and through the Class 1 passive systems. In the AP1000 design the fundamental function of the Class 2 systems is to reliably support normal operation and minimise the demand on the passive systems. The Class 1 systems provide the primary means of ensuring the safety

functions. These systems will not be used for normal operation of the plant. The combination of active defence in depth (Class 2) and passive features (Class 1) provides a robust design with multiple lines of defence.

Reliance on operator actions during shutdown modes is only credited when there is indication from Class 1 instruments and when there is at least 30 minutes for the operator to take action. These actions are specifically addressed in Sections 9.8.4 to 9.8.5 as part of the assessment of each potential fault identified.

9.8.2 Potential Faults during Shutdown Modes

The following three-step approach has been taken to ensure a rigorous evaluation of shutdown faults:

1. First, all at-power events identified in the fault schedule (Appendix 8A) are evaluated to (1) identify whether they are applicable to shutdown modes, as discussed in Section 9.8.1 and shown in Table 8A-2; (2) identify if applicable, what the plant response to the event will be, compared against the at-power response, and especially considering the availability of different Class 1 equipment credited in the accident mitigation during shutdown conditions; (3) provide a design basis analysis for the event. In most cases, this analysis is provided by already completed analyses of at-power events, but in some cases shutdown specific analyses may be required. Also, in some cases, multiple analyses, covering different shutdown modes, may be required due to different availability of Class 1 equipment. In these cases, separate cases are presented in the discussion covering different modes.

    a. A critical consideration for the evaluation of shutdown faults is the availability of different Class 1 engineered safety features during the different operating modes, as well as the plant specific design features designed specifically to address shutdown modes. Section 9.8.3 provides a summary description of AP1000 key design features relative to shutdown modes. Additionally, Table 9.8.3-1 provides a summary of the availability of relevant Class 1 systems over different shutdown modes.

    b. Section 1 of Table 8A-2 includes at-power design basis faults, and they have been re-evaluated for shutdown mode considerations.

    c. Section 9.8.4 provides a discussion and assessment of each fault in different shutdown modes. For each, reference to the fault schedule ID (Table 8A-2) for each fault is also provided.

2. During shutdown modes, the RNS is aligned to provide heat removal from the reactor coolant system. As such, potential faults specific to this mode of operation need to be identified and addressed.

    a. Section 2 of Table 8A-2 includes potential faults associated with RNS operation that are included in this assessment. It is noted that this table identifies all modes over which the fault is relevant, but mode-specific assessment may be required to consider the availability of different Class 1 equipment.

    b. Section 9.8.5 provides a discussion and assessment of each fault identified,and for each, reference to the fault schedule ID is provided.

3. Finally, additional faults associated with refuelling (Mode 6) are identified in Sections 2 and 3 of Table 8A-2.

    a. All of these faults have either been screened out (see Appendix 8A) or are discussed elsewhere in this chapter, as identified in Appendix 8A.

9.8.3 AP1000 Design Features to Address Shutdown Safety

The AP1000 has incorporated design features that address issues related to shutdown operations. This section provides a discussion of the RCS design features that are incorporated to address shutdown operations or that are important to minimizing the risk to plant safety during shutdown.

Table 9.8.3-1 provides a summary of the availability of Class 1 passive core cooling equipment during different operational modes.

Westinghouse has considered shutdown modes, shutdown alignments, and industry issues related to shutdown in the design of the AP1000 Class 1 and Class 2 systems designed to operate or be available during shutdown. This section provides descriptions of the important systems designed to operate during shutdown and includes specific design features that have been incorporated for shutdown operations with a discussion of their operating modes or alignment during shutdown.

In this section, references are made to the various AP1000 plant operating modes. The AP1000 plant operating modes are defined in Table 9.8.1-1. The mode definitions for the AP1000 design are similar to those of current Westinghouse PWRs, with the difference being the definition of Mode 4, safe shutdown.

In the AP1000, Mode 4 has been redefined as safe shutdown and corresponds to the range of RCS temperature between 215.6°C (420°F) and 93.3°C (200°F). The upper temperature limit corresponds to the RCS temperature that can be achieved by the passive Class 1 systems 36 hours after shutdown. The ability of the passive Class 1 systems to achieve Mode 4 within 36 hours is shown in Section 9C.3.1.1.1.

9.8.3.1 RCS Design Features for Shutdown

The AP1000 design has incorporated design features that address issues related to shutdown operations. This section provides a discussion of the RCS design features that are incorporated to address shutdown operations or that are important to minimizing the risk to plant safety during shutdown.

9.8.3.1.1 Loop Piping Offset

The RCS hot legs and cold legs are vertically offset. This permits draining of the steam generators for nozzle dam insertion with the hot leg level much higher than in traditional designs. The RCS must be drained to a level sufficient to provide a vent path from the pressuriser to the steam generators. This loop piping offset also allows an RCP to be replaced without removing the full core.

9.8.3.1.2 RCS Instrumentation Designed to Support Shutdown Operations

Instrumentation is provided to monitor the RCS process parameters as required by the PLS and PMS as discussed in Chapter 19. This section describes RCS instrumentation designed to accommodate shutdown operations.

9.8.3.1.2.1 RCS Hot Leg Level

There are four Class 1 RCS hot leg level channels, two located in each hot leg. These level indicators are provided primarily to monitor the RCS water level during mid-loop operation following shutdown operations. Each has a level tap on the bottom of the hot leg, and another tap on the top of the hot leg close to the steam generator at the high point of the tubing run. The level tap for the instrument in the hot leg with the RNS step-nozzle suction line connection is between the reactor vessel and the step-nozzle. Figure 9.8.2-1 shows a simplified sketch of the RCS level instruments.

These channels provide Class 1 signals for the following protection functions:

- Isolation of letdown on low level on a two-out-of-four basis.
- Actuation of fourth-stage ADS valves on low (empty) hot leg level on a two-out-of-four basis. Actuation of fourth-stage ADS causes actuation of IRWST injection.

These functions protect the plant during shutdown operations. Letdown isolation assists the operators when draining the RCS to a mid-loop level. If the operators fail to isolate letdown, these channels send a signal to close the letdown valves and stop the draining process.

In the event of a loss of the RNS during shutdown, coolant inventory could be boiled away. When the hot leg water level indicates that the loops are empty, IRWST injection and fourth-stage ADS are actuated 25 minutes after receipt of the empty hot leg level signal. See Section 9.8.5.3.2.2.

These channels also provide signals to the letdown flow control valve to control the drain rate of the RCS via the letdown line during the transition to mid-loop operation. When the hot legs are full, the drain rate can proceed at a high level. As the water level is reduced to the hot legs, the drain rate is automatically decreased to a rate of approximately 4.5 m^3/hr (20 gpm).

These channels are also used to generate the alarms on low hot leg water level. The alarm setpoints are selected to give the operator sufficient time to take manual actions that would prevent the automatic actuation described previously. Indication of these channels is available in the main control room. This variable is used by the operator to monitor the status of RCS inventory following an accident and is, therefore, classified as a post-accident monitoring system (PAMS) variable.

The accuracy and response time of the hot leg level instruments are consistent with the standard ESF actuation discussed in Section 19.2. Concerns related to potential problems of noncondensable gases in the hot leg level instrument lines that have been raised in industry have been addressed in the layout of the instrument lines. In addition, as the hot leg level instruments are provided primarily for shutdown operations, off-gassing due to sudden depressurisation of the RCS in shutdown modes is not a concern.

In the AP1000 design, draining of the RCS to mid-loop conditions is achieved in a controlled manner as discussed in Section 9.8.3.1.4. Due to the low RCS drain rate, and the RCS step-nozzle as discussed in Section 9.8.3.1.3, the amount of air-entrainment, and therefore RCS level perturbation during mid-loop, is negligible. Draining of the RCS is conducted in a quasi-steady-state, and the reliability of an accurate level reading is high.

9.8.3.1.2.2 Pressuriser Level

A fifth, non Class-1 (GNS), independent pressuriser level transmitter, calibrated for low temperature conditions, provides water level indication during startup, shutdown, and refuelling operations in the main control room and in the remote shutdown workstation. The upper level tap is connected to an ADS valve inlet header above the top of the pressuriser. The lower level tap is connected to the bottom of the hot leg. This provides level indication for the entire pressuriser and a continuous reading as the level in the pressuriser decreases to mid-loop levels during shutdown operations

9.8.3.1.2.3 RCS Hot Leg Wide-Range Temperatures

The RCS contains two Class 1 thermowell-mounted hot leg wide-range temperature detectors, one in each hot leg. The detectors' indication of RCS Hot Leg temperature below 93ºC (200°F) assures that inadvertent RCS venting does not occur during Reactor Head Vent Valve in-service testing during shutdown conditions. The orientation of the resistance temperature detectors enables measurement of the reactor coolant fluid in the hot leg when in reduced inventory conditions. Their range is selected to accommodate the low RCS temperatures that can be attained during shutdown. In addition, at least two incore thermocouple channels are available to measure the core exit temperature during mid-loop RNS operation. These two thermocouple channels are associated with separate electrical divisions.

9.8.3.1.2.4 Pressuriser Surge Line Temperatures

There are three Class 2 temperature detectors located on the RCS pressuriser surge line. These instruments monitor the pressuriser surge line fluid temperature during plant normal operations to detect thermal stratification in the surge line. Two of the temperature detectors are on a moderately sloped run approximately midway between the RCS hot leg and the pressuriser. One detector is on the bottom of the pipe and the other detector is on the top. The third detector is located on the pressuriser surge line close to the pressuriser nozzle. This detector is used to monitor cold water insurges to the pressuriser during transient operations.

The temperature is monitored at the three locations using strap-on resistance temperature detectors. Temperature indication is provided in the main control room. One low-temperature alarm is provided to alert the operator of thermal stratification in the surge line. This alarm is associated with the detector on the bottom of the pipe.

During shutdown operations, this temperature instrumentation will be monitored to detect possible surge line stratification. If stratification is detected, the operators can increase spray flow to increase the outsurge from the pressuriser and reduce stratification in the surge line.

9.8.3.1.3 Step Nozzle Connection

The AP1000 RNS uses a step-nozzle connection to the RCS hot leg. The step-nozzle connection has two effects on mid-loop operation. One effect is to lower the RCS hot leg level at which a vortex occurs in the residual heat removal pump suction line due to the lower fluid velocity in the hot leg nozzle. This increases the margin from the nominal mid-loop level to the level where air entrainment into the pump suction begins.

Another effect of the step-nozzle is that, if a vortex should occur, the maximum air entrainment into the pump suction as shown experimentally will be no greater than 5 percent (Reference 9.8-1). The RNS pumps can operate with 5% air-entrainment. As discussed in NUREG-0897 (Reference 9.8-2), low levels of air ingestion can be tolerated, and a pump inlet void fraction of 5% has been shown experimentally to reduce the pump head less than 15%. At this level of degradation, the RNS pumps would maintain decay heat removal. The

step-nozzle thereby precludes air binding of the pump and will allow for RNS pump operation with low water levels in the hot leg.

9.8.3.1.4 Improved RCS Draindown Method

During cooldown operations, the RCS water level is drained to a mid-loop level to permit steam generator draining and maintenance activities. The AP1000 has improved the reliability of draindown operations by incorporating a dedicated drain path, controlled in the main control room, to be used to reduce the water level in the RCS. In current plants, various drain paths can be used either locally or remotely from the control room. These drain paths include the Class 1 residual heat removal system, loop drain valves, and letdown. The result is that draining of the RCS can be difficult to control, and perturbations in water level can occur due to inadvertent system manipulations of which the operators are not always aware.

The AP1000 RCS drain path is via the CVS letdown line from the RNS cross-connect provided to maintain full RCS purification flow during shutdown. The letdown line flow control valve controls the letdown rate, which controls the RCS draindown rate. At the appropriate time during the cooldown, the operator initiates the draindown by placing the CVS letdown control valve into a refuelling draindown mode. At this time, the makeup pumps are turned off and the letdown flow control valve controls the drain rate to the liquid radwaste system at the initial maximum rate of approximately 22.7 m^3/hr (100 gpm). The rate is reduced once the level in the RCS is to the top of the hot leg. The letdown rate is manually controlled based upon the difference in flow instruments readings in the CVS letdown line and injection line. The letdown flow control valve as well as the letdown line containment isolation valve receives a signal to automatically close once the appropriate level is attained. Class 1 alarms actuate in the control room if the RCS level falls below the automatic letdown valve closure setpoint so that the operator is alerted to manually isolate the letdown line. Furthermore, an automatic isolation of the letdown line is actuated on low hot leg level via the Class 1 PMS. This draindown method provides a reliable means of attaining mid-loop conditions.

9.8.3.1.5 ADS Valves

The ADS stage 1, 2, and 3 valves, connected to the top of the pressuriser, are open whenever the CMTs are blocked during shutdown conditions while the reactor vessel upper internals are in place. This provides a vent path to preclude pressurisation of the RCS during shutdown conditions if decay heat removal is lost. This also allows the IRWST to automatically provide injection flow if it is actuated on a loss of decay heat removal. In addition, two of the four ADS fourth-stage valves are required to be available during reduced inventory operations to preclude surge line flooding following a loss of the RNS.

9.8.3.1.6 Steam Generator Channel Head

The AP1000 steam generator is a vertical-shell U-tube evaporator with integral moisture separating equipment. The generator is discussed in Appendix 20C.

On the primary side, the reactor coolant flow enters the primary chamber via the hot leg nozzle. The lower portion of the primary chamber is hemispherical and merges into a cylindrical portion, which mates to the tubesheet. This arrangement provides enhanced access to all tubes, including those at the periphery of the bundle, with robotics equipment. This feature enhances the ability to inspect, replace, and repair portions of the AP1000 unit compared to the more hemispherical primary chamber of earlier designs. The channel head is divided into inlet and outlet chambers by a vertical divider plate extending from the apex of the head to the tubesheet.

The reactor coolant enters the inverted U-tubes, transferring heat to the secondary side during its traverse, and returns to the cold leg side of the primary chamber. The flow exits the steam generator via two cold leg nozzles to which the reactor coolant pumps are directly attached.

The AP1000 steam generator channel head has provisions to drain the head. For minimizing deposits of radioactive corrosion products on the channel head surfaces and for enhancing the decontamination of these surfaces, the channel head cladding is machined or electropolished for a smooth surface.

The steam generator is equipped with permanently mounted nozzle dam brackets, which are designed to support nozzle dams during refuelling operations. The design pressure of the nozzle dam bracket and nozzle dam is selected to withstand the RCS pressures that can occur during a loss of shutdown cooling. The nozzle dam design pressure is at least 0.345 MPa abs (50 psia).

The AP1000 nozzle dams can be installed with the hot leg water level at the nominal water level for mid-loop operations. The nozzle dams can be inserted via the steam generator manway. The ADS valves connected to the pressuriser are open during all reduced inventory operations including nozzle dam installation, and provide a vent path to preclude pressurisation of the reactor coolant system following a loss of decay heat removal when the nozzle dams are installed.

9.8.3.2 PXS Design Features for Shutdown

A significant improvement in shutdown safety for the AP1000 design is the availability of a dedicated Class 1 system that can be automatically or manually actuated in response to an accident that can occur during shutdown. In current plants, the safety systems that mitigate the consequences of an accident are also the operating systems that are used for decay heat removal. In the AP1000 design, Class 2 active systems provide the first level of defence, while the passive Class 1 systems are available during shutdown modes to mitigate the consequences of an accident. This design approach results in a significant improvement in the AP1000 plant shutdown risk.

9.8.3.2.1 Core Makeup Tanks

The CMTs provide RCS makeup. During shutdown, the CMTs are available in Modes 3, 4, and 5, until the RCS pressure boundary is open and the pressuriser water level is reduced. During power operation, the CMTs are automatically actuated on various signals including a safeguards actuation signal (low RCS pressure, low RCS temperature, low steam line pressure, and high containment pressure) and on low pressuriser water level. See Chapter 19 for a description of the AP1000 PMS actuation logic. In shutdown modes, portions of the safeguards actuation signal are disabled to allow the RCS to be cooled and depressurised for shutdown. For instance, the low RCS pressure and temperature, and low steam line pressure signals are blocked in Mode 3 prior to cooling and depressurising the RCS. Therefore, during shutdown Modes 3, 4, and 5, the primary signal that actuates the CMTs due to a loss of inventory is the pressuriser level signal. In Mode 5, with the RCS open (in preparation for reduced inventory operations), the low pressuriser level signal is blocked prior to draining the pressuriser. Therefore, in Mode 5 with the RCS open, the CMTs are not required to be available and the RCS makeup function is provided by the IRWST.

The CMTs also provide an emergency boration function for accidents such as steam line breaks. However, the signals that provide the primary protection for this function (low steam line pressure, low RCS pressure, and low RCS temperature) are blocked in Mode 3 as discussed above. Prior to blocking these signals in Mode 3, the Technical Specifications

require that the RCS be sufficiently borated. For these events, the pressuriser level signal provides automatic actuation of the CMTs for a steam line break that might occur due to the RCS shrinkage that would occur.

9.8.3.2.2 Accumulators

The PXS accumulators provide safety injection following a LOCA. In Mode 3, the accumulators must be isolated to prevent their operation when the RCS pressure is reduced to below the set pressure of their contained nitrogen gas. The accumulator isolation valves are closed when the RCS pressure is reduced to 6.895 MPa gauge (1000 psig) to block their injection when the RCS pressure is reduced to below the normal accumulator pressure.

9.8.3.2.3 In-containment Refuelling Water Storage Tank

The IRWST provides long-term RCS makeup. During shutdown, the IRWST is available until Mode 6, when the reactor vessel upper internals are removed and the refuelling cavity flooded. At that time, the IRWST is not required, due to the large heat capacity of the water in the refuelling cavity.

The IRWST injection paths are actuated on a low-6 CMT water level. This signal is available in shutdown Modes 3, 4, and 5, with the RCS intact. When the RCS is open to transition to reduced inventory operations, the CMT actuation logic on low pressuriser level is removed, and the CMTs can be taken out of service. For these modes, automatic actuation of the IRWST can be initiated (on a two-out-of-two basis) on low hot leg level.

9.8.3.2.4 Passive Residual Heat Removal Heat Exchanger

The PRHR HX provides decay heat removal during power operation and is required to be available in shutdown Modes 3, 4, and 5, until the RCS is open. In these modes, the PRHR HX provides a passive decay heat removal path. It is automatically actuated on a CMT actuation signal, which would eventually be generated on a loss of shutdown decay heat removal, as shown in the analysis provided in Section 9.8.4. In modes with the RCS open (portions of Mode 5 and Mode 6), decay heat removal is provided by “feeding” water from the IRWST and “bleeding” steam from the ADS.

9.8.3.2.5 Reduced Challenges to Low-Temperature Overpressure Events

Another design feature of the PXS that reduces challenges to shutdown safety is the elimination of high-head safety injection pumps in causing low temperature overpressure events. In current plants, during water solid operations that may be necessary to perform shutdown maintenance, the high-head safety injection pumps are a major source of cold overpressure events. To address this, plants are required to lock out safety injection pumps to prevent them from inadvertently causing a cold overpressure event. This eliminates a potential source of safety injection for a loss of inventory event that could occur at shutdown. With the AP1000 PXS, the CMTs are not pressurised above RCS pressure and are, therefore, not capable of causing a cold overpressure event. Therefore, they are not isolated until the pressuriser is drained for mid-loop. Low-temperature overpressure events are discussed in Section 9.8.4.5.1.

9.8.3.2.6 Containment Recirculation Screens

The PXS containment recirculation screens may have to function in the longer-term during a shutdown accident that results in ADS operation. Effective screen design, plant layout, and other factors prevent clogging of these screens by debris during such accident operations.

- Two very large interconnected screens are provided.
- A significant delay is provided between the accident/ADS stage opening and the initiation of recirculation (at least 2 hours).
- Deep flood up levels are provided post ADS operation (9.4 m (31 ft) of water above the lowest level in containment and 7.8 m (25.5 ft) above floors around screens).
- Bottom of screens are located well above the lowest containment level (4.1 m (13.5 feet)) as well as the floors around them (0.6 m (2 feet)).
- Top of screens are located well below the containment floodup level (~3 m (~10 ft) from top screens to minimum flood level).
- Screens have protective plates located no more than 0.38 m (1 foot, 3 inches) above the top of the screens and extend at least 2.7 m (8 feet, 11 inches) in front and 2.1 m (7 feet) to the side of the screens.
- Screens have conservative flow areas to account for plugging. Operation of the Class 2 normal residual heat removal pumps with suction from the IRWST and the containment recirculation lines is considered in sizing screens. Note that adequate PXS performance can be supported by one screen with more than 90 percent of its surface area completely blocked.
- During recirculation operation, the velocity approaching the screens is very low, which limits the transport of debris.
- Each screen has a fine screen.
- Technical Specifications require the screens to be inspected during each refuelling outage.
- A cleanliness program limits the amount of foreign materials that might be left in the containment following refuelling and maintenance outages and become debris during an accident.

9.8.3.2.7 Containment System

9.8.3.2.7.1 Containment Closure at Shutdown.

The AP1000 has addressed the issue of containment closure at shutdown and incorporated the following requirements in the Technical Specifications. In shutdown Modes 3 and 4, containment status is the same as at-power. Specifically, containment integrity is required, the major equipment hatches are closed and sealed, and containment air locks and isolation valves are operable.

In Modes 5 and 6, containment closure capability is required during shutdown operations when there is fuel inside containment. Containment closure is required to maintain, within containment, the cooling water inventory. Due to the large volume of the IRWST and the reduced sensible heat during shutdown, the loss of some of the water inventory can be accepted.

In Modes 5 and 6, there is no potential for steam release into the containment immediately

following an accident. Steam release into containment could occur only after heatup of the IRWST due to PRHR HX operation (Mode 5 with RCS intact), after heatup of the RCS with direct venting to the containment (Mode 5 with reduced RCS inventory or Mode 6 with the refuelling cavity not fully flooded), or after heatup of the RCS and refuelling cavity (Mode 6 with refuelling cavity fully flooded). To limit the magnitude of cooling water inventory losses and because local manual action may be required to achieve containment closure, the containment hatches, air locks, and penetrations must be closed prior to steaming into containment.

9.8.3.2.7.2 Containment Equipment Hatches

The containment equipment hatches, which are part of the containment pressure boundary, provide a means for moving large equipment and components into and out of containment. If closed, the equipment hatch is held in place by at least four bolts. If open, each equipment hatch can be closed using a dedicated set of hardware, tools, and equipment. A self-contained power source is provided to drive each hoist while lowering the hatch into position. Large equipment and components may be moved through the hatches as long as they can be removed and the hatch closed prior to steaming into the containment.

9.8.3.2.7.3 Containment Air Locks

The containment air locks, which are also part of the containment pressure boundary, provide a means for personnel access during Modes 1, 2, 3, and 4 unit operation. Each air lock has a door at both ends. The doors are normally interlocked to prevent simultaneous opening when containment operability is required. The interlocks are necessary for the Personnel Airlock to be operable. In the event that the interlock is broken in Modes 1-4 (or a door is broken) the Personnel Airlock must be closed and locked, otherwise containment would be considered breached. Although some containment penetrations can be opened during normal operation, the Personnel Airlock cannot be. The interlock can only be disengaged in Modes 5 & 6. If a door is broken, or the interlock has failed, the airlock must be closed and locked.

During periods of unit shutdown when containment closure is not required, the door interlock mechanism may be disabled, allowing both doors of an air lock to remain open for extended periods when frequent containment entry is necessary. Temporary equipment connections (for example, power or communications cables) are permitted as long as they can be removed to allow containment closure prior to steaming into the containment.

9.8.3.2.7.4 Containment Penetrations

Containment penetrations, including purge system flow paths, which provide direct access from containment atmosphere to outside atmosphere must be isolated or isolatable on at least one side. Isolation may be achieved by an operable automatic isolation valve or by a manual isolation valve, blind flange, or equivalent.

9.8.3.2.7.5 Containment Spare Penetrations

Containment spare penetrations, which also provide a part of the containment boundary, provide for temporary support services (electrical, I&C, air, and water supplies) during Modes 5 and 6. Each penetration is flanged and normally closed. During periods of plant shutdown, temporary support systems may be routed through the penetrations; temporary equipment connections (for example, power or communications cables) are permitted as long as they can be removed to allow containment closure prior to steaming into the containment.

The spare penetrations must be closed or, if open, capable of closure prior to reaching boiling

conditions within reactor coolant system. Temporary containment penetrations that may be employed during shutdown modes must have a design pressure equal to the containment design pressure of 0.407 MPa gauge (59 psig).

9.8.3.2.7.6 Fuel Transfer Canal

The fuel transfer canal may be opened to provide for the transfer of new and spent fuel into and out of containment during Modes 5 and 6. At times when the canal is opened, it must be isolatable on at least one side by closure of the flange within containment or the gate valve outside containment.

9.8.3.3 AP1000 Class 2 Systems Design Features to Address Shutdown Safety

In the following sections the SGS, main and startup feedwater system (FWS), CVS and RNS features are discussed. It is especially the RNS, and its associated Class 2 cooling chain (CCS and SWS) and supporting systems (e.g., onsite standby Diesel Generators), that will be most relevant to the fault analyses discussed in the following sections.

9.8.3.4 Steam Generator and Feedwater Systems Design Features for Shutdown

This section discusses the AP1000 steam generator system (SGS) and the FWS designs as they relate to shutdown operations.

9.8.3.4.1 Feedwater Control

The AP1000 provides improvements in feedwater control that minimizes the probability of loss of feedwater transients during low power and shutdown modes. The main feedwater pumps are capable of providing feedwater during all modes of operation, including plant startup and standby conditions. In addition, the startup feedwater pumps are automatically started in the event that the main feedwater pumps are unable to continue to operate. The startup feedwater pumps are also automatically loaded on the diesels for operation following a loss of offsite power, during operating modes when the steam generators can be used for decay heat removal.

9.8.3.4.2 Safety Actuation in Shutdown Modes

The AP1000 design has Class 1 actuations associated with the SGS that are operable during shutdown modes. These include the PRHR HX actuation on low steam generator level during shutdown modes, and this is discussed in Section 9.8.4.2.3. Also included is the isolation of the main steam line on a high (large) negative rate of change in steam pressure. This Class 1 signal is provided to address a steam line break that could occur in Mode 3. If actuated, this signal causes the MSIVs to close to terminate the blowdown of the SGS following a steam line break. This signal is placed into service below the setpoint that disables the low steam line pressure signal (P11) that actuates steam line isolation. When the operator manually blocks the low steam line pressure signal, the steam line high pressure-negative rate signal is automatically enabled.

This steam line high pressure-negative rate signal is operable during Mode 3 when a secondary side break or stuck open valve could result in the rapid depressurisation of the steam line(s). In Modes 4, 5, and 6, this function is not needed for accident detection and mitigation. Section 9.8.4.1.3 discusses steam line break events that could occur in shutdown modes.

9.8.3.4.3 Steam Generator Cooling in Shutdown Modes

The secondary side of the steam generators can be cooled during shutdown by circulating their contents through the blowdown system to prevent heat transfer from the steam generators to the primary system. This feature reduces the challenges to low-temperature overpressure events. During RCS water-solid operation, heat input from the steam generators is capable of challenging the low-temperature relief valve. The Technical Specifications prevent the operators from starting an RCP with the steam generator secondary side temperature more than 27.8°C (50°F) higher than the primary side, with the pressuriser water-solid. With the RCS water-solid, the heat input that could occur would cause the system to be pressurised to the setpoint of the low-temperature overpressure relief valve in the RNS.

When the RCPs are operating, the secondary side of the steam generator is cooled by steaming to the MSS. Once the RNS is aligned, and steaming to the MSS is decreased, the secondary side of the steam generators is cooled by operation of the RNS. However, once the RCPs are tripped, water does not circulate through the primary side of the tubes and the secondary side of the steam generators remains at elevated temperature. With the ability to circulate the secondary side via the blowdown system, the AP1000 design reduces the probability that an RCP would be started with the secondary side of the generator at elevated temperature.

The AP1000 design has also incorporated steam generator fluid thermocouples to monitor the temperature of the fluid in the secondary side of the steam generator. This improves the ability of the operators to monitor this temperature to prevent them from inadvertently starting an RCP with the secondary side at elevated temperatures.

9.8.3.4.4 Normal Residual Heat Removal System

The AP1000 has incorporated various design features to improve shutdown safety. The RNS features that have been incorporated to address shutdown safety are described in this section.

9.8.3.4.4.1 RNS Pump Elevation and NPSH Characteristics

The AP1000 RNS pumps are located at the lowest elevation in the auxiliary building. This location provides the RNS pumps with a large available net positive suction head (NPSH) during all modes of operation including RCS mid-loop and reduced inventory operations. The large NPSH provides the pumps with the capability to operate during most mid-loop conditions without throttling the RNS flow. If the RCS is at mid-loop level and saturated conditions, some throttling of a flow control valve is necessary to maintain adequate net positive suction head for the RNS pumps. The RNS pumps can be restarted and operated with RCS conditions that might occur following a temporary loss of RNS cooling.

The plant piping configuration, piping elevations and routing, and the pump characteristics allow the RNS pumps to be started and operated at their full design flow rates in most conditions without the need to reduce RNS pump flow to meet pump NPSH requirements. This reduces the potential failure mechanism that exists in current PWRs, where failure of an air-operated control valve can result in pump runout and cavitation during mid-loop operations.

9.8.3.4.4.2 Self-Venting Suction Line

Most of the RNS pump suction line is sloped upward from the pump to the RCS hot leg. In the level portions of piping, there are no local high points. This eliminates potential problems

with refilling the pump suction line if an RNS pump is stopped due to pump cavitation and/or excessive air entrainment. With the self-venting suction line, the line will refill and the pumps can be immediately restarted once an adequate level in the hot leg is re-established.

9.8.3.4.4.3 IRWST Injection via the RNS Suction Line

During shutdown modes, initiating events such as the loss of the Class 2 RNS are postulated. Such events would require IRWST injection as discussed in Section 9.8.3.2, and as shown in the accident analyses provided in Section 9.8.4. For initiating IRWST injection, the operation of PXS squib valves in the IRWST injection line is required. However, the operators can use the RNS pump suction line that connects to the IRWST to provide controlled IRWST injection. This flow path, shown in Figure 9.8.2-2, connects the IRWST directly to the RCS via the RNS hot leg suction isolation valves and provides a diverse method for IRWST injection. In addition, it would be the preferred method of providing IRWST injection because the flow would be controllable by the operation of the IRWST suction line isolation valve. The RNS isolation valve is equipped with a throttle capability to provide the operators with the capability to control the injection flow via this path. The operator would monitor the RCS hot leg level while controlling flow through this valve. This path provides IRWST injection regardless of whether the RNS pumps are operating.

9.8.3.4.4.4 Codes and Standards/Seismic Protection

The entire RNS pressure boundary is classified as Safety Class 1 and thus as seismic Category I.

9.8.3.4.4.5 Increased Design Pressure

The portions of the RNS from the RCS to the containment isolation valves outside containment are designed to the operating pressure of the RCS. The portions of the system downstream of the suction line containment isolation valve and upstream of the discharge line containment isolation valve are designed so that its ultimate rupture strength is not less than the operating pressure of the RCS. The design pressure of the RNS is 6.205 MPa gauge (900 psig), which is 40 percent of operating RCS pressure.

9.8.3.4.4.6 Normal Residual Heat Removal System Relief Valve

An inside containment RNS relief valve is connected to each residual heat removal pump suction line. Each valve is designed to provide low-temperature, overpressure protection of the RCS. The valves, connected to the high-pressure portion of the pump suction lines, reduce the risk of overpressurising the low-pressure portions of the system.

9.8.3.4.4.7 Reactor Coolant System Isolation Valve

The RNS contains isolation valves in the pump suction lines from the RCS. These motor-operated containment isolation valves are designed to the RCS pressure. They provide an additional barrier between the RCS and lower pressure portions of the RNS.

9.8.3.4.4.8 Features Preventing Inadvertent Opening of Isolation Valves

The RCS isolation valves are interlocked to prevent their opening at RCS pressures above 3.103 MPa gauge (450 psig). The power to these valves is administratively blocked during normal power operation.

In addition, these valves are interlocked with the RNS/IRWST isolation valves to prevent their opening with the RNS open to the IRWST. This precludes the blowdown of the RCS to the IRWST through the RNS upon system initiation.

9.8.3.4.4.9 RCS Pressure Indication and High Alarm

The AP1000 RNS contains an instrumentation channel that indicates pressure in each normal residual heat removal pump suction line. A high-pressure alarm is provided in the main control room to alert the operator to a condition of rising RCS pressure that could eventually exceed the design pressure of the RNS.

9.8.3.4.5 Chemical and Volume Control System

The AP1000 CVS is a Class 2 system. However, portions of the system are Class 1 and perform Class 1 functions, such as containment isolation, termination of inadvertent RCS boron dilution, RCS pressure boundary preservation, and isolation of excessive makeup.

Boron dilution events during low power modes can occur for a number of reasons, including malfunctions of the reactor makeup control system. Regardless of the cause, the protection is the same. The CVS is designed to avoid and/or terminate boron dilution events by automatically closing either one of two series, Class 1 valves in the demineralized water supply line to the makeup pump suction to isolate the dilution source. Additionally, the suction line for the CVS makeup pump is automatically realigned to draw borated water from the boric acid tank. The automatic boron dilution protection signal is Class 1 and is generated upon any reactor trip signal, source-range flux multiplication signal, low input voltage to the Class 1 IDS battery chargers, or a safety injection signal.

The safety analysis of boron dilution accidents is provided in Section 9.4.6 and is discussed in Section 9.8.4.4.5. For dilution events that occur during shutdown, the source-range flux-doubling signal is used to isolate the line from the demineralized water system by closing the two Class 1 remotely operated valves. The three-way pump suction control valve aligns the makeup pumps to take suction from the boric acid tank and, therefore, stops the dilution. For diverse mitigation of boron dilution events at shutdown, a DAS actuation based on the intermediate range nuclear instrumentation (IRNI) results in a trip of the RCPs and RNS pumps, isolation of boron dilution sources, and CMT actuation. Boron addition following CMT actuation results in a negative reactivity addition and terminates the event.

For refuelling operations, administrative controls are used to prevent boron dilutions by verifying that the valves in the line from the demineralized water system are closed and locked. These valves block the flow paths that can allow unborated makeup water to reach the RCS. Makeup required during refuelling uses borated water supplied from the boric acid tank by the CVS makeup pumps.

During refuelling operations (Mode 6), two source-range neutron flux monitors are operable to monitor core reactivity. This is required by the plant Technical Specifications. The two operable source-range neutron flux monitors provide a signal to alert the operator to unexpected changes in core reactivity. The potential for an uncontrolled boron dilution accident is precluded by isolating the unborated water sources. This is also required by the plant Technical Specifications.

9.8.4 AP1000 Safety Evaluation of Postulated Initiating Events at Shutdown

This section reviews each of the at-power faults identified for evaluation with respect to lower power and shutdown modes in Section 1 of Table 8A-2.

9.8.4.1 Increase in Heat Removal from the Primary System

9.8.4.1.1 Feedwater System Malfunctions Which Increase Heat Removal from the Primary System (Faults 1.15.13 – 1.15.14a)

Faults that decrease feedwater temperature or increase feedwater flow can be postulated in the feedwater system. These faults could increase heat removal from the primary system, which reduces RCS temperature. The reduction in RCS temperature could lead to an increase in core power generation (due to a negative moderator temperature coefficient) and result in a reduction in margin-to-core design limits. Unchecked, excessive feedwater flow could also result in overfilling the steam generators.

Discussions and analyses, initiated from Modes 1 and 2, of RCS cooldowns caused by feedwater system malfunctions are presented in Sections 9.1.1 and 9.1.2. Section 9.1.1 covers reductions in feedwater temperature, and Section 9.1.2 covers increases in feedwater flow. These faults are categorised as DB2 frequent faults for Modes 1 and 2, which are the limiting initial conditions for feedwater system induced RCS cooldown transients. Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, these faults would be categorised as DB1 infrequent faults for shutdown modes,

Protection against feedwater system induced cooldown transients is provided by the PMS through automatic functions that trip the reactor and isolate the feedwater system. The protection functions are available in all modes during which the feedwater system is in operation. Reactor trip signals include overpower ΔT, high power-range nuclear flux, high intermediate-range nuclear flux, or high source-range nuclear flux. The PMS closes the main feedwater control valves on low-1 RCS average temperature signal. The PMS also closes the main feedwater isolation valves and trips the booster/main feedwater pumps when RCS average temperature decreases below the low-2 RCS T_{avg} setpoint. These protection functions are arranged to detect symmetrical plant transients with a channel out of service and a single channel failure.

Additional PMS functions are provided to detect and protect against asymmetrical feedwater system malfunctions. Automatic reactor trip, closure of the main feedwater control and isolation valves, closure of the startup feedwater control and isolation valves, tripping of the booster/main feedwater pumps, and tripping of the startup feedwater pumps occur if the level in a single steam generator is above the High-3 water level setpoint. Similar actions occur if cold leg temperature in a single RCS loop decreases below the Low-2 T_{cold} setpoint. The High-3 steam generator level setpoint is active in Modes 1 through 4 unless the various feedwater valves are closed. This ensures that the steam generators cannot inadvertently be overfilled. The Low-2 T_{cold} signal is available in Modes 1 through 3. In Mode 3 prior to blocking the Low-2 T_{cold} signal, the RCS must be borated to cold shutdown conditions, in accordance with the plant Tech Specs. With the RCS borated, no feedwater malfunction can be postulated to cool the RCS such that a core power excursion would occur.

The feedwater malfunction associated with a drop in feedwater temperature is less severe as power level is decreased. Normal operating feedwater temperature decreases as plant power level decreases. Therefore, if a fault suddenly reduces the feedwater temperature, the maximum change in feedwater temperature will occur if the plant is operating at full power.

In Modes 2 and below, feedwater entering the steam generators is routed through the startup feedwater control valves. The maximum achievable flow rate through the startup feedwater path is much less than when flow is being controlled by the main feedwater control valves. Therefore, failure of a main feedwater control valve in Mode 2 and below is not likely. The

assumption of a failed open startup feedwater control valve, in Mode 2 and below, will result in a relatively slow transient due to low feedwater flow rate.

The most severe RCS cooldowns caused by feed system malfunctions will occur in Modes 1 or 2. In Modes 3 or 4, RCS cooldowns due to feedwater malfunctions would be precluded, inconsequential, or less severe than in Modes 1 or 2. In Modes 5 and 6, any cooldown caused by feedwater system malfunction is meaningless because the RCS is already cold, and the RNS system effectively decouples the steam generators from the core. The analyses presented in Section 9.1 bound the consequences of this class of events initiated in the shutdown modes.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of these events presented in Sections 9.1.1.4 and 9.1.2.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. In addition, due to the likelihood of these faults occurring at shutdown conditions being categorised as an infrequent fault, diverse mitigation is not explicitly required. However, since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, and no further discussion is provided here.

9.8.4.1.2 Excessive Increase in Secondary Steam Flow (Faults 1.15.18 and 1.15.18a)

An excessive increase in secondary steam flow (excessive load increase) is caused by a rapid increase in steam flow that results in a power mismatch between the reactor core power and the steam generator load demand. The PLS is designed to accommodate a 10-percent step load increase in steam flow in the range of 25 to 100 percent of full power. Analyses results for a 10-percent step increase in steam flow are presented in Section 9.1.3. The analyses are performed for Mode 1 from full-power initial conditions. Depending upon the plant and PMS characteristics (setpoint uncertainties), a reactor trip signal may or may not be generated for an excessive load increase from full power.

This fault is categorised as a DB2 frequent fault for occurrences in Modes 1 and 2. Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, these faults would be categorised as DB1 infrequent faults for shutdown modes,

An excessive load increase in Mode 1 is considered limiting because an excessive load increase at full power will put the plant at the highest achievable power level. Load increases at less than full power, or during startup (Mode 2), will not reach as high a power level. The excessive load increase, in Mode 2, will not be as severe as the Mode 1 excessive load increase.

In Mode 3, the excessive load increase may be considered to be a simple steam release because there can be no load, per se, when the turbine is off-line and the core is subcritical. The Mode 3 load increase will be less limiting than the Mode 1 or Mode 2 case because the core is already subcritical. Automatic safeguards actuation signals may not be available if blocked by the operator (blocking is necessary to depressurise and cool down the RCS). However, the RCS must be borated to meet shutdown margin requirements at cold shutdown (93.3°C [200°F]) prior to blocking automatic safeguards actuation signals to prevent a return to criticality in the event of a cooldown.

The Mode 4 situation is bounded by Mode 3 because pressure and temperature conditions in

the primary and secondary systems are reduced. At some point in Mode 4, the RNS will be placed in service. In Modes 5 and 6, the RNS should be in operation. Any steam release will have little or no effect upon the core.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of this event presented in Section 9.1.3.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. In addition, due to the likelihood of this fault occurring at shutdown conditions being categorised as an infrequent fault, diverse mitigation is not explicitly required. However, since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, and no further discussion is provided here.

9.8.4.1.3 Steamline Breaks (Faults 1.15.19, 1.21.1 – 1.21.3. and 1.22.1 – 1.22.2a)

This section includes both DB2 frequent faults (spurious opening of a SG relief valve) and DBL infrequent faults (postulated design basis break of the main steam line) events. Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, these faults would be categorised as DB1 infrequent faults or beyond design basis for shutdown modes.

The spurious opening of a steam generator safety or relief valve is a DB2 event and referred to as a credible steam line break. This event affects the core like a load increase but different analysis assumptions are applied. The credible steam line break is usually assumed to be an unisolatable, uncontrolled steam release, which causes a non-uniform core cooldown (typical of an open safety valve) during the period immediately following a reactor trip which inserts all but the most reactive RCCA. The resulting reactivity excursion may be large enough to overcome the shutdown margin and return the core to critical, especially when there is little or no decay heat (with power peaking in the region of the stuck RCCA). The credible steam line break is analysed in Mode 2, and the results are presented in Section 9.1.4. The assumptions used in the analysis lead to a more severe, post-trip transient than will result from a load increase initiated in Mode 1.

In Mode 1, prior to reactor trip, the transient characteristics of an inadvertent opening of a steam generator safety or relief valve are similar to the excessive load increase. A reactor trip signal, if needed, may result from overpower ΔT logic. After the reactor trip, the concern becomes a possible return to criticality with the most reactive RCCA stuck in the fully withdrawn position, leading to high local power levels. However, a post-trip return to criticality is less likely when this event occurs in Mode 1 than in Mode 2 because there will be more decay heat present, which tends to retard the cooldown.

In Mode 3, results are expected to be better than the Mode 2 case because pressure, temperature, and flow conditions will be less limiting. An occurrence in Mode 4 will be less severe than in Modes 2 or 3 due to the lower initial RCS temperature, and an effective decoupling of the secondary system from the primary system as the RCPs are removed from service and the RNS is started. Automatic safeguards actuation signals are available through Mode 3, until the RCS is borated and the automatic safeguards signals are blocked (see excessive load increase discussion). Both CMTs continue to be available for automatic actuation on low-2 pressuriser level or manual actuation through Mode 4 with the RCS not being cooled by the RNS (see Technical Specification LCO 3.5.2). In Mode 4 with the RNS

in operation and in Mode 5 with the RCS pressure boundary intact, one CMT is available for actuation if needed.

Any cooldown in Modes 5 and 6 caused by depressurisation of the secondary system is meaningless because the RCS is already cold, and the RNS system effectively decouples the steam generators from the core.

The steam line rupture is a DBL infrequent fault event, producing a greater uncontrolled steam release than the spurious opening of a steam generator safety valve (described above), but the relative effects in the various modes and requirements for protection equipment are the same. This is the most severe cooldown event.

The radiological consequences of these events presented in Sections 9.1.4.4, 9.1.5.4, and 9.1.6.4 are limiting because the coolant temperature, secondary side releases and RCS activity concentrations (including consideration of iodine spikes) bound those that would exist in the other modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. In addition, due to the likelihood of these faults occurring at shutdown conditions being categorised as an infrequent or beyond design basis fault, diverse mitigation is not explicitly required. However, since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.1.4 Inadvertent PRHR HX Operation (Faults 1.15.15 – 1.15.17)

Inadvertent actuation of the PRHR HX causes an injection of relatively cold water into the RCS. This produces a reactivity insertion in the presence of a negative moderator temperature coefficient. Because the PRHR HX is connected to only one RCS loop, the cooldown resulting from its actuation is asymmetric with respect to the core. Inadvertent actuation of the PRHR HX could lead to an asymmetric power increase and a reduction in margin-to-core design limits.

A limiting analysis of an inadvertent actuation of the PRHR HX heat exchanger is presented in Section 9.1.7. The analysis is initiated in Mode 1 from hot full-power conditions, where this fault is categorised as a DB2 frequent fault; this is the most limiting case. This fault is also categorised as a DB2 frequent fault during shutdown conditions due to the initiator, a valve misalignment, being just as likely at any time of operation.

The PRHR HX heat transfer rate is a function of the inlet temperature to the heat exchanger and the flow rate through the heat exchanger. PRHR HX heat transfer rate is higher with high flow rates and high inlet temperatures. Therefore, the maximum heat removal rate will occur when the plant is at full-power condition with forced RCS flow and a high hot leg temperature. At plant full-power conditions, the PRHR HX heat removal rate is approximately 10 percent of full power. At HZP conditions with natural circulation, heat removal by the PRHR HX is approximately 1.5 percent to 2 percent of full power.

The heat sink for the PRHR HX is the IRWST, in which the heat exchanger is submerged. Prior to actuation of the PRHR HX, the fluid within the heat exchanger is in thermal equilibrium with the fluid in the IRWST. Thus, the PRHR HX is initially filled with relatively cold fluid which is at containment ambient temperature. When the PRHR HX is actuated, the initial fluid outsurge is fluid at containment ambient temperature. Once the original fluid in the PRHR HX is purged, the out-flow temperature trend of the heat exchanger is set by the temperature entering the heat exchanger from the RCS hot leg minus the temperature drop

through the heat exchanger. Thus, the outlet fluid temperature is limited by the cooling capacity of the PRHR HX.

In Mode 3, because the reactor is subcritical, inadvertent actuation of the PRHR HX produces a less severe power excursion than if the reactor is at power or at HZP with the reactor just critical. If in Mode 3 below no-load temperature, the cooldown caused by the actuation of the PRHR HX results in the cold leg temperature dropping below the Low-2 T_{cold} safeguards signal setpoint. This function actuates a reactor trip, initiates boration by the CMTs, and most importantly, trips all the RCPs. When the RCPs trip, natural circulation flow begins in the RCS and the PRHR HX loop. When natural circulation flow is initiated, the heat removal capability of the PRHR HX decreases to approximately 1.5 percent of full power and the severity of the transient is minimized. With the RCS in natural circulation, the cooldown rate of the RCS is also slowed. If criticality is obtained, boration by the CMTs will bring the core subcritical again.

The Low-2 T_{cold} safeguards signal may be blocked by the operator in Mode 3 to allow plant depressurisation and cooldown to lower modes. However, prior to blocking the Low-2 T_{cold} safeguards signal, the RCS is borated to the shutdown margin requirements at cold shutdown (93.3°C [200°F]). Therefore, in Mode 3 with safeguards signals blocked or in Mode 4, cooldown of the RCS by inadvertent actuation of the PRHR HX will not result in a reactivity excursion, which produces a power increase.

In Modes 5 and 6, the RCS will be borated such that a cooldown-induced power excursion could not be postulated. The RCS will be at (93.3°C [200°F]) or less, and with initial RCS temperatures this low, no significant cooling of the RCS by inadvertent actuation of the PRHR HX could be postulated.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of this event presented in Section 9.1.7.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. Since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.2 Decrease in Heat Removal by the Secondary System

9.8.4.2.1 Loss of Load, Turbine Trip, Inadvertent MSIV closure, and Loss of Condenser Vacuum (Faults 1.12.8 – 1.12.11, 1.16.7, and 1.18.1)

Discussions and analyses of the consequences of loss of load, turbine trip, inadvertent closure of MSIVs, or loss of condenser vacuum are presented in Sections 9.2.2 through 9.2.5. These DB2 frequent fault events are characterized by a rapid reduction in steam flow from the steam generators. This results in an increase in steam pressure and a heatup of the primary side if the reactor power is not reduced. The effects of the primary to secondary power mismatch during these events are mitigated by tripping the reactor and opening secondary and primary side safety valves. The severity of these events is increased if the primary to secondary power mismatch is increased. Therefore, the most severe results occur if the plant is initially operating in Mode 1 at maximum-rated plant power conditions rather than lower power conditions. The turbine is off-line below Mode 1 and transients related to turbine-related faults cannot occur.

In Modes 2, 3, or 4, the plant may be removing decay heat by dumping steam to the condenser. In Mode 4 when the RCS is below 176.7°C (350°F), decay heat is removed using the RNS. In Modes 2, 3, or 4, the transient response to a loss of condenser vacuum or inadvertent MSIV closure is bounded by the turbine trip analysis from full power because the power mismatch is low. Decay heat removal can still be accomplished by the steam generators through atmospheric steam relief through PORVs if available or through steam generator safety valves, which are available through Mode 4 (see Technical Specification LCO 3.7.1). Additionally, decay heat can be removed with the PRHR HX, which is available through Mode 5 with the RCS intact (see Technical Specifications LCO 3.5.4 and 3.5.5).

In Mode 5, with RCS open, and in Mode 6, the event is clearly not applicable.

The initiating event does not result in fuel damage and the primary and secondary circuits remain intact. The radiological consequences of this event presented in Section 9.2.3.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in Modes 3 or 4 because the coolant temperature, secondary side releases and RCS activity concentrations bound those that would exist in the other modes. In Modes 4 or 5 with the RNS in operation there is no release of activity to the environment because offsite power remains available.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. Since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.2.2 Loss of ac Power (Faults 1.19.1 and 1.19.2)

A discussion and an analysis of a loss of ac power event are provided in Section 9.2.6. The loss of ac power, which is a DB2 frequent fault in all modes, results in the loss of forced primary coolant flow and the loss of main feedwater flow. This results in a heatup and pressurisation of the RCS. If the reactor is at power, the event is mitigated by tripping the reactor. The reactor may be automatically tripped on low RCP speed, low RCS flow, low steam generator level, or several other primary side heatup signals. Also reactor trip may occur due to the loss of power to the control rod drive mechanisms.

Following reactor trip, the PRHR HX is activated for decay heat removal. Automatic PRHR HX actuation on low steam generator level is available in Modes 1 through 3 and in Mode 4 when the RCS is not being cooled by the RNS. The most limiting case for loss of ac power would be if the plant were at full rated power. This will result in the highest decay heat levels and stored energy in the RCS and the heat removal capability of the PRHR HX will be maximized. In Modes 4 or 5 with the RNS in operation, the plant response to a loss of ac power is the same as the loss of RNS cooling discussed in Section 9.8.5.

The radiological consequences of this event presented in Section 9.2.6.4 are limiting compared to the event occurring in Modes 3 or 4 because the coolant temperature, secondary side releases and RCS activity concentrations bound those that would exist in the other modes. In Modes 4 or 5 with the RNS in operation, the radiological consequences of a loss of ac power are the same as the loss of RNS cooling discussed in Section 9.8.5.1.3.3.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. Since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.2.3 Loss of Normal Feedwater (Faults 1.16.1 – 1.16.3, 1.17.1, and 1.20.1 – 1.20.2)

The main feedwater system is in operation during Modes 1 and 2. The startup feedwater system is used in Mode 2 below approximately 2 percent power, in Mode 3, and in Mode 4 before the RNS is aligned. In Mode 4 with the RNS aligned and in Modes 5 and 6, the feedwater system is not used, and therefore, loss of feedwater events is irrelevant. The 'corresponding' shutdown event is the loss of RNS cooling, which is discussed and analysed in Section 9.8.5

A discussion and an analysis of a loss of normal feedwater event from rated full-power conditions are provided in Section 9.2.7; it is categorised as a DB2 frequent fault. The loss of normal feedwater flow results in a heatup and pressurisation of the RCS. If the reactor is at-power, the event is mitigated by tripping the reactor on low steam generator level.

Following reactor trip, the PRHR HX is activated for decay heat removal. Automatic PRHR HX actuation on low steam generator level is available in Modes 1 through 3 and in Mode 4 when the RCS is not being cooled by the RNS. The most limiting case for a loss of normal feedwater is with the plant initially at full rated power. This case will have the highest decay heat levels and stored energy in the RCS and the heat removal capability of the PRHR HX will be maximized. The analysis initiated from full power bounds cases initiated from the shutdown modes.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of this event presented in Section 9.2.7.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. Since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.2.4 Feedwater System Pipe Break (Faults 1.16.8 – 1.16.10)

Depending upon the size of the break and plant operating conditions, the break could cause either an RCS heatup or an RCS cooldown. The cooldown aspects are less severe than a steam line break, which is discussed in Section 9.8.4.2.3 and is not considered in the following discussion.

The main feedwater system is in operation during Modes 1 and 2. The startup feedwater system is used in Mode 2 below approximately 2 percent power, in Mode 3, and in Mode 4 before the RNS is aligned. In Mode 4 with the RNS aligned and in Modes 5 and 6, the feedwater system is not used, and therefore, a loss of feedwater caused by a feedwater system pipe break will not cause a heatup of the RCS.

A discussion and an analysis of a DBL infrequent fault feedwater system pipe break from rated full-power conditions are provided in Section 9.2.8. A rupture of a feedwater system pipe results in a loss of feedwater flow causing a heatup and pressurisation of the RCS. If the reactor is at-power, the event is mitigated by tripping the reactor on low steam generator level.

Following reactor trip, the PRHR HX is activated for decay heat removal. Automatic PRHR HX actuation on low steam generator level is available in Modes 1 through 3 and in

Mode 4 when the RCS is not being cooled by the RNS. The most limiting case for a feedline break occurs with the plant at full rated power. This case will have the highest decay heat levels and the highest stored energy in the RCS and the heat removal capability of the PRHR HX will be maximized.

The radiological consequences of this event presented in Section 9.2.8.4 are limiting because the coolant temperature, secondary side releases and RCS activity concentrations bound those that would exist in the other modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. Since the required protection functions are available in all modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.3 Decrease in Reactor Coolant System Flow Rate

9.8.4.3.1 Partial and Complete Loss of Forced RCS Flow (Faults 1.13.1 – 1.13.3)

A partial loss of forced RCS flow may be caused by a mechanical or an electrical failure in an RCP or from a fault in the power supply to the pumps. An RCP failure will result in only the loss of a single RCP. A fault in the power supplies for the RCPs could result in the loss of one, two, or all four RCPs. These faults are categorised as DB2 frequent faults for Modes 1 and 2.

The loss of one or more RCPs reduces the heat removal rate from the primary to the secondary coolant system and thereby causes a heatup in the RCS. The heatup of the RCS results in an increase in RCS pressure and a decrease in margin-to-core design limits (that is, DNB). An occurrence at full power will produce a greater and more rapid heatup than at part-power conditions or low-power conditions in Mode 2. Therefore, for evaluating the maximum RCS pressure or the minimum DNB ratio, analyses are performed at full-power conditions. Analyses for partial loss of forced RCS flow transients are presented in Section 9.3.1. Analyses for a complete loss of flow are presented in Section 9.3.2. These analyses bound loss of flow events initiated in other modes.

Protection for loss of forced RCS flow events is provided by tripping the reactor. This reduces reactor power and preserves margin-to-DNB limits. The AP1000 PMS includes a reactor trip on low RCS flow in any cold leg and a reactor trip on low RCP speed in any two of four RCPs. These two reactor trips are used to detect all possible partial and complete loss of RCS flow transients. Opening of the pressuriser safety valves in conjunction with the reactor trip prevents overpressurisation of the RCS.

Below Mode 2, when the core is subcritical, forced RCS flow is not needed because margin-to-DNB is not an issue. It is common to have one or more RCPs out of service below Mode 2 because full RCS flow is no longer needed. In Modes 3 through 5, LCO 3.4.5 of the Technical Specifications requires that all four RCPs need to be operating if the reactor trip breakers are closed, to ensure that DNB limits are not exceeded, in the event RCCAs are inadvertently withdrawn. If the trip breakers are open and RCCA withdrawal is precluded, no RCPs are required to be operating in Modes 3 through 5. Note that RCPs are not operated in Mode 6.

Following reactor trip in loss of forced RCS flow events, decay heat removal is required. The PRHR HX or the steam generators can be used for decay heat removal. In the event of a complete loss of forced RCS flow, RCS natural circulation is adequate to remove core decay heat. This is demonstrated by the loss of ac power analysis presented in Section 9.2.6.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of these events presented in Sections 9.3.1.4 and 9.3.2.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. Since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.3.2 Reactor Coolant Pump Shaft Seizure or Break (Faults 1.13.11 – 1.13.12a)

An RCP shaft seizure or break results in a partial loss of forced RCS flow, and is categorised as a DB1 infrequent fault. The results are similar to partial loss of flow events discussed in Section 9.8.4.3.1 except that the rate of flow reduction is much more rapid if an RCP shaft breaks or seizes. Like the partial loss of flow, a locked or broken RCP shaft reduces the heat removal rate from the primary to secondary coolant system and thereby causes a heatup of the RCS. An occurrence at full power produces the most severe heatup transient. The discussion for the partial loss of flow with respect to limiting modes and protection is applicable to the RCP shaft seizures or breaks.

Analyses and evaluation of RCP shaft seizures and breaks for Mode 1, from full-power conditions, are provided in Sections 9.3.3 and 9.3.4. The analyses bound events initiated from the shutdown modes for reasons discussed in Section 9.8.4.3.1.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of this event presented in Section 9.3.3.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. Since the required protection functions are available in applicable modes of operation, no further discussion is provided here.

9.8.4.4 Reactivity and Power Distribution Anomalies

9.8.4.4.1 Uncontrolled RCCA Bank Withdrawal from a Subcritical Condition (Faults 1.15.1 – 1.15.3)

An uncontrolled RCCA bank withdrawal from a subcritical condition could cause a reactivity excursion, which if not terminated by a reactor trip, could result in DNB. Section 9.4.1 presents an analysis for the uncontrolled RCCA bank withdrawal from a subcritical condition in Mode 2, which is categorised as a DB2 frequent fault. Assumptions are used that make the analysis bound an occurrence in Modes 2, 3, 4, or 5. Specific conservative assumptions are made for the number of RCPs operating, the reactor trip functions credited, initial RCS temperature, and the magnitude of the reactivity excursion.

A single failure in the rod control system could cause the withdrawal of only one bank, and its withdrawal rate would be expected to be slower than the maximum rod speed possible when in automatic rod control. The analysis assumes the simultaneous withdrawal of the combination of two sequential RCCA banks having the greatest combined worth at the

maximum possible speed.

LCO 3.3.1 of the AP1000 plant Technical Specifications gives the operational requirements for reactor trips. The source-range high neutron flux trip must be in operation in Modes 3, 4, and 5 if the reactor trip breakers are closed. If the reactor trip breakers are open, then an RCCA withdrawal is precluded from occurring. The source-range high neutron flux trip is available in Mode 2 if power is below the P-6 interlock. In these instances, the source-range high neutron flux trip would be available to terminate the event, by tripping any withdrawn and withdrawing rods, before any significant power level could be attained. Therefore, DNB would be precluded. The intermediate-range high neutron flux reactor trip is also available in Mode 2. The analysis assumes that reactor trip does not occur until the power-range (low setting) high neutron flux setpoint is reached. No credit is assumed in the analysis for the source-range high neutron flux reactor trip or the intermediate-range high neutron flux reactor trip.

LCOs 3.4.4 and 3.4.5 of the AP1000 Technical Specifications give the operation requirements for RCPs. LCO 3.4.4 specifies that all four RCPs must be operating whenever the reactor trip breakers are closed in Modes 1 through 5. Rod control is not applicable in Mode 6.

The RCS temperature is assumed to be at the HZP value in the analysis. This is more limiting than that of a lower initial system temperature for DNB and core kinetics feedback calculations.

These conservative assumptions result in the core returning to critical and generating power before reactor trip occurs. The analysis presented in Section 9.4.1 bounds the inadvertent RCCA bank withdrawal from a subcritical condition transient in Modes 2 through 5.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment, as indicated in Section 9.4.1.3.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. Since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.4.2 Uncontrolled RCCA Bank Withdrawal at Power (Fault 1.15.4)

By definition, this transient is only applicable to Mode 1.

9.8.4.4.3 RCCA Misalignment (Faults 1.15.5 – 1.15.5c)

RCCA misalignment events are analysed in Section 9.4.3. RCCA misalignment events include the following:

- One or more dropped RCCAs (DB2 frequent fault)
- Statically misaligned RCCA (DB2 frequent fault)
- Withdrawal of a single RCCA (DB1 infrequent fault)

Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, these faults would be categorised as DB1 infrequent faults or beyond design basis for shutdown modes. These events may result in core radial power distribution perturbations, which may cause allowable design power peaking factors and DNB design limits to be exceeded. Therefore, these events are a concern only in the at-power modes, and the severity will be

increased at high power. If the reactor is subcritical, DNB will not be a concern.

Following the dropping of one or more RCCAs while at-power, core power will immediately be reduced. The reduced core power and the continued steam demand to the turbine causes a reactor coolant temperature decrease. If the reactor is in manual control, the core power rises due to moderator feedback to the initial power level at a reduced core inlet temperature. If the reactor is in automatic control, the control system detects the drop in power and initiates withdrawal of a control bank. Power overshoot above the initial power level may occur as the control system withdraws a bank. Following dropping of one or more RCCAs, the most severe results occur when the control system overshoots the initial power level in conjunction with a perturbation in the radial power distribution. This is the most limiting case for this event, and the results are presented in Section 9.4.3. If the reactor is in any of the subcritical modes, dropping RCCAs will not result in any power transient.

As in the case of dropped RCCAs, statically misaligned RCCAs have no effect in the absence of a critical neutron flux and are not a concern below Mode 2. The most limiting case, and analysis, is for Mode 1 which also bounds Mode 2 operation.

The most limiting case for the withdrawal of a single RCCA is an occurrence while in Mode 1. An occurrence in any of the subcritical modes will have no effect. The shutdown margin requirements are specified in LCO 3.1.1 of the AP1000 Technical Specifications. The shutdown margin requirements are determined assuming the most reactive RCCA is fully withdrawn from the core. Therefore, no single RCCA withdrawal initiated from the subcritical modes will insert enough reactivity to attain criticality.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of these events presented in Sections 9.4.3.4.1 and 9.4.3.4.2 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. In addition, due to the likelihood of these faults occurring at shutdown conditions being categorised as an infrequent or beyond design basis fault, diverse mitigation is not explicitly required. However, since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.4.4 Startup of an Inactive Reactor Coolant Pump at an Incorrect Temperature (Fault 1.15.6)

This event is precluded from occurring during at-power modes by Technical Specifications. Startup of an inactive RCP while in any of the subcritical modes will have relatively little effect upon core temperature because there will be little or no temperature difference between the loops. Section 9.4.4 discusses the consequences of this event for the AP1000 design.

9.8.4.4.5 Chemical and Volume Control System Malfunction That Results in a Decrease in the Boron Concentration in the Reactor Coolant (Faults 1.15.7 – 1.15.9)

Boron dilution analyses and evaluations for Modes 1 through 5 are provided in Section 9.4.6. Therefore, the design basis analysis documented therein already covers shutdown Modes 3 to 5, which are categorised as DB2 frequent faults.

In Mode 6, administrative controls (operating procedures, system interlocks, and PLS control

logic) isolate the RCS from potential sources of unborated water by locking closed specified valves (DWS header isolation valves, CVS Makeup Flow Containment penetration isolation valves, and the 3-way blend valve) in the CVS, and thereby preclude an uncontrolled boron dilution transient. All of these valves are Class 1 with the exception of the 3-way blend valve, which is C-3. The isolation of all unborated water sources is required by the plant Technical Specifications. Makeup needed during refuelling is supplied from the boric acid tank which contains borated water.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of this event presented in Section 9.4.6.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes.

Since the required protection functions discussed in Section 9.4.6 are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.4.6 Inadvertent Loading of a Fuel Assembly in an Improper Position (Fault 1.15.10)

Fuel loading errors – such as inadvertent loading of one or more fuel assemblies into improper positions, having a fuel rod with one or more pellets of the wrong enrichment, or having a fuel assembly with pellets of the wrong enrichment – may result in power shapes in excess of design values. Section 9.4.7 presents Mode 1 results for this event which bound the results for operation in Mode 2. This event is meaningful only if the reactor is at-power and, therefore, not applicable in the subcritical Modes of 3 through 6.

9.8.4.4.7 RCCA Ejection (Faults 1.15.11 and 1.15.12)

Analyses for RCCA ejections in Mode 1 and Mode 2 are presented in Section 9.4.8, and these are categorised as DB1 infrequent faults. The cases analysed in Section 9.4.8 are the most limiting cases. The shutdown margin requirements are specified in LCO 3.1.1 of the AP1000 plant Technical Specifications. The shutdown margin requirements are determined assuming the most reactive RCCA is fully withdrawn from the core. Therefore, the ejection of a single RCCA initiated from the subcritical modes would not insert enough reactivity to attain criticality.

9.8.4.5 Increase in Reactor Coolant Inventory (Faults 1.12.1 – 1.12.5)

An increase in RCS inventory could be caused by inadvertent actuation of the CMTs or by malfunctions in the CVS system, both of which are categorised as DB2 frequent faults. Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, these faults would be categorised as DB1 infrequent faults for shutdown modes. Analyses of events that increase the RCS inventory are provided in Section 9.5. Section 9.5.1 presents the analysis results for inadvertent actuation of the CMT. Section 9.5.2 contains results from the analysis of a CVS malfunction which increases RCS inventory. These events do not present a challenge to core design limits. If unchecked, these events could lead to overfill of the pressuriser and possible loss of reactor coolant from the system. The increase in pressuriser water volume is slow during these events and is determined by the injection rate, core decay heat produced, and heat removal rate from the RCS. While the pressuriser safety valves may open, the steam relief from the pressuriser safety valves is low and no serious challenge to the RCS pressure boundary occurs (if the pressuriser does not fill).

The analyses for these events are performed with the plant initially in Mode 1 at full-power

conditions. This results in the maximum amount of stored energy in the plant and in the maximum core decay heat. If the plant was assumed to be at part power, or in the subcritical modes, the amount of stored energy and decay heat will be significantly reduced.

If a spurious "S" signal occurs causing the CMTs to be actuated, the reactor is also tripped and the PRHR HX is also actuated. The CMTs will begin injecting cold, borated fluid into the RCS. The injected fluid expands as it is heated in the RCS by decay heat. The expansion is counteracted by decay heat removal through the PRHR HX. The severity of the expansion is increased with higher decay heat levels.

Malfunctions in the CVS, which add excess inventory to the RCS, are protected against by the inclusion of automatic CVS isolation functions in the PMS. If a safeguards signal has occurred (which also would activate the CMTs), the CVS is automatically isolated if the pressuriser level exceeds the high-1 pressuriser level setpoint. Above the high-1 pressuriser level setpoint, there is a high-2 pressuriser level setpoint, which also isolates the CVS. The high-2 pressuriser level function is not interlocked with the safeguards signal. The high-2 function protects in situations where the reactor is at-power or a safeguards signal has not occurred. The high-2 pressuriser level function is available in Modes 1 through Mode 3 and in Mode 4 when the RNS is not operating. These functions effectively prevent overfilling of the pressuriser when the CVS acts alone or where CVS interacts to also cause the CMTs to be actuated.

Isolation of CVS on high-2 pressuriser level is available in Modes 1 through 4 until the plant is operating on RNS. There are applications where the RCS may be filled water-solid when the RNS is in operation. In Modes 4, 5, and 6 when the RNS is in operation, low-temperature overpressure protection (LTOP) of the RCS pressure boundary is provided by the RNS relief valve(s). A discussion of this is provided in Section 9.8.4.5.1, below.

Because the primary and secondary circuits remain intact and offsite power remains available, there is no release of activity to the environment. Therefore, the radiological consequences of these events presented in Sections 9.5.1.4 and 9.5.2.4 for the release of activity resulting from a case where offsite power is lost are limiting compared to the event occurring in lower modes. In the event of RCS inventory loss through the RNS relief valve(s) at lower modes, the radiological consequences would be bounded by an RNS line break scenario (See Section 9.8.5.3).

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. Since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.5.1 Low Temperature Overpressure Protection

For the AP1000 design, an RNS suction relief valve is located in each of the two RNS trains, immediately downstream of the RCS suction isolation valves. Each of these relief valves protects the RNS from over pressurisation and provides LTOP for the RCS components when an RNS train is aligned to the RCS to provide decay heat removal during plant shutdown and startup operations. The RNS relief valves are sized to provide LTOP by limiting the RCS and RNS pressure to less than the steady-state pressure limit. Section 17.5.7.2 provides a discussion of the LTOP design bases.

Typically, during normal operations, both RNS trains will be in use during plant cool-downs because that would significantly reduce the duration of the outage compared to use of a single train. In addition, the Short Term Availability Controls prohibit entering reduced inventory

Modes of operation without both RNS trains operable. With both RNS trains operable, there is single failure tolerance for the RNS relief valves.

Although unlikely, it is possible for the plant to enter Modes 4 and 5 with only one RNS train operable. In this case there is no failure tolerance for the RNS relief valves; however, this situation is acceptable because:

- It is unlikely to be in a shutdown condition with only one RNS train operable.
- It is unlikely to have a cold over pressure event in the AP1000 plant.
    - Unlike other PWRs, the AP1000 design does not have any high head safety injection pumps; whereas other PWRs typically have two to four. These pumps are a major source of potential cold over pressure.
    - The AP1000 design only has two CVS makeup pumps and they inject through a common cavitating venturi, which limits their combined makeup. Other PWRs typically have three such pumps and no cavitating venturi.
    - Most of the time during shutdown conditions there is a steam bubble in the pressuriser or the RCS is vented to the containment. Even with just a pressuriser steam bubble, the operator would have time to isolate the water makeup before having a cold over pressure event.
- The RNS relief valves are simple and reliable valves.
    - They are simple spring loaded designs with no C&I controls, valve operators, or power supplies.
    - These UK Safety Class 1 valves undergo extensive equipment qualification testing and additional in-service testing during plant operation.
        - Same valve type as those used for pressuriser steam generators, and elsewhere. Single failures are not considered credible in any of these applications, consistent with the ASME code.
- In the unlikely multi-failure event where only one RNS train was in service, a CVS pump spuriously operated without RCS letdown, and the RNS relief valve failed, core cooling would not be lost.
    - The limiting failure would be a rupture of the RNS piping outside containment. This is a design basis fault (Table 8A-2, faults 2.3.1-2.3.3) where the ADS valves would be opened and the RNS automatically isolated using Class 1 SSCs.

9.8.4.6 Decrease in Reactor Coolant Inventory

9.8.4.6.1 Inadvertent Opening of a Pressuriser Safety Valve or Inadvertent Operation of the Automatic Depressurisation System (Fault 1.5.2)

Section 9.6.1 includes analyses and evaluations of the inadvertent opening of a pressuriser safety valve, a DB1 infrequent fault, or the inadvertent operation of the ADS, a beyond design basis fault.

When analysed as depressurisation events, inadvertent opening of primary side relief valves, if the reactor is at-power, could result in exceeding core design limits, specifically DNB criteria. Violation of DNB criteria is not a realistic concern if the reactor is in any of the subcritical modes. Therefore, these events are analysed in Mode 1 at the maximum rated power and the analysis performed bounds cases initiated from Mode 2. These events bound events that can occur at shutdown.

The inadvertent ADS event is analysed as a loss-of-coolant accident in Mode 1 to demonstrate acceptance to the limits specified in 9.6.5. As described in Section 9.6.5, this

analysis is a "no-break" small-break LOCA calculation. The inadvertent opening of the 4-inch (102 mm) nominal size ADS Stage 1 valves is a situation that minimizes the venting capability of the RCS. Only the ADS valve vent area is available; no additional vent area exists due to a break. This case examines whether sufficient vent area is available to completely depressurise the RCS and achieve injection from the IRWST without core uncovery. The case analysed at-power bounds the inadvertent ADS during shutdown because the lower decay heat levels at shutdown reduce the challenge to the ADS vent capacity. More limiting loss-of-coolant accidents at shutdown are described in Section 9.8.5.

The radiological consequences of this event presented in Section 9.6.1.4 are limiting because the assumed consequential fuel damage bounds that which could result in the other modes.

Thus, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. Since the required protection functions are available in applicable modes of operation, no further discussion is provided here.

9.8.4.6.2 Failure of Small Lines Carrying Primary Coolant Outside Containment (Fault 1.9.2)

This DB2 frequent fault event is reported in Section 9.6.2 as the rupture of a primary coolant sample line; the radiological consequences of this event are analysed during Mode 1 because the coolant temperature and activity concentrations bound those that would exist in the other modes. Concerning shutdown risk, the consequences of a sample line break during Modes 2, 3, 4, or 5 are no more severe than if the accident occurs during Mode 1 operation.

Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, this fault would be categorised as a DB1 infrequent fault for shutdown modes. As discussed above, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided. In addition, due to the likelihood of this fault occurring at shutdown conditions being categorised as an infrequent fault, diverse mitigation is not explicitly required. However, since the required protection functions are available in applicable modes of operation, for both primary and diverse mitigation considerations, no further discussion is provided here.

9.8.4.6.3 Steam Generator Tube Rupture (Faults 1.11.1 – 1.11.3)

The DB2 cliff edge frequent fault SGTR analysis presented in Section 9.6.3 is the limiting case with respect to offsite doses. Assuming a reduction in frequency of $1/20^{th}$ for the same event at shutdown conditions, this fault would be categorised as a DB1 infrequent fault for shutdown modes. The analysis was performed at full power because this results in the maximum offsite dose. The key inputs from the thermal-hydraulic SGTR analysis to the offsite dose analysis are the amount of primary to secondary break flow and the steam released from the ruptured steam generator. Both of these will be significantly reduced at lower power levels and in lower modes of operation. Also the RCS activity concentrations (including consideration of iodine spikes) bound those that would exist in the other modes.

A margin to overfill analysis is presented in Section 9.6.3. The analysis is performed to demonstrate margin to steam generator overfill with no operator actions modelled. This is necessary because the dose analysis does not include consideration of water relief from the ruptured steam generator PORV/main steam safety valve (MSSV). This margin to steam generator overfill analysis was supported by the assertion that an analysis with operator actions modelled will also demonstrate margin to overfill. The overfill analysis with no operator actions discussed in Section 9.6.3 was initiated at full power. WCAP-10698-P-A (Reference 9.8-3) indicates that margin to overfill is reduced when the SGTR is initiated at

zero power because of the higher initial steam generator secondary liquid inventory. WCAP-10698-P-A concludes that zero power and lower mode SGTR overfill analyses are not limiting, based primarily on more rapid operator responses expected in those conditions. This is discussed further in the Appendices to WCAP-10698-P-A. When operator actions are credited for SGTR mitigation for the AP1000 design, the plant behaves in a manner comparable to a standard Westinghouse PWR and the conclusions of WCAP-10698-P-A apply.

When operator actions are not relied upon and only the automatic RCS cooling and depressurisation are credited, margin to overfill would still be maintained for SGTR events initiated at lower power levels and lower modes despite the increased initial steam generator secondary side inventory corresponding to the lower initial power assumption. This is because the automatic protection system actions that prevent overfill are independent of the operator actions. For operating plants, there is a set period of time from the start of the event until the operator can reverse the trend toward filling the steam generator. Therefore, the initial margin to overfill directly impacts the final margin. For the AP1000 design, the primary cooldown and depressurisation occur automatically when the PRHR HX is actuated on a low pressuriser pressure "S" signal or low pressuriser level CMT actuation signal. The primary pressure may still be held up by the CVS, until it is isolated on a high steam generator level signal. For the AP1000 design, a higher initial steam generator water level results in the CVS flow being terminated earlier.

In Mode 4, the PRHR HX actuation is provided only by the low pressuriser level signal. Although this results in delayed cooling and depressurisation, margin to steam generator overfill is still maintained. The increase in mass in the secondary side of the ruptured steam generator is directly related to the reduction in pressuriser water level, because (once the CVS is isolated on high steam generator water level) there is no source of makeup to the RCS. The steam generator secondary side can accommodate the amount of fluid initially contained in the pressuriser and still retain a significant amount of margin to steam generator overfill. The PRHR HX will, therefore, be actuated on low pressuriser water level in sufficient time for the PRHR HX to cool and depressurise the primary and terminate break flow before steam generator overfill will occur.

In Modes 5 and 6, the RCS pressure and temperature are reduced; thus, an SGTR event is not considered credible. In summary, this event during any shutdown mode is less limiting than the at-power conditions for which a design basis analysis is provided, as discussed above. In addition, due to the likelihood of this fault occurring at shutdown conditions being categorised as an infrequent fault, diverse mitigation is not explicitly required. Since the required protection functions are available in applicable modes of operation no further discussion is provided here.

9.8.4.6.4 Loss-of-Coolant Accident Events in Shutdown Modes (Faults 1.2.1 – 1.2.3, 1.4.1 – 1.4.3, 1.6.1, 1.7.1, 1.8.1 – 1.8.4, 1.9.1 – 1.9.2, and 1.10.1)

Section 9.6 presents a spectrum of break sizes of the postulated LOCAs at the full-power operating condition. Other things being equal, the reduction in power to decay heat levels associated with shutdown mode operations will make all LOCA events less limiting than those analysed at full power and reported in Section 9.6. However, as the plant proceeds through shutdown modes of operation, various PXS equipment are removed from service at identified points in time. One particularly significant action in the elimination of PXS equipment in the course of taking the AP1000 plant to cold shutdown, is the isolation of the accumulators at 6.895 MPa gauge (1000 psig). This procedural action reduces the capability of the PXS to mitigate LOCAs. For assessing the adequacy of the remaining PXS

components to mitigate postulated LOCA events, the limiting double-ended cold-leg guillotine (DECLG) break, analysed in Section 9.6.4, is analysed assuming it occurs immediately after the isolation of the accumulators (this results in limiting conditions as it maximises decay heat, since the time from shutdown is shorter, and the initial temperature and pressure are higher). The analysis is performed using the AP1000 Large-Break LOCA WCOBRA-TRAC model used for the at-power Design Basis Accident analysis. Only Class 1 systems are modelled in the analysis of this event.

Depressurisation of the AP1000 primary system during shutdown operations will be performed with the same care taken to avoid the flashing of liquid in the core and upper head that is taken by current operating plants. Prudent plant operation dictates that subcooling margin be retained as pressure is reduced. Therefore, since the AP1000 plant shutdown operations will be conducted in a prudent, controlled manner, it is anticipated that the RCS temperature will be near the 215.6°C (420°F) lower limit of Mode 3 when the accumulators are isolated.

For these analyses, the plant was assumed to be shut down in Mode 3 at steady-state conditions of 6.895 MPa gauge (1000 psig) and 218.3ºC (425°F) with the accumulators isolated. An initial pressure of 6.895 MPa gauge (1000 psig) is assumed because this is the highest pressure with the accumulators isolated and a hot-leg temperature of 218.3ºC (425°F) is the highest expected temperature when the pressure is 6.895 MPa gauge (1000 psig). The decay heat level is determined at 2.78 hours after reactor shutdown based on the time estimate to cool down the plant from full-power operation to 218.3ºC (425°F) at a cooldown rate of 27.8°C (50°F) per hour. The low pressuriser pressure safeguards signal is also assumed to be disabled because the initial pressure is below the setpoint.

Note, the assumed temperature of 218.3ºC (425°F) reflects normal operating practice, and is approximately 40ºC (72°F) lower than the maximum allowable hot leg temperature required by operating procedures to ensure RCS subcooling. However, the assumption is not expected to have a large impact on the analysis results.

The standard plant shutdown LOCA analyses are limited to a Mode 3 large-break LOCA due to the fact that this fault has the highest level of decay heat with accumulators unavailable, the largest break size, and thus the most severe depressurisation and loss of coolant. This fault is expected to be more limiting than a smaller break loss of coolant accident and/or a LBLOCA at any other lower mode. These expectations will be confirmed during site licensing and documented accordingly.

9.8.4.6.4.1 Double-Ended Cold-Leg Guillotine

The DECLG break is analysed using the WCOBRA/TRAC computer code and the AP1000-specific noding, which is based on the AP600 noding, presented in WCAP-14171, Revision 2 (Reference 9.8-4). Table 9.8.4-1 summarises the results.

This case models the double-ended rupture of one of the two cold legs in the RCS loop without the PRHR HX at a pressure of 6.895 MPa gauge (1000 psig) just after the accumulators are isolated. Only the CMTs and IRWST are available to deliver PXS flow. Analysis of this break evaluates the ability of the plant to withstand a large LOCA during shutdown with associated conditions and equipment availability. The nominal discharge coefficient (1.0) is modelled. The analysis is performed with conservative decay heat in alignment with that used in the at-power design basis analysis, and Technical Specification/Core Operating Limits Report maximum peaking factors.

The break is assumed to open instantaneously at 0.0 seconds. The subcooled discharge from

the broken cold leg (Figure 9.8.4-1) causes a rapid RCS depressurisation (Figure 9.8.4-2). In Figure 9.8.4-1, the positive flow direction is the normal operation direction. The reversal of flow entering the vessel to flow out of the break is shown. Due to High-1 containment pressure, an "S" signal is generated at 2.2 seconds. Following a 2.0-second delay, the isolation valves on the CMT and PRHR HX outlet lines begin to open. The reactor coolant pumps trip at 9.5 seconds.

Within a few seconds, the collapsed liquid level drops within the upper plenum due to voiding (Figure 9.8.4-3). The downcomer collapsed liquid level (Figure 9.8.4-4) quickly falls below the elevation of the cold legs; the elevation of the top of the core is 6.26 meters (20.54 feet) above the bottom of the reactor vessel.

CMT injection from both tanks replenishes the RCS mass inventory. Injection from the CMTs as the RCS pressure declines terminates the PCT transient because the stable injection of water from the CMTs exceeds the break flow. The core collapsed level refills are as shown in Figure 9.8.4-5. The draining of the CMTs is delayed by condensation occurring at the top of the tank (Figure 9.8.4-7); the CMT connected to the broken cold leg via the balance line does not begin to drain until the end of blowdown. The maximum PCT value is approximately 910°C (1671°F) for this bounding break size as shown in Figure 9.8.4-6, and all the acceptance criteria are met.

The radiological consequences of these events presented in Section 9.6 are limiting because the assumed consequential fuel damage bounds that which could result in the other modes.

9.8.4.6.4.2 DBA Credited SSCs

For the design basis evaluation of this DB1 infrequent fault, no claim is placed on systems which are not Class 1. The PMS provides the following:

- CMTs and containment isolation on High-2 containment pressure
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS 4 actuation signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

9.8.5 AP1000 Safety Evaluation of Faults Specific to Shutdown Modes

9.8.5.0 Introduction and Overview of Faults

Section 2 of Table 8A-2 includes identification of potential faults to be considered that are specific to shutdown modes. As discussed in the review of postulated initiating events in Section 9.8.4, these faults are associated with the alignment of the RNS system to provide decay heat removal in Modes 4, 5 and 6. With RNS operation, most of the protection and transient evolution discussed for the at-power events is not applicable, and hence specific design basis analyses have been performed.

9.8.5.0.1 Failure of RNS during Mode 4 and 5, with RCS intact (Fault 2.1.2)

Section 9.8.5.1 provides the design basis analysis for this case. In Table 8A-2, this fault is identified as a frequent fault (DB2) and as such diverse core cooling analysis cases are required.

To bound all potential initiating events, the following assumptions are made in the design basis analysis:

a. The initiating event is postulated as a loss of offsite power, followed by a complete failure of the Class 2 cooling chain (e.g., loss of both DG trains or loss of both RNS trains, or loss of both SWS/CCS trains). Thus, only Class 1 features are credited in the analysis.

b. The worst initiating conditions are assumed from Mode 4 operation including the highest RCS temperatures and decay heat.

c. The worst assumptions relative to availability of Class 1 features between Mode 4 and Mode 5 (with RCS intact) are made. These are summarised by Table 9.8.3-1.

9.8.5.0.2 Failure of RNS during Mode 5 and 6, with RCS open (Faults 2.1.3 and 2.1.4)

Section 9.8.5.2 provides the design basis analysis for this case and bounds faults 2.1.3 and 2.1.4. In Table 8A-2 this fault is identified as an infrequent fault (DB1).

To bound all potential initiating events, the following assumptions are made in the design basis analysis:

a. The initiating event is postulated as a loss of offsite power, followed by a complete failure of the Class 2 cooling chain (e.g., loss of both DG trains, or loss of both RNS trains, or loss of both SWS/CCS trains). Thus, only Class 1 features are credited in the analysis.

b. The worst initiating conditions are assumed from Mode 5 operation including the highest RCS temperature and decay heat consistent with reduced RCS inventory.

c. The worst assumptions relative to availability of Class 1 features between Mode 5 (with RCS open) and Mode 6 are made. These are summarised by Table 9.8.3-1.

9.8.5.0.3 Loss of Coolant Accidents Involving RNS (Fault 2.3.1 – 2.3.3)

Section 9.8.5.3 provides the design basis analysis for this case and bounds faults 2.3.1-2.3.3. In Table 8A-2 this fault is identified as an infrequent fault. This section discusses postulated breaks in the RNS piping during RNS operation in shutdown Modes 4, 5, and 6. Breaks in the RNS inside containment are bounded by the MBLOCA (Faults 1.4.1 – 1.4.3) in Modes 4, 5, and 6 presented in Section 9.8.4.6.4. For breaks outside of containment, the break flow is lost and is therefore unavailable for containment recirculation flow, so the scenario is not bounded by an MBLOCA inside containment. This section therefore provides the analysis of RNS breaks outside of containment.

9.8.5.1 Failure of RNS During Mode 4 and 5, with RCS intact (Fault 2.1.2)

9.8.5.1.1 Identification of Causes and Accident Description

For this analysis, it is assumed that the RNS has just been placed in operation at 2 hours after reactor shutdown with the RCS at 176.7°C (350°F) and 2.76 MPa gauge (400 psig). It is assumed that a loss of offsite power occurs, followed by a failure of the Class 2 cooling chain, resulting in a loss of flow through the RNS, and thus, in a loss of RNS cooling. The MSS is assumed to be unavailable for heat removal during the event except for the MSSVs. The steam generator secondary side is assumed to be at saturated conditions for 176.7°C (350°F) with the normal water level. Because the Mode 4 plant conditions assumed for the analysis are more limiting than Mode 5 conditions, this analysis also bounds a loss of RNS cooling in Mode 5 when the RCS is intact.

It is assumed that only one CMT is available for injection because Technical Specifications permit one CMT to be taken out of service in Mode 4. If both CMTs are available, the overall results should be similar, although the timing of the event will be affected by the additional injected makeup mass. Even though all of the fourth-stage ADS valves are available in Mode 4, the Technical Specifications permit one of the fourth-stage ADS valves to be out of service in Mode 5 when the RCS is intact. Thus, it was assumed that only three of the fourth-stage ADS valves are available for operation to bound the equipment availability in Mode 5. In addition, one of the three available fourth-stage ADS valves is assumed to fail to open on demand as the single failure, consistent with the single failure assumption used for the full power small-break LOCA analyses. The assumption of a failure of one ADS fourth-stage valve is more important than the number of CMTs available considering that the RCS has so little stored energy and decay heat.

One design basis case was analysed. This case credits the PMS, PRHR, CMT, ADS 1, 2, 3, and 4, IRWST injection and containment recirculation. As such it allows for automatic safety system actuation on a low pressuriser level signal later in the event. Until this time, the primary mechanism for removing decay heat is boiling off the RCS inventory and venting through one RNS relief valve.

Two diverse cases are provided, including a primary diverse case and a backup diverse case. The primary case credits the PMS, CMT, ADS 1, 2, 3, and 4, IRWST injection and containment recirculation. As such it allows for automatic safety system actuation on a low pressuriser level signal. Until this time, the primary mechanism for removing decay heat is boiling off the RCS inventory and venting through one RNS relief valve. The diverse case credits DAS and PRHR. Manual operator action is credited at 1800 seconds (30 minutes) after the loss of RNS cooling. With the more reasonable assumptions appropriate for diverse cases the PRHR is able to successfully cool the core without the need for ADS.

9.8.5.1.2 DBA and Diverse Credited SSCs for Accident Mitigation

For this fault, the available SSCs credited are listed in fault 2.1.2 in Table 8A-2. All of these SSCs are Class 1 except for the Class 2 DAS in the Backup Diverse case.

For the DBA, the PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown
- PRHR, CMTs, and containment isolation on Low-2 pressuriser level
- ADS 1-4 on Low CMT level

- IRWST injection on Low CMT level (via ADS 4 actuation signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure.

For the primary diverse case, the PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown
- CMTs, and containment isolation on Low-2 pressuriser level
- ADS 1-4 on Low CMT level
- IRWST injection on Low CMT level (via ADS 4 actuation signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure.

For the backup diverse case, the DAS provides the following:

- No reactor trip is required, as the reactor is already shutdown.
- Manual PRHR actuation
- PCS and containment isolation on High containment temperature

9.8.5.1.3 Analysis of Effects and Consequences

9.8.5.1.3.1 DBA Case - Automatic Safety Injection Actuation

The accident analysed is a loss of RNS cooling, which is assumed to result in a complete loss of heat removal for the RCS. The sequence of events for this analysis is presented in Table 9.8.5-1. The loss of RNS cooling occurs at 2 hours after reactor shutdown.

Following the loss of RNS cooling, there is no active mechanism for heat removal from the RCS. The core decay heat generation causes the reactor coolant temperature and pressure to increase. Although the MSS is assumed to be unavailable for heat removal (with the exception of the MSSVs), the steam generators represent a heat sink that slows the rate of heatup of the reactor coolant. The fluid temperature at the core outlet for the transient is shown in Figure 9.8.5-1. The reactor coolant heatup causes the system pressure to increase, as shown in Figure 9.8.5-2, until the pressure reaches the RNS relief valve setpoint of 3.45 MPa gauge (500 psig) at approximately 2.19 hours. The normal relieving capacity of one RNS relief valve is 225 m^3/hr (991 gpm) at 3.79 MPa (550 psig), and the pressure is maintained at the relief valve setpoint as the temperature continues to increase and reactor coolant is discharged from the relief valve. Flow out the relief valve is shown in Figure 9.8.5-3. The expansion of the water due to the coolant temperature increase also causes the pressuriser level to increase slightly as shown in Figure 9.8.5-4.

The loss of reactor coolant through the relief valve is not sufficient to remove the core decay

heat, and the reactor coolant temperature continues to increase until the core outlet temperature reaches saturation near the relief valve setpoint at approximately 2.73 hours. The generation of steam in the core causes the system pressure to increase above the RNS relief valve setpoint and the pressuriser level to continue to increase. A mixture level begins to form in the upper plenum at approximately 2.74 hours and drops to the top of the hot-leg elevation as shown in Figure 9.8.5-5. At about 2.88 hours, enough mass has been discharged such that a mixture level also forms in the downcomer (Figure 9.8.5-6) and the downcomer two-phase level begins to decrease. As the boiling front moves lower and lower into the core, more steam generation occurs and the pressure continues to increase. Once the entire core length is boiling, the upper plenum mixture level is within the hot-leg perimeter. There is a brief period of two-phase discharge out the RNS relief valve when the upper plenum mixture level drops near the bottom of the hot leg at approximately 4 hours. Following this period there is sufficient steam generation due to the loss of the heat sink that vapour is able to flow into the pressuriser and promote pressuriser draining.

As the pressuriser level decreases, a CMT actuation signal is generated automatically on low pressuriser level. Following a 2.0-second delay, the isolation valves on the available CMT tank delivery lines begin to open and CMT injection flow is initiated at approximately 4.23 hours as shown in Figure 9.8.5-7. This signal also trips the RCPs. The opening of the PRHR HX isolation valve on a CMT actuation signal starts the flow through the heat exchanger. The CMT injection and PRHR actuation causes the reactor coolant pressure to decrease below the RNS relief valve setpoint, and the loss of reactor coolant is terminated at approximately 4.37 hours. As the CMT level decreases (Figure 9.8.5-8), the first-stage ADS setpoint at 67.5 percent volume is reached and flow initiates at 4.36 hours. The second-stage and third-stage ADS valves also open following the timer delays for the actuation of the second-stage and third-stage ADS valves. The vapour and liquid flow through the ADS valves (Figures 9.8.5-9 and 9.8.5-10) results in a rapid depressurisation of the reactor coolant system. The CMT reaches the fourth-stage ADS setpoint of 20 percent volume and two of the four fourth-stage paths open at 4.53 and 4.55 hours. As noted previously, it is assumed that one of the fourth-stage paths is out of service and one path is assumed to fail as the single active failure. The vapour and liquid flow through the fourth-stage ADS paths (Figures 9.8.5-11 and 9.8.5-12) further reduces the pressure to the point where IRWST injection begins at approximately 4.73 hours (Figure 9.8.5-13).

The CMT and IRWST injection reverses the decrease in the core stack and downcomer mixture levels as shown in Figures 9.8.5-5 and 9.8.5-6, respectively. As shown in Figure 9.8.5-5, the core stack mixture level is maintained above the elevation of the top of the core active fuel (6.26 m [20.54 feet] above the bottom of the reactor vessel) throughout the transient. At the end of the transient, the core stack mixture level has been restored to within the hot-leg perimeter and the downcomer mixture level has been restored to the DVI nozzle elevation. The fluid temperature at the core outlet has also been reduced and is being maintained at less than 121.1°C (250ºF). As shown in Figure 9.8.5-14, the reactor coolant mass inventory twice reaches a minimum of approximately 55,000 kg (122,000 lbm) and then 48,000 kg (106,000 lbm) when the CMT and IRWST injection then increase the inventory. The reactor coolant mass inventory has stabilized near 65,000 kg (144,000 lbm) at the end of the transient. Thus, it is concluded that the consequences of a loss of RNS in Modes 4 and 5 with the RCS intact are acceptable.

9.8.5.1.3.2 Primary Diverse Case – Automatic Safety Injection Actuation

This case has not been analysed at this time. However, it is fully expected to be successful because, as compared to the design basis case:

- A reduction of decay heat margin to be in line with that used for all other non-LOCA

faults. The analysis currently uses the more restrictive LOCA decay heat margin.
- An increase in the time assumed when RNS is initially aligned to cool RCS. It is currently conservatively assumed to occur faster than any realistic plant schedule would allow.
- The single failure of one ADS stage four valve to open need not be assumed since a CCF of the PRHR is assumed.

Since the PRHR HX is not credited in this diverse case, that will tend to shorten the time window available for action after the loss of RNS. However, this difference is more than compensated for by the above noted analysis improvements. As further evidence, the diverse core cooling case for loss of main feedwater (presented in Section 9.2.7.3.2) also credits core cooling by passive feed and bleed. This case credits a similar set of SSCs (PMS, CMTs, ADS, IRWST injection and Containment recirculation). The only difference in credited SSCs is that both CMTs are available to inject instead of one; however, this is offset by a higher RCS initial temperature and initial decay heat levels as well as early ADS actuation.

9.8.5.1.3.3 Backup Diverse Case – Manual PRHR HX actuation

This case has not been analysed at this time. However, it is fully expected to be successful because, as compared to the design basis case:

- A reduction of decay heat margin to be in line with that used for all other non-LOCA faults. The analysis currently uses the more restrictive LOCA decay heat margin.
- An increase in the time assumed when RNS is initially aligned to cool RCS. It is currently conservatively assumed to occur faster than any realistic plant schedule would allow.
- PRHR HX performance will be improved and more realistic, as it currently is artificially degraded for DBA SBLOCA analyses to conservatively account for uncertainties.

In this case, ADS is not credited so the PRHR HX by itself must limit the RCS mass loss out the RNS relief valve(s) and prevent core uncovery. The above differences significantly improve the PRHR HX performance. Over time, as RCS mass is lost, the hot legs will void, which will allow steam to enter the PRHR HX. In this mode of operation the PRHR HX heat transfer is enhanced by two effects. One is the greater density difference between hot water and steam, and the other is the higher heat transfer coefficient for steam condensation compared with water. This functionality was examined in detail in support of the frequent fault SBLOCA diversity analyses (See Section 9.6.5.3.4.2).

9.8.5.1.3.4 Radiological Consequences

The radiological consequences of a postulated loss of RNS cooling are evaluated.

9.8.5.1.3.4.1 Source Term

There is no fuel damage as a result of the accident. Therefore, the only activity available for release is that present in the primary coolant. The initial reactor coolant system noble gases, alkali metals, and iodines concentrations are assumed to be those associated with the equilibrium operating limit for primary coolant iodine activity. This evaluation conservatively includes consideration of an iodine spike that has resulted in an increased level of iodine in the reactor coolant. This spike is assumed to have resulted from the plant shutdown, cooldown and depressurisation associated with the transition from power operation to shutdown cooling. This spike is considered unlikely and not required for consideration in the accident dose calculations. Despite this the spike has been included in this evaluation. This spike has been included even though it is not a normal occurrence and increased clean

up would be initiated in response to its occurrence such that by the time an accident occurs there would no longer be an elevated iodine concentration.

9.8.5.1.3.4.2 Release Pathways

Failures of the RNS to cool the RCS would result in boiling of the RCS and the steam generated would be released to containment (directly if the RCS is open and via vent paths if the RCS is closed). The doses resulting from failures of the RNS are conservatively estimated assuming all activity in the RCS becomes airborne in containment. The resulting doses therefore bound failures of the RNS in both non-drained and drained conditions.

It is assumed that following a loss of RNS cooling containment would be closed prior to initiation of RCS boiling. Prior to allowing containment to be opened the standard practice would be to perform an assessment of the potential for boiling if a loss of cooling would occur and only open containment if this evaluation shows that sufficient time would be available to re-close containment before RCS boiling. It is noted that the plant Technical Specifications, Limiting Condition for Operation 3.6.8, includes requirements that open equipment hatches, air lock doors and spare penetrations can be closed prior to steaming into the containment. This provides a high level of confidence that a loss of RNS would not result in a release of significant RCS activity without containment being isolated.

9.8.5.1.3.4.3 Dose Calculation Models

The models used to calculate offsite and control room doses are provided in Appendix 9A.

9.8.5.1.3.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the dose analysis are listed in Table 9.8.5-5. Instead of a detailed analysis the dose is conservatively estimated by comparing the activity that could become airborne in containment following a loss of RNS to that modelled in the LOCA analysis presented in Section 9.6.4.4 and calculating a proportional change in the doses.

9.8.5.1.3.4.5 Doses

The conservatively estimated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 0.225 mSv Worker dose: 0.326 mSv

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite) as required for the loss of RNS in Modes 4 or 5 with the RCS closed. Therefore, these doses also support the infrequent fault Target 4 BSL for the loss of RNS in Modes 5 and 6 with the RCS open.

9.8.5.1.3.5 ALARP Evaluation

For this fault, Class 1 SSCs has been shown to be adequate to meet DB requirements. In addition, since this fault is classified as DB2, diverse mitigation is provided. The diverse mitigation uses Class 1 SSCs except for the C&I which is Class 2.

As discussed in Chapter 9.0.15, the standard AP1000 design has incorporated ALARP considerations throughout its development. Furthermore, the standard AP1000 plant design incorporates numerous features that reduce shutdown risk as discussed in Section 9.8.3. One of the more important features is reduced containment leak paths (fewer penetrations,

improved isolation valves, backup DAS actuation, and passive containment cooling) and the ability to close containment during shutdowns. In addition, the current risk of a large radioactivity release during shutdown conditions is significantly less than the SAP Target 8 BSO.

The radiological consequences presented to cover this fault (See Section 9.8.5.1.3.4) are slightly above the Target 4 BSO. However, the analysis performed during the Generic Design Assessment (GDA) has considerable conservatism, as the current analysis is an evaluation using a more limiting event. A commitment exists to update all radiological consequences analyses during site licensing. There are reasonable adjustments to be incorporated into the analysis for the loss of RNS faults that will bring the resultant doses below the Target 4 BSO. These include performing an event specific analysis rather than a comparison evaluation to more limiting faults.

Additionally, there are a number of conservatisms in the presented thermal hydraulic analyses that could be adjusted in order to demonstrate additional margin with respect to acceptance criteria. These include a reduction in decay heat margin for this fault to be in line with that used for all other non-LOCA faults and use of more realistic PRHR performance for the diverse cases.

Nonetheless, several potential enhancements have been identified for further evaluation in site licensing to confirm risks have been reduced ALARP. These potential enhancements include:

- A Technical Specification change to adjust the point when RNS is initially aligned to cool the RCS; specifically, to consider limiting RNS alignment to a point with a specific decay heat level. This would allow for a mechanistic, yet still conservative, timing assumption to be included in the presented analyses. Currently, RNS alignment is conservatively assumed to occur faster than any realistic plant schedule would allow.
- Consideration of instituting an automatic start of PRHR via DAS on a lower high hot leg temperature setpoint during shutdown conditions. This would primarily benefit the diversity evaluation for this fault.

Accounting for the ALARP considerations that went into the AP1000 design development, its low risk profile, and the expected demonstration of meeting the Target 4 BSO during site licensing as discussed above, making further improvements to the design are expected to be grossly disproportionate to the risk reduction that might be achieved. As a result, the current design with the above potential enhancements is considered ALARP.

9.8.5.2 Failure of RNS during Mode 5 and 6, with RCS Open (Faults 2.1.3 and 2.1.4)

9.8.5.2.1 Identification of Causes and Accident Description

For this analysis, it is assumed that the RNS is in operation in Mode 5 at 24 hours after reactor shutdown with the ADS Stage 1, 2, and 3 valves open and the RCS vented to the IRWST (see Table 9.8.3-1). The reactor coolant temperature is assumed to be at 71.1°C (160°F), and the pressuriser pressure is assumed to be at atmospheric pressure plus the elevation head in the IRWST, or 0.125 MPa abs (18.2 psia). The steam generator secondary side is assumed to be drained, and thus, there is no secondary heat sink for this case. It is assumed that the CMTs and the PRHR are not available because the Technical Specifications permit them to be taken out of service in Mode 5 with the RCS open. It is also assumed that only two of the fourth-stage ADS valves are available for potential use by the operators because the Technical Specifications permit two of the fourth-stage ADS valves to be out of

service in Mode 5 when the RCS is open. In addition, one of the two available fourth-stage ADS valves is assumed to fail to open on demand as the single failure. The Technical Specifications also permit one of the two IRWST injection paths to be out of service in Mode 5 with the RCS open, and thus, only one of the IRWST injection paths is assumed to be available.

It is assumed that a loss of offsite power occurs, followed by a complete loss of the Class 2 cooling chain, resulting in a loss of RNS flow, and thus a loss of RNS cooling. The sequence of events for this analysis is presented in Table 9.8.5-2.

9.8.5.2.2 DBA Credited SSCs

For the DBA, no claim is placed on systems which are not Class 1. The PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown.
- ADS 4 on Low hot leg level; no ADS 1-3 actuation is required as the valves are already open in Mode 5 with the RCS open and Mode 6. Only 1 of 4 ADS-4 valves is assumed available (2 out of service and 1 single failure).
- IRWST injection on Low hot leg level
- Containment recirculation on Low IRWST level
- PCS and containment isolation on High containment temperature

9.8.5.2.3 Analysis of Effects and Consequences

9.8.5.2.3.1 Mode 5 RCS Open Prior to Draining

For this case, the loss of RNS cooling is conservatively assumed to occur at 24 hours; this is the earliest timing of an RCS open condition and leads to the most highest initial decay heat and the most limited venting capability to the RCS. The loss of RNS cooling causes the failure of the normal RCS cooling mechanism. Core decay heat generation then results in an increase in the reactor coolant temperature. The fluid temperature at the core outlet for the transient is shown in Figure 9.8.5-18. The core outlet fluid temperature increases steadily until approximately 24.61 hours when saturation temperature is reached and voiding is initiated in the core. Because the RCS is vented to the IRWST via the already open ADS Stages 1, 2, and 3, the pressure initially remains constant until approximately 24.5 hours as shown in Figure 9.8.5-19. As the void generation in the system increases, the vapour flow through ADS Stages 1, 2, and 3 is not sufficient to maintain the pressure. The pressure increases to approximately 0.410 MPa abs (59.5 psia), and then begins to decrease. As shown in Figure 9.8.5-20, the pressuriser level also increases as the reactor coolant temperature increases. The level subsequently reaches the top of the pressuriser as a result of the steam generation in the system. As shown in Figures 9.8.5-21 and 9.8.5-22, a mixture of steam and water is discharged via ADS Stages 1, 2, and 3 after the pressuriser fills.

The continued loss of reactor coolant through ADS Stages 1, 2, and 3 causes the pressure to begin to decrease at approximately 25 hours. The core outlet temperature is at saturation and also begins to decrease as the pressure decreases. A mixture level begins to form in the upper plenum at approximately 24.65 hours, and the level begins to decrease, as shown in Figure 9.8.5-23, as the voiding continues in the system. At about 24.70 hours, enough mass has been discharged that a mixture level forms in the downcomer (Figure 9.8.5-24) and the

downcomer level also begins to decrease. The pressuriser level does not decrease significantly due to an increasing void fraction in the pressuriser.

As the voiding in the core continues, the core stack mixture level continues to decrease as shown in Figure 9.8.5-23. The mixture level in the hot legs begins to decrease after 24.66hours (Figure 9.8.5-25). The hot legs are approximately empty by 25.16 hours. Hot leg empty is the normal signal for opening the fourth-stage ADS valves and to initiate IRWST injection when the systems are aligned for automatic actuation[1]. It is also the indication that will prompt operators to actuate the fourth-stage ADS valves and as such, it is assumed that the operator will initiate manual action shortly before 25.20 hours (following a two minute delay) to open the fourth-stage ADS valves and to open the IRWST flow path to permit IRWST injection when the downcomer pressure is sufficiently low. Discharge through one of the fourth-stage ADS valves is initiated at 25.20 hours as shown in Figures 9.8.5-26 and 9.8.5-27. As noted previously, one of the two available fourth-stage ADS paths is assumed to fail to open as the single active failure. The flow through the fourth-stage ADS path results in a further reduction in the pressuriser pressure and a rapid decrease in the pressuriser level. The downcomer pressure is also reduced to the point where IRWST injection is initiated at approximately 25.35 hours (Figure 9.8.5-28).

The IRWST injection reverses the decrease in the core stack and downcomer mixture levels as shown in Figures 9.8.5-23 and 9.8.5-24, respectively. As shown in Figure 9.8.5-23, the core stack mixture level is maintained well above the elevation of the top of the core active fuel (6.26 m [20.54 feet] above the bottom of the reactor vessel) throughout the transient. At the end of the transient, the core stack mixture level has been restored to approximately the middle of the hot-leg elevation. The fluid temperature at the core outlet has also been reduced to approximately 121.1°C (250°F). As shown in Figure 9.8.5-29, the reactor coolant mass inventory reaches a minimum of approximately 55,000 kg (122,000 lbm) and then begins to increase as a result of the IRWST injection. Thus, it is concluded that when the appropriate operator action is performed, one ADS Stage 4 valve is effective in reducing system pressure so that the consequences of a loss of RNS in Mode 5 with the RCS vented are acceptable.

9.8.5.2.3.2 Mode 5 Mid-Loop Operation

This additional case presented is a conservative analysis of a loss of RNS cooling during reduced inventory conditions (i.e., minimum inventory). During Mode 5, prior to draining to mid-loop conditions, from a water solid initial condition the operator manually opens the ADS Stages 1 through 3 paths to the IRWST. With the RCS “open,” the operator could then proceed to slowly drain the RCS to “mid-loop” conditions for performing steam generator maintenance or other maintenance that requires a reduced RCS water level. Before the operator starts draining to “mid-loop”, it is postulated that a loss of decay heat removal via the Class 2 RNS occurs. A loss of RNS cooling at this time is selected because it is the earliest time the RCS could be placed into a reduced inventory (that is, RCS open) condition. In addition, the backpressure on the reactor vessel, due to the presence of water in the pressuriser, is higher at this time. This presents the most challenging condition for the ADS to depressurise the RCS to IRWST cut-in pressure. This transient represents the most limiting “surge line flooding” scenario, a term commonly used for operating plants to refer to the phenomenon associated with water in the pressuriser and surge line causing a high backpressure in the RCS. For these operating plants this potentially challenges the ability of the low head safety injection systems to inject properly.

[1] This automatic actuation has a 25 minute delay; the manual actuation discussed in this analysis is in advance of the automatic actuation.

For a loss of the RNS during mid-loop operations, calculations have been performed to determine the time until core uncovery would occur. The results of these calculations are presented in Table 9.8.5-3. A loss of RNS cooling during mid-loop results in a heatup of the core to saturation, followed by a boiling off of the coolant to the IRWST via the ADS Stages 1, 2, and 3 valves. The conditions in the RCS following IRWST and fourth-stage ADS actuation are similar to the other cases in this evaluation. As shown in Table 9.8.5-3, the operator has at least 42 minutes from the loss of RNS cooling until the onset of core uncovery to manually actuate the IRWST and ADS Stage 4. In general, when considering appropriate operator action to mitigate the event, the results of a loss of RNS during mid-loop conditions are similar, but slightly less severe than the other cases presented in this evaluation due to the lower levels of decay heat and to the absence of the initial water inventory in the pressuriser. This serves to reduce the surge line flooding phenomenon that degrades the depressurisation capability of the ADS Stages 1 through 3 vent paths.

9.8.5.2.3.3 Radiological Consequences

The radiological consequences presented in Section 9.8.5.2.3.3 for the frequent fault loss of RNS faults also bound those for the infrequent fault scenarios.

9.8.5.2.3.4 ALARP Evaluation

The ALARP evaluation presented in Section 9.8.5.1.3.5 for the frequent fault loss of RNS scenarios also applies to these infrequent fault scenarios.

9.8.5.3 Loss of Coolant Accidents Involving RNS (Faults 2.3.1 – 2.3.3)

9.8.5.3.1 Identification of Causes and Accident Description

As discussed in Section 9.8.5.0.3, this section discusses postulated breaks in the RNS piping during RNS operation in shutdown Modes 4, 5, and 6. These faults are categorised as infrequent faults (DB1). The analysis presented below assumes that the RNS is isolated 30 minutes after the break occurs which is consistent with operator action. The plant has automatic Class 1 RNS isolation which is not credited here but the analysis will be revised during site licensing to incorporate the automatic actuation logic added to the design.

For a postulated RNS break outside the containment while in Modes 4 and 5 with the RCS pressure boundary intact, the RCS would lose inventory through the postulated break and the pressuriser water level would decrease. A low pressuriser level signal will automatically actuate the CMTs. When the RCS cold legs void, the CMTs would begin to drain and eventually ADS Stages 1, 2, 3, and later ADS Stage 4 would be actuated on low CMT level signals. The ADS Stage 4 signal would actuate IRWST injection and would also isolate the containment and RNS. The automatic RNS and containment isolation on an ADS Stage 4 signal reduces the RCS inventory lost outside containment and increases the inventory margin for passive containment recirculation over that shown in this analysis.

For a reduced inventory case in Modes 5 and 6 with the RCS pressure boundary open in the event of an RNS break outside the containment, the RCS would lose inventory. On low hot leg level, ADS Stage 4 and IRWST injection would be actuated. The ADS Stage 4 signal also isolates the RNS and containment. Technical Specifications require that the equipment hatches, containment air locks, and containment spare penetrations shall be capable of being closed before steaming into the containment. Therefore, RNS and containment isolation on an ADS Stage 4 signal and containment penetrations isolation will preserve enough inventory in case of RNS leakage to allow passive containment recirculation.

9.8.5.3.2 DBA Credited SSCs

For the DBA, no claim is placed on systems which are not Class 1. In Modes 4 and 5 with the RCS intact, the PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown
- CMT on Low-2 pressuriser level
- ADS 1-4 on Low CMT level
- IRWST injection and containment isolation (including RNS) on Low CMT level (via ADS 4 actuation signal)
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure.

In Mode 5 with the RCS open, the PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown.
- ADS 4, IRWST injection, and containment isolation (including RNS) on Low hot leg level
- Containment recirculation on Low IRWST level
- PCS on High-2 containment pressure

In Mode 6, the PMS provides the following:

- No reactor trip is required, as the reactor is already shutdown.
- Manual actuation of ADS 4, IRWST injection, containment recirculation, and RNS isolation
- PCS and containment isolation on High-2 containment pressure.

9.8.5.3.3 Analysis of Effects and Consequences

9.8.5.3.2.1 Mode 4 and 5 with RCS Pressure Boundary Closed

For a postulated RNS break outside containment in these plant Modes, the RCS will lose inventory through the postulated break and the pressuriser water level will decrease. A low pressuriser level signal will automatically actuate the CMTs. Once the RCS level has decreased such that the cold legs void, the CMTs will also start to drain. When the CMTs have drained to approximately 71 percent of their volume, ADS stages 1, 2 and 3 will be actuated. Following the actuation of ADS stages 1, 2, and 3, ADS stage 4 and IRWST injection will be opened when the CMTs have drained to approximately 25 percent of their volume. ADS stage 4 actuation would also initiate automatic containment and RNS isolation.

To assess the capability of the plant to address this postulated RNS break, an analysis has been performed and the results show that the calculated containment water level is 102.41 m

(107.92 ft)[2], whereas the minimum-required containment water level to support passive containment recirculation is 102.39 m (107.85 ft). The minimum calculated containment water level is coincident with operator action at 30 minutes. Significant conservative assumptions in the analysis are included in this result. For example, the assumption of a constant break flow calculated according to the event initial conditions instead of allowing break flow to vary as conditions change. In addition, the automatic isolation signal for the RNS was not credited. With the minimum level maintained, no core damage will occur and long-term core cooling is ensured. This analysis demonstrates that sufficient time is available for the operator action before the loss of mass from the RCS and IRWST could challenge the long-term cooling capability. The sequence of events for this case is contained in Table 9.8.5-4.

9.8.5.3.2.2 Mode 5 with RCS Pressure Boundary Open

The RCS water level is initially assumed to be at mid loop (approximately 80% level of the Hot Legs). An RNS pipe break outside of the containment would quickly drain the RCS hot leg. A low Hot Leg level signal automatically actuates ADS Stage 4 and IRWST injection after a 25-minute time delay. The time delay is intended to allow for personnel that might be inside the containment to leave and also to close up the containment (as required by the Tech Spec). During this 25 minute time delay core cooling would be provided by heatup of the water in the reactor coolant system (below the mid loop level. The 25 minute time delay allows for the operators to assess the situation and determine what has happened and whether the event was a failure that caused loss of cooling or was caused by a pipe break. In the event of a pipe break, the operators would likely isolate the RNS manually in advance of the time that the low HL level signal would automatically open ADS 4 and initiate IRWST injection. Also note that the RNS is arranged in two separate trains such that a RNS pipe break would not disable both trains of RNS. If the faulted RNS train could be identified, it would be possible to isolate the faulted train and (after adding water to the RCS) to use the intact RNS to provide core cooling. If this was not achieved, IRWST injection and ADS stage 4 would provide feed and bleed cooling. When the IRWST level decreased, containment recirculation would be initiated to establish the long-term cooling mode. PCS operation would auto-actuate on high containment pressure to limit the containment pressure.

It was calculated that within 25 minutes, collapsed water level in the reactor vessel would be between the top core elevation, 98.24 m (94.22 ft) and bottom hot leg elevation 99.99 m (99.96 ft), thus conservatively ensuring that the core remains covered and no significant clad heatup would occur.

Containment water level is determined with a partial IRWST volume (the calculation assumes that during 5 minutes, the time difference between low hot leg level being reached and when operator action is needed, IRWST injection is lost through the postulated break) and volume corresponding to the top core elevation. It was shown that the containment water level is above the minimum required. This demonstrates that for Mode 5 with RCS open, passive recirculation will be established providing long term core cooling.

9.8.5.3.2.3 Mode 6 with Refuelling Cavity Flooded

In this case, a RNS break would drain water out of the Refuelling Cavity (RC) through the RCS via the removed Reactor Vessel head. The initial limiting break flow of 17.03 m^3/min (4500 gpm), assumed to remain constant, was used to determine how much of the reactor

2. Note that the basis for all elevations is set to 100 feet in US design and 100 m in metric design.

coolant inventory would drain out before the manual operator action would need to be claimed. It was shown that the final RC level, 107.74 m (125.41 ft), is well above the RV flange when the operator isolates the RNS break. After that time, the water in the RCS and RC heats up until it starts to boil. After boiling starts, the steam flows to and pressurises the containment, which results in automatic actuation of the PCS. The PCS water drains on the outside of the containment, cooling the containment shell and condensing the steam inside the containment.

The steam condensate is routed back from the containment shell to the IRWST through the PXS downspouts and gutters. In addition, it will be necessary for the operators to open one IRWST injection line. This will allow the water that is accumulating in the IRWST to return to the RCS to prevent the RCS from losing too much inventory. This establishes long term cooling and an equilibrium between IRWST and refuelling cavity levels.

It is also important to note that the configuration alignment of the reactor internals will impact the accident transient. In the event that internals are installed, ADS stage 4 actuation would be required to maintain sufficient depressurisation of the core. If the internals are removed, ADS stage 4 actuation is not required due to the large open area available to prevent pressurisation.

Consequently, long term core cooling for this Mode is ensured.

9.8.5.3.2.4 Radiological Consequences

The radiological consequences of a postulated break in RNS piping outside containment are evaluated.

9.8.5.3.2.4.1 Source Term

There is no fuel damage as a result of the accident. Therefore, the only activity available for release is that present in the primary coolant. The initial reactor coolant system noble gases, alkali metals, and iodines concentrations are assumed to be those associated with the equilibrium operating limit for primary coolant iodine activity. This evaluation conservatively includes consideration of an iodine spike that has resulted in an increased level of iodine in the reactor coolant. This spike is assumed to have resulted from the plant shutdown, cooldown and depressurisation associated with the transition from power operation to shutdown cooling. This spike is considered unlikely and not required for consideration in the accident dose calculations. Despite this the spike has been included in this evaluation. This spike has been included even though it is not a normal occurrence and increased clean up would be initiated in response to its occurrence such that by the time an accident occurs there would no longer be an elevated iodine concentration.

9.8.5.3.2.4.2 Release Pathways

It is assumed that the RNS pipe breaks outside containment and the break flow path is assumed to allow all of the activity in the RCS to be discharged into the auxiliary building. This assumption provides for a conservative dose calculation. A portion of the iodine and alkali metal activity, and all of the noble gas activity, transferred outside containment is assumed to become airborne.

9.8.5.3.2.4.3 Dose Calculation Models

The models used to calculate offsite and control room doses are provided in Appendix 9A.

9.8.5.3.2.4.4 Analytical Assumptions and Parameters

The assumptions and parameters used in the analysis are listed in Table 9.8.5-6. The limiting worker dose reported is the control room operator dose conservatively calculated neglecting actuation of the main control room emergency habitability system (VES) even though the setpoint would be reached.

9.8.5.3.2.4.5 Doses

The conservatively estimated maximum doses for all relevant pathways (inhalation, cloudshine, and groundshine) are as follows:

- Offsite dose: 52 mSv Worker dose: 323 mSv

These doses are within the Target 4 BSL for infrequent faults with IEF<1E-04 (100 mSv offsite and 500 mSv onsite). This analysis is significantly conservative due to assumptions that do not credit mechanistic and/or realistic limitations to the radiological consequences, such as:

- Maximum possible iodine spike
- Complete discharge of the initial RCS activity (i.e., no credit for containment isolation)
- No credit for delay, plate-out, or hold-up of radioactivity within the auxiliary building prior to being released to the environment
- No credit for the operation of the Class 2 HVAC system
- No credit for the Class 1 MCR HVAC system, VES

9.8.5.3.2.5 ALARP Evaluation

For this fault, Class 1 SSCs has been shown to be adequate to meet DB requirements.

As discussed in Chapter 9.0.15, the standard AP1000 design has incorporated ALARP considerations throughout its development. Furthermore, the standard AP1000 plant design incorporates numerous features that reduce shutdown risk as discussed in section 9.8.3. One of the more important features is reduced containment leak paths (fewer penetrations, improved isolation valves, backup DAS actuation, and passive containment cooling) and the ability to close containment during shutdowns. In addition, the current risk of a large radioactivity release during shutdown conditions is significantly less than the SAP Target 8 BSO.

The radiological consequences presented for this fault (See Section 9.8.5.3.2.4) are less than the Target 4 BSLs, but above the BSO. However, the analysis performed during GDA has considerable conservatism, and a commitment exists to update all radiological consequences analyses during site licensing. There are reasonable adjustments to the analysis for the RNS LOCA faults that will bring the resultant doses closer to the Target 4 BSO. However, due to the direct release of primary coolant outside of containment, it is not expected for the doses to be reduced below the BSO value. Considerations for improving the radiological consequences analyses include:

- Reduction of the assumed RCS activity levels to more realistic, but appropriately conservative, values based on more recent operating experience
- Reduction of the RCS mass loss assumed outside containment by crediting the automatic isolation of RNS
- Crediting Class 1 VES operation to reduce the worker doses

- Crediting reduction in offsite doses provided by Auxiliary Building structure

The adoption of a two train separated RNS system design reduces the likelihood of this fault and improves the mitigation capability. The use of two trains with smaller pipe diameters slows the inventory loss in the event of a line break, and the ability to use the two trains independently allows for continued cooling without reliance on the Class 1 passive safety systems by isolating the damaged train (if possible). Additionally, several enhancements have been identified for further evaluation in site licensing to confirm risks have been reduced ALARP. These potential enhancements include:

- A Technical Specification change to adjust the point when RNS is initially aligned to cool the RCS; specifically, to consider limiting RNS alignment to a point with a specific decay heat level. This would allow for a mechanistic, yet still conservative, timing assumption to be included in the presented analyses. Currently, RNS alignment is conservatively assumed to occur faster than any realistic plant schedule would allow.
- Improvement to the automatic RNS isolation functionality to reduce the RCS mass loss outside containment.
- Updates to the standard AP1000 plant Technical Specifications, which currently only require VES to be operable during Modes 1 – 4 as well as any time irradiated fuel is being moved. Specifically, adding an operability requirement during Mode 5 when there is high RCS activity would have a significant improvement to worker doses.

Accounting for the ALARP considerations that went into the AP1000 design development, its low risk profile, and the expected demonstration of improvements to the radiological consequences discussed above, making further improvements to the AP1000 design are expected to be grossly disproportionate to the risk reduction that might be achieved. As a result, the current design with the above potential enhancements is considered ALARP.

9.8.6 Conclusion

In order to demonstrate the plant shutdown safety case has reduced plant risk ALARP, a systematic evaluation of the AP1000 design with respect to faults during shutdown operations was provided. As demonstrated in this section, the plant is designed to mitigate events that can occur during all shutdown modes. All faults have demonstrated primary mitigation using only Class 1 SSCs, and where necessary, frequent faults also include demonstration of diverse mitigation using mostly Class 1 SSCs and supplemented with limited use of Class 2 SSCs.

The risk of core damage as a result of an accident that may occur during shutdown has been demonstrated to be acceptably low. In addition, conservatively calculated radiological consequences are within the Target 4 BSLs. The standard AP1000 plant design incorporates numerous features that reduce shutdown risk as discussed in Section 9.8.3. Nonetheless, while evaluating the shutdown safety case during GDA, additional design enhancements were incorporated in order to ensure that plant shutdown risks were reduced ALARP:

- Automatic containment and RNS isolation occur upon receipt of an ADS stage 4 signal in order to limit the amount of RCS coolant that could be lost in the event of an RNS line break outside of containment (Section 9.8.5.3)
- Automatic isolation of CVS dilution sources, CMT actuation, RCP trip, and RNS pump trip via a DAS connection to the intermediate range ex-core detectors to prevent a return to criticality during a boron dilution event at shutdown (Section 9.8.4.4.5)
- Adoption of a two train separated RNS system design, which provides reduced RNS pipe sizes as well as increasing the likelihood of continued RNS operation in the event of a

line break.

These features will be credited in analysis updates going forward in site licensing. Additional improvements that will be evaluated during site licensing that might further reduce shutdown risk ALARP include:

- Consideration of using an alternate RNS isolation signal so that less RCS inventory is discharged outside containment and only the faulted RNS train is isolated. One possibility would be the low Pressuriser level signal. Another might be high RNS train flow rates or large differences in train flow rates.
- Changes to the Technical Specifications to require the VES to be operable during Modes 4, 5, and 6 except when the RCS activity is low. Selection of what is sufficiently "low" will require a balance the need for VES planned maintenance, in-service inspections, in-service testing, avoidance of undesirable power reductions of the plant only to restore VES operability (in case of failures) with the reduction in post-accident MCR doses.
- Justification of using a lower RCS activity level (iodine spike) for RNS breaks based on more recent operating experience. This may be reflected in the plant design via a Technical Specification change that would preclude RNS operation with RCS activity levels above a specified limit.

6	Refuelling[3]	NA	NA	NA

Notes:

1. Excluding decay heat
2. All reactor vessel head closure bolts fully tensioned
3. One or more reactor vessel head closure bolts less than fully tensioned

Table 9.8.3-1. Availability of Class 1 Passive Core Cooling Equipment During Operational Modes

Equipment	Availability				
	Mode 1-2	Mode 3	Mode 4	Mode 5	Mode 6
CMTs	Y	Y(1)	Y(1, 2)	Y(1, 2) – RCS closed N(3) – RCS Open	N(3)
Accumulators	Y	N(4)	N(4)	N(4)	N(4)
IRWST	Y	Y	Y	Y(5)	N(6)
PRHR	Y	Y(7)	Y(7)	Y(7) – RCS closed N(8) – RCS Open	N(8)
ADS 1-3	Y	Y	Y	Y(9)	Y(9)
ADS 4	Y	Y	Y	Y(10)	Y(10)

Notes:

1. In shutdown modes, portions of the safeguards actuation signal are disabled to allow the RCS to be cooled and depressurised for shutdown and the primary signal that actuates the CMTs due to a loss of inventory is the pressuriser level signal.
2. In Mode 4 and 5, with RNS aligned and RCS closed, operation is allowed with 1 (rather than both) CMTs aligned. See also Section 9.8.5.0.1.
3. In Mode 5 with the RCS open, the CMTs are not required to be available and the RCS makeup function is provided by the IRWST.
4. In Mode 3, the accumulators must be isolated to prevent their operation when the RCS pressure is reduced to below their set pressure. The accumulator isolation valves are closed when the RCS pressure is reduced to 1000 psig (6.895 MPa gauge).
5. When the RCS is open to transition to reduced inventory operations, the CMT actuation logic on low pressuriser level is removed, and the CMTs can be taken out of service. For these modes, automatic actuation of the IRWST can be initiated (on a two-out-of-two basis) on low hot leg level. Also, in this mode only one injection flow path and one containment recirculation flow path are required to be available.
6. The IRWST is available until Mode 6, when the reactor vessel upper internals are removed and the refuelling cavity flooded. At that time, the IRWST is not required, due to the large heat capacity of the water in the refuelling cavity. Also, in this mode only one injection flow path and one containment recirculation flow path are required to be available.
7. In these modes, the PRHR HX provides a passive decay heat removal path. It is automatically actuated on a CMT actuation signal
8. In modes with the RCS open (portions of Mode 5 and Mode 6), decay heat removal is provided by “feeding” water from the IRWST and “bleeding” steam from the ADS.
9. The ADS first-, second-, and third-stage valves, connected to the top of the pressuriser, are open whenever the CMTs are blocked during shutdown conditions while the reactor vessel upper internals are in place. This provides a vent path to preclude pressurisation of the RCS during shutdown conditions if decay heat removal is lost.
10. Two of the four ADS fourth-stage valves are required to be available during reduced inventory operations to preclude surge line flooding following a loss of the RNS.

Table 9.8.4-1. Double-Ended Cold-Leg Guillotine Break – Sequence of Events

Event	Time (seconds)
Break open	0.0
"S" signal receipt	4.2
RCPs start to coast down	9.5

9.9 Dropped Loads

This section considers specific faults from dropped loads from lifting equipment such as cranes and hoists. The potential for dropped loads, both within the reactor containment and for other facilities on the site, is extensively considered in Chapter 11, Internal Hazards. A dropped load event is considered to be one that may directly cause harm or damage and consequently presents a threat to the fundamental safety functions. Chapter 11 discusses the safety aspects of the lifting equipment, load paths, and operation; and identifies any safety-significant items that could be damaged as a result of failure. This section considers specific fault sequences that require more detailed analysis, particularly with regard to radiological consequences.

Crane Faults Considered

The cranes used in the AP1000 plant facility are fixed as opposed to mobile cranes, which are commonly seen on construction sites. Therefore, because of the nature of cranes used in the AP1000 plant facility, faults associated with cranes and lifting equipment that are excluded from this study are: slewing (lateral movement of the crane's boom or jib), jibbing (moving the crane's lifting apparatus closer to/further from the working radius), swinging loads, and crane or hoist collapse.

9.9.0 Introduction and Overview of Faults

A number of faults were identified from the fault list. The faults fall into two groups:

- Drop of a fuel cask
  - Dropped fuel cask in loading bay (spent fuel). The loading bay is also known as the rail car bay in the auxiliary building
  - Dropped fuel cask in spent fuel storage pool (spent or new)
- Dropped fuel assembly onto other fuel
  - Damage to fuel assembly/core following drop of assembly on reactor core
  - Damage to fuel assembly (spent or new) resulting from drop in refuelling cavity
  - Dropped fuel assembly in spent fuel storage pool (spent or new)

A number of other faults were identified at hazard identification exercises (described in Chapter 8) but were screened out in the fault list (Appendix 8A). Additional fuel cask drops are examined in the dropped loads internal hazards section, see Section 11.8.

9.9.0.1 Drop of a Fuel Cask

Description

The identified faults can result in three potential outcomes: activity release, a threat to the structural integrity of the building fabric, and a threat to an SSC that could be damaged by a dropped load.

Fault 3.1.9 - dropped fuel cask in rail car bay, involves a fuel cask being dropped. If the containment of the fuel cask is damaged, a release of activity could result. This fault also has the potential to damage the building fabric or an SSC.

Fault 3.2.12 - dropped fuel cask in spent fuel storage pool (spent or new), is screened out because the cask handling crane is mechanically prevented from travelling over the SFP by use of a restricted length of crane rails (which support the crane). Therefore, the fault cannot occur.

Initiating Event Frequency[1]

The AP1000 design PSA does not give the IEF for the dropped fuel cask in rail car.

The dropped fuel cask in spent fuel storage pool cannot occur.

Design Basis Class

The event is in the DB0 class.

9.9.0.2 Dropped Fuel Assembly onto Other Fuel

Description

The identified faults can result in three potential outcomes: activity release, a threat to the structural integrity of the building fabric, and a threat to an SSC that could be damaged by a dropped load.

Fault 2.4.9 - damage to fuel assembly/core following drop of assembly on reactor core, involves a dropped load falling onto the reactor core, potentially causing a release of activity. This fault also has the potential to damage the building fabric or an SSC.

Faults 3.1.4 and 3.2.11 consider the movement of fuel under water. The fault scenario is that control of the movement of fuel underwater is lost and fuel is dropped and its cladding is damaged. This causes a release of activity into the water, some of which is then released into the air. This has the potential to give rise to an operator dose. Release of this activity through the facility's ventilation system could give rise to a public dose. All dropped loads are examined regarding the potential to damage the building fabric or an SSC from this fault scenario.

Initiating Event Frequency[1]

The AP1000 design PSA gives the IEF for the dropped fuel assembly faults as less than 1.0E-3/yr (Table 8A-2). Therefore this can be classified as an infrequent fault.

Design Basis Class

The unmitigated consequences of a dropped assembly are assumed to be less than the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite). Given the IEF above, the event is in the DB0 class.

---

[1] As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.

9.9.1 Dropped Fuel Cask in Rail Car Bay (Fault 3.1.9)

9.9.1.1 Identification of Causes and Accident Description

This fault considers the dropping of a fuel cask in the rail car bay in the auxiliary building. The fault could occur by a variety of initiators, such as operator error or failure of lifting equipment. It involves the movement of the cask both onto and from the train or a road vehicle.

The capacity of the cask handling crane (MHS-MH-02) is 136.1 tonnes (136 Mg).

The cask handling crane is designed to lower spent fuel casks through hatches at the 110.74 m (135'-3")[1] elevation down to a cask transporter located at the 100 m (100'-0") elevation. Therefore, the drop height is 10.74 m (35'-3"), excluding the clearance of the transporter base. No loss of spent fuel cask containment would take place for this drop, as the cask transport safety case (to be produced) will demonstrate the robustness of the cask to prevent a release of activity.

The device used to move fuel casks, the cask handling crane, is described as follows.

The cask handling crane lifts the spent fuel shipping cask from the cask transporter in the rail car bay, into the fuel handling area of the auxiliary building, places the cask in the cask washdown and cask loading pits, is used to remove and replace the cask lid, and lowers the loaded cask onto the cask transporter. The crane is designed to operate in the fuel handling area environmental conditions, and is typically used only when fuel movement activities associated with refuelling the reactor are not in progress.

Movements of the bridge, trolley, main, and auxiliary hoists can be controlled from a radio remote control or from a pendant suspended from the crane. Both the pendant and radio remote controls include a main power control switch. The crane is equipped with a keylock switch that inhibits control from the radio remote control and the pendant at the same time. Motion control push buttons on the radio remote control and on the pendant return to the OFF position when released.

9.9.1.2 Analysis of Effects and Consequences

A fuel cask can contain either new or spent fuel. The most onerous radiological consequences come from spent fuel, so this is considered as the bounding case for this fault.

There are two fault modes that may result from the dropping of a fuel cask: a release of activity from the loss of containment of the cask, and damage to the building fabric or to an SSC from the impact.

Loss of Cask Containment from a Dropped Fuel Cask

If a fuel cask is dropped, then it could become damaged and lose containment. However, there will be a transport safety case for the cask. This will need to consider the integrity of the cask when dropped from specific heights and orientations and onto appropriate surfaces. In short, the cask transport safety case will need to demonstrate that the cask can withstand such initiators when being transported on public roads and on the licencee's site. Therefore, it is assumed that the cask transport safety case is adequate to justify that the cask will not release

1. Note that the basis for all elevations is set to 100 feet in US design and 100 m in metric design.

its contents during reasonable fault conditions that may be experienced in the AP1000 plant facility. Consequently, this fault mode is not considered further.

Damage to the Building Fabric or to SSCs from the Impact of a Dropped Fuel Cask

This fault mode considers the damage that could be done by dropping a fuel cask onto the building fabric or onto an SSC. For the former, the building fabric will be designed to withstand a minimum dropped load, and it is assumed that the dropping of a fuel cask (with a known mass) from a known height in any orientation will not threaten the structural integrity of the building.

As the fuel cask is one of many objects that could be dropped, it is judged that evidence of substantiation of structural integrity will be attained by the normal design process. The AP1000 plant facility will be constructed to UK standards, and a designation is made as follows:

- **SSC** – Walls and floors
- **Safety function** – To maintain structural integrity following impact from a fuel cask when dropped from the cask handling crane

The latter consequence results in an SSC being damaged and failing to perform its function. Clearly, if the fuel cask fell onto a pump, then it is conceivable that the pump could be damaged. To provide confidence that no Categroy A or B safety function is interrupted by a dropped load, it is standard practice to analyse the load paths for any crane or lifting equipment. An evaluation of all SSCs under the hook coverage that could be affected by a dropped load is completed in Section 11.8.

9.9.1.3 Radiological Consequences

Dropping a fuel cask may jeopardise the operation of the train or road transport device used to move the casks into and out of the AP1000 plant facility, but this would cause operational difficulties rather than a radiological hazard.

The ability of the building structure to withstand a dropped fuel cask (as described above) is ensured by the engineering design (Chapter 16, Civil Engineering). Assuming that the building integrity is not damaged from a dropped fuel cask (as described above) and that no SSCs can be damaged by a dropped fuel cask, then there are no radiological consequences from this fault to operators or to members of the public.

9.9.1.4 As Low As Reasonably Practicable Assessment

Although the radiological consequences of this fault are deemed to be zero, it is still prudent to minimise the number of lifts of fuel casks. Elimination of dropped load hazards is highly challenging when using any lifting equipment. Human error may be a common initiating event, yet operators are needed to operate most lifting equipment, and the cranes and hoists in the AP1000 plant facility are no exception.

Substituting any of the proposed cranes or hoists for other engineered measures will not reduce risks involving human error, as operators are still required to operate the machinery.

Use of cranes and lifting equipment is subject to the Lifting Operations and Lifting Equipment Regulations 1998, Safe Use of Work Equipment Regulations 1998, and Provision and Use of Work Related Equipment Regulations 1998.

Other systems are also used by licencees to manage lifting hazards, such as permit to work and safe systems of work. These methods prompt operators to consider factors such as barriers and fencing involved with each lift. Lifting equipment is inspected, often daily, for crane and carrier systems. Maintenance will be carried out and equipment will be calibrated. Use of markings will be made on lifting equipment, such as the safe working load.

No further measures are practicable, and the risk is considered to be ALARP. As such, this fault is not considered further.

9.9.1.5 Conclusion

Damage to SSCs within the hook coverage of the cask crane has been evaluated in Section 11.8, and the risks have been reduced to be ALARP. The Category A safety functions of SSCs reviewed in Section 11.8 are maintained. Structural integrity of the building is also maintained. Radiological consequences of a dropped cask are evaluated by the site specific safety case for the chosen design of cask.

9.9.2 Dropped Fuel Assembly onto Other Fuel

9.9.2.1 Identification of Causes and Accident Description

This fault considers the dropping of fuel in water, either onto stored fuel or onto a reactor core. It considers three faults that were identified in the fault list (Appendix 8A): fault 2.4.9, damage to fuel assembly/core following drop of assembly on reactor core; fault 3.1.4, damage to fuel assembly (spent or new) resulting from drop in refuelling cavity; and fault 3.2.11, dropped fuel assembly in spent fuel storage pool.

9.9.2.1.1 Bounding Case

Of the three faults considered in this group, the highest radiological consequences are judged to involve the dropping of a fuel assembly onto fuel either in the reactor core (fault 2.4.9) or in the SFP (fault 3.2.11), as these locations contain the highest fuel inventory. Regarding fault 3.1.4, only a limited number of fuel assemblies are stored in the refuelling cavity at any one time, and they are afforded some protection by the storage racks.

Faults 2.4.9 and 3.2.11 are considered here to determine the appropriate bounding case.

- Fault 3.2.11, dropped fuel assembly in spent fuel storage pool

  The fuel handling machine is required to move new and irradiated fuel from the fuel storage racks in the auxiliary building fuel handling area to the fuel transfer system outside containment. The fuel handling machine is also designed so that during operation when handling irradiated fuel assemblies, there will always be an adequate depth of water to maintain sufficient shielding of personnel on the fuel handling machine gantry.

- Fault 2.4.9, damage to fuel assembly/core following drop of assembly on reactor core

  The function of the refuelling machine (RM) is to move new and spent fuel from the RV to the fuel transfer system in containment. It is also designed to maintain a minimum depth of water cover to act as shielding to protect operators on the RM gantry.

- Comparison of faults 3.2.11 and 2.4.9

Fuel movements involving the RM or the fuel handling machine are always carried out underwater in both cases. The following are considered in determining whether the radiological consequence of a fuel assembly dropped by the RM is bounded by a fuel assembly dropped by the fuel handling machine:

- The minimum depth of water cover when using the RM to move a fuel assembly is at least equal to that described when fuel assemblies are moved by the fuel handling machine.
- The maximum distance of a fuel assembly dropped by the RM is not greater than the maximum distance of a fuel assembly dropped by the fuel handling machine.
- The activity released by a fuel assembly dropped from the RM is not greater than the activity released from a fuel assembly dropped by the fuel handling machine.

The fuel assembly is lifted a predetermined height from the reactor core to still leave sufficient water covering the fuel assembly. The minimum depth of water cover required for normal fuel movement is 2.667 m (8.75 ft).

It is assumed that dropping any fuel assembly will not result in structural damage. Damage to SSCs within the load path is evaluated in Section 11.8 and is found to be within acceptable limits.

Fault 3.2.11 is considered to be the bounding case, and the assessment continues on this basis.

9.9.2.2 Analysis of Effects and Consequences

9.9.2.2.1 Fuel Handling Machine

Fuel assemblies are moved by the fuel handling machine.

The fuel handling machine is used to handle new fuel assemblies in the rail car bay, new fuel rack, and new fuel elevator. The capacity of the fuel handling machine, while over the new fuel storage rack, is limited to lifting a fuel assembly, control rod assembly, and handling tool. The new fuel storage rack is not accessed by the cask handling crane. This precludes the movement of loads greater than fuel components over stored new fuel assemblies.

The fuel handling machine traverses the spent fuel pool, the fuel transfer canal, the cask loading pit, the new fuel storage pit, and the rail car bay. It is used in the movement of both new and spent fuel assemblies. The fuel handling machine is used to transfer new fuel assemblies from the new fuel storage rack into the spent fuel pool. A new fuel elevator in the spent fuel pool lowers the new fuel to an elevation accessible by the fuel handling machine.

In the fuel handling area, fuel assemblies are moved about by the fuel handling machine. Initially, a short tool is used to handle new fuel assemblies and place them in the new fuel elevator. The new fuel elevator must be used to lower the assembly to a depth at which the fuel handling machine and a long handling tool can place the new fuel assemblies into or out of the new fuel elevator or the spent fuel storage racks.

The fuel handling machine performs fuel handling operations in the new and spent fuel handling area. It also provides a means of tool support and operator access for long tools used in various services and handling functions. The fuel handling machine is equipped with two 2-ton (2-Mg) hoists, one of which is single failure proof.

9.9.2.2.2 Structural Damage

Spent fuel is designed to be lifted a maximum height of 2.667 m (8.75 ft) above the fuel rack to maintain adequate water cover to shield operators.

The spent fuel hoist (one of two hoists on the fuel handling machine) is designed to prevent the lifting of fuel higher than 304.8 mm (12") above a fuel rack.

Reference 9.9-2, Section 2.8.5 examines three scenarios of a drop from a height of 914.4 mm (36 inches):

1. A drop of a fuel assembly with a control rod assembly plus a handling tool (conservatively modelled as a total mass of 1363.63 kg (3100 lb)) from 914.4 mm (36 inches) above the top of the spent fuel storage rack with subsequent impact on the edge of a cell

2. A drop of a fuel assembly with a control rod assembly plus a handling tool from 914.4 mm (36 inches) above the top of the rack down through an empty cell with impact on the rack baseplate away from the rack pedestal

3. A drop of a fuel assembly with a control rod assembly plus a handling tool from 914.4 mm (36 inches) above the top of the rack down through an empty cell with impact on the rack baseplate directly above the rack pedestal

For all three hypothetical drop scenarios, the results are, respectively:

1. The active fuel region remains surrounded by an undamaged cell wall.
2. Only the dropped fuel assembly is moved downward more than 51 mm (2 inches).
3. The postulated drop event will not breach the SFP floor liner.

Therefore, it is concluded that a dropped fuel assembly will not cause the spent fuel storage pool to lose containment. Therefore, this fault mode is not considered further.

9.9.2.2.3 Damage of Fuel Rod Cladding

This is discussed in “Radiological Consequences” below.

9.9.2.3 Radiological Consequences

A fuel assembly contains 264 fuel rods. If a fuel assembly is dropped, then it is pessimistic to assume that cladding on all the fuel rods are damaged enough to lose containment.

Operational evidence states that in fuel drop incidents from around the world, often no fuel rods are damaged (see Chapter 17 for details).

For the purposes of this fault assessment, it is assumed that two fuel rods have been damaged and that their cladding has released all the activity contained within the fuel gap (the space between the fuel matrix and the interior surface of the cladding).

Many factors are inputs into the dose assessment calculations (Reference 9.9-3), including the release fraction of material leaving the fuel matrix and entering the gap between the matrix and the internal surface of the cladding (the gap inventory) and the DF associated with the depth of water above the damaged fuel required by Technical Specifications.

One other pertinent factor is the decay period. The length of time used in this assessment could have been longer, which would have reduced the calculated doses. However, the period of 48 hours was used and is retained here as a practicable period of time to allow outage work to begin on the reactor without delaying operations.

The consequence assessment (Reference 9.9-3) states that the calculated doses are as follows:

Offsite dose: 0.26 mSv Worker dose: 1.21 mSv.

These doses are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

9.9.2.3.1 Operator Dose Uptake

Fuel assemblies are generally moved during an outage (although fuel can be moved during all modes); each outage is expected to last approximately 2 to 3 weeks. In terms of whether a dropped fuel assembly is a revealed or unrevealed event, it is conceded that it is not as revealed as a drop of a fuel cask from a crane positioned at significant height. However, at least one operator involved with moving a fuel assembly will be expected to observe it while it is being moved (the person operating the lifting machinery or the banksman standing near the water's edge).

Outage tasks will involve suitable training and briefing of all relevant personnel. Regarding the movement of a fuel assembly, it is assumed that the person organising work (POW) will brief these relevant personnel at the beginning of each shift or day.

- **Operating instruction –** The POW will brief all personnel associated with tasks involving the movement of a fuel assembly at the beginning of each shift or day.

The POW will be the one individual who, if required, would communicate to the rest of the team when to instigate an evacuation procedure in the event of a dropped fuel assembly. This minimises confusion regarding who has responsibility for reporting the event, as the operator charged with moving the fuel assembly need only be concerned with telling the POW if the POW has not already noticed that the fuel assembly has dropped.

So, if a fuel assembly is dropped, it is assumed that the POW would realise it quickly and instruct operators to evacuate as follows:

- **Operating instruction –** In the event of a dropped or mishandled fuel assembly, personnel should evacuate immediately when told to do so by the POW.

In this event, activity has the potential to be released through the water of the spent fuel storage pool and into the operating area. Activity-in-air monitors and alarms will be in place to warn personnel to evacuate; these are described below.

Minimising Operator Dose Uptake from Airborne Activity

Activity-in-air monitors are designed to alert personnel in the event of airborne activity breaching a predetermined limit. Air exhausted from the auxiliary building, fuel handling area of the auxiliary building, and the annex building is monitored for high airborne activity. Means are provided to shut off supply air and divert exhaust air through high efficiency particulate air filters and charcoal adsorbers upon detection of high airborne activity. Alarms are provided in the main control room for these discharge flows.

The activity-in-air instrument (VAS-JE-RE001) can be used to alert operators of an abnormally high airborne concentration. The fuel handling area exhaust radiation monitor (VAS-JE-RE001) measures the concentration of radioactive materials in the exhaust air from the fuel handling area. This radiation monitor is located upstream of the exhaust air isolation damper. When a predetermined setpoint is exceeded, the fuel handling area exhaust radiation monitor provides signals to alarm in the main control room, to initiate closure of the fuel handling area supply and exhaust air isolation dampers, to open the fuel handling area exhaust air isolation damper to the containment air filtration exhaust units, and to start a containment air filtration exhaust unit. These actions provide a filtered air path from the fuel handling area to the plant vent. The fuel handling area exhaust radiation monitor is an inline monitor that uses a beta-sensitive scintillation detector. It is located with the sensitive volume inside the exhaust duct.

The activity-in-air instrument (fuel handling area exhaust radiation monitor VAS-JE-RE001) is able to alert operators to evacuate and reduce the risk of exposure from airborne contamination; on this basis, it is designated as follows:

- **SSC** – Fuel handling area exhaust radiation monitor (activity-in-air monitor VAS-JE-RE001)

- **Safety function** – To minimise operator exposure to airborne activity, Category B, Class 2

In order to ensure that the consequences of a dropped fuel assembly are <20 mSv to the operator (as detailed below), a safety instruction is raised to ensure that personnel start to evacuate within 1 minute:

- **Safety instruction** – In the event of a dropped or mishandled fuel assembly, personnel should evacuate the fuel handling area within 1 minute.

Table 9.9-4 summarises the SSCs from this fault assessment.

Table 9.9-5 provides the operator actions relevant to this fault assessment.

Table 9.9-6 provides the LCOs related to the dose assessment for this fault.

9.9.2.4 As Low As Reasonably Practicable Assessment

As the assessment of the consequences and frequency are in the DB0 category, there is no formal requirement to designate any safety measures. However, the requirement to carry out an ALARP assessment still holds.

First, the operator dose calculation assumes that the operator will begin to evacuate the area within 1 minute. It is expected that an operator would leave much more quickly than this, thereby reducing dose uptake. One minute has been used to determine the DB dose. Shorter times would be more appropriate in the probabilistic assessment.

Second, there are a number of features of the refuelling machine that have not been formally claimed in the above assessment. The following design intentions are provided, although these are not claimed in the above assessment:

- The RM can only place a fuel assembly in the core, in the in-containment storage rack, or in the fuel transfer system.

- When the RM gripper is engaged, the machine cannot traverse unless the fuel assembly bottom nozzle is clear of the lower core plate alignment pins.

- When the RM gripper is disengaged, the machine cannot traverse unless the gripper is withdrawn into the mast.

- Simultaneous traversing and hoisting operations are prevented.

- The fuel gripper is monitored by devices to confirm operation to the fully engaged or fully disengaged position. Alarms are actuated if both engage and disengage switches are actuated at the same time, or if neither is actuated.

- Lowering of the gripper is not permitted if slack cable exists in the hoist.

- The gripper tube is prevented from lowering completely out of the mast.

- Before the fuel gripper can release a fuel assembly, the fuel gripper must be in its down position in the core, in-containment storage rack, or fuel transfer system.

- The weight of the fuel assembly must be off the gripper before the fuel gripper can release a fuel assembly.

- The RM hoist is prevented from moving in the transfer machine zone unless the up-ender is vertical. An interlock is provided from the fuel transfer system to the RM to accomplish this.

As Low As Reasonably Practicable Discussion – Operator Dose

No further measures are practicable and the risk to operators is considered to be ALARP.

As Low As Reasonably Practicable Discussion – Public Dose

Technology is available to reduce the public dose from this fault mode by way of capturing the nuclides that enter the ventilation system. HEPA filters and charcoal adsorbers are capable of capturing nuclides to reduce activity released to the atmosphere.

The main contributor to dose uptake is I-131 (Reference 9.9-3). A charcoal filter can retain I-131 for approximately 6 weeks (Reference 9.9-1, Datasheet 5.2), by which time the activity will reduce to insignificant levels (Reference 9.9-1, Datasheet 5.2). (I-131 half-life is approximately 8 days (Reference 9.9-3).)

The subsystem of the VAS that serves the fuel handling area is equipped with HEPA filtration, which provides protection to members of the public; on this basis, the HEPA filters in the VAS are claimed in order to reduce risk to members of the public. A designation is made on this basis:

- **SSC** – HEPA filters and charcoal adsorbers in the VAS

- **Safety function** – To minimise dose uptake to members of the public. Category B, Class 2

A DF of 1E4 is possible with charcoal filters (Reference 9.9-1, Datasheet 5.2). Even if the charcoal filtration units were underperforming, a DF of 10 is still possible because of bypassing and leakage (Reference 9.9-1, datasheet 5.2).

No further measures are practicable and the risk to members of the public is considered to be ALARP. As such, this fault is not considered further.

9.9.2.5 Conclusion

Radiological consequences are within the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite), and the risks have been reduced to be ALARP.

Table 9.9-6. LCOs for Dropped Fuel Assembly onto Other Fuel

Limit or Condition	Technical Specification Identification and Notes
Spent Fuel Pool Water Level	3.7.5 The spent fuel pool water level shall be ≥ 7.0 m (23 ft) above the top of irradiated fuel assemblies seated in the storage racks.
Refuelling Cavity Water Level	3.9.3 Refueling Cavity Water Level shall be maintained ≥ 7.0 m (23 ft) above the top of the reactor vessel flange.
Refuelling Machine	The minimum depth of water between the top of a fuel assembly and the surface of the water is not to be less than 2.667m (8.75 ft) when fuel assemblies are moved by the Refuelling Machine.

9.10 Operator Exposure Faults

A hazard identification exercise was undertaken as part of the development of the AP1000 design PCSR GDA step 4 (See Chapter 8). This process identified a number of hazards that have the potential to be a hazard to the operator and members of the public. The pre-construction safety case for the operation of the AP1000 reactor must address non-reactor faults (i.e., faults that are unrelated to the reactor but that may still occur within the facility). This section covers faults that result in operators being exposed to radiation during reactor startup, maintenance, refuelling, and spent fuel storage.

Faults Considered

Operators may be exposed to radiation from non-reactor faults in a variety of ways, from direct exposure to inhalation or ingestion of contamination. These faults are mainly associated with operations during refuelling within the fuel storage pool or flooded refuelling cavity, or from general use of sources of radiation within the controlled areas.

9.10.0 Introduction and Overview of Faults

A total of 13 faults were identified at hazard identification exercises (See Chapter 8); subsequently, nine of them (3.1.7, 3.2.15, 3.2.16, 3.3.1, 3.3.2, 3.4.9, 3.4.10, 3.6.4, and 3.6.5) were screened out in the fault list with the reasons presented in Table 9.10-1.

The remaining four faults, identified below, are grouped into two fault modes: dose uptake by the operator through falling into the pool or cavity water, and dose because of working in an area of increased activity.

Fault ID	Description
3.1.5	Operator falls into flooded refuelling cavity
3.1.6	Water level fall in refuelling cavity (shielding lost)
3.2.13	Operator falls into spent fuel storage pool
3.2.14	Water level fall in spent fuel storage pool (shielding lost)

For faults 3.1.5 and 3.2.13, the operator falls into the storage pool or refuelling cavity (when flooded), resulting in the operators receiving a direct dose from the fuel and any activity dissolved in the water plus an ingestion dose from swallowing pool water.

For faults 3.1.6 and 3.2.14, the water level falls in the storage pool or refuelling cavity, resulting in an increased direct dose to operators.

9.10.1 Operator Falls into Flooded Refuelling Cavity or Fuel Storage Pool (Faults 3.1.5 and 3.2.13)

9.10.1.1 Identification of Causes and Accident Description

Removal of spent fuel from the reactor and transfer operations to the fuel storage pool are performed under borated water to provide radiation protection and maintain subcriticality. During these operations, operators are required to work around and above the fuel storage pool and the flooded refuelling cavity. This fault considers the potential consequences of an operator falling into the pool or flooded cavity during refuelling operations.

The minimum allowable water depths above active fuel in a fuel assembly during fuel handling are 2.667 m (8.75 ft) in the reactor cavity and 2.667 m (8.75 ft) in the fuel transfer canal and spent fuel pool. This limits the dose to personnel on the spent fuel pool handling machine to less than 0.025 mSv/hr for an assembly in a vertical position. The minimum water depth above the stored assemblies is about 7.92 m (26 ft), and for this depth the dose rate at the pool surface is small.

The spent fuel pool cooling system clarification capability is sufficient to permit necessary operations that must be conducted in the spent fuel pool area. The spent fuel pool cooling system is designed to perform its purification function in accordance with the following additional criterion:

- The spent fuel pool cooling system is designed to limit exposure rates to personnel on the spent fuel pool fuel handling machine to less than 0.025 mSv/hr. This corresponds to an activity level in the water of approximately 185 Bq/g (0.005 μCi/g) for the dominant gamma-emitting isotopes at the time of refuelling.

The concentration of tritium in the SFP water is maintained at less than 18.5 kBq/g (0.57 μCi/g).

Initiating Event Frequency

An IEF is not assigned to this fault. The estimated dose is minimal, and hence a probabilistic assessment is not required (see Section 9.10.1.3).

Design Basis Class

The consequences of an operator falling into the flooded refuelling cavity or fuel storage pool are calculated to be 0.091 mSv worker dose and nothing to members of the public (see Section 9.10.1.3). These doses are less than the Target 4 basic safety objectives (BSOs) of 0.1 mSv for the workers and 0.01 mSv for the public.

There is no requirement for a DB0 fault assessment, but an ALARP assessment is provided in Section 9.10.1.4.

Bounding Case

An operator could fall into the pool when there are no fuel movements, for example, during maintenance activities of fuel handling equipment (i.e., when all spent fuel is stored with more than 7.9 m (26 ft) of water as a shield). This scenario is deemed to correspond to a situation where there is an insignificant dose rate at the pool surface, and therefore is not bounding.

The most onerous, and therefore bounding, radiological consequence is considered to occur if an operator falls into the pool during spent fuel movements, i.e., with a covering depth of water of approximately 2.667 m (8.75 ft) over a single raised high burnup fuel element.

9.10.1.2 Analysis of Effects and Consequences

Should an operator fall into the pool during fuel movements, it is assumed that the time spent under the water is minimal, but that the operator remains on the surface of the water for 5 minutes in close proximity to the fuel handling machine and swallows up to 50 ml (50 g) of pool water before being recovered. (Note that when the pool contains fuel, the water will be

acidic and borated, and therefore, unlike clean fresh water, it will be obvious to the operator that pool water has entered the mouth.)

9.10.1.3 Radiological Consequences

It is assumed that there is no newly failed fuel within the pool at the time of the accident and that the dominant isotope in the pool water is Co-60, as the other significant isotope, I-131, has a relatively short half-life of approximately 8 days. The dominant dose uptake will be from direct gamma radiation and ingestion of pool water.

The worst-case dose rate at the pool surface during spent fuel movement is 0.25 mSv/hr, which, for a 5-minute exposure at the surface, would equate to a whole body dose of 0.021 mSv.

It is assumed that approximately 50 ml (i.e., 50 g) of pool water is ingested containing 18.5 kBq/g (0.57 μCi/g) tritium (H-3) and 185 Bq/g (0.005 μCi/g) of the dominant gamma isotope, Co-60. Reference 9.10-2 shows that the committed effective dose equivalents (CEDEs) for ingestion are as follows:

- CEDE for Co-60 is 3.4E-9 Sv/Bq
- CEDE for H-3 is 4.2E-11 Sv/Bq

Therefore, for a 50-g ingestion, the Co-60 dose is 3.4E-9 Sv/Bq × 185 Bq/g × 50g = 0.000031 Sv or 0.031 mSv

For a 50-g ingestion, the H-3 dose is 4.2E-11 Sv/Bq × 1.85E4 Bq/g × 50 g = 0.000039 Sv or 0.039 mSv

Therefore, the total dose assuming the operator remains at the pool surface = (0.021+0.031+0.039) mSv = 0.091 mSv

9.10.1.4 As Low As Reasonably Practicable Assessment

Although the radiological consequences of this fault are deemed to be very low, it is still required that the potential for an operator to fall into the fuel storage pool or flooded refuelling cavity is minimised. This is especially the case for this particular scenario, as the most severe consequence for an operator from falling into water is a fatality as a result of drowning.

Therefore, where there is a requirement for operators to work near or over the storage pool or flooded cavity, the risks, where practicable, should be minimised. This will primarily be achieved by the adoption of standard building and industrial practices. For example, the edge of the pool and cavity is protected by walls and/or the use of handrails. Egress ladders should be provided at points around the pool and any requirement to work on access platforms (e.g., for fuel handling over the water), especially over water, will require suitable railings. If work is required outside these barriered areas, then the utility must provide harnesses, and operators must use them.

Within the area of the storage pool and flooded refuelling cavity, lifebuoys and equipment suitable for retrieving a person in the water, such as suitable egress ladders, shepherd's hooks, and poles, should be provided.

Therefore, considering the recommendations above, the radiological risks to an operator from falling into the storage pool or flooded refuelling cavity are ALARP.

9.10.1.5 Conclusion

Radiological consequences are within the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.10-2

LCOs related to the dose assessment for this fault are provided in Table 9.10-3

9.10.2 Water Level Fall in the Refuelling Cavity or Storage Pool (Faults 3.1.6 and 3.2.14)

9.10.2.1 Identification of Causes and Accident Description

Removal of spent fuel from the reactor and transfer operations to the fuel storage pool are performed under borated water to provide radiation protection and maintain subcriticality. During these operations, operators are required to work around and above the fuel storage pool and the flooded refuelling cavity. This fault considers the potential consequences of a significant fall in the water level in the flooded refuelling cavity or storage pool during these operations.

The minimum allowable water depths above active fuel in a fuel assembly during fuel handling are 2.667 m (8.75 ft) in the reactor cavity and 2.667 m (8.75 ft) in the fuel transfer canal and spent fuel pool. This limits the dose to personnel on the spent fuel pool handling machine to less than 0.025 mSv/hr for an assembly in a vertical position. The minimum water depth above the stored assemblies is about 7.92 m (26 ft), and for this depth the dose rate at the pool surface is small.

The connections from the spent fuel pool cooling system to the pool are such that leakage in the spent fuel pool cooling system will not result in the pool water level falling to unacceptable levels.

Connections to the spent fuel pool are made at an elevation to preclude the possibility of inadvertently draining the water in the pool to an unacceptable level.

The spent fuel pool cooling system is connected to the spent fuel pool at two locations. The two suction lines connect to the spent fuel pool at an elevation 6 feet (1.83 m) below the operating deck. Each line has a skimmer connection to take suction from the water surface of the spent fuel pool. This suction arrangement prevents the spent fuel pool from inadvertently being drained below a level that would prevent the water in the spent fuel pool from performing its safety related function.

The water level in the storage pool is maintained within strict limits above the top of the active fuel when stored correctly within the fuel racks:

- Maximum level (high alarm) – 8.14 m (26.7 ft)
- Minimum level (low alarm) – 7.97 m (26.1 ft)
- Lowest level (low-low alarm) – 7.33 m (24 ft)

In the unlikely event of an extended loss of normal spent fuel pool cooling, the water level will drop. Low spent fuel pool level alarms in the control room will indicate to the operator the need to initiate makeup water to the pool.

The minimum volume in the passive containment cooling water storage tank for spent fuel pool makeup is 2864.42 m^3 (756,700 US gallons).

Initiating Event Frequency

An IEF is not assigned to this fault. The estimated dose is negligible, and hence a probabilistic assessment is not required (see Section 9.10.2.3).

Design Basis Class

The direct radiological consequences of a fall in the water level in the refuelling cavity or storage pool to workers are minimal and to members of the public are negligible (see Section 9.10.2.3). These doses are significantly less than the Target 4 BSOs of 0.1 mSv for the workers and 0.01 mSv for the public.

There is no requirement for a DB0 fault assessment, but an ALARP assessment is provided in Section 9.10.2.4.

Bounding Case

The loss of pool water has much more significant consequences than local operator dose from, for example, loss of or reduced fuel cooling. However, there are two general ways in which the pool (or cavity) water level could reduce: over an extended period of time because of inadequate management of water levels as a result of low rate leaks or evaporation, or quickly as a result of a seismic event causing failure of pool cooling water pipework.

For the purpose of this assessment, it is considered that a reduction of water level over an extended period of time would be identified (level alarms, routine monitoring, and general observation by operators) and easily corrected by topping up the pool water. Therefore, the most significant fault would be the rapid loss of water from the pool while operators are working adjacent to or over the pool.

9.10.2.2 Analysis of Effects and Consequences

The rapid loss of pool water could occur as a result of a failure of pipework, such as the pool cooling circuit, resulting from, for example, a seismic event. However, even a significant event, such as failure of cooling system pipework, would not cause an instant lowering of the pool level, as this would occur over many minutes or even hours. Therefore, with the provision of seismically qualified level alarms to AP1000 plant Class C seismic Category I as well as operator awareness (especially for a seismic event,) and the large volume of pool makeup water available in the passive containment cooling water storage, it is unlikely that any DB event could lead to a significant direct radiation dose to the operators.

In the event of a sudden loss of pool water or a seismic event, the operators would be expected to place any raised spent fuel assembly in a safe location and leave the storage pool or containment area within a few minutes.

9.10.2.3 Radiological Consequences

During defueling and refuelling operations, operators could be located over the storage pool or cavity. However, it is considered that the radiological consequences will be insignificant, as the operators would place any raised spent fuel assembly in a safe location and leave the area within a few minutes of an uncontrolled lowering of the water level, and it is inconceivable that any fuel could become uncovered because connections to the SFP are made at an elevation to preclude the possibility of inadvertently draining the water in the pool to an unacceptable level.

Outside refuelling or fuel transfer operations, the fuel is stored in the pool with a normal minimum-covering depth of water of 7.92 m (26 ft) that corresponds to an insignificant dose at the pool surface. The loss of 1.83 m (6 ft) of water from the pool would not lead to a significant increase in dose rates from fuel stored in the racks and would certainly result in an alarm to the control room and action taken to top up the pool, exclude operators from the area, or a combination of these actions.

It is considered inconceivable that a member of the public would receive any dose from this fault.

9.10.2.4 As Low As Reasonably Practicable Assessment

Although the probability of significant radiological consequences of this fault are deemed to be very low and are within the BSO, it is still required that the potential for an operator to receive a dose from this potential accident is minimised.

The fuel storage pool has level alarms set at a minimum level of 7.92 m (26 ft) and at a lowest level (the low-low alarm) of 7.33 m (24 ft) above the top of the active fuel. Low SFP level alarms in the control room will indicate to the operator the need to initiate makeup water to the pool. These level instruments in the SFP are seismically qualified.

Therefore, the risks to an operator from direct radiation as a result of the water level falling in the storage pool or flooded refuelling cavity are ALARP.

9.10.2.5 Conclusions

Radiological consequences are within the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.10-4.

LCOs related to the dose assessment for this fault are provided in Table 9.10-5.

9.10.3 References

9.10-1 ICRP Publication 72, “Age-dependent Doses to Members of the Public from Intake of Radionuclides: Part 5 Compilation of Ingestion and Inhalation Dose Coefficients,” Annals of the ICRP, Volume 25, No. 3-4, 1996.

Table 9.10-1. Screened-out Faults

Fault No.	Fault Description	Description – Screened Out
3.1.7 and 3.2.15	Over-raising fuel in refuelling cavity; storage pool	The lift height of the RM mast and fuel handling machine hoist(s) is limited such that the minimum required depth of water shielding is maintained. The RM and fuel handling machine will be tested by attempting to raise a dummy fuel assembly with success if the bottom of the dummy fuel assembly cannot be raised to within 7.47 m (24.5 ft) of the operating deck.
3.2.16	Exposure in areas contaminated by pool water	Pool water is cleaned by the pool water cooling plant. Normal contamination levels are limited to 185 Bq/g (0.005 μCi/g) gamma emitting isotopes and 18.5 kBq/g (0.57 μCi/g) tritium. These levels of contamination in the form of a puddle of spilled water would give very low dose rates, and areas where spills could occur would be routinely monitored by health physics and be easily cleaned.
3.3.1 and 3.4.9	Unauthorised operator entry into active areas/areas of high dose	The Combined Licence applicant will address the administrative controls for use of the design features provided to control access to radiologically restricted areas, including potentially very high radiation areas, such as the fuel transfer tube during refuelling operations and the reactor cavity. Based on actual operating plant data, ingress or egress of plant operating personnel to radiologically restricted areas will be controlled and monitored.
3.3.2	Inappropriate handling or use of other sources	There are no significant neutron or radioactive sources outside the reactor fuel. All other radioactive sources required for use on the station, such as X-ray machines for radiography or test sources for radiation monitoring equipment, will be subject to controls as required by the ionising radiation regulations. All such radiation sources would be held and used only under the local control of health physics.
3.4.10	Failure to adequately control chemistry to manage dose rates (approach to be decided)	Management of water chemistry will be a routine task. Operators required to work in potentially active areas will be subject to monitoring and control access (see faults 3.22 and 3.32).
3.6.4	Operator exposure from stored waste because of inadequate shielding or waste consignment error	Shielding is provided as necessary for the waste storage areas in the radwaste building to meet the radiation zone and access requirements. Temporary partitions and shield walls will be provided, as required, to supplement the permanent shield walls surrounding the waste accumulation and packaged waste storage rooms inside the radwaste building. Health physics will control the monitoring of radwaste consignments.
3.6.5	Operator exposure from incorrect consignment of waste because of assessment, clerical, or sampling errors	All radwaste packaged and accumulated by an AP1000 reactor unit will be transferred for disposal. The AP1000 plant has no provisions for permanent storage of radwaste. Packaging will be done in accordance with local and national requirements. Health physics will control the monitoring of radwaste consignments.

Table 9.10-2. Operator Actions for Section 9.10.4

Operator Action	Class
(None)	N/A
ALARP recommendation	2
1. Consider providing safety harnesses for operators working outside barriered areas over deep water.	2
2. Consider providing lifebuoys and equipment suitable for retrieving a person from the water, e.g., egress ladders.	2

Table 9.10-3. LCOs for Section 9.10.4

Limit or Condition	Technical Specification Identification and Notes
Fuel storage pool water gamma activity	Maximum activity level in the water of 185 Bq/g (0.005 μCi/g) for the dominant gamma-emitting isotopes at the time of refuelling.
Fuel storage pool water tritium	Maximum concentration of tritium in the SFP water maintained at less than 18.5 kBq/g (0.57 μCi/g).
Fuel storage pool water levels	Maximum (high-level alarm) 8.14 m (26.7 ft); minimum (low-level alarm) 7.97 m (26.1 ft).

Table 9.10-4. Operator Actions for Section 9.10.5

Operator Action	Class
Maintain water level in the fuel pool between 7.97 m (26.1 ft) and 8.14 m (26.7 ft) and initiate makeup water to the pool if the SFP low-level alarm actuates in the control room.	2

Table 9.10-5. LCOs for Section 9.10.5

Limit or Condition	Technical Specification identification and Notes
Fuel handling	Minimum allowable water depths above active fuel in a fuel assembly during fuel handling are 2.667 m (8.75 ft) in the reactor cavity and 2.667 m (8.75 ft) in the fuel transfer canal and SFP. (This limits the dose to personnel on the SFP handling machine to less than 0.025 mSv/hr for an assembly in a vertical position.)

9.11 Safety Assessment of Heating, Ventilation, and Air Conditioning Faults

9.11.1 Introduction

The hazard identification exercise undertaken as part of the development of the AP1000 plant PCSR GDA step 4 (as discussed in Chapter 8 of this PCSR) identified a number of faults relating to the use of the HVAC systems that have the potential to present a hazard to the operator and members of the public.

9.11.2 Normal Operations

The systems that serve the various building and structures of the plant in terms of air conditioning, cooling and ventilation comprise the following:

- Nonradioactive ventilation system (VBS)
- Annex/auxiliary building nonradioactive HVAC system (VXS)
- Diesel generator building heating and ventilation system (VZS)
- Containment recirculation cooling system (VCS)
- Turbine building ventilation system (VTS)
- Health physics and hot machine shop HVAC system (VHS)
- Radiologically controlled ventilation system (VAS)
- Containment air filtration system (VFS)
- Radwaste building HVAC system (VRS)

Figure 9.11-1 is a schematic diagram illustrating aerial release vents from the AP1000 plant and their associated monitors.

The ventilation systems serving the following structures are considered to be potentially radioactive and hence are considered in this assessment:

- Containment building (served by the VFS)
- Annex / Auxiliary building (served by the VAS)
- Fuel handling area of auxiliary building (served by the VAS)
- Radwaste building (served by the VRS)
- Health physics and hot machine shop (served by the VHS)

The MCR is considered to be a nonradioactive area. Other structures contain insignificant sources of airborne radioactivity and are not addressed any further in this assessment.

9.11.2.1 Ventilation Subsystems

Health Physics and Hot Machine Shop Heating, Ventilation, and Air Conditioning System

The VHS supply air system serves one annex building stairwell, the personnel decontamination area, frisking and monitoring facilities, containment access corridor, and health physics facilities of the hot machine shop; and provides radiation monitoring of the exhaust prior to release to the environment.

In addition it also provides:

- Conditioned air to work areas to maintain acceptable temperatures for equipment and personnel working in those areas

- Air movement from clean to potentially contaminated areas to minimise the spread of airborne contamination
- An exhaust route from the welding booths, grinders, and other miscellaneous equipment in the hot machine shop
- Radiation monitoring of exhaust air prior to release to the environment
- HEPA filtration of the exhaust to prevent release of particulate activity or transport of contamination
- Negative pressure to the access control area and hot machine shop with respect to the outside environment and the clean areas of the annex building to prevent unmonitored releases of radioactive contaminants
- Humidity at a minimum of 35 percent

The hot machine shop provides a dedicated workshop/location within the controlled area for repair and refurbishment of items of equipment from within the controlled area (they may not actually be contaminated or activated). Operations in the hot machine shop are conventional hands-on work (i.e., there is no provision for remote handling).

The exhaust ducts have isolation dampers that close to protect the areas served by the VHS system from radiation inleakage when the VHS system is off.

In the event that a high amount of radiation is detected in the exhaust air flow, the VHS exhaust air is diverted to the VFS system.

A further description of the VHS is given in Chapter 23.

Radwaste Building Heating, Ventilation, and Air Conditioning System

The VRS serves the radwaste building and provides radiation monitoring of exhaust prior to release to the environment. The VRS also serves the clean electrical/mechanical equipment room and the potentially contaminated HVAC equipment room, the packaged waste storage room, the waste accumulation room, and the mobile system facility.

The VRS is a once-through ventilation system that consists of the radwaste building supply air system and the radwaste building exhaust system. The radwaste building exhaust system has HEPA-filtered exhaust to prevent release of activity or transport of contamination.

These subsystems operate in conjunction with each other to maintain temperatures in the areas served, while controlling airflow paths and building negative pressure. This system is discussed in more depth in Chapter 23.

Radiologically Controlled Area Ventilation System

The VAS serves the fuel handling area of the auxiliary building and the radiologically controlled portions of the auxiliary and annex buildings, with the exception of areas served by the VHS. It consists of two subsystems: the auxiliary/annex building ventilation system and the fuel handling area ventilation subsystem. These subsystems are discussed in more depth in Chapter 23.

The fuel handling area ventilation subsystem and exhaust ductwork is arranged to exhaust the SFP area separately from the auxiliary building. It provides directional airflow from the rail car/bay filter storage area into the spent resin equipment rooms. The exhaust fans discharge filtered air into the plant vent for monitoring of offsite airborne gaseous and other radiological releases. Routine releases for the fuel handling area are low. The potential for accidental release is low; however, if radiation monitors detect a high level of radiation, the fuel handling exhaust is diverted to the VFS, which contains HEPA and charcoal filters.

The auxiliary building and annex building exhaust air ductwork is routed to minimise the spread of airborne contamination. The supply airflow is directed from the low-radiation access areas into the radioactive equipment and piping rooms that have a greater potential for airborne contamination. The exhaust ducts have isolation dampers that close to isolate the auxiliary and annex building from the outside environment when high airborne activity is detected in the exhaust air duct. The dampers are also configured so that two building zones can be independently isolated. A radiation monitor is located in the duct for each zone.

Each subsystem functions to:

- Provide ventilation to maintain the occupied areas and access and equipment areas within design temperature range.
- Provide outside air for plant and personnel and prevent the unmonitored release of airborne radioactivity to the atmosphere or adjacent plant areas.
- Isolate automatically selected building areas by closing the supply and exhaust duct isolation dampers.
- Start the VFS when high airborne radioactivity in the exhaust air duct or high ambient pressure differential is detected.

The VAS overall airflow direction is from areas of lower potential airborne contamination to areas of higher potential contamination. The VAS operates at a slightly negative pressure to prevent the uncontrolled release of airborne radioactivity to the atmosphere or adjacent clean plant area.

The fuel handling area ventilation subsystem has passive HEPA-filtered exhaust to prevent release of activity or transport of contamination.

Containment Air Filtration System

The VFS provides intermittent flow of outdoor air to purge and filter the containment atmosphere of airborne radioactivity during normal plant operation, and continuous flow during hot or cold plant shutdown conditions to reduce airborne radioactivity levels for personnel access. The VFS also provides filtered exhaust for the VAS and VHS during abnormal conditions.

The VFS is controlled by the PLS except for the containment isolation valves, which are controlled by the PMS and DAS. It preserves the containment integrity (by isolation of the VFS lines penetrating containment); and provides the intermittent flow of outdoor air to purge the containment atmosphere during normal plant operations, and continuous flow during hot or cold plant shutdown conditions.

The VFS serves the containment, fuel handling area, and the other radiologically controlled areas of the auxiliary and annex buildings.

The VFS purges the containment by providing fresh air from outside and exhausting air to plant vents. The VFS exhausts areas served by the VAS and VHS after receipt of a high-radiation signal in the VAS or the VHS exhaust, respectively. The air exhausted by the VFS is filtered sequentially by high efficiency filters, charcoal filters, and post-filters.

The VFS comprises two parallel systems that may be operated individually or simultaneously as required by the operating regime, with or without associated inlet air handling units (AHUs). Each system is equipped with HEPA filtration and charcoal filters for the removal of particulate and iodine vapour, respectively. A high-efficiency filter is installed before the HEPA filter to increase operational life and reduce the quantity of low-level waste (LLW).

The exhaust air filtration units are located within the radiologically controlled area of the annex building. The units are connected to a ducted system (with isolation dampers) and provide HEPA filtration and charcoal adsorption of exhaust air from containment, the fuel handling area, and the radiological controlled areas of the auxiliary and annex buildings. A gaseous radiation monitor (located downstream of the exhaust air filtration units in the common ductwork) provides an alarm if abnormal gaseous releases are detected.

9.11.3 Overview of Faults

The safety case for operation of the AP1000 reactor includes non-reactor faults (i.e., faults that are unrelated to the reactor but that still occur within the facility). These non-reactor faults include HVAC faults.

9.11.4 Analysis of Faults

Nine faults were identified and are extracted from the fault list (Appendix 8A):

Fault No.	Fault
3.5.1	Failure of HVAC filter leading to a potential external release of radioactivity
3.5.2	Blockage of HVAC filter leading to an increase in air radioactivity level in the affected working area
3.5.3	Failure of HVAC fans leading to an increase in air radioactivity level in the affected working area
3.5.4	Failure of HVAC dampers leading to an increase in air radioactivity level in the affected working area
3.5.5	Leakage leading to an increase in air radioactivity level in the affected working area
3.5.6	Fire resulting in the release of trapped activity from filters involved in the fire leading to an increase in air radioactivity level in the affected working area and a potential external release of radioactivity
3.5.7	Dropped filters during handling (filter exchange, transfer to or processing in radwaste building) leading to an increase in air radioactivity level in the affected working area
3.5.8	Failure of gaseous radwaste system (WGS) beds, leading to a potential release of

radioactive gas

3.5.9 Failure of stack monitoring system, leading to an inability to monitor routine discharges

Fault 3.5.9 was identified at the hazard identification exercise (described in Appendix 8A), but was screened out during the exercise as an operability issue in the fault list that did not result in any abnormal discharges (Appendix 8A).

Fault 3.5.5 was identified at the hazard identification exercise (described in Appendix 8A) and was screened out. The HEPA filter banks are designed with replaceable cells that are clamped in place against compression seals. Normal operations dictate that when the filters are replaced, they are pressure-tested to ensure that they are seated in the housing correctly and can maintain pressure. The pressure differential across a filter bank is used as an indication of correct installation. Pressure indication and high differential pressure alarms are provided for filters in the AHUs and room coolers. These alarms will sound if the filters are incorrectly installed, and thus alert operators to a fault. In addition, the filter housing is designed and tested to be airtight with bulkhead-type doors that are closed against compression seals, and thus any leak would stay within the filter house.

9.11.5 Fault Groups

From analysis of the faults listed above, similar faults can be bounded into groups. For brevity, it has been decided to create three groups: the first will consider filter failures in the HVAC system (Faults 3.5.1, 3.5.6, and 3.5.8); the second will consider dropped HVAC filters during handling (Fault 3.5.7); and the third will consider reduced airflow in the HVAC system because of failure of the HVAC fans and dampers, and blockage of HVAC fans (Faults 3.5.2, 3.5.3, and 3.5.4).

Therefore, this assessment considers the following three groups:

1. Failure of filters in HVAC system
2. Dropped filters
3. Reduced airflow

9.11.6 Failure of Filters in the Heating, Ventilation, and Air Conditioning System (Faults 3.5.1, 3.5.6, and 3.5.8)

9.11.6.1 Fault Group Description

This fault considers the failure of a filter in the HVAC systems. The fault could occur by a variety of initiators, including operator error causing damage during installation or change procedures, or by a filter fire caused by a burning particle drawn into the exhaust system. The worse-case scenario would be if the filters in the VFS were to ignite as they were filtering all the unfiltered vents from several areas of the plant, and hence would be likely to contain the most activity.

This fault group also considers fires in the charcoal guard and delay beds. The radioactive gases removed from the RCS at the WLS vacuum degasifier are directed through the gas cooler, moisture separator, charcoal guard bed, and two charcoal delay beds. The effluent is then discharged via the plant vent. The radwaste assessment (Section 9.12) identifies the possibility of a fire in the radwaste system as being very low. Additionally, the inventory of

the charcoal guard and delay beds is purely noble gases and as such, there will be no inhalation dose if they catch fire. From further examination of a potential fire in the charcoal guard and delay beds, it is concluded that this fault is bounded by the filter fire fault and so it is not discussed any further.

9.11.6.2 Initiating Event Frequency

An IEF is not assigned to this fault. The estimated dose is minimal and hence a probabilistic assessment is not required (see Section 9.11.6.6).

9.11.6.3 Design Basis Class

The consequences from a release of the inventory from an HVAC filter resulting from a fire are calculated to be 2.05E-5 mSv for members of the public and 6.38E-4 mSv for worker dose (Reference 9.11-1), which is significantly less than the Target 4 BSOs of 0.01 mSv for the public and 0.1 mSv for the workers.

There are no requirements for a DB0 fault assessment, but an ALARP assessment should be considered.

9.11.6.4 Bounding Fault

For filter failure, the bounding fault would be a filter fire leading to the release of the inventory of the filters in the VFS.

9.11.6.5 Design Basis Fault Progression and Assessment

Filters could potentially be ignited by a burning particle drawn into the exhaust system. However, there is no mechanism for a fire to start spontaneously in a filter, so there has to be a fire somewhere else, either in the filter housing itself or somewhere else connected by ventilation ducting.

The potential for a fire in the filter housing is controlled by good housekeeping procedures, ensuring that there is a lack of combustible material stored in or near the filter housing. Normal good housekeeping procedures will ensure that any combustible waste is placed in robust containers (fire-resistant if appropriate) and the contents are emptied on a regular basis (see Section 11.2). In addition, early detection and warning of fire will be provided by the automatic fire detection and alarm system (AFD). The AFD is provided throughout the AP1000 plant and will be designed, installed, and commissioned in accordance with appropriate standards. The AFD provides audible and visual alarms, as well as system trouble annunciation in both the MCR and the security central alarm station, and thus will alert operators to a fire in a ventilation system. Operators will be able to investigate and control a fire in the filter housing in accordance with firefighting procedures (see Section 11.2).

The fire damper design used in the VFS does not require any external power source or actuation signals. Actuation is achieved by heat from the air in the duct melting the fusible link and a spring mechanism closing the damper. This provides a high degree of inherent safety and high reliability. There is extensive experience with operating these types of dampers to give confidence that, if they are adequately maintained, they will not seize or jam and will move to the closed position when the temperature rises above a specified point (see Section 23.3).

Differential pressure indication and high differential pressure alarms are provided for filters in the AHUs and room coolers. Pressure differential indication and alarms are provided via

instruments (VAS-030, VAS-032, VAS-033, and VAS-034) to control the negative pressure in the radiologically controlled areas of the auxiliary and annex buildings. A filter fire would result in a loss of pressure and hence the alarms would sound, thereby alerting operators to a potential problem with the filters. Assuming that activity is released during the fire, activity-in-air monitors would alert personnel in the event of airborne activity breaching a predetermined limit.

Therefore, either the filter will not be affected by a fire or any release will be mitigated by the operation of the fire dampers, differential pressure indication alarms, and activity-in-air alarms.

9.11.6.6 Radiological Consequences

A calculation has been performed to determine the doses to the public and to the workers (Reference 9.11-1). This calculation assumes the contact dose rate on a filter to be 1 mSv/hr. This is significantly greater than what would be expected for normal filter change operations: filters would normally be monitored to ensure that they do not exceed contact dose rates for LLW and may also be changed at a predetermined pressure drop or age, well before significant activity levels are reached.

A dose rate of 1 mSv/hr equates to an inventory of 1E8 Bq (2.70E3 μCi) Cs-134 and 4E7 Bq (1.08E3 μCi) Cs-137 based on the primary coolant nuclide activities. The consequences are calculated to be 2.05E-5 mSv for members of the public and 6.38E-4 mSv for worker dose (Reference 9.11-1), which is significantly less than the Target 4 BSOs of 0.01 mSv for the public and 0.1 mSv for the workers; therefore, no further discussion is required.

9.11.6.7 As Low As Reasonably Practicable Assessment

The general design of the ventilation system is to have enough duct length to ensure that a burning particle has extinguished before it reaches the filters. In addition, in-situ ventilation spark arresters will prevent a burning particle from reaching the filters. There will also be fire dampers at each fire barrier the duct crosses between the fire compartment and the filter. These are rated the same as the barrier (generally 2 or 3 hours); so as long as they operate, the filter will be protected.

Passive FPSs are used to protect ventilation ductwork from the effects of fire. A 3-hour fire-rated ventilation ductwork enclosure/shaft is used to segregate the VXS and VFS from one another as they enter and leave the Lower South Air Handling Equipment Room in the annex building.

The plant vent radiation monitor measures the concentration of radioactive airborne contamination being released through the plant vent. The plant vent is a post-accident monitor and is sampled continuously for the full range of concentrations between normal conditions and those postulated. Alarms are provided in the MCR if radioactivity concentrations exceed predetermined setpoints. The plant vent radiation monitor also provides data for plant effluent release reports.

No further measures are practicable and the risk is considered to be ALARP.

9.11.6.8 Conclusions

Radiological consequences are within the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.11-1.

LCOs related to the dose assessment for this fault are provided in Table 9.11-2.

9.11.7 Dropped Filters (Fault 3.5.7)

9.11.7.1 Fault Group Description

This fault considers the consequences of a dropped filter during an outage for maintenance purposes.

9.11.7.2 Initiating Event Frequency

An IEF is not assigned to this fault. The estimated dose is minimal and hence a probabilistic assessment is not required (see Section 9.11.7.5).

9.11.7.3 Design Basis Class

Reference 9.11-1 calculates the worker and public consequences from the release of the inventory of an HVAC filter to be 1.3E-4 mSv to the worker and 4.1E-6 mSv to members of the public, which is significantly less than the Target 4 BSOs of 0.01 mSv for the public and 0.1 mSv for the workers.

There are no further requirements for a DB0 fault assessment, but an ALARP assessment should be considered.

9.11.7.4 Design Basis Fault Progression and Assessment

If a filter is dropped, it could become damaged and release activity into the local area and potentially result in a public dose. The loading of the filters and adsorbers with radioactive material during normal plant operation is a slow process. In addition to monitoring for pressure drop, the filters are checked for radioactivity on a scheduled maintenance basis with portable equipment. The filter elements are replaced before the radioactivity level is of sufficient magnitude to create a personnel hazard. In the case of excessive radioactivity caused by a postulated accident, the filter is replaced before normal personnel access is resumed. It is not necessary for workers to handle filter units immediately after a DB accident, so exposure can be minimised by allowing the short-lived isotopes to decay before changing the filter.

Access to ventilation systems in potentially radioactive areas can result in operator exposure during maintenance, inspection, and testing. Equipment locations are selected to minimise personnel exposure. The outside air supply units and building exhaust system components are located on the roof of the Auxiliary Building. These areas are accessible to the operators. Work space is provided around each unit for anticipated maintenance, testing, and inspection.

Radioactive filters from ventilation exhaust filtration units are bagged and transported to the radwaste building, where they are temporarily stored. The filters may be compacted along with other dry radioactive wastes. It is noted that compaction is outside the scope of this assessment.

It is expected that mobile handling equipment will be used to move filters if the radioactivity readings make it ALARP to do so. It is also assumed that if a filter is dropped, the POW will instigate the evacuation procedure of all personnel in the affected area:

- **Operating Instruction -** In the event of a dropped filter, the POW must instigate the evacuation procedure.

The dropping of a filter under the circumstances described above is classified as a revealed event.

9.11.7.5 Radiological Consequences

A calculation of dose has been performed in Reference 9.11-1. This assumes an initial inventory of 1E8 Bq (2.70E3 μCi) Cs-134 and 4E7 (1.08E3 μCi) Bq Cs-137 based on a 1-mSv/hr contact dose rate and the primary coolant nuclide activities. The consequences are calculated to be 1.3E-4 mSv to a worker and 4.1E-6 mSv to a member of the public, which are significantly less than the Target 4 BSOs of 0.1 mSv for the public and 0.01 mSv for the workers.

9.11.7.6 As Low As Reasonably Practicable Assessment

Under normal operations, the HVAC filters are monitored to ensure that they do not exceed the allowable dose limits for contact handleable LLW.

It is assumed that a standard safe change bagging procedure is used to change the filters and that the filters will be changed at least once every 5 years.

It is assumed that operators performing filter change operations will be wearing appropriate personal protective equipment (PPE). Respirators are able to offer a minimum DF of 40 (Reference 9.11-2). The PPE requirements will be determined by the health physics team at the time of use and therefore are not designated here.

Other assumptions that will reduce the risk associated with this fault are that suitable training and briefing of infrequent procedures (such as moving filters) will be carried out.

No further measures are practicable and the risk is considered to be ALARP.

9.11.7.7 Conclusions

Radiological consequences are within the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.11-3.

LCOs related to the dose assessment for this fault are provided in Table 9.11-4.

9.11.8 Reduced Airflow (Faults 3.5.2, 3.5.3, and 3.5.4)

9.11.8.1 Fault Group Description

This fault considers a reduction in airflow in the HVAC system. The fault could occur by a variety of initiators, such as an operator error causing dampers to be closed, filters becoming blocked, or fans failing. These faults could potentially result in an increased operator dose.

9.11.8.2 Initiating Event Frequency

An IEF is not assigned to this fault. The estimated dose is minimal and hence a probabilistic assessment is not required (see Section 9.11.8.4).

9.11.8.3 Design Basis Fault Progression and Assessment

This fault considers the failure of dampers and fans and partial blockage of filters. Partial failure of a filter is bounded by a failure of the filters (as discussed in Section 9.11.6), and so a partial blockage in a filter will not be considered any further in this section, as it would only result in a reduced flow rate. This section will only consider the failure of dampers and fans. It is considered that failure of fans and dampers in the VFS would present the worst case.

Fan Failure

Operation of the supply and exhaust fans ensures that a suitable airflow can be achieved through the containment purge operations to reduce radiation levels in the containment environment. The exhaust fans provide a filtered exhaust route from the fuel handling area, auxiliary building, or annex building, maintaining a negative pressure differential relative to the surrounding areas. The supply and exhaust fans operate in response to signals from the PLS (see Section 23.3 of this PCSR). They are manually operated for containment purge functions, so a fault with the fans would be revealed during containment purge. The exhaust fans respond automatically to signals that include high/low pressure differential in the fuel handling area, auxiliary area, or annex building; and high radiation in these areas.

Conceivable failure modes for this type of fan include items such as failed bearings or a failed drive belt. These types of mechanical failures are avoidable with appropriate maintenance and can be readily detected and rectified. There is extensive experience in operating these types of fans (designed and constructed to similar standards) to give confidence that, if they are adequately maintained, they will have a good reliability in service and will be able to meet their safety requirements.

Failure of the exhaust fans when demanded to exhaust from the fuel handling area, auxiliary, or annex buildings may prevent the maintenance of a pressure differential in those areas and lead to an unmonitored release of air to the operational environment or surrounding areas. The exhaust fans also function to maintain a negative pressure differential in the fuel handling area, auxiliary or annex building areas served by the VAS following detection of high radiation. This prevents an unmonitored release of air to the environment and surrounding areas. In doing this, the fans control the level of radioactivity released to the working environment.

Two exhaust fans are installed; only one fan is required to meet the demand, however, and will start and operate to exhaust air from the fuel handling area, auxiliary, or annex building areas following detection of high radiation by the VAS (see Section 23.3).

The air exhausted by the VFS is filtered sequentially with high-efficiency filters, charcoal filters, and post filters. The VFS also exhausts areas served by the VAS and VHS after receipt of a high-radiation signal in the VAS or the VHS exhaust, respectively. Therefore, any dose to the public is bounded by failure of a filter as discussed in Section 9.11.6; as such, no further assessment is required.

Failure of Dampers

If high airborne activity is detected in the exhaust air from the auxiliary or annex buildings, the supply and exhaust duct isolation dampers automatically close to isolate the affected area from the outside environment. The VFS mitigates the resuspension of unfiltered airborne activity by maintaining the isolated zone at a slightly negative pressure with respect to the outside environment and adjacent unaffected plant areas.

If high airborne activity is detected in the exhaust air from the health physics and hot machine shop areas, the supply and exhaust duct shutoff dampers automatically close to isolate the affected areas from the outside environment. The VFS mitigates the resuspension of unfiltered airborne activity by maintaining the isolated zone at a slightly negative pressure with respect to the outside environment and adjacent unaffected plant areas.

The auxiliary/annex building subsystem remains in operation at a reduced capacity if either the auxiliary or annex building is not isolated. A disruption in the normal ventilation airflow rate that causes a high differential with respect to the outside environment causes the same automatic actuations. The VFS maintains negative pressure with respect to the outside environment until operation of the auxiliary building/annex building subsystem is restored.

If high airborne radioactivity is detected in the exhaust air from the fuel handling area, the supply and exhaust duct dampers automatically close to isolate the fuel handling area from the outside environment. The VFS mitigates resuspension of unfiltered airborne activity by maintaining the isolated zone at a slightly negative pressure differential with respect to the outside environment and adjacent unaffected plant areas. A disruption in the normal ventilation airflow rate that causes a high pressure differential with respect to the outside environment causes the same automatic actuations. The VFS maintains a slightly negative pressure differential with respect to the outside environment until operation of the fuel handling area ventilation subsystem is restored.

The isolation and shutoff dampers operate in response to signals from the PLS (Section 23.3).

The dampers are manufactured to appropriate industrial or nuclear standards to ensure a high reliability. Balancing dampers are set during commissioning and are not required to actuate during operation. In general, active dampers are located in redundant supply/exhaust lines such that failure of a damper will not prevent the VFS from performing its safety function. It is considered that the likelihood of coincidental failure of an isolation damper and the occurrence of an event leading to a release of activity in a working area is very low. As such, no further assessment is required.

9.11.8.4 Radiological Consequences

Section 9.11.6 calculates the failure of filters in the HVAC system. The consequences for the failure of fans will be bounded by this calculation, and hence will be significantly less than the Target 4 BSOs of 0.1 mSv for the public and 0.01 mSv for the workers. Therefore, no further discussion is required (see Section 9.11.6.6).

9.11.8.5 As Low As Reasonably Practicable Assessment

Redundant fans are provided in the design to further reduce the risk of a total failure of the VFS exhaust from the fuel handling area, auxiliary, or annex building areas (see Section 9.11.8.6).

Maintenance will be performed in line with the manufacturer's information. There is extensive experience in operating these types of fans (designed and constructed to similar standards) to give confidence that, if adequately maintained, they will have good reliability in service and be able to meet their safety requirements.

Radioactivity indication and alarms are provided to inform the MCR operators of gaseous radioactivity concentrations in the exhaust ducts from the fuel handling area and the radiologically controlled areas of the auxiliary and annex buildings. These local alarms would alert workers to increased activity in the area and prompt an evacuation.

Activity-in-air monitors are designed to alert personnel in the event of airborne activity breaching a predetermined limit.

Air exhausted from the auxiliary building, fuel handling area of the auxiliary building, and the annex building is monitored for high airborne activity. Means are provided to shut off supply air and divert exhaust air through high efficiency particulate air filters and charcoal adsorbers upon detection of high airborne activity. Alarms are provided in the main control room for these discharge flows.

The activity-in-air instrument (VAS-JE-RE001) can be used to alert operators of an abnormally high airborne concentration in the fuel handling area. This is an example of one of the activity-in-air instruments and additional airborne monitors are located in the auxiliary building and annex building (VAS-JE-RE002 and 003).

The fuel handling area exhaust radiation monitor (VAS-JE-RE001) measures the concentration of radioactive materials in the exhaust air from the fuel handling area. This radiation monitor is located upstream of the exhaust air isolation damper.

The fuel handling area exhaust radiation monitor is an inline monitor that uses a beta-sensitive scintillation detector. It is located with the sensitive volume inside the exhaust duct.

The activity-in-air instrument (fuel handling area exhaust radiation monitor (VAS-JE-RE001)) can alert operators to evacuate and reduce the risk of exposure from airborne activity; on this basis, it is designated as follows:

- **SSC** – fuel handling area exhaust radiation monitor (activity-in-air monitor VAS-JE-RE001)
- **Safety function** – to minimise operator exposure to airborne activity

No further measures are practicable and the risk is considered to be ALARP.

9.11.8.6 Summary of Safety Designations

Radiological consequences are within the Target 4 BSOs (0.01 mSv offsite and 0.1 mSv onsite), and the risks have been reduced to be ALARP.

Table 9.11-5 summarises the SSCs from this fault assessment.

Operator actions relevant to this fault assessment is provided in Table 9.11-6

LCOs related to the dose assessment for this fault is provided in Table 9.11-7.

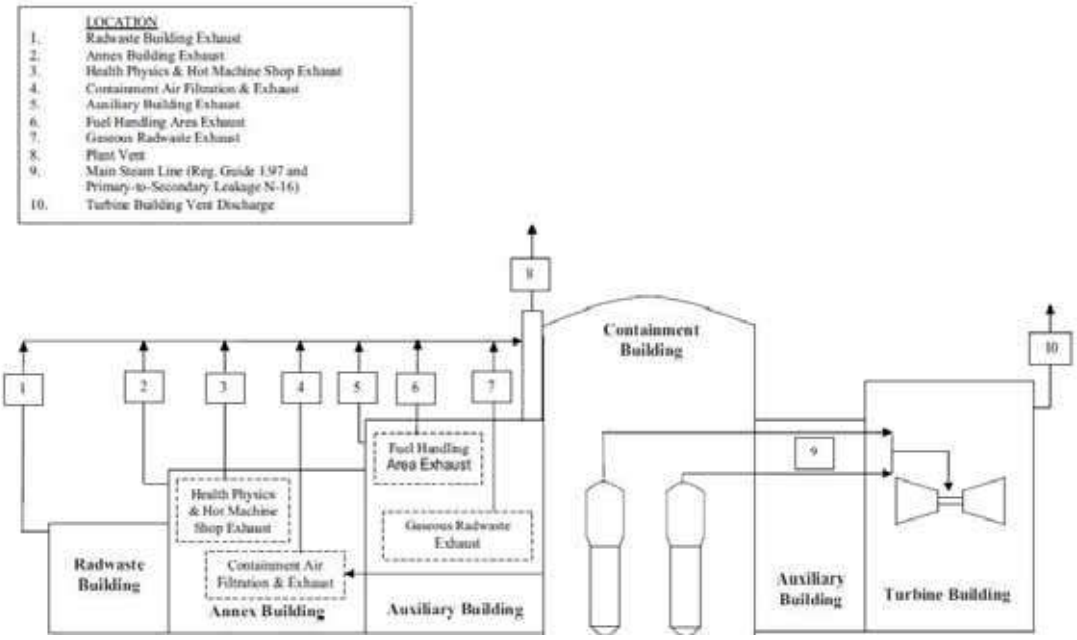

Figure 9.11-1. Schematic of Plant HVAC System

9.12 Radioactive Waste Handling

9.12.1 Introduction and Overview of Faults

The safety case for the operation of the AP1000 reactor includes non-reactor faults. These non-reactor faults include those associated with handling radioactive waste (radwaste).

9.12.2 Overview of the Solid, Liquid, and Gaseous Waste Management Systems

Chapter 26 provides an in-depth discussion of the AP1000 radioactive waste management systems. Chapter 26 also addresses the radioactive waste management strategy and discusses the WGS, the WLS, and the solid radwaste system (WSS). The chapter provides details on the sources of the various waste streams and provides details on the emissions to air; liquid discharges; and the minimisation, handling, and storage of solid waste.

A brief overview of the systems designed to manage solid, liquid, and gaseous radioactive wastes is presented below.

9.12.2.1 Solid Waste Management

The WSS is designed to collect and accumulate spent ion exchange resins, deep-bed filtration media, spent filter cartridges, dry radioactive wastes, and mixed wastes generated as a result of normal plant operation. The system is located in the auxiliary and radwaste buildings.

Processing and packaging of wastes are by mobile systems in the auxiliary building rail car bay and by mobile and fixed systems in the mobile systems facility in the radwaste building. The packaged waste may be accumulated in the auxiliary and radwaste buildings until it is moved to longer-term storage or disposal.

This system does not handle large, radioactive waste materials such as core components or radioactive process wastes from the plant's secondary cycle.

9.12.2.2 Liquid Waste Management

The systems that process liquid radwaste include the following:

- WLS
- Radioactive waste drain system (WRS)

The WLS is designed to control, collect, process, handle, store, and dispose of liquid radioactive waste in a controlled manner. Liquid waste is produced on both the primary side (primarily from adjustment of reactor coolant boron concentration and from reactor coolant leakage) and the secondary side (primarily from SG blowdown processing when there is secondary-side leakage). The AP1000 plant does not recycle primary-side effluents for re-use (except for RCS degasification in anticipation of shutdown). Primary effluents are discharged to the environment after processing. Liquids collected by drains in the WRS are also treated by the WLS.

Radioactive inputs to the WLS include fission and activation products produced in the core and reactor coolant system.

Ion Exchange Media Replacement

When ion exchange media are spent and ready to be transferred to the WSS, the vessel containing the media is isolated from the process flow. The flush water line is opened to the sluice piping, and demineralised water (DMW) is pumped into the vessel through the normal process outlet connection upward through the media retention screen. When the bed has been fluidised, the sluice connection is opened and the bed is sluiced to the spent resin tanks in the WSS. DMW flow continues until the bed has been removed and the sluice lines are clean of spent resin.

9.12.2.3 Gaseous Management

The WGS is a once-through, ambient temperature, activated-carbon delay system. The system includes a gas cooler, a moisture separator, an activated-carbon-filled guard bed, and two activated-carbon-filled delay beds. Also included in the system are an oxygen analyser subsystem and a gas sampling subsystem.

The radioactive fission gases entering the system are carried by hydrogen and nitrogen and are cooled to about 4°C (39°F). Radioactive decay of the fission gases during the delay period significantly reduces the radioactivity of the gas flow leaving the system.

9.12.3 Assumptions – Radwaste Generation

The expected radwaste generation rate is based upon the following:

- All ion exchange resin beds are disposed of and replaced every refuelling cycle.
- The WGS activated-carbon guard bed is replaced every refuelling cycle.
- The WGS delay beds are replaced every 10 years.
- All wet filters are replaced every refuelling cycle.

The maximum radwaste generation rate is based upon the following assumptions:

- The maximum expected rates of compactable and noncompactable radwaste, chemical waste, and mixed wastes are about 50 percent greater than the expected volumes to be generated.

- The ion exchange resin beds are replaced based upon operation with 0.25-percent fuel defects.

- The WGS activated-carbon guard bed is replaced twice every refuelling cycle.

- The WGS delay beds are replaced every 5 years.

- All wet filters are replaced based upon operation with 0.25-percent fuel defects.

- Primary-to-secondary system leakage contaminates the condensate polishing system and steam generator blowdown system (BDS) resins and membranes, which are designed to be replaced.

9.12.4 Analysis of Faults

The potential for a radioactive release from AP1000 plant subsystems events include, but are not limited to, the following:

- Gas waste management system leak or failure
- Liquid waste management system leak or failure (atmospheric release)
- Releases of radioactivity to the environment via liquid pathways

No analysis is provided of a gas waste management system leak or failure, as it would result in an insignificant release. Therefore, this event was not considered at the hazard identification exercise as a credible fault and so is not discussed any further in this chapter. However, the hazard identification exercise did identify a potential issue with wet activated carbon; which is discussed later.

Similarly, no analysis is provided for an atmospheric release in the liquid waste management system because of a leak or failure, as the effluent is routed via the WLS vacuum degasifier before being stored in the effluent holdup tanks. Therefore, the liquid radwaste tanks will not contain significant gaseous activity. This fault is not discussed any further in this section of the PCSR.

Releases of radioactivity to the environment were considered as part of the hazard identification exercise, as discussed below:

A total of 15 faults were identified at hazard identification exercises; the following six faults were screened out in the fault list (Appendix 8A) for the reasons presented below:

- Fault 3.6.3, setting fire to solid waste (WSS)

  The potential for a fire is controlled by good housekeeping procedures, ensuring a lack of combustible material stored in or near potential sources of ignition. Electrical ignition sources, such as those from machinery and electrical items, are minimised because of a number of factors. Items will be tested and maintained in accordance with statutory legislation and approved codes of practice. Further details can be found in Chapters 17 and 18. Normal good housekeeping procedures will ensure that any combustible waste is placed in robust containers (fire-resistant if appropriate) and the contents emptied on a regular basis (Section 11.4). In addition, early detection and warning of fire will be provided by the AFD. The AFD is provided throughout the AP1000 plant and will be designed, installed, and commissioned in accordance with appropriate standards. The AFD provides audible and visual alarms, as well as system trouble annunciation, in both the MCR and the security central alarm station, and thus will alert operators to a solid waste fire. Operators will be able to control and extinguish the fire. The fire loads at any point in time of the life of the AP1000 plant facility will be low when compared with older existing nuclear licensed sites because of it being built to modern standards. This basis will minimise the risk that fires will spread within the facility; the number of locations of fire is expected to be comparatively small.

  Section 9.11 considers filter fires and fires in the charcoal and delay beds.

  From an examination of a potential fire in the charcoal guard and delay beds, it is concluded that this fault is bounded by the filter fire fault (see Section 9.11), and so it is not discussed any further in this section.

- Fault 3.6.6, spills of liquid waste (leak to ground from vessel or pipework) (WLS)

  Normally nonradioactive liquid waste sumps and tanks are sampled for radioactivity to determine whether the liquid wastes have been inadvertently contaminated.

The design process has considered leaks that have been identified in this fault schedule as initiators; therefore, it is proposed to screen out faults 3.6.6 and 3.6.7 and not consider them further in the PCSR.

- Fault 3.6.7, spills of liquid waste (leak to drain) (WLS)

  As for fault 3.6.6, all streams of nonradioactive liquid waste, chemical, detergent, and oily waste are collected in the appropriate tanks and sumps. Radwaste is collected in the radwaste system. All nonradioactive tanks and sumps are routinely monitored. Therefore, active spills into any normally nonactive system would be detected prior to disposal.

- Fault 3.6.8, unauthorised discharge of gaseous waste (WGS)

  The WGS is designed to receive hydrogen-bearing and radioactive gases generated during process operation. The WGS is designed to reduce the controlled activity releases in support of the overall AP1000 plant release goals. To prevent an unauthorised gaseous discharge, however, each licencee's management systems will need to be robust enough to prevent an act of noncompliance.

- Fault 3.6.9, unauthorised discharge of liquid (WLS)

  The liquid radwaste system provides the capability to reduce the amounts of radioactive nuclides released in the liquid wastes through the use of demineralization and time delay for decay of short-lived nuclides.

  Before radioactive liquid waste is discharged, it is pumped to a monitor tank. A sample of the monitor tank contents is analysed, and the results are recorded. In this way, a record is kept of planned releases of radioactive liquid waste.

  The liquid waste is discharged from the monitor tank in a batch operation, and the discharge flow rate is restricted as necessary to maintain an acceptable concentration when diluted by the circulating water discharge flow. These provisions preclude uncontrolled releases of radioactivity.

  In addition, the discharge line contains a radiation monitor with diverse methods of stopping the discharge. The first method closes an isolation valve in the discharge line, which prevents any further discharge from the liquid radwaste system. The valve automatically closes and an alarm is actuated if the activity in the discharge stream reaches the monitor setpoint. The second method stops the monitor tank pumps.

  To minimize leakage from the liquid radwaste system, the system is of welded construction except where flanged connections are required to facilitate component maintenance or to allow connection of temporary or mobile equipment. Air-operated diaphragm pumps or pumps having mechanical seals are used. These pumps minimize system leakage thereby minimizing the release of radioactive gas that might be entrained in the leaking fluid to the building atmosphere.

  Provisions are made to control spills of radioactive liquids due to tank overflows. In addition, the radioactive waste collection tanks (i.e., the effluent holdup tanks, waste holdup tanks, and chemical tank) are located within the auxiliary building, which is well sealed and equipped with an extensive floor drain system. The radwaste monitor tanks are located in the auxiliary building and in the radwaste building, which has a well sealed, contiguous basemat with integral curbing and a floor drain system. Routing of both of the auxiliary building and radwaste building floor drain systems are to the liquid radwaste

system. This eliminates the potential for undetected tank leakage to the environment.

The monitored radwaste discharge pipeline is engineered to preclude leakage to the environment. This pipe is routed from the auxiliary building to the radwaste building (the short section of pipe between the two buildings is fully available for visual inspection as noted above) and then out of the radwaste building to the licensed release point for dilution and discharge. The discharge radiation monitor and isolation valve are located inside the radiologically controlled area. The exterior piping is designed to preclude inadvertent or unidentified releases to the environment; it is either enclosed within a guard pipe and monitored for leakage, or accessible for visual inspection. No valves or vacuum breakers are incorporated outside of monitored structures. This greatly reduces the potential for undetected leakage from this discharge to the environment at a non-licensed release point.

To prevent an unauthorised gaseous discharge, however, each licencee's management systems will need to be robust enough to prevent an act of noncompliance.

- Fault 3.6.10, mispackaging of waste for offsite disposal (WSS)

  Each licencee will have its own management systems to control the sentencing of waste consignments. All radwaste that is packaged and accumulated by an AP1000 reactor unit will be transferred for disposal. The standard AP1000 plant has no provisions for permanent storage of radwaste, but licensees may construct facilities for radwaste storage. Packaging will be done in accordance with local and national requirements. Health physics will control the monitoring of radwaste consignments.

  The consequences realised in this fault would require a failure of these systems, which incorporate health physics checks. Even if intermediate-level waste (ILW) was erroneously consigned instead of LLW by the site, it may not yield a significant public dose if the recipient has its own checks to determine that the waste meets its acceptance criteria.

The remaining nine faults, identified below, are assessed within this section unless as noted below:

Fault ID	Description
3.4.2	Fault in handling spent resins (ILW); leakage during transfer to collection tank, tank overfill, or tank rupture/leakage (WSS)
3.4.3	Fault in handling spent resins (LLW and WSS)
3.4.4	Fault in handling wet activated carbon (WGS)
3.4.5	Fault in handling SG blowdown material (resins) (WLS)
3.4.6	Fault in handling SG blowdown material (membranes) (WLS)
3.4.7 and 3.4.8	Fault in handling spent filters (higher activity)
3.6.1	Drop/impact of solid waste (LLW and WSS)
3.6.2	Drop/impact of solid waste (ILW and WSS)

Fault ID	Description
3.5.7	Dropped filters during handling (filter exchange, transfer to, or processing in radwaste building) (WSS) (Addressed in Section 9.11.7)

A number of other faults were identified during hazard identification exercises (described in Chapter 8) but were screened out in the fault list (Appendix 8A).

The initiators of the nine identified faults can result in two fault modes: loss of containment of spent resin, and dropping of radioactive exchangeable items (filters and charcoal adsorbers).

- Fault 3.4.2 involves the movement of spent resin from ion exchangers positioned around the plant. DMW is used to flush the spent resin into spent resin collection tank. The fault also considers the dropping of spent resin during the preparation of a shipping container for permanent storage offsite.

  Numerous initiators could result in the loss of containment of spent resin. The fault would result in a dose to an operator. As the movement of spent resin is contained entirely within the AP1000 plant facility where ventilation systems use filtration technology, the public consequences from this fault are deemed to be insignificant.

- Fault 3.4.3 considers the same scenario as that described in fault 3.4.2, except that it is assumed that the activity of the resin is less onerous (LLW as opposed to ILW).

- Fault 3.4.4 is involved with the handling of wet activated carbon. This carbon arises from the charcoal adsorbers, which are expected to be exchanged once every refuelling cycle (every 18 months); the maximum exchange rate is twice every 18 months.

- Faults 3.4.5 and 3.4.6 discuss the resin and membranes, respectively, involved with SG blowdown. Although there are many steps involved with this task, the fault here analyses a drop of resin and of a membrane from the filter used with the blowdown process.

- Faults 3.4.7, 3.4.8, and 3.5.7 describe the dropping of a filter.

9.12.5 Fault Groups

From analysis of the faults listed above, similar faults can be linked into fault groups. For brevity, it has been decided to create two groups.

1. Loss of containment of spent resin
2. Dropping of radioactive exchangeable items (filters and charcoal adsorbers)

9.12.5.1 Bounding Faults

Each of the above groups contains a bounding fault used as the basis of study.

The bounding fault for the loss of containment of spent resin group is considered to be the loss of containment of the spent resin collection tanks. This is because the volume of spent

resin considered here (15.6 m^3 (550 ft^3)) is greater than the volume of a container used for shipping the spent resin.

For the dropping of radioactive exchangeable items group, many items can be dropped. However, in comparing the annual production of spent resin to that of filters, it was determined that there is more activity associated with resin than with a filter. Therefore, the bounding fault is the dropping of spent resin.

9.12.6 Loss of Containment of Spent Resin (Faults 3.4.2 and 3.4.3)

9.12.6.1 Fault Group Description

This group considers two scenarios: mechanical failure (from a ruptured tank or failed valve, for example) and the dropping of a shipping flask containing spent resin destined for permanent offsite storage. Both scenarios result in a loss of containment of spent resin.

The resin change operation is described below. This illustrates the plant and equipment used to move the spent resin from the ion exchangers situated throughout the plant to the two spent resin collection tanks (MV01A/B) situated in the southwest corner of the auxiliary building.

Resin Change Operation

Spent resin is stored in tanks and a basis of a minimum of 30-day storage prior to interim storage on site or permanent storage offsite is assumed. This allows activity to fall prior to shipment.

The resin transfer lines from the ion exchangers are routed to the spent resin collection tanks on the 100-m level in the southwest corner of the auxiliary building. The spent resin system pumps, valves, and piping are located in shielded rooms near the spent resin collection tanks.

DMW is used to pump spent resins from the various ion exchangers to the spent resin tanks. The resin mixing pump is aligned to discharge excess transfer water through the resin fines filter to the liquid waste processing system. During the transfer operation, the tank level is monitored and the resin mixing pump is operated, if required, to limit tank water level. The operator stops the transfer when the closed-circuit television camera viewing the sight glass indicates on a control panel monitor that the sluice water is clear and the transfer line is, therefore, flushed of resins.

The radwaste building houses the mobile systems facility. It also includes the waste accumulation room and the packaged waste storage room. These rooms are serviced by the mobile systems facility crane.

Fault Mechanism

<u>Loss of Containment from Plant and Equipment of the Resin Change System</u>

The fault considers the release of spent resin through the loss of containment of plant and equipment involved with the movement of the spent resin from the ion exchangers to the spent resin collection tanks (MV01A/B).

The two spent resin collection tanks are effectively joined by common feed pipework. Failure of a valve could result in spent resin accumulating beneath these tanks.

The fault pessimistically considers an inventory of the maximum amount of resin produced by the plant in 1 year (15.6 m^3 (550 ft^3)), which is twice that of the normal amount expected to be produced each year.

Each of the two tanks has a maximum volume of 7.8 m^3 (275 ft^3)[2] of spent resin. In the event of valve failure, the maximum spilled volume is 2×7.8 m^3 (275 ft^3) = 15.6 m^3 (500 ft^3) and the fault is considered on this basis.

The failure of a valve in a room not normally occupied, behind significantly thick concrete shielding, would mean that this fault is likely to be unrevealed.

Dropping of a Shipping Container

Other initiators can result in the release of spilled, spent resin. For example, a shipping container could be filled with spent resin and then be dropped. The volume of a shipping container, however, is expected to be significantly less than 15.6 m^3 (500 ft^3). It is also noted that the dropping of a shipping container is more likely to be a revealed event.

9.12.6.2 Bounding Fault

The bounding fault for this group considers the loss of containment from plant and equipment of the resin change system of a volume 15.6 m^3 (500 ft^3) of spent resin.

9.12.6.3 Initiating Event Frequency[1]

The IEF is calculated on the volumetric basis, mentioned above, that the maximum volume of spent resin produced in 1 year is the volume of two spent resin collection tanks (15.6 m^3 (500 ft^3)). Also mentioned above is that the expected volume of spent resin to be produced each year is actually half this figure (7.8 m^3 (275 ft^3)). Therefore, it is reasonable to assume that the spent resin collection tanks will be required to be emptied less than once per year.

Many initiators could cause the spent resin collection tanks to fail (as identified in Appendix 8A). Although mechanical failure of valves or welds would have a low IEF, human error may be involved in a scenario where a valve has been left in the wrong orientation when the spent resin collection tanks are being emptied. This would cause unplanned emptying of the tanks' contents, possibly unrevealed for some time. The volume of spent resin would only reach 15.6 m^3 (500 ft^3) if the fault occurred in the latter part of a rolling 12-month period. On this basis, a human error value of 1E-03/yr^{-1} is assumed for the probability of failure on demand (pfd) using the same methodology as in Chapter 13. The IEF is calculated as the pfd multiplied by the number of demands per year. As the frequency of moving the spent resin from a spent resin collection tank is <1/yr^{-1}, the IEF is <1E-03/yr^{-1}.

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10.
2. Note that actual usable volume of the tank is 7.0 m^3 (247 ft^3) and thus assuming a higher maximum volume of spent resin is conservative.

9.12.6.4 Design Basis Class

Using the above-mentioned IEF and the calculation used to support this FSG (Reference 9.12-2), it can be seen that the operator and public doses from this fault are categorised as DB0.

9.12.6.5 Design Basis Fault Progression and Assessment

The failure of a valve near the spent resin collection tanks would cause a spillage onto the area below the tanks. As this area is not normally manned, it would only give rise to an operator dose if an operator were in the vicinity. This fault could not give anything more than a trivial dose to a member of the public. Airborne contamination is assumed to be released in trace amounts because of the filtration technology (HEPA filters and charcoal adsorbers) in the ventilation system.

As mentioned above, the spent resin collection tanks are connected, so it is assumed that the entire volume of 15.6 m^3 (500 ft^3) is released in this fault.

Access to the solid waste storage areas is controlled. Therefore, it is expected that health physics monitors carrying detection instrumentation will accompany an operator entering the spent resin collection tanks area (the WSS valve and piping area on the 7.62-m (25 ft) level above grade) to allow access to the ladder down toward the tanks.

In the event of a spillage, it is assumed that operators discovering it would be trained to evacuate the area and report the spillage to a superior. The superior member of personnel would then be assumed to organise the recovery and cleanup process.

The dose to an operator is below 20 mSv (see the "Radiological Consequences" section below). This leads to the following operating instruction:

Operating instruction – A spillage of spent resin is to be reported to a team leader, who will then instigate evacuation procedures.

9.12.6.6 Radiological Consequences

The supporting calculation (Reference 9.12-2) contains many assumptions. First, as spent resin is classified as ILW, no operator is expected to be within 6 m (19.7 ft) of the spent resin collection tanks under normal circumstances:

Operating instruction – Unless instructed to do so by a team leader, no personnel are to be within 6 m (19.7 ft) of the spent resin collection tanks.

This is not thought to be too restrictive, as there is approximately 6 m (19.7 ft) from the midpoint between the spent resin collection tanks to the back of the rail car bay. There is also over 10 m (32.8 ft) of vertical distance between the removable cover on the operating deck (situated 10.7 m (35.1 ft) above ground, allowing access to the spent resin collection tanks) and the base of the tanks.

Concerning the spillage of spent resin from a dropped shipping container, the crane operator will be positioned up to 15.4 m (50.5 ft) from the waste disposal containers used to ship the spent resin from the AP1000 plant facility. The exposure time used in the calculation (Reference 9.12-2) was 5 minutes, as it is assumed that if a crane operator were required to evacuate, sufficient time would be required to exit the crane control cab. However, for most

personnel needing to evacuate because of a spillage of resin, it is assumed that evacuation time would be significantly less than 5 minutes.

The calculation (Reference 9.12-2) states that the dose to an operator is 10.4 mSv. A calculation for dose to members of the public shows that the highest dose is to a 1-year-old child and is 0.45 mSv (Reference 9.12-3).

Respirators are able to offer a DF of 40 (Reference 9.12-5). It is considered that the donning of a respirator could be designated here; however, it may be restrictive (e.g., it may restrict vision). The PPE requirements will be determined by the health physics team at the time of use and are therefore not designated here.

In summary, the doses to the operator and to members of the public for this FSG are below the Target 4 BSL for frequent faults (1 mSv offsite and 20 mSv onsite).

9.12.6.7 As Low As Reasonably Practicable Assessment

Instrumentation such as activity-in-air monitors and level detectors near spent resin collection tanks could be designated but the areas are not normally manned. Health physics teams would be expected to accompany personnel routinely upon entry into such unmanned areas. In the event of an operator attending a normally unmanned area in response to an instrument alarm, it would also be expected that health physics monitors would need to be present to determine that it is safe for the operator to enter. Such a regime would preclude the need for instrumentation to be situated permanently in such rooms, so no designation is made here.

Other factors that have the potential to reduce the risk associated with this fault are that suitable training and briefing of infrequent procedures will be performed on tasks associated with the emptying of the spent resin collection tanks. It is also assumed that those operators will be donning appropriate PPE.

No further measures are practicable and the risk is considered to be ALARP.

9.12.6.8 Conclusion

Radiological consequences are within the Target 4 BSLs for frequent faults (1 mSv offsite and 20 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.12-1.

LCOs related to the dose assessment for this fault are provided in Table 9.12-2.

9.12.7 Dropping of Radioactive Exchangeable Items (Filters and Charcoal Adsorbers) (Faults 3.4.4 through 3.4.8 and Faults 3.6.1 to 3.6.2)

9.12.7.1 Fault Group Description

This fault considers the dropping or mishandling of a number of potentially radioactive objects, each of which is considered below.

Dropped Filter

A filter transfer cask is used to change the higher-activity filters of the CVS and spent fuel cooling system. The filter vessel is drained and the filter cover is opened remotely. The shield plug of the port over the filter is removed and the transfer cask, without its bottom shield cover, is lifted and positioned on the port directly over the cartridge in the filter vessel.

A grapple inside the transfer cask is remotely lowered and connected to the filter cartridge. The cartridge is lifted into the transfer cask, and the cask is transferred over plastic sheeting to the bottom shield cover. The dose rate of the cartridge is measured with a long probe, and the cask is lowered onto and connected to the bottom shield cover. The transfer cask is then moved to the auxiliary building rail car bay.

Radioactive filters from ventilation exhaust filtration units are bagged and transported to the radwaste building, where they are temporarily stored. The filters may be compacted along with other dry radioactive wastes. It is noted that compaction is outside the scope of this assessment.

A cartridge unit is described as stainless-steel housing and pleated polypropylene cartridge with stainless-steel screen outer jacket. A filter cartridge is a metallic cylinder, where the maximum volume produced is 0.4 m^3/yr (14 ft^3/yr).

Wet Activated Carbon

No inventory information appears to exist for activated carbon, but it is classified as ILW.

Steam Generator Blowdown Material: Resins and Membranes

No inventory information appears to exist for resins and membranes associated with SG blowdown, but it is classed as LLW.

9.12.7.2 Bounding Fault

From inspection of the above, the most onerous scenario is a dropped filter.

9.12.7.3 Initiating Event Frequency[1]

The IEF for dropping a filter is assumed to comprise human error and error associated with remote handling.

Reference is made to a study analysing 34 years of crane operating experience of US reactors (Reference 9.12-1). This report (page B-15) gives a failure rate (including failures of the crane itself and human errors) of 6.7E-06 per demand.

It is not clear how often a filter will require to be replaced. However, it is assumed that it will be significantly less than 100 times per year.

1. As discussed in Chapter 8, the frequency for initiating events from the PSA is used in both Chapters 8 and 9 with the sole purpose of supporting the categorisation of the fault to a specific DB category. As noted in Chapter 8, these probabilities should not be considered to be representative of actual frequency of the events, and for several events they can be significantly conservative. Detailed PSA results and their basis are discussed in Chapter 10 of this PCSR.

Even assuming 100 filter replacements per year, this would give an IEF of 6.66E-04/yr^{-1}.

Reference 9.12-1 states that the mean annual failure rate is to be used in connection with a distribution curve and more accurate values are calculated when using the mean failure rate and percentiles. The mean failure rate of 6.7E-06 per demand corresponds to a percentile value of approximately 71; in other words, there is 71-percent likelihood that the failure rate is less than 6.7E-04/yr^{-1}.

9.12.7.4 Design Basis Class

The consequences have been calculated below as being 0.29 mSv. Using the IEF value calculated above and considering that the consequences to the operator are less than 2 mSv which is less then the Target 4 BSL for frequent faults of 20 mSv to workers, this puts the fault into the DB0 category. The dose to a member of the public has not been calculated, as it is assumed to be significantly less than the Target 4 BSL for frequent faults of 1 mSv to the public.

9.12.7.5 Design Basis Fault Progression and Assessment

The transfer cask bottom cover is disconnected. The transfer cask is lifted by the crane and transferred to a position over a waste container via a port in the top of a portable processing and storage cask. Plastic coverings are removed; and the container is capped, smear-surveyed, and decontaminated as required, using reach-rod tools through a cask port. The dose rate survey is also made through a cask port.

Transfer of the filled waste container to the transfer cask, including cask cover handling, is then performed using remote control. Radioactive filters from ventilation exhaust filtration units are bagged and transported to the radwaste building, where they are temporarily stored.

As the items listed above contain a potentially significant amount of activity, it is prudent to designate an operating instruction to ensure that a minimum distance is maintained between the operator and the unshielded source:

- **Operating instruction –** No personnel are to be positioned within 4 m (13.1 ft) of an unshielded cartridge, filter, or charcoal adsorber while it is being moved or replaced.

This requirement is not considered to be too restrictive, as it is expected that mobile handling equipment will be used to move filters if the radioactivity readings make it ALARP to do so. It is also assumed that if a filter is dropped, then the POW instigates the evacuation procedure of all personnel in the affected area:

- **Operating instruction –** In the event of a dropped filter, the POW must instigate the evacuation procedure.

The dropping of a filter under the circumstances described above is classified as a revealed event.

9.12.7.6 Radiological Consequences

A calculation has been performed on the radiological consequences to an operator (Reference 9.12-4). It is assumed that the evacuation time is 5 minutes to allow personnel such as crane operators time to leave the crane cab. For most operators, however, this is pessimistic, as evacuation would be expected to be carried out well within 5 minutes for such a revealed event.

Respirators are able to offer a DF of 40 (Reference 9.12-5). It is considered that the donning of a respirator could be stated as a requirement here; however, it may be restrictive (e.g., it may restrict vision). The PPE requirements will be determined by the health physics team at the time of use and therefore are not designated here.

Assuming that the operator is positioned at least 3.63 m (11.9 ft) away from the dropped filter, the dose to the operator is 0.29 mSv.

A calculation of dose to members of the public has not been prepared, as it is assumed to be significantly less than the Target 4 BSL for frequent faults of 1 mSv because of the DF afforded by the HEPA filter and charcoal adsorbers.

9.12.7.7 As Low As Reasonably Practicable Assessment

Assumptions that will reduce the risk associated with this fault are that suitable training and briefing of infrequent procedures (such as moving filters) will be performed. It is also assumed that those operators will be donning appropriate PPE.

No further measures are practicable and the risk is considered to be ALARP.

9.12.7.8 Conclusions

Radiological consequences are within the Target 4 BSLs for frequent faults (1 mSv offsite and 20 mSv onsite), and the risks have been reduced to be ALARP.

Operator actions relevant to this fault assessment are provided in Table 9.12-3.

LCOs related to the dose assessment for this fault are provided in Table 9.12-4.

Limit or Condition	Technical Specification Identification and Notes
(None)	

Table 9.12-3. Operator Actions Relevant to Section 9.12.7

Operator Action	Class
No personnel are to be positioned within 4 metres (13.1 ft) of an unshielded cartridge, filter, or charcoal adsorber whilst it is being moved or replaced.	2
In the event of a dropped filter, the person organising work must instigate the evacuation procedure.	2

Table 9.12-4. LCOs Related to the Dose Assessment for Section 9.12.7

Limit or Condition	Technical Specification Identification and Notes
Radwaste generation :	All ion exchange resin beds are disposed and replaced every refuelling cycle or with >0.25% fuel defects
Radwaste generation :	The WGS activated carbon guard bed is to be replaced every refuelling cycle
Radwaste generation :	The WGS delay beds are to be replaced every 10 years.
Radwaste generation :	All wet filters are to be replaced every refuelling cycle.

9.13 Conclusions

This chapter has presented a description and/or analysis of each design basis fault listed in Table 8A-2. The DB response of the system and of the corresponding SSCs to mitigate each fault has been analysed to demonstrate that the dose targets given in the ONR SAPs, specifically Target 4, are met. The set of SSCs required to ensure that the targets are met have been assigned the appropriate classification and the corresponding safety function(s) to the appropriate category, using the scheme described in Chapter 5.

Where the fault falls into the category of frequent faults (i.e., IEF > 1E-03 events/year), a diverse means of providing the necessary safety functions has also been identified to comply with the SAPs requirement that frequent faults should have diverse means of providing the necessary safety functions.

Also as part of this process, as required under site licence condition (SLC) 23, limits and conditions have been identified that may be candidates for Operating Rules or that may have Operating Rules associated with them. Similarly, required operating instructions (applicable, for example, to manually initiated safety systems) have been identified. These operating instructions are considered in Chapter 13. Finally, other SSCs have been identified that may provide defence in depth and contribute to reducing risks ALARP.

Chapter 9 demonstrates that DB dose targets are met when the identified SSCs are operating and the identified limits and conditions are met. Furthermore, for all the faults, the risks from all modes of normal operation and fault conditions are shown to be ALARP.

9A Evaluation Models and Parameters for Analysis of Radiological Consequences of Accidents

This appendix contains the parameters and models that form the basis of the radiological consequences analyses for the various postulated accidents.

9A.1 Offsite Dose Calculation Models

Radiological consequences analyses are performed to determine the total effective dose equivalent (TEDE) doses associated with the postulated accident. The determination of TEDE doses takes into account the CEDE dose resulting from the inhalation of airborne activity (that is, the long-term dose accumulation in the various organs) as well as the effective dose equivalent (EDE) dose resulting from immersion in the cloud of activity and dose resulting from deposition on the ground.

Credit is taken for the decay of radionuclides until release to the environment. After release to the environment, no credit is taken for radioactive decay or cloud depletion by ground deposition during transport offsite.

9A.1.1 Immersion Dose (Effective Dose Equivalent)

Assuming a semi-infinite cloud, the immersion doses are calculated using the equation:

$$D_{im} = \sum_i DCF_i \sum_j R_{ij} (\chi/Q)_j$$

where:

D_{im} = Immersion (EDE) dose (Sv)

DCF_i = EDE dose conversion factor for isotope i (Sv-m^3/Bq-s)

R_{ij} = Amount of isotope i released during time period j (Bq)

$(\chi/Q)_j$ = Atmospheric dispersion factor during time period j (s/m^3)

9A.1.2 Inhalation Dose (Committed Effective Dose Equivalent)

The CEDE doses are calculated using the equation:

$$D_{CEDE} = \sum_i DCF_i \sum_j R_{ij} (BR)_j (\chi/Q)_j$$

where:

D_{CEDE} = CEDE dose (Sv)

DCF_i = CEDE dose conversion factor (Sv per Bq inhaled) for isotope i

R_{ij} = Amount of isotope i released during time period j (Bq)

$(BR)_j$ = Breathing rate during time period j, 6.02E-5 m^3/s (1-2 year child), 3.10E-4 m^3/s (adult) (m^3/s)

$(\chi/Q)_j$ = Atmospheric dispersion factor during time period j (s/m^3)

9A.1.3 Ground Deposition Dose (Effective Dose Equivalent)

Assuming a semi-infinite cloud, the ground deposition doses are calculated using the equation:

$$D_{gd} = (S_{gd}) \sum_i DCF_i \sum_j (IAR)_{ij}$$

where:

D_{gd} = Ground deposition (EDE) dose (Sv)

S_{gd} = Shielding factor for dose from ground deposition dose (unitless)

DCF_i = EDE dose conversion factor for isotope i (Sv-m^3/Bq-s)

$(IAR)_{ij}$ = Integrated activity for isotope i deposited on ground during time period j (Bq-s/m^3)

The assumed deposition velocities of 0.01 m/sec for iodine or 0.002 m/sec for other nongaseous nuclides (the noble gases do not deposit in the soil).

9A.1.4 Total Dose (Total Effective Dose Equivalent)

The TEDE doses are the sum of the EDE and the CEDE doses.

9A.2 Main Control Room Dose Models

Radiological consequences analyses are performed to determine the TEDE doses associated with the postulated accident. The determination of TEDE doses takes into account the CEDE dose resulting from the inhalation of airborne activity (that is, the long-term dose accumulation in the various organs) as well as the EDE dose resulting from immersion in the cloud of activity.

There are two approaches used for modelling the activity entering the main control room. If power is available, the HVAC system will switch over to a supplemental filtration mode.

Alternatively, if the normal HVAC is inoperable or, if operable, the supplemental filtration train does not function properly resulting in increasing levels of airborne iodine in the main control room, the emergency habitability system would be actuated when High-2 iodine or particulate radioactivity is detected. The emergency habitability system provides passive pressurisation of the main control room from a bottled air supply to prevent inleakage of contaminated air to the main control room. The bottled air also induces flow through the passive air filtration system which filters contaminated air in the main control room. There is a 72-hour supply of air in the emergency habitability system. After this time, the main control room is assumed to be opened and unfiltered air is drawn into the main control room by way of an ancillary fan. After 7 days, offsite support is assumed to be available to re-establish operability of the control room habitability system by replenishing the compressed air supply.

The main control room is accessed by a vestibule entrance, which restricts the volume of contaminated air that can enter the main control room from ingress and egress. The design of the

VES provides clean air to the control room and maintains it in a pressurised state. The path for the purge flow out of the main control room is through the vestibule entrance and this should result in a dilution of the activity in the vestibule and a reduction in the amount of activity that might enter the main control room. However, no additional credit is taken for dilution of the vestibule via the purge. The dose analyses allow for a limited amount of outside air infiltration.

Control room model input is provided in Table 9A-8.

9A.2.1 Immersion Dose Models

Due to the finite volume of air contained in the main control room, the immersion dose for an operator occupying the main control room is substantially less than it is for the case in which a semi-infinite cloud is assumed. The finite cloud doses are calculated using the geometry correction factor from Murphy and Campe (Reference 9A-1).

The equation is:

$$D_{im} = \frac{1}{GF} \sum_i DCF_i \sum_j (IAR)_{ij} O_j$$

where:

D_{im} = Immersion (EDE) dose (Sv)

GF = Main control room geometry factor
= $352/V^{0.338}$

V = Volume of the main control room (m^3)

DCF_i = EDE dose conversion factor for isotope i (Sv-m^3/Bq-s)

$(IAR)_{ij}$ = Integrated activity for isotope i in the main control room during time period j (Bq-s/m^3)

O_j = Fraction of time period j that the operator is assumed to be present

9A.2.2 Inhalation Dose

The CEDE doses are calculated using the equation:

$$D_{CEDE} = \sum_i DCF_i \sum_j (IAR)_{ij} (BR)_j O_j$$

where:

D_{CEDE} = CEDE dose (Sv)

DCF_i = CEDE dose conversion factor (Sv per Bq inhaled) for isotope i

$(IAR)_{ij}$ = Integrated activity for isotope i in the main control room during time period j (Bq-s/m^3)

$(BR)_j$ = Breathing rate during time period j, 3.10E-4 m^3/s (adult) (m^3/s)

O_j = Fraction of time period j that the operator is assumed to be present

9A.2.3 Total Dose (Total Effective Dose Equivalent)

The TEDE doses are the sum of the EDE and the CEDE doses.

9A.3 General Analysis Parameters

9A.3.1 Source Terms

The sources of radioactivity for release are dependent on the specific accident. Activity may be released from the primary coolant, from the secondary coolant, and from the core if the accident involves fuel failures. The radiological consequences analyses use conservative design basis source terms.

9A.3.1.1 Primary Coolant Source Term

The accident dose analyses apply primary coolant source terms for iodines and noble gases consistent with the technical specification limits of 9.25E6 Bq/kg (0.25 μCi/g) dose equivalent I-131 for the iodines and 2.6E9 Bq/kg (70 μCi/g) dose equivalent Xe-133 for the noble gases. The alkali metals are based on continuous plant operation with 0.25-percent fuel defects. Table 9A-1 lists the concentrations of isotopes considered in the analyses.

The radiological consequences analyses for certain accidents also take into account the phenomenon of iodine spiking, which causes the concentration of radioactive iodines in the primary coolant to increase significantly. This is an iodine spike that occurs prior to the accident and for which the peak primary coolant activity is reached at the time the accident is assumed to occur. These isotopic concentrations are defined as 5.55E8 Bq/kg (15 μCi/g) dose equivalent I-131 (60 times the values listed in Table 9A-1). This corresponds to the short term abnormal operation technical specification limit. The probability of this adverse timing of the iodine spike and accident is small.

Although it is unlikely for an accident to occur at the same time that an iodine spike is at its maximum reactor coolant concentration, for many accidents it is expected that an iodine spike would be initiated by the accident or by the reactor trip associated with the accident. Table 9A-2 lists the iodine appearance rates (rates at which the various iodine isotopes are transferred from the core to the primary coolant by way of the assumed cladding defects) for normal operation. The iodine spike appearance rates are assumed to be as much as 500 times the normal appearance rates.

9A.3.1.2 Secondary Coolant Source Term

The secondary coolant source term used in the radiological consequences analyses is conservatively assumed to be 10 percent of the primary coolant equilibrium source term, consistent with the ratio of the primary and secondary technical specification limits for equilibrium iodine concentrations.

Because the iodine spiking phenomenon is short-lived and there is a high level of conservatism for the assumed secondary coolant iodine concentrations, the effect of iodine spiking on the secondary coolant iodine source terms is not modelled.

There is assumed to be no secondary coolant noble gas source term because the noble gases entering the secondary side due to primary-to-secondary leakage enter the steam phase and are discharged via the condenser air removal system.

9A.3.1.3 Core Source Term

Table 9A-3 lists the core source terms at shutdown for an assumed three-region equilibrium cycle at end of life after continuous operation at 1 percent above full core thermal power. The main feedwater flow measurement supports a 1-percent power uncertainty. In addition to iodines and noble gases, the source terms listed include nuclides that are identified as potentially significant dose contributors in the event of a degraded core accident. The design basis loss-of-coolant accident analysis is not expected to result in significant core damage, but the radiological consequences analysis assumes severe core degradation.

9A.3.2 Nuclide Parameters

The radiological consequence analyses consider radioactive decay of the subject nuclides prior to their release, but no additional decay is assumed after the activity is released to the environment. Table 9A-4 lists the half-lives for the nuclides of concern.

Table 9A-4 also lists the dose conversion factors for calculation of the doses.

The CEDE dose conversion factors (DCFs) model the dose due to inhalation of activity and the values are taken from Annex III of the 96/29/Euratom document (Reference 9A-2). Bounding values were selected.

The combined effect of the age-related dose conversion factors and breathing rates were evaluated and it was determined that the limiting child age range is the 1-2 year old child. Doses for other age ranges are not calculated.

The EDE DCFs model the dose due to submersion in a cloud of activity and the values are taken from the electronic supplement to U.S. Federal Guidance Report 13 (Reference 9A-3). Note that the EDE value listed for Cs-137 is that provided in Reference 9A-3 for Ba-137m. The Ba-137m value is much higher than that for Cs-137. Since Ba-137m is produced by the decay of Cs-137 and has a short half-life, the dose associated with its decay is included as being from Cs-137.

The DCFs for activity deposited on the ground are obtained from the electronic supplement to U.S. Federal Guidance Report 13 (Reference 9A-3). Note that, as with the EDE DCF, the value listed for Cs-137 is that provided for Ba-137m.

9A.3.3 Atmospheric Dispersion Factors

Table 9A-5 lists the off-site short-term atmospheric dispersion factors (χ/Q) for the reference site. The atmospheric dispersion factors (χ/Q) to be applied to air entering the main control room following a design basis accident are specified at the HVAC intake and at the annex building entrance (which would be the air pathway to the main control room due to ingress/egress). A set of reference AP1000 χ/Q values is identified for each potential activity release location that has been identified and the two control room receptor locations. These reference AP1000 χ/Q values are listed in Table 9A-6 and are provided in Table 2-1 (Sheet 3 of 3).

The site-specific control room χ/Q values shall be bounded by the values in Table 9A-6. For a site selected that has χ/Q values that exceed the values in Table 9A-6, how the radiological consequences associated with the controlling design basis accident continue to meet the control

room operator dose limits using site-specific χ/Q values should be addressed. Topographical characteristics in the vicinity of the site for restrictions of horizontal and/or vertical plume spread, channelling or other changes in airflow trajectories, and other unusual conditions affecting atmospheric transport and diffusion between the source and the receptors should be considered. No further action is required for sites within the bounds of the site parameters for atmospheric dispersion.

Table 9A-7 identifies the AP1000 source and receptor data to be used when determining the site-specific control room χ/Q values.

The main control room reference AP1000 χ/Q values do not incorporate occupancy factors.

The locations of the potential release points and their relationship to the main control room air intake and the annex building access door are shown in Figure 9A-1.

9A.4 Moisture Carryover

The moisture carryover is used to define the particulate (non-volatile) iodine and alkali metal releases from the steam generators. Moisture carryover at lower powers is much lower than the typical full power design value. Low power moisture carryover ranges from 10E-5 to 10E-4, depending on whether recirculating conditions are maintained. Recirculating conditions are assumed to be maintained when the water level is greater than 65% of the tube bundle height. From Reference 9A-4, the moisture carryover under non-recirculating conditions may be taken to be 10E-4 or 0.01%. However, it is also noted that moisture carryover increases when secondary relief valves are opened and that the maximum expected moisture carryover when the water level is below the dryer inlet is 0.05% and 0.4% when the water level is above the dryer inlet. To determine the moisture carryover fraction(s) modelled in each dose analysis, an assessment of the water level relative to the dryer inlet is made.

Thus, the moisture carryover is modelled as 0.05% unless the water level reaches the dryer inlet. If the water level reaches the dryer inlet the moisture carryover changes to 0.4%.

9A.5 Iodine Chemical Forms

The chemical form of iodine present is determined by whether or not reducing (i.e., excess hydrogen) conditions are maintained and whether oxygen is present. In the RCS, a reducing environment is maintained to limit corrosion. Under normal operating conditions the RCS H_2 concentration is maintained at >25 cc H_2 (STP)/kg H_2O, with STP defined as 0°C (32 °F) and 101.3 kPa (14.7 psia). The reducing environment, combined with the high electronegativity of iodine, will favour the formation of ionic iodine (I^-). Ionic iodine is the anionic component of iodine salts, such as CsI, which are particulates.

The design of the AP1000 significantly limits the introduction of oxygen to the RCS post-accident. In the AP1000 design, the CMT, which provides passive boration, is filled with heavily-borated primary reactor coolant at a pressure on the order of RCS operating pressure; as such, it is not open to the atmosphere and would not be a source of oxygen.

However, operation of the CVS is conservatively assumed to provide make up flow. The CVS makeup flow originates from the Boric Acid Storage Tank, which communicates with the atmosphere. Thus, the CVS is assumed to be a source of oxygen. Although the H_2 injection subsystem would be expected to be online when the H_2 concentration approaches 25 cc H_2 (STP)/kg H_2O, credit for the hydrogen injection system is not taken post-accident.

Consistent with Reference 9A-4, Section 4.4.4, the oxygen introduced via CVS is assumed to react stoichiometrically with Hydrogen (H_2) according to the equation:

$$H_2 + 0.5*O_2 = H_2O$$

Thus, the oxygen would act to decrease the hydrogen concentration with time. From Section 4.4.5 of Reference 9A-4, reducing conditions with respect to iodine are assumed to be lost when

$$[H_2]/[I] > 3.65E5$$

To conservatively estimate when reducing conditions are lost, the change in RCS H_2 and iodine concentrations are needed. After reducing conditions are lost, some of the oxygen entering the RCS is assumed to react with iodine, forming volatile iodine species.

Section 9A.5.1 presents the calculations of the RCS iodine concentration. Section 9A.5.2 presents the hydrogen concentration in the RCS. Section 9A.5.3 determines the assumptions to be applied with respect to iodine chemical forms modelled in the analysis.

9A.5.1 RCS Iodine Concentration

The concentration of RCS iodine vs. time can be calculated from the initial concentrations in t from Table 9A-1 and assumed spike rates and durations. Table 9A-1 considers I-130 though I-135, which are the iodine nuclides with the most significant dose impact. Additionally, more stable iodine nuclides (I-127 and I-129) must also be considered because the stable iodines dominate the mass of iodine in the primary coolant. Coolant concentrations of 4.55E-01 Bq/kg (1.23E-08 µCi/g) for I-129 and 1.32E-11 kg/kg for I-127 are used in the calculation of the RCS iodine concentration. The mass of iodine is calculated from the specific activities and half-lives as applicable. A total RCS iodine mass of 1.52E-02 g (3.351E-05 lbm) is calculated, dominated by I-129. Thus, 129 g/mol is taken as a representative molar mass for iodine, resulting in a calculated 1.18E-04 mol of iodine in the RCS.

An RCS mass of 1.684E5 kg (371,258 lbm) is used, consistent with the dose analysis assumptions. A density of 0.725 kg/L (45.26 lbm ft^{-3}) (reflecting expected operating condition) is used to calculate an RCS volume of 2.323E5 L (8204 ft^3).

With an RCS volume of 2.323E5 L, the molar concentration of iodine is 5.08E-10 mol/L.

9A.5.2 RCS Hydrogen Concentration

Under normal operating conditions, the RCS H_2 concentration is maintained at >25 cc H_2 (STP)/kg H_2O, with STP defined as 0°C (273 K) and 101.3 kPa. To calculate the molar concentration in the RCS (mol/L), the number of moles is needed as is the RCS volume.

H_2 is assumed to behave as an ideal gas, and the number of moles in 25 cc at the defined STP is calculated:

$n=PV/RT$

Where

P = 101.3 kPa

V = 25 cc (25 cm^3)

T = 273 K

R = 8.314E3 kPa*cm^3/mol*K

n is calculated to be 1.116E-03 mol, which is per kg H_2O in the RCS.

The RCS mass modelled is 1.684E5 kg, thus the total H_2 in the RCS is 1.879E2 mol.

The RCS volume was calculated to be 2.323E5 L.

The initial RCS H_2 concentration is calculated 1.879E2 mol / 2.323E5 L = 8.09E-04 mol/L.

9A.5.3 RCS Iodine Chemical Fractions

From Section 4.4.5 of Reference 9A-4, reducing conditions with respect to iodine are assumed to be lost when

$[H_2]/[I] > 3.65E5$

The initial H2 concentration was calculated as 8.09E-04 mol/L. Thus, reducing conditions are assumed to be lost when:

[I] > (8.09E-04 mol/L)/3.65E5

or

[I] > 2.22E-09 mol/L.

The calculated initial iodine concentration for the analysis was calculated as 5.08E-10 mol/L. It is apparent that any significant perturbation in iodine concentration (e.g. iodine spike or release from failed fuel) would cause the iodine concentration to increase above 2.22E-09 mol/L. Thus, it is conservatively assumed that reducing conditions are lost at the start of the event.

From the discussion in Section 4.4.5 and Figure 11 of Reference 9A-4, the maximum percentage of oxidized iodine is 0.07% at temperatures above 140 °C.

The RCS temperatures during the period of interest are well above 140°C, and thus, the maximum degree of oxidation expected is 0.07%. For conservatism, 0.1% of the iodine in the RCS is modelled as being in an oxidized (i.e., volatile) form. The volatile iodines will be assumed to be 97% elemental and 3% organic.

Note that, for additional conservatism, during periods where flashing of primary to secondary leakage is assumed, the amount of iodine assumed to be volatile is arbitrarily doubled to 0.2%.

9A.5.4 SG Iodine Chemical Fractions

Under normal operating conditions, reducing conditions are maintained in the SGs to limit corrosion. Unless SFW is running, the SGs are not fed post-trip, and thus there is no introduction of oxygen into the SGs. With SFW available, further oxidation of the iodide to convert it to the volatile form is possible with the added oxygen in the feedwater. However, this is insignificant owing to the rapid stripping of dissolved oxygen into the steam and low rate of thermal oxidation of iodide, as stated on page 35 in Reference 9A-4. Therefore, the iodine in the SGs is assumed to remain in a reduced (i.e., non-volatile particulate) form.

1. These dispersion factors are to be used 1) for the time period preceding the isolation of the main control room and actuation of the emergency habitability system, 2) for the time after 72 hours when the compressed air supply in the emergency habitability system would be exhausted and outside air would be drawn into the main control room, and 3) for the determination of control room doses when the non-safety ventilation system is assumed to remain operable such that the emergency habitability system is not actuated.
2. These dispersion factors are to be used when the emergency habitability system is in operation and the only path for outside air to enter the main control room is that due to ingress/egress.
3. These dispersion factors are used for analysis of the doses due to a postulated small line break outside of containment. The plant vent and PCS air diffuser are potential release paths for other postulated events (loss-of-coolant accident, rod ejection accident, and fuel handling accident inside the containment); however, the values are bounded by the dispersion factors for ground level releases.
4. The listed values represent modelling the containment shell as a diffuse area source, and are used for evaluating the doses in the main control room for a loss-of-coolant accident, for the containment leakage of activity following a rod ejection accident, and for a fuel handling accident occurring inside the containment.
5. The listed values bound the dispersion factors for releases from the steam line safety & power-operated relief valves. These dispersion factors would be used for evaluating the doses in the main control room for a steam generator tube rupture, a main steam line break, a locked reactor coolant pump rotor, and for the secondary side release from a rod ejection accident.
6. The listed values bound the dispersion factors for releases from the fuel storage and handling area. The listed values also bound the dispersion factors for releases from the fuel storage area in the event that spent fuel boiling occurs and the fuel building relief panel opens on high temperature. These dispersion factors are used for the fuel handling accident occurring outside containment and for evaluating the impact of releases associated with spent fuel pool boiling.
7. This release point is included for information only as a potential activity release point. None of the design basis accident radiological consequences analyses model release from this point.

Table 9A-7. Control Room Source/Receptor Data For Determination Of Atmospheric Dispersion Factors

Source Description	Release Elevation(1) m (ft)	Horizontal Straight-Line Distance To Receptor		
		Control Room HVAC Intake (Elevation 19.9 m [65.3 ft]) (Δ1)	Annex Building Access (Elevation 1.5 m [4.9 ft]) (Δ2)	Comment

9B Code Verification and Validation

9B.1 Introduction

The description of the design basis analysis of bounding faults presented in the main body of Chapter 9 shows that the analyses utilise computer codes extensively to demonstrate compliance with AP1000 plant design criteria. Assurance of the validity of such analyses relies on systematic and thorough verification and validation of the computer codes employed. The HSE nuclear division (ND) technical assessment guide T/AST/042 (Reference 9B-1) defines verification and validation as follows:

- **Verification** is the process of ensuring that the controlling physical equations have been correctly translated into computer code or, in the case of hand calculations, correctly incorporated into the calculational procedures.

- **Validation** is the testing and evaluation of the whole system at the completion of its development to ensure compliance with the requirements specified. In fault analysis, validation can be defined as the evidence which demonstrates that the computer code or calculational method is correct by comparison of models with experimental or other available data.

The term evaluation model (EM) is used for the calculational framework for evaluating the behaviour of the reactor system during a postulated transient or design-basis accident. As such, the EM may include one or more computer programmes, special models, and all other information needed to apply the calculation methodology to a specific event. Most EMs used to analyse transient events rely on a systems codes that describe the transport of fluid mass, momentum, and energy throughout the reactor coolant systems. The extent and complexity of the physical models needed in the systems code are strongly dependent on the reactor design and the transient being analysed. Often a general purpose systems code may be developed to address similar phenomenological aspects of several diverse classes of transients. This presents unique challenges in the definition, development, assessment, and review of those codes as they apply to a particular transient EM. The NRC refers to the latter activities under the acronym EMDAP (Evaluation Model Development and Review Process) and has issued guidelines as to how this should be conducted and due process demonstrated. EMDAP comprises four sequential elements, which enable a decision to be made concerning the adequacy of the EM (see Figure 9B-1).

The development of a phenomena identification and ranking table (PIRT) is a significant component of element 1 of the EMDAP process. The PIRT provides a means to identify and classify, in terms of importance, the thermal-hydraulic phenomena expected to occur in transients and accidents that must be included in the analytical models, and for which data must, therefore, be available to evaluate those analytical models. Section 2 of WCAP-15613 (Reference 9B-2) contains separate PIRTs for LBLOCAs, SBLOCAs, and non-LOCA transients for the AP1000 plant design, as well as those for the AP600 plant design.

Element 2 of EMDAP requires the establishment of an adequate experimental database for the EM assessment and development process. In particular, separate effects experiments are needed to develop and assess empirical correlations and other closure models used within the EM. Also, integral systems tests are undertaken to assess system interactions and global code capability. It needs to be demonstrated that the experimental facilities used to obtain relevant data are scaled appropriately to minimise any distortions introduced by the reduction in geometrical size.

For PWR systems in general, few full scale (geometrical) primary circuit transient experiments have been performed (largely on grounds of rig construction and operating costs) and consequently the majority of the pertinent integral experimental data has been obtained at smaller scales. Even where, in some cases, the experimental rig has been engineered to replicate the scale of the full size plant in one dimension (e.g., by retaining full height to faithfully replicate gravitational effects), design constraints dictate a reduction in scale in the other two dimensions. The effect of scaling is therefore an important issue and the objectives of scaling analysis are to identify:

(a) Design parameters for reduced-size test facilities;

(b) Conditions for operating experiments, such that at least the dominant phenomena taking place in the full-size plant are reproduced in the experimental facility, over the range of plant conditions;

(c) Non-dimensional parameters which facilitate the efficient and compact presentation and correlation of experimental results which, by virtue of similarity and the parameter selection, apply to many systems, including both the test facility and the full-size plant;

(d) The extent of scale distortion and the uncertainty that this may introduce in assessments made using the EM.

A number of methodologies which aim to meet the objectives (a) to (d) above have been described in the literature. The approach used initially for AP600 and latterly for AP1000, has followed Zuber's H2TS system. H2TS is the scaling method expounded by Zuber (References 9B-3 and 9B-4), originally for severe accident type scenarios, but it has a very general applicability to complex systems. Zuber's presentation of the methodology (References 9B-3 and 9B-4) is generalised and consequently is not easy to follow in terms of its direct applicability to PWR analysis. The application of the principles however, was placed on a firmer foundation by Reyes (Reference 9B-5) in the context of the scaling analysis of the OSU AP600 test facility APEX. Further work extended the scaling analysis to AP1000 (Reference 9B-6).

The development of the EM model, which includes aspects such as the model representation of the plant or individual components and nodalisation scheme, are included within element 3.

Element 4 of EMDAP covers the appropriate comparisons between experiment and calculation that establish the extent of the applicability, fidelity, accuracy, and scalability of the EM for its intended purpose.

It is considered that EMDAP fully addresses the following principles relating to the assurance of validity of data and models as identified in the ONR SAPs (Reference 9B-7).

AV.1 Theoretical models should adequately represent the facility and site.

AV.2 Calculational methods used for the analyses should adequately represent the physical and chemical processes taking place.

AV.3 The data used in the analysis of performance with safety significance should be shown to be valid for the circumstances by reference to established physical data, experiment or other appropriate means

AV.6 Studies should be carried out to determine the sensitivity of the analysis (and the conclusions drawn from it) to the assumptions made, the data used and the methods of calculation.

The following sections of this appendix provide a brief summary of the codes used to perform design basis fault transient analysis and provide the link to external documented evidence (as required by SAP AV.5) that should facilitate independent review of the adequacy of the EM models and data. Quality assurance procedures implemented by Westinghouse for computer models and datasets used to support the analysis (as required by SAP AV.4) are outlined. Provision for data collection throughout the operational life of a facility (SAP AV.7) and update and review of the fault analysis (SAP AV.8) is also mentioned.

9B.2 Brief Description of Codes Used in Fault Studies Analysis

9B.2.1 LOFTRAN

The LOFTRAN (Reference 9B-8) programme is used for studies of transient response of a pressurised water reactor system to specified perturbations in process parameters. LOFTRAN simulates a multi-loop system by a model containing reactor vessel, hot and cold leg piping, steam generator (tube and shell sides), and pressuriser. The pressuriser heaters, spray, and safety valves are also considered in the programme. Point model neutron kinetics, and reactivity effects of the moderator, fuel, boron, and rods are included. The secondary side of the steam generator uses a homogeneous, saturated mixture for the thermal transients and a water level correlation for indication and control. The protection and safety monitoring system is simulated to include reactor trips on high neutron flux, over temperature ΔT, high and low pressure, low reactor coolant flow, and high pressuriser level. Control systems are also simulated, including rod control, turbine bypass, feedwater control, and pressuriser level and pressure control. The emergency core cooling system, including the accumulators, is also modelled. LOFTRAN is a versatile programme, suited to accident evaluation and control studies, as well as parameter sizing. LOFTRAN also has the capability of calculating the transient value of DNBR based on the input from the core limits. The core limits represent the minimum value of DNBR as calculated for typical or thimble cell. The LOFTRAN code is modified to allow the simulation of the PRHR heat exchanger, CMTs, and associated protection and safety monitoring system actuation logic.

A discussion of these models and additional validation is presented in WCAP-14234 (Reference 9B-9).

9B.2.2 FACTRAN

FACTRAN (Reference 9B-10) calculates the transient temperature distribution in a cross section of a metal-clad UO2 fuel rod and the transient heat flux at the surface of the cladding using as input the nuclear power and the time-dependent coolant parameters (pressure, flow, temperature, and density). The code uses a fuel model which simultaneously exhibits the following features:

- A sufficiently large number of radial space increments to handle fast transients such as rod ejection accidents

- The necessary calculations to handle post-DNB transients: film boiling heat transfer correlations, zircaloy-water reaction, and partial melting of the materials

FACTRAN is further discussed in WCAP-7908-A (Reference 9B-10).

9B.2.3 NOTRUMP

NOTRUMP (References 9B-18 and 9B-19) is a general one-dimensional nodal network code. NOTRUMP is used in the analysis of DBA small and medium break LOCAs in the reactor coolant system. A detailed description of the code as it relates to these analyses is presented in Section 9.6.5.2.1.

In ATWT analyses, NOTRUMP is used to calculate steam generator tube bundle heat transfer degradation as inventory is depleted in the secondary-side of the steam generator and to correlate steam generator inventory with actual and measured secondary-side level.

Important phenomena for calculating steam generator transients are addressed in NOTRUMP and include single and two-phase flow, heat transfer through the steam generator tube bundle, critical flow, and special steam generator separator models for mechanical separation of fluid phases. The code-modelling concept is one of using multiple independent fluid control volumes (nodes) interconnected by appropriate flow paths (flow links) to allow mass and energy exchange. NOTRUMP uses a control volume model that has options to simulate either a single homogeneous region within a control volume or two separate regions (upper and lower regions) within a control volume including a distinct mixture level. The volume of each of the regions within a control volume can vary with time and the regions can be in thermal non-equilibrium with each other. Flows and pressure drops associated with the flow paths are applied one-dimensionally between the control volumes. The flow path model includes options for calculating the pressure drop for cross flow and parallel flow in a steam generator tube bundle. The NOTRUMP code includes many slip and drift flux correlations which are used to calculate the flow quality in the flow paths.

In the ATWT NOTRUMP model, the primary side of the steam generator tube bundle, the heat transfer through the tube walls, and the secondary side of the steam generator is simulated. Heat transfer from the tube bundle into control volumes is determined from the local primary and secondary-side control volume fluid conditions and tube wall characteristics. The code includes heat transfer correlations appropriate for single-phase convection heat transfer and pool-boiling heat transfer. Boundary conditions to the NOTRUMP steam generator model are supplied by the system code LOFTRAN. The boundary conditions consist of the reactor coolant flow, temperature and pressure entering the primary side of the steam generator tubes. On the secondary side of the NOTRUMP steam generator model, feedwater flow and steam system flow are supplied as boundary conditions.

9B.2.4 VIPRE-01

The VIPRE-01 core model as approved by the NRC (Reference 9B-11) is used with the applicable DNB correlations to determine DNBR distributions along the hot channels of the reactor core under all expected operating conditions. The VIPRE-01 modelling method is described in Reference 9B-11, including empirical models and correlations used. The effect of crud on the flow and enthalpy distribution in the core is not directly accounted for in the VIPRE-01 evaluations. However, conservative treatment by the Westinghouse VIPRE-01 modelling method has been demonstrated to bound this effect in DNBR calculations (Reference 9B-11).

Extensive additional experimental verification of VIPRE-01 is presented in Reference 9B-12. The VIPRE-01 analysis is based on a knowledge and understanding of the heat transfer and hydrodynamic behaviour of the coolant flow and the mechanical characteristics of the fuel elements. The use of the VIPRE-01 analysis provides a realistic evaluation of the core performance.

VIPRE-01 is capable of transient DNB analysis. The conservation equations in the VIPRE-01 code contain the necessary accumulation terms for transient calculations. The input description can include one or more of the following time dependent arrays:

1. Inlet flow variation
2. Core heat flux variation
3. Core pressure variation
4. Inlet temperature or enthalpy variation

At the beginning of the transient, the calculation procedure is carried out as in the steady state analysis. The time is incremented by an amount determined either by the user or by the time step control options in the code itself. At each new time step the calculations are carried out with the addition of the accumulation terms which are evaluated using the information from the previous time step. This procedure is continued until a pre-set maximum time is reached. At time intervals selected by the user, a complete description of the coolant parameter distributions, as well as DNBR, is printed out. In this manner the variation of any parameter with time can be readily determined.

The VIPRE-01 code is described in detail in Reference 9B-12, including discussions on code validation with experimental data.

9B.2.5 WGOTHIC

WGOTHIC is used for the licensing basis analyses of LOCA and secondary side high energy line breaks to predict containment temperatures and pressures. WGOTHIC is also used to predict containment temperature and pressure increases due to mass and energy releases to the containment during other non-LOCA and ATWT events. During non-LOCA and ATWT events, heat transfer through the PRHR heat exchanger into the IRWST can cause steaming from the IRWST into containment. Fluid releases through the pressuriser safety valves into the containment may occur during ATWT events.

The Westinghouse GOTHIC (WGOTHIC) computer code (Reference 9B-13) is a computer programme for modelling multiphase flow in a containment transient analysis. It solves the conservation equations in integral form for mass, energy, and momentum for multi-component flow. The momentum conservation equations are written separately for each phase in the flow field (drops, liquid pools, and atmosphere vapour). The following terms are included in the momentum equation: storage, convection, surface stress, body force, boundary source, phase interface source, and equipment source.

To model the passive cooling features of the AP1000, several assumptions are made in creating the plant input. The external cooling water does not completely wet the containment shell; therefore, both wet and dry sections of the shell are modelled in the WGOTHIC analyses. The analyses use conservative coverage fractions to determine evaporative cooling. Heat conduction from the dry to wet section is considered in the analysis. The combination of passive containment cooling system coverage area and heat conduction from the dry to wet sections is explained in Chapter 7 of Reference 9B-13. The effects of water flowing down the shell from gravitational forces are explicitly considered in the analysis. The passive internal containment heat sink data used in the WGOTHIC analyses is presented in Reference 9B-13, Chapter 13. Data for both metallic and concrete heat sinks are presented.

9B.2.6 RELAP

The RELAP family of codes was developed to perform analyses of postulated accidents in nuclear power plants. The RELAP5 (Reference 9B-14) computer code performs calculations

to simulate multi-dimensional thermal-hydraulics, heat transfer, and control systems. The thermal hydraulics behaviour under single phase and two phase conditions is simulated. The hydrodynamics models track the flow of liquid, vapour and non-condensable gases. RELAP5 includes component models of valves, separators, dryers, pumps, electric heaters, turbines, and accumulators. The control system models include functions for trip logic and arithmetic functions for simulation of system filters.

Some of the non-LOCA events, such as loss of reactor coolant flow, have a small amount of steam voids generated in the core. The LOFTRAN model assumes homogeneous flow in the RCS outside the reactor vessel. The validity of the LOFTRAN model for these cases has been verified by analysis with RELAP or a LOCA code such as NOTRUMP.

For RCS depressurisation, a LOCA code such as RELAP is used when void formation in the RCS goes beyond the point where LOFTRAN is useful.

9B.2.7 TWINKLE

This multidimensional spatial neutronics code uses an implicit finite-difference method to solve the two-group transient neutronics equations in one, two, and three dimensions. TWINKLE (Reference 9B-15) can be used to calculate the kinetic response of a reactor for transients, such as the RCCA bank withdrawal from subcritical conditions and RCCA ejection events, which cause a major perturbation in the spatial neutron flux distribution. As documented in Reference 9B-15 the NRC has approved this code for operating Westinghouse plants. Since the AP1000 fuel design is similar to that of operating Westinghouse plants (i.e., falls within the NRC-approved applicable range of the code), the application of the TWINKLE code to the AP1000 for analysis of kinetic responses is acceptable.

9B.2.8 WCOBRA/TRAC

WCOBRA/TRAC is a thermal-hydraulic computer code that calculates realistic fluid conditions in a PWR during the blowdown and reflood of a postulated large-break LOCA. The methodology used for the AP1000 analysis is documented in WCAP-12945-P-A, WCAP-14171, Revision 2, WCAP-16009-P-A (References 9B-20, 9B-21 and 9B-22), and Reference 9B-23.

WCOBRA/TRAC is used in the analysis of Large Break LOCAs and a description of the code is presented in Section 9.6.4.1.1.

9B.2.9 Data Transfer Between Codes

See Figure 9B-2.

9B.3 Code Validation and Verification

Reference 9B-17 documents an assessment performed by Westinghouse of the safety analysis codes that were developed and approved for the AP600 plant to determine their applicability and use for the AP1000 plant. The analysis codes that were approved for the purpose of performing safety analyses of the AP600 passive plant are:

- LOFTRAN – transient analyses
- NOTRUMP – small-break LOCA analyses
- WCOBRA/TRAC – large-break LOCA and long-term cooling analyses
- WGOTHIC – containment analyses

9B.4 Quality Assurance Arrangements

The Westinghouse Quality Management System and Westinghouse Level 2 Policies and Procedures provide the governing procedures, including those for software control. The Level 2 software control procedures include processes for development, validation, configuration control, software error reporting, and maintenance. These procedures are utilised for all safety-related software applications, such as the safety analysis codes.

9B.5 Ongoing Data Collection Throughout Facility Life

A database of inputs to the safety analyses has been created for the standard plant and can be maintained on a plant-specific basis. Changes to the safety analysis data can be evaluated via the safety evaluation process.

9B.6 Update and Periodic Review of Safety Analysis

Safety analyses can be reviewed periodically, typically on a reload basis, for important reload parameter changes and for errors that have been identified.

9C Assessment of Safe Shutdown for Design Basis Faults

9C.1 Introduction

This appendix demonstrates the ability of the AP1000 plant to achieve a safe shutdown state following design basis faults. The short term mitigation of design basis faults is presented in the various detailed accident analyses contained within Chapter 9. This appendix shows that the plant can transition from the conditions after short term mitigation to a safe shutdown state.

Table 8A-2 lists all of the AP1000 design basis faults. For these faults, the plant will eventually reach one of two different end states, considering the type of initiating event and the Class 1 passive systems used to mitigate the event. Those two end states are:

1. The RCS pressure boundary is intact with closed loop cooling provided by the PRHR HX

2. The RCS pressure boundary is not intact with open loop cooling provided by ADS and PXS injection

End state 1 usually occurs after intact circuit (i.e., non-LOCA) faults, such as loss of main feedwater. However, it also occurs after a SGTR; this fault generally behaves like an intact circuit fault because the PRHR HX operation automatically terminates the RCS leak into the SG.

End state 2 usually occurs after open circuit faults such as LOCAs. However, it is also the credited diverse means of core cooling for frequent fault intact circuit faults. This diverse means of core cooling for intact circuit faults uses the same SSCs that are used for the non-intact circuit faults except for the C&I functionality, where DAS is used instead of PMS. Because of the design of DAS, some actuations are manual. There is a variation in end state 2 that applies to frequent fault small-break LOCAs, which relies on the use of the Class 2 RNS for injection and diverse portions of the Class 1 passive features.

Section 9C.2 describes the operation of different systems and components used in achieving safe shutdown for these faults. This section includes discussion on the primary Class 1 passive SSCs as well as the limited use of Class 2 SSCs to support claims for diverse mitigation of frequent faults.

Limiting faults have been analysed in order to bound all other design basis faults. Section 9C.3 describes the behaviour and analysis results of the AP1000 plant during mitigation of faults on the path to reaching safe shutdown. UKP-PXS-GLR-001 (Reference 9C-1) summarizes the basis supporting the condensate return analysis including relevant documentation regarding identification of important phenomena, design changes, and analyses demonstrating long term PRHR HX operation.

Note that the AP1000 plant has a list of operating modes that are used in the Technical Specifications (see Table 8A-1). One of those modes is called “Safe Shutdown”. This mode only applies to normal operation and does not apply to post faults conditions; as a result, it does not apply to the safe shutdown discussion in this appendix.

9C.1.1 Safe Shutdown Considerations

Acceptance Criteria

Chapter 9 presents the accident analyses for design basis faults that challenge the reactor from a thermal hydraulic perspective. At the end of each of these analyses the plant has achieved a safe, stable state with the reactor subcritical and all applicable safety criteria limits met. These short-term acceptance criteria vary based on the initiating event, and are summarised in Table 9.0-3; additionally, they are clarified as part of each individual analysis discussion throughout Chapter 9.

Following the end of these accident analyses, it is required to demonstrate that the plant transitions to the safe shutdown condition. This transition involves reducing the RCS temperature to less than 216ºC (420ºF) while maintaining the reactor subcritical and continuing to satisfy all other applicable safety criteria, as noted above. Regardless of initiating event, once the plant reaches an open loop cooling state, core cooling is maintained for an indefinite time.

As intact circuit faults may eventually require open loop cooling in the event that offsite power is not restored after an extended duration, the acceptance criteria for these faults (Table 9C.3-4) also includes the ADS actuation criteria. This progression from intact RCS conditions with the PRHR HX removing decay heat to open loop cooling with operation of ADS and passive injection is always available. The emergency procedures direct the operators to initiate open loop cooling in the longer term based on specific plant parameters, primarily high RCS temperature or pressure (Reference 9C-4).

Transition Time to Safe Shutdown

The duration of the cooldown for the plant to transition from this safe, stable state in the short-term to the final safe shutdown condition varies based on the initiating event. Some transition times include:

1. Infrequent fault LOCAs (breaks greater than 5.1 cm [2 inch]) – Less than 1 hour
2. Frequent fault small-break LOCAs (and RCS leaks) - Several hours to several days
3. Intact circuit faults – More than 72 hours

All of these transition times are demonstrated to be safe and are considered adequate.

Consequential Faults While At Safe Shutdown Conditions

There is a potential concern with long transition times in that there may be a risk of an independent event occurring during that time. However, most initiating events are not applicable once the reactor is shutdown and passive Class 1 SSCs are in use. Examples of such faults include:

- Loss of offsite power
    - The reactor and the RCPs are shutdown and AC power is not used to support passive system operation
- Loss of non-Class 1 systems required for normal plant operation such as main feedwater, condenser cooling, auxiliary cooling water systems, HVAC, instrument air, etc.

  - None of these non-Class 1 systems are used to support passive system operation

- Reactivity faults such as RCCA withdrawal, boron dilution, etc.
  - The RCCAs are inserted and boron dilution sources are isolated.

The remaining fault of concern is a LOCA occurring following an intact circuit fault with extended loss of ac power. Smaller LOCAs, the most likely fault based on event frequency, have an initiating event frequency in the range of 1E-03 to 1E-04 per year (Table 8A-2). If the RCS remained near normal operating pressures and temperatures for an extended time following an intact circuit fault, a small LOCA might occur. However, the risk of a small LOCA occurring following an intact circuit fault is acceptably low based on the following:

- Assuming conservative, bounding intact circuit operation (including high decay heat and minimum PRHR performance) the RCS temperature will be near normal hot standby temperatures and the RCS pressure will drop to about saturation, less than 11.0 MPa (1600 psia) (Reference 9C-1). However, the plant will eventually see an increase in the RCS pressure and temperature due to a decrease in the IRWST level and uncovery of the PRHR tubes; Supporting analyses discussed in Reference 9C-1 indicate this could occur in approximately 7 days or longer. The plant operators would then manually initiate passive feed and bleed operation based on their emergency procedures.
- Assuming realistic intact circuit operation (including expected decay heat and PRHR performance) the RCS temperature and pressure would reduce to a significantly lower value (less than the safe shutdown temperature of 216ºC [420ºF]) within 36 hours. This condition can be maintained for greater than 14 days, and supporting analyses discussed in Reference 9C-1 indicate approximately 30 days or longer. Eventually, the RCS pressure and temperature will increase due to a decrease in the IRWST level and uncovery of the PRHR tubes.

It should also be recognized that operation of the PRHR during intact circuit faults is considered a success path in Chapter 8 and in the PSA. In both Chapter 8 frequent fault sequences and in the PSA, the PRHR is claimed as a success path and open loop passive feed and bleed is a diverse backup. In both of these situations the use of realistic analysis assumptions is appropriate. Also note that Reference 9C-1 shows that the probability of the PRHR operation duration being limited by conservative bounding assumption is very low and need not be considered in either of these situations.

9C.2 Required SSCs to Achieve Safe Shutdown

This section describes the different SSCs that are used to establish safe shutdown conditions for the plant following different types of initiating events. Generally, these SSCs are actuated automatically and no operator actions are required. The Class 1 SSCs relied upon for safe shutdown are listed in Table 9C.1-1. The limited Class 2 SSCs relied upon for diverse safe shutdown capabilities are included in Tables 9C.3-1 and 9C.3-2. Additionally, the AP1000 plant design also has defence in depth features that can support safe shutdown; however, they are not credited in the deterministic UK safety case and are provided as a demonstration of additional means of protection.

9C.2.1 Safe Shutdown Using Primary and Diverse Means

Class 1 passive systems provide the primary means to achieve safe shutdown. For frequent faults, which require a diverse means, different SSCs are required. For the AP1000 plant

design, these different SSCs are generally other Class 1 SSCs. There are a few exceptions where a few Class 2 SSCs are credited with different Class 1 SSCs in the diverse means to achieve safe shutdown.

When only Class 1 safety systems are credited, offsite electrical power sources are not essential and are assumed to be lost during the event. This results in a loss of the reactor coolant pumps. With loss of the reactor coolant pumps, reactor coolant system natural circulation flow initiates and transfers core heat to the steam generators. Although feedwater flow is lost, the existing steam generator water inventory provides initial decay heat removal capability. With the loss of main ac power, the Class 1 dc batteries are relied upon to supply power to the Class 1 dc power distribution network and the four Class 1 ac instrumentation divisions via the inverters.

The following sections describe the use of Class 1 safety systems to provide the primary and diverse means of achieving and maintaining safe shutdown.

9C.2.1.1 Safe Shutdown for Intact Circuit Faults with Class 1 SSCs, Primary Means

Note that power from the four Class 1 batteries is not required for this intact circuit fault since all of the passive means associated with the primary Class 1 systems fail to their safe conditions on loss of dc power. This includes the PRHR HX, CMTs, and PCS.

If the Class 1 dc power is not lost, the PRHR HX is actuated by the PMS due to low steam generator water level. The PRHR HX removes decay heat from the core by transferring this heat to the IRWST. Initially, the PRHR HX does not completely match the decay heat and as a result some heat is removed by steaming of the initial SG inventory through the SG safety valves. Once the decay heat level drops below the PRHR HX capacity, steaming from the SG will stop and the RCS temperature will begin to decrease.

As the RCS cooldown continues, the RCS pressure decreases due to contraction of the RCS inventory since the pressuriser heaters are de-energised. An engineered safety system actuation signal occurs when pressuriser pressure decreases below a setpoint. This actuates the CMTs, if they had not been previously actuated due to a low pressuriser level. The CMTs provide borated water injection to the RCS. The injection of boron supplements the control rods, RCS cooldown compensates for decay of xenon and other poisons.

The engineered safety function actuation signal generated on low pressuriser pressure also actuates containment isolation. Note that the containment isolation valves that are connected directly to the RCS or to the containment atmosphere are also fail safe (closed) valves. This prevents loss of water inventory and any release of radioactive materials from containment and permits long-term operation of the PRHR HX.

The IRWST starts to boil approximately four hours after PRHR HX operation is initiated. Once boiling occurs, the IRWST begins steaming to containment which transfers heat to the containment atmosphere and also to the containment shell. This steaming causes the containment pressure to increase and automatically actuates the PCS on a high containment pressure signal. When the setpoint is reached, this signal opens the valves that allow water to drain from the PCCWST onto the outside of the containment shell which provides heat removal from the containment through evaporative cooling to the outside air. Note that the challenge to the passive containment cooling capability for this sequence is much less than for the limiting challenge to the containment, which comes from a large LOCA that releases a higher amount of mass and energy in containment. The performance of the PCS during the

limiting faults is demonstrated in Appendix 9D. Since the challenge to the PCS is much less during intact circuit faults, additional discussion is not necessary.

The PCCWST is sized for 72 hours. After 72 hours, more water will be transferred to the PCCWST by small pumps (either installed or brought in from offsite).

Gutters located at several elevations in the containment (operating deck, stiffener and polar crane girder) collect condensate from the inside of the containment shell. Pipes connected to those gutters normally drain the condensate to the containment waste sump. A PRHR HX actuation signal closes redundant fail safe valves in this line to divert the condensate back to the IRWST. The return of condensate to the IRWST provides for long-term operation of the PRHR HX.

Once the RCS and the safety systems are in this configuration, the plant is in a safe, stable shutdown condition. Section 9C.3.1.1 shows that with conservative design basis assumptions, the PRHR HX can maintain the plant in a safe stable state for at least 72 hours. In addition, as discussed in Section 9C.1.1, the RCS temperatures and pressures are expected to slowly decrease, reaching 216°C (420°F) within 36 hours based on realistic assumptions (Reference 9C-1). This reduced temperature condition is expected to be maintained for greater than 14 days. Note that the duration of operation in this condition can be limited by RCS leakage (see 9C.3.2) or by the fraction of IRWST steam condensate returned to the IRWST.

Four 24 hour Class 1 dc batteries provide power to actuate the ADS, IRWST injection and containment recirculation valves for at least 24 hours. There is a timer that measures the time that ac power sources are unavailable. This timer provides for automatic actuation of these valves before the 24 hour Class 1 dc batteries are discharged. The emergency response guidelines direct the operator to assess the need for ADS before the timer completes its count (approximately 22 hours). The operator assessment considers CMT level, and RCS hot leg level, temperature, and pressure. If ADS is not needed, the operator is directed to de-energise all loads on the 24 hour Class 1 dc batteries. This action preserves the capability for the operator to initiate ADS at a later time based on assessment of the same parameters.

Note that the CMTs can only supply a limited amount of makeup in the event there is RCS leakage. Eventually the volume of the water in the CMTs will decrease to the first stage ADS setpoint. With normal RCS leak rates it is expected that the CMTs can make up for the leakage for many weeks. However, if there was an abnormally high RCS leak the operators could conclude (at 22 hours) that there will be a need for ADS in the near future and not take action to de-energise the battery loads.

Some of the IRWST steam condensate will not return to the IRWST. Over time, these losses will reduce the IRWST water level and the PRHR HX heat transfer. Reference 9C-1 provides an evaluation of how this loss affects IRWST water level and as a result the PRHR HX and resultant plant performance. This evaluation shows that the PRHR HX is expected to be able to operate for greater than 14 days before the PRHR HX heat removal would fall behind decay heat and ADS might be needed.

When the four actuation battery loads are de-energised, the operators would monitor the RCS conditions using power from two Class 1 batteries which are sized for 72 hours. After 72 hours, if normal ac power (offsite or onsite) was not recovered, power would be provided by two, small diesel generators (either the installed Ancillary DGs or DGs brought in from offsite).

If the RCS conditions degraded sufficiently (i.e. RCS temperature or pressure increased above values specified in the procedures) the operators would re-connect the four Class 1 batteries and allow the PMS cabinets to actuate ADS, IRWST injection and containment recirculation. These actuations would maintain the plant in safe shutdown using an open loop cooling process. The discussion that follows on non-intact circuit faults provides more detail on this mode of operation.

The ADS can be manually initiated by the operator at any time, but no operator action is needed to provide safe shutdown conditions. Once the ADS sequence initiates, the plant automatically transitions to lower pressure and temperature conditions that establish and maintain long term safe shutdown of the plant.

9C.2.1.2 Safe Shutdown for Intact Circuit Faults with Class 1 SSCs, Diverse Means

The above discussion also applies to the primary mitigation of a frequent intact circuit fault. In addition, frequent faults also require another, diverse means of mitigation. This section describes a situation where following an intact circuit frequent fault, there has been a low probability CCF affecting the primary means (Class 1 passive systems) of achieving safe shutdown. Such CCFs need only be considered for frequent faults. If such a low probability CCF occurred, different Class 1 passive systems can be used to bring the plant to a safe shutdown. Table 9C.3-1 lists these systems. Note that Table 9C.3-1 treats the systems used to provide the primary and the diverse means as two separate groups. This is a conservative approach and is not necessary since there is no single CCF could cause all of the primary systems to fail. For example, a CCF could cause the PMS to fail but that CCF would not affect the mechanical parts of the passive fluid systems; in this case the DAS would automatically actuate the same systems that PMS would have actuated for an intact circuit fault (PRHR, CMT, and PCS).

The diverse means to achieve safe shutdown following an intact circuit fault uses a passive feed-and-bleed approach. The bleed, release of RCS energy, is performed by manual actuation of the ADS. The feed, RCS inventory makeup, is performed by the accumulators and IRWST gravity injection. In the long term, when the IRWST reaches a low level, recirculation from the containment will be started. These features provide core cooling, long-term reactivity control, and RCS inventory control sufficient to bring the plant to safe shutdown conditions.

As indicated above, diversity is required in the safety functions credited in mitigating frequent faults. Table 8A-4 lists the features that provide this diversity. Note that for the AP1000 plant, the ultimate heat sink is provided by the PCS for both the primary and the backup diverse cases. This is acceptable because there is no CCF that can cause the PCS to fail to meet its diverse cooling requirements. Section 8A.1 provides a more detailed discussion of the diverse aspects of the PCS design and operation.

9C.2.1.3 Safe Shutdown for Non-Intact Circuit Faults with Class 1 SSCs, Primary Means

The Class 1 passive safety systems identified in Table 9C.3-2 bring the plant to a controlled state following a LOCA. These same systems also bring the plant to a safe shutdown state. This discussion bounds the system operation for different size and location LOCAs.

In the event of a LOCA, operation of the PRHR HX will be limited; once ADS is actuated the PRHR HX becomes in-effective. In such a fault, open loop reactor cooling and inventory control is provided by the ADS and PXS water injection tanks. Note that this mode is also applicable to excessive RCS leak situations, where the CMT inventory drops to the ADS

stage 1, 2, and 3 setpoint at a later time than for a LOCA; depending on the leak rate ADS could be actuated anywhere between a half of a day out to several weeks.

The CMTs provide RCS injection at high pressures. For small LOCAs, they start injecting in recirculation mode without draining. If the CLs void, the CMTs will start to drain with a higher flow rate. When the CMT level decreases to a low level setpoint, level sensors in the tanks actuate ADS stages 1, 2, and 3. This signal automatically actuates the first stage depressurisation valves, which initiates the RCS depressurisation sequence. The second and third stage depressurisation valves open in turn, based on automatic timers that are started upon the actuation of the first stage depressurisation valves. The water and steam vented from the RCS flows into the IRWST and the steam is initially condensed. As this operation continues, water will overflow into the refuelling canal and then into the containment. This overflow initiates the floodup of containment.

The RCS pressure decreases due to ADS operation and the LOCA break, which allows for the accumulators to inject borated water into the RCS. The accumulators inject for a limited duration (several minutes). When the volume of the water in the CMTs decrease to the fourth stage automatic depressurisation system setpoint, the fourth stage depressurisation valves and the IRWST injection valves are opened. The fourth stage ADS valves reduce RCS pressure sufficiently so that IRWST injection can begin as the CMTs empty. The CMT drain down injection duration lasts for about [ ].

The drain down of the IRWST is relatively slow, taking several hours. As the IRWST continues to inject, the floodup level in the containment rises and eventually reaches a level that can provide for natural circulation flow from the containment into the RCS. When the IRWST level drops to nearly empty, the containment recirculation valves automatically open to allow for containment recirculation.

The final long term safe shutdown plant conditions are maintained with the RCS depressurised to about [ ] at saturated conditions, venting steam through the ADS valves to containment, with heat transferred to the outside atmosphere via the PCS. Note that by the time IRWST injection begins, the RCS pressure has been reduced to about [ ] and since the RCS coolant will be saturated, its temperature will be at approximately [ ]. As a result, the plant will be in safe shutdown conditions. Containment isolation maintains the water inventory inside containment and provides for an indefinite cooling water supply for core decay heat removal.

In this mode of operation (with the RCS open and containment recirculation by Class 1 passive core cooling means), the only change that can occur is a slight reduction in the containment water level caused by water leaking into a couple of rooms that don't initially flood. Section 9.6.6 describes this reduction in water level and its timing.

9C.2.1.4 Safe Shutdown for Non-Intact Circuit Faults with Class 1 SSCs, Diverse Means

There are three different non-intact circuit frequent faults. Because of their high frequency they are classified as DB2 faults and as a result require diverse mitigation.

- Small LOCAs (<5.1 cm [2"])
- RCS leaks with failure of CVS makeup
- SGTRs

The RCS leak fault is not discussed further since it is bounded by the small LOCA case. The SGTR systems operation is not discussed further since it is identical to intact circuit faults; note that the concern over back flow from the SG diluting the RCS boron concentration is addressed separately in the results section (See Section 9C.3.3).

For small LOCA frequent faults, three different sets of SSCs have been defined to provide diverse core cooling considering a single common cause failure. Two of the sets of SSCs are considered primary cases (#1 and #2) and use the PMS, passive IRWST injection and passive containment recirculation. The diverse case uses DAS and RNS. The PRHR HX, CMTs, accumulators, and the ADS stages are divided up in these three cases. Table 9C.3-2 lists the SSCs credited in each case.

In the primary 1 case, the ADS stages 1-3 and accumulators are not credited so that they can be used in other cases. The PRHR HX provides the initial decay heat removal and functions to reduce RCS pressure (together with the break) to a low enough pressure that ADS stage 4 can be successfully actuated. In a low probability sequence such as this, the RCS pressure could be as high as 4.1 MPa gauge (600 psig) for ADS stage 4 actuation. The CMTs provide RCS injection, long-term boration, and automatic control of ADS stage 4. Passive IRWST injection and containment recirculation are credited.

In the primary case 2, the PRHR HX and accumulators are not credited so that they can be used in other cases. In this case, manual actuation of ADS stages 1-3 provides the RCS pressure reduction to allow successful ADS stage 4 actuation. Passive IRWST injection and containment recirculation are credited.

In the diverse case, the CMTs and the IRWST passive injection and passive containment recirculation are not credited so that they can be used in other cases. The PRHR HX provides the initial decay heat removal. Manual actuation of ADS stages 1-3 is credited so that PRHR HX operation need not be credited after the accumulators empty and nitrogen gas enters the RCS, potentially degrading the PRHR HX performance. The accumulators provide RCS injection during the transition to lower pressure conditions. Manual actuation of RNS injection provides low pressure injection and later containment recirculation, without the need for ADS stage 4 and the passive IRWST injection and recirculation valves.

Additional diversity cases for the small-break LOCA fault are evaluated for ATWT considerations, as discussed in 9.6.5.3

9C.2.2 Safe Shutdown Using Defence in Depth Means

Use of these Class 2 systems is not credited in the deterministic UK safety case other than as discussed in Section 9C.2.1.

9C.2.2.1 Safe Shutdown Using Class 1 and 2 SSCs

As discussed in Section 9C.1.1, the plant can be placed in a safe shutdown condition and maintained there using Class 1 systems and no operator actions. This section describes situations where Class 2 safety features of the plant are used together with Class 1 systems to establish safe shutdown conditions.

Following PRHR HX actuation the IRWST heats up and starts to boil after about four hours of operation. If normal steam generator heat removal is re-established, then PRHR HX operation may be terminated. If SG heat removal is not re-established, then the operators can align the RNS to cool the IRWST. This operation prevents significant steaming to the containment.

In case the ADS is actuated, the operators are instructed to align the RNS pumps to provide injection to the RCS. This action causes the CMT level to remain above the fourth stage ADS valve actuation setpoint and prevents significant steaming to and flooding of the containment.

Use of these Class 2 systems is not credited in the deterministic UK safety case other than as discussed in Section 9C.2.1.

9C.2.2.2 Safe Shutdown Using Class 2 Systems

This section describes the process to establish and maintain safe shutdown conditions using the Class 2 safety systems. The Class 2 safety systems normally used to support plant shutdown operations are expected to be available. These Class 2 systems would be powered by onsite diesel generators in case offsite power was unavailable. The use of these Class 2 systems is not credited in the deterministic UK safety case, with the exception for a frequent fault small break LOCA where the RNS is credited to support the backup diverse capability.

For the purposes of this discussion, the Class 2 safety system operation following a reactor trip is described. As assumed in the discussion in Section 9C.1.1 on safe shutdown using Class 1 systems, the RCS is assumed to be intact during plant safe shutdown operations.

The Class 2 safety systems and equipment used to establish and maintain safe shutdown conditions are the same systems and equipment that are operated during normal plant startup and shutdown evolutions. The safe shutdown capability using the Class 1 safety systems, described in Section 9C.1.1, is only expected to be used in the event that the Class 2 safety systems are not available.

The Class 2 safety systems actuate automatically to establish and maintain the safe shutdown conditions within the time limits discussed in Section 9C.1.1. The operational philosophy following any event is to maintain appropriate safe shutdown conditions based on the duration of the shutdown, until the plant is able to re-start.

Cold shutdown conditions would only be established if it is necessary for equipment repair or due to limitations of the Class 2 safety systems in maintaining safe shutdown conditions (such as feedwater system water inventory). This philosophy reduces unnecessary challenges to plant safety due to the transition from operating systems to infrequently operated standby systems.

If offsite electrical power is available, the normal Class 3 systems would automatically maintain short-term safe shutdown conditions. This operation would involve the RCS forcing flow through the steam generators, feedwater from the main feedwater pumps, steam from the steam generators directed to the main condenser using turbine bypass valves, condenser heat removal provided by the main circulating water system, RCS inventory and boration control by the CVS and RCS pressure control using pressuriser heaters and normal spray.

If offsite power is not available, the reactor coolant pumps, main feedwater pumps, and main circulating water pumps will not be operating. However, Class 2 safety systems would automatically maintain safe shutdown conditions without offsite electrical power as follows:

- Electrical power provided to the required Class 2 safety systems by the diesel-generators of the onsite standby power system
- Heat removal by the steam generators directly to the atmosphere through the power-operated relief valves

- Feedwater from the startup feedwater system
- RCS flow to the steam generators via natural circulation
- RCS inventory and boration control by the CVS
- RCS pressure control using pressuriser heaters and auxiliary spray.

Operation of the Class 2 safety systems in this mode maintains safe shutdown conditions and RCS temperature and pressure remain near no-load conditions. If it becomes necessary to perform a plant cooldown and depressurisation, the Class 2 safety systems are used, following the normal plant cooldown procedures. Manual boration to the cold shutdown boron concentration is provided by the CVS by initiating RCS letdown in combination with makeup pump operation. After the boration is completed and letdown is secured, the makeup pumps automatically maintain RCS inventory throughout the remainder of the cooldown process.

When offsite electrical power is unavailable, reactor coolant temperature is automatically maintained by the steam generator atmospheric power-operated relief valves instead of the turbine bypass valves. The steam generator power-operated relief valves maintain a pre-set steam generator pressure by throttling the steam discharged directly from the steam generators to the atmosphere. Automatic operation of the startup feedwater subsystem maintains steam generator inventory with the pumps powered from the diesel-generators. The direct discharge of steam to the atmosphere prevents condensate recovery, which limits the water inventory for the startup feedwater system.

Without offsite electrical power, the pressuriser heaters are manually energised after the diesel-generators start. Without reactor coolant pump operation, normal pressuriser spray is unavailable to counteract system pressure increases. Therefore, auxiliary spray provided by the CVS makeup pumps is manually initiated to decrease RCS pressure, if necessary. The operation of the CVS makeup pumps to maintain RCS inventory is similar to their operation when offsite power is available, except that the pumps are manually controlled and powered from the diesel-generators.

When the RCS temperature and pressure are reduced to within the capabilities of the RNS, at approximately 177°C (350°F) and 2.76 MPa gauge (400 psig), the system is manually aligned to the RCS and started to continue the cooldown process. The final shutdown conditions established would be dependent upon the specific maintenance required.

The use of the Class 2 safety systems and equipment for safe shutdown also requires the operation of associated support systems. These normally operating support systems include component cooling water, service water, chilled water, compressed air, area ventilation, and Class 2 safety instrumentation and control power. These systems are started as required following a loss of offsite power, once the Class 2 safety diesel-generators are started.

9C.3 Results for Safe Shutdown for Design Basis Faults

The list of design basis faults is shown in Appendix 8A; this table includes internal faults and internal/external hazards.

As described in 9C.1 there are two basic safe shutdown sequences. The limiting initiating fault for each is described:

- Intact circuit faults using closed loop cooling by the PRHR HX. The limiting initiating fault is a loss of main feedwater (Reference 9C-1). The operation of the plant for this fault is described in Section 9C.3.1.

- Non-intact circuit faults using open loop cooling by ADS and PXS injection. The bounding initiating fault is a DVI LOCA. This LOCA is limiting because containment recirculation is reached the fastest (resulting in higher decay heat) and the initial containment water level is lowest (due to flooding of a PXS compartment, which is normally avoided in a normal floodup scenario). The operation of the plant for this fault is described in Section 9C.3.2.

The frequent fault diversity cases are not limiting for safe shutdown because:

- Frequent intact circuit faults use open loop cooling as do LOCAs, however containment recirculation occurs several hours later (resulting in lower decay heat) and the initial containment water level is higher (neither PXS room floods).

- Frequent small break LOCA faults use open loop cooling crediting different combinations of the SSCs credited in infrequent LOCAs as well as the RNS. Three different combinations of SSCs are considered to allow for a common cause failure and provide the necessary shutdown functions as described in Section 9C.2.1.4.

The following sections describe the plant behaviour for the different initiating events that need to be considered for the safe shutdown of the plant. These include:

- Intact Circuit Safe Shutdown (Section 9C.3.1),

- Post-LOCA Long-Term Cooling (Section 9C.3.2), and

- SGTR Safe Shutdown (Section 9C.3.3).

The sections describe the response of the plant and the systems required to achieve safe shutdown under each scenario.

9C.3.1 Results for Safe Shutdown for Intact Circuit Faults

The primary means that are relied upon to achieve safe shutdown following a design basis intact circuit fault are the Class 1 passive safety systems (PRHR HX, CMTs, and PCS). For intact circuit frequent faults, the diverse means of achieving safe shutdown are different Class 1 passive systems (passive feed and bleed). The design also provides Class 2 active DiD systems that provide a third way of achieving safe shutdown of the plant (Section 9C.2.2), although they are not required to meet UK relevant good practice. The specific systems used in these three different means are listed in Table 9C.3-1.

Section 9C.3.1.1 discusses the "Primary" means (Class 1 passive systems) that are relied upon to achieve safe shutdown. Section 9C.3.1.2 discusses the "Diverse" means (alternative Class 1 passive systems) that are relied upon for intact circuit frequent faults to achieve safe shutdown.

9C.3.1.1 Results for Safe Shutdown for Intact Circuit Faults, Primary Means

The primary means of achieving safe shutdown for intact circuit faults in described in Section 9C.2.1.1. As discussed in Section 9C.1.1, the plant is considered to have reached long term safe shutdown if all applicable acceptance criteria are met, and the reactor is kept in a safe, stable state for at least 72 hours. Additionally, realistic analyses support that the plant meets the applicable acceptance criteria core average temperature is reduced to less than 216ºC (420ºF) within 36 hours, and these conditions can be maintained for greater than 14 days. The conservative design basis case is discussed below. The expected cooldown performance is discussed in Reference 9C-1.

As discussed in Section 9C.1.1 and Reference 9C-1, the PRHR HX operates to remove decay heat and then transition to, and maintain the plant in a safe stable state for at least 72 hours. An analysis of the loss of main feedwater with a loss of ac power event demonstrates that the passive systems can transition the plant to a safe stable state following postulated transients. A conservative bounding analysis is represented in Figures 9C.3-1 through 9C.3-5. The progression of this event is outlined in Table 9C.3-3.

The performance of the PRHR HX is affected by the containment pressure. Containment pressure determines the PRHR HX heat sink (the IRWST water) temperature. The WGOTHIC containment response model described in Appendix 9D was used to determine the containment pressure response to this transient, which was used as an input to the plant cooldown analysis performed with LOFTRAN.

The PRHR HX performance is also affected by the IRWST water level when the level drops below the top of the PRHR HX tubes. The IRWST water level is affected by the heat input from the PRHR HX and by the amount of steam that leaves the IRWST and does not return to the IRWST through the IRWST gutter arrangement. The principal steam condensate losses include steam that stays in the containment atmosphere, steam that condenses on heat sinks inside containment other than the containment vessel, and dripping or splashing losses from obstructions on the inner containment vessel wall. The WGOTHIC analysis inputs (including the mass of the heat sinks and heat transfer rates) were biased to increase steam condensate losses to maximize condensate losses. The WGOTHIC model provides the time-dependent condensate return rate, which was incorporated into the LOFTRAN computer code described in Appendix 9B to demonstrate that the RCS would be maintained in a safe stable state for at least 72 hours.

Summarizing this transient, the loss of normal ac power occurs (offsite and onsite), followed by the reactor trip. The PRHR HX is actuated on the low steam generator narrow range level coincident with low startup feed water flow rate signal. Eventually a safeguards actuation signal is generated on low cold leg temperature and the CMTs are actuated.

Once actuated, the CMTs operate in recirculation mode, injecting cold borated water into the RCS. The CMTs operate in conjunction with the PRHR HX to effectively reduce RCS temperature. However, when the CMT cooling effect decreases the RCS starts to heat up. The RCS temperature increases until the PRHR HX matches decay heat. The PRHR HX maintains safe, stable conditions for at least 72 hours as shown in Figures 9C.3-1 through 9C.3-5. The safety criteria applicable to this event are presented in Table 9C.3-4.

The AP1000 plant design meets all of the intact circuit fault safety criteria for the bounding safe shutdown state described in Section 9C.1.1, and presented in Table 9C.3-4, for 72 hours. Figure 9C.3-1 is the plot for the DNBR which remains above the minimum allowable value throughout the event. Figure 9C.3-2 is the plot for the RCS loop temperatures remain below the no-load temperature after PRHR HX actuation. Figure 9C.3-3 is the plot for RCS pressure which remains below the maximum allowable RCS pressure throughout the event. Figure 9C.3-4 is the plot for pressuriser water volume which remains below the maximum allowable pressuriser water volume throughout the event. Figure 9C.3-5 is the plot for the SG pressures which remains below the maximum allowable SG pressure throughout the event.

In addition to the above analysis discussion, Reference 9C-1 shows that with reasonable assumptions that the PRHR HX is capable of reducing the RCS temperature to below 216°C (420°F) within 36 hours and to maintain this temperature for greater than 14 days. As described in Section 9C.1.1, should power not be restored, the PRHR HX performance will degrade and ADS actuation would eventually be required to enter open loop passive feed and bleed cooling.

9C.3.1.2 Results for Safe Shutdown for Intact Circuit Faults with Class 1 SSCs, Diverse Means

This section describes a situation where following an intact circuit frequent fault, there has been a low probability CCF affecting the Class 1 primary means of achieving safe shutdown as described in Section 9C.2.1.2.

The diverse means of mitigating a frequent intact circuit fault utilizes passive feed and bleed cooling. The short term results are described in Section 9.2.7.3.2. In the long term, these same SSCs will continue to operate. As discussed in Section 9C.3.2.1, the only change that occurs in the long term is a slight reduction in the containment water level. The impact of this reduction in water level (discussed in Section 9.6.6) bounds this diverse case since it uses the same mode of passive system operation and this diverse case uses nominal conditions and assumptions appropriate for a diverse case, which will increase margins.

9C.3.2 Results for Safe Shutdown for Non-Intact Circuit Faults

For infrequent LOCA faults, the means of providing safe shutdown are discussed in Section 9C.3.2.1. For cliff edge frequent fault LOCAs, the primary and the diverse means of achieving safe shutdown are discussed in subsequent sections. Note that most LOCAs are infrequent faults and only small-break LOCAs and RCS leaks with failure of CVS makeup are considered cliff edge frequent faults. The small-break LOCA discussed in the following sections bounds an RCS leak fault.

9C.3.2.1 Results for Safe Shutdown for Infrequent Non-Intact Circuit Faults

Since this event is an infrequent fault, a CCF need not be considered and only one means of mitigation is required. Note that this category includes all LOCAs except for small-break LOCAs and RCS leaks with failure of the CVS makeup; these LOCAs are cliff edge frequent faults.

For these infrequent LOCAs, the passive features (PRHR HX, CMTs, accumulators, ADS stages 1-4) provide the initial response and bring the plant to a safe stable state. The specific timing and sequence of the initial actions vary somewhat based on the LOCA size and location. Refer to Sections 9.6.4 and 9.6.5 for discussion of the initial response of the plant for different sizes and locations of LOCAs. During all LOCAs, the plant will transition to the same end condition, with the RCS pressure reduced to low values by the ADS and with

IRWST providing gravity injection. At this time, the plant will be in a safe shutdown state because the RCS temperature is less than 215ºC (420ºF), and all other applicable acceptance criteria are met. Section 9.6.6 describes what happens after IRWST injection begins out through long term safe shutdown operations.

This description addresses the bounding LOCA case (DVI LOCA) since that results in the earliest initiation of containment recirculation (higher decay heat) and lowest initial recirculation water level (due to the DVI break causing flooding of one PXS valve room). In addition, this description also addresses a longer term situation where the two rooms that do not initially flood in this case, eventually do flood.

9C.3.2.2 Results for Safe Shutdown for Frequent Fault Non-Intact Circuit Faults, Primary and Diverse Cases

Three different sets of SSCs are described in Section 9C.2.1.4, to provide diverse core cooling mitigation of the frequent fault small LOCA. Table 9C.3-2 lists these SSCs.

Refer to Section 9.6.5.3 for a discussion of the results for these three cases (additional cases are also presented for ATWT considerations). During these three frequent fault LOCA cases, the plant will transition to essentially the same condition, with the RCS pressure reduced to low values by the ADS and with IRWST providing injection either by gravity injection or by RNS pump head. At this time, the plant will be in a safe shutdown state because the RCS temperature is less than 216ºC (420ºF), and all other applicable acceptance criteria are met.

This analysis shows that adequate core cooling is provided in each case. These cases confirm that:

Primary Case 1 – shows that the PRHR HX together with the LOCA bring the RCS pressure down to below the maximum allowable ADS stage 4 actuation pressure of 4.1 MPa gauge (600 psig). This case also shows that sufficient IRWST injection is achieved.

Primary Case 2 – Shows that sufficient IRWST injection is achieved when manual actuation of ADS stages 1-3 provides the RCS pressure reduction to allow successful ADS stage 4 actuation.

Diverse Case - Shows that operators have enough time to manually actuate ADS 1-4 and RNS. Also shows that no accumulator nitrogen is injected to the RCS before ADS is manually actuated which prevents the possibility of the nitrogen degrading the performance of the PRHR HX.

The same SSCs that provide short-term core cooling continue to operate and provide long term safe shutdown operation. As discussed in Section 9C.3.2.1, the only change that occurs in the long term is a slight reduction in the containment water level. The impact of this reduction in water level (discussed in Section 9.6.6) bounds the two primary cases since they are both based on passive system operation and with the use of nominal conditions and assumptions appropriate for these diverse cases the margins would increase. The diverse case uses the RNS pumps to provide long-term recirculation. In this case, the containment water level provides NPSH to the pumps. As the water level slowly decreases, the operators can reduce the RNS pump flow if needed to ensure that sufficient NPSH is available.

9C.3.3 Safe Shutdown for Steam Generator Tube Rupture Faults

As discussed in 9C.2.1.4, SGTR faults are considered cliff edge frequent faults and as such diverse means of achieving safe shutdown needs to be demonstrated. The SSCs used to provide primary and diverse mitigation of a SGTR are the same used to mitigate intact circuit faults and in the long-term these same SSCs continue to operate. The primary SSCs are the Class 1 PMS, PRHR HX, CMTs, containment isolation, and PCS. The diverse SSCs are those used for passive feed and bleed (ADS 1-4, accumulators, IRWST injection and containment recirculation, containment isolation and PCS). These specific systems are listed in Table 9C.3-1.

The unique capability of the primary passive SSCs is their ability to terminate the SG tube rupture leak automatically. Following break flow termination, the primary means of bringing the plant to a safe shutdown state is the continued operation of the same Class 1 passive systems that provided the initial fault mitigation.

The short term plant response using the primary and diverse SSCs is described in Section 9.6.3. Sections 9C.3.3.1 and 9C.3.3.2 provide discussion of the long term response using these two different sets of SSCs. These sections also discuss the claims made on operator actions and management of criticality challenges. Note that an SGTR does not present a challenge to containment and thus containment threats are not discussed further.

9C.3.3.1 Results for Safe Shutdown for SGTR Faults, Primary Means

The SGTR is analysed to demonstrate margin to ruptured SG overfill and to generate mass releases for the dose calculation. The limiting assumption for the margin to overfill is the failure of the start-up feedwater system (SFW, Class 2) to throttle when the setpoint is reached. The SFW is subsequently isolated automatically on a high SG water level signal in the ruptured SG. The limiting single failure for the mass release for dose analysis is the failure of the power operated relief valve (PORV, Class 2) on the ruptured SG in the open position. This is assumed to occur coincident with the actuation of the PRHR and CMT. The MSIV and PORV block valve associated with the SG with the ruptured tube automatically close on a low SG pressure signal.

The following describes how the plant is brought to a safe shutdown state using these same passive systems. Basically, in this case the operators do nothing and the PRHR HX operation automatically brings the plants to a safe shutdown. With the conservative bounding analysis assumptions the RCS remains in a safe stable state for at least 72 hours. The RCS temperature does not cool down very much although it is sufficient to reduce the RCS pressure and terminate the leak. With this analysis, there is no challenge to core shutdown margin since there is little if any back flow from the ruptured SG to the RCS.

However, the more likely situation is for the PRHR HX to cool the RCS down to 216ºC (420ºF) within 36 hours; this is similar to the intact circuit conclusions presented in Section 9C.3.1.1. In this situation, the RCS pressure will decrease further and some back flow will occur from the ruptured SG. The potential for this back flow to bring less borated SG secondary side water into the RCS and reduce the core shutdown margin has been analysed in Reference 9C-11. Note that this long-term mode of operation has two advantages:

1. It requires no operator actions

2. It minimises offsite radiological releases

3. It minimises the contamination, cleanup of the secondary side, impact to turbine island SSCs

Adequate core shutdown margin has been demonstrated using conservative assumptions including maximum SFW additions, maximum initial RCS boron concentration, and minimum CMT boron concentration, stuck rod, and no xenon. The RCS boron concentration remains well above the safe shutdown boron concentration.

The conservative hand calculation method used in Reference 9C-11 assumes that the RCS volume remains well mixed as water from the ruptured SG flows back into the RCS during the RCS cooldown caused by long term PRHR HX operation. This assumption is readily supported if there is forced circulation. Natural circulation conditions also support this assumption. Figure 3.2-4 of Reference 9C-3 provides evidence for crediting adequate mixing under natural circulation conditions. With natural circulation cooldown, during the post-SGTR recovery, the RCS cooldown rate is limited by the PRHR HX and the primary-to-secondary pressure differential and resultant reverse break flow rate would be low. With a low reverse break flow rate, the potentially unborated water entering into the RCS volume would mix with the circulating RCS coolant, and significant mixing would occur.

9C.3.3.2 Results for Safe Shutdown for SGTR Faults, Diverse Means

The diverse means to achieve safe shutdown uses a passive feed-and-bleed approach using DAS for the C&I. The bleed is performed by manual actuation of the ADS. The feed is performed by the accumulators and IRWST gravity injection. In the longer term, when the IRWST reaches a low level, recirculation from the containment will be actuated. These features provide core cooling, long-term reactivity control, and RCS inventory control sufficient to bring the plant to safe shutdown conditions.

This diverse safe shutdown uses passive containment cooling; refer to Section 9C.2.1.2 for discussion of the diversity within the PCS.

Reactivity concerns are avoided during the ADS operation because of the large, rapid injection of borated water from the accumulators and the IRWST as well as by a void that occurs in the core.

9C.4 Summary and Conclusions

The assessment of plant progression to a safe shutdown controlled state for all design basis faults is documented herein.

Chapter 8 contains a comprehensive list of all design basis faults. Section 9C.1 describes that these faults only result in two different reactor conditions at the end of the short-term mitigation.

The operation of the SSCs credited in providing safe shutdown for the plant is described in Section 9C.2. This description includes the primary Class 1 SSCs as well as the diverse SSCs (for frequent faults). Intact circuit faults as well as non-intact circuit faults (LOCAs and SGTRs) are included.

The resulting plant thermal hydraulic behaviour for each type of fault and mitigating SSCs is described in Section 9C.3. The analysis described shows that these SSCs allow the plant to reach and maintain the specified safe shutdown condition for the specified durations.

Notes: (1) These features are only required in LOCA faults or for intact circuit faults where in the long term it becomes necessary to transition from closed loop RCS cooling using the PRHR HX to open loop cooling using ADS.

Table 9C.3-1. Safe Shutdown SSCs for Intact Circuit Faults[1]

Function	Primary (Class 1 Passive)	Diverse Core Cooling (Class 1 and 2)	Diverse ATWT (Class 1 and 2)
Reactivity Control, Short-Term	Control rods	Control rods	Note 3
Reactivity Control, Long-Term	CMTs	Accumulators, IRWST injection	CMTs
Heat Removal, Short-Term (RCS to Ultimate Heat Sink)	PRHR HX, PCS	ADS, Accumulators, IRWST injection, PCS[5]	PRHR HX, PCS[5]
Heat Removal, Long-Term (RCS to Ultimate Heat Sink)	PRHR HX, PCS	ADS, Containment recirculation (gravity), PCS[5]	PRHR HX, PCS[5]
RCS Inventory	CMTs	Accumulators, IRWST	CMTs
Electrical Power	None (all fail safe on loss of power)	IDS, EDS[4]	EDS[4]
C&I	PMS	DAS[4]	DAS[4]

Notes:

1. Note that not all intact circuit faults are frequent faults. Note that these same cases also apply to SGTR.
2. Not used.
3. Short-term reactivity is provided for this case by a combination of core reactivity characteristics and core voiding. See Chapter 9 for descriptions of the different frequent intact circuit faults and a discussion of diverse means used to provide short-term reactor shutdown for ATWT sequences.
4. The DAS is a Class 2 system that has its own dedicated batteries.
5. The PCS incorporates diversity such that a CCF cannot cause its failure. Refer to Section 9C.2.1.2 for additional discussion.

Table 9C.3-2. Safe Shutdown SSCs For LOCA Faults

Function	Infrequent LOCAs (Class 1 Passive)[1]	Primary 1 for FF LOCAs (Class 1 Passive)	Primary 2 for FF LOCA (Class 1 Passive)	Diverse for FF LOCAs (Class 1 and 2)[2]
Reactivity Control, Short-Term	Control rods or RCS voiding	Control rods	Control rods	Control rods[6]

Notes:

1. Most LOCA faults are infrequent faults; the only exceptions are small-break LOCAs and RCS leaks (with failure of CVS) which are “cliff edge” frequent faults.
2. The “diverse” means of providing the AP1000 plant safe shutdown uses both Class 1 and Class 2 components.
3. The containment recirculation includes four paths. Two of the paths use valves that are diverse from the other two paths so that one CCF cannot cause all four paths to fail.
4. The DAS is a Class 2 system that has its own dedicated batteries.
5. The PCS incorporates diversity such that a CCF cannot cause its failure. Refer to Section 9C.2.1.2 for additional discussion.
6. An alternate ATWT case (without rod insertion) is discussed in Section 9.6.5.

Table 9C.3-3. Safe Shutdown Sequence of Events Following a Loss of AC Power (Bounding Case for 72 Hours)

Event	Time (seconds)
Feedwater is Lost	10.0
Low-2 Steam Generator Water Level (Narrow-Range) Reactor Trip Setpoint Reached	60.2
Rods Begin to Drop	62.2
RCPs Trip due to Loss of ac Power	70.2
Low Steam Generator Water Level (Wide-Range) Reached	214.5
PRHR HX Actuation on Low-2 Steam Generator Water Level (Narrow-Range Coincident with Low Startup Feedwater Flow)	214.5
Low-2 T_{cold} Setpoint Reached	8,319.7
Steam Line Isolation on Low-2 T_{cold} Signal	8,331.7
CMTs Actuated on Low-2 T_{cold} Signal	8,336.7
IRWST Reaches Saturation Temperature	15,900
Heat Extracted by PRHR HX Initially Matches Core Decay Heat	~30,000

Table 9C.3-4. Safe Shutdown Acceptance Criteria

Criterion	Safety Limit
After PRHR HX matches decay heat, RCS T_{avg} < ADS actuation temperature	296°C (565°F)
RCS pressure less than limit(1)	18.9 MPa (2749 psia)
Pressuriser water volume less than full	62.3 m^3 (2200 ft^3)
SG pressure less than limit(1)	9.1 MPa (1319 psia)
DNB Ratio greater than limit	Safety Analysis Limit(2)

Notes: (1) Pressure limit is ASME upset pressure limit of 110% of design pressure
(2) Specific limit maintained in Reference 9C-2

9D.1 Containment Structure

9D.1.1 Design Basis

The containment system is designed such that for all break sizes, up to and including the double-ended severance of a reactor coolant pipe or secondary side pipe, the containment peak pressure is below the design pressure. A summary of the results is presented in Table 9D.1-1.

This capability is maintained by the containment system assuming the worst single failure affecting the operation of the PCS. For primary system breaks, LOOP is assumed. For secondary system breaks, offsite power is assumed to be available when it maximises the mass and energy released from the break. Additional discussion of the assumptions made for secondary side pipe breaks may be found in subsection 9D.3.

The single failure postulated for the containment pressure/temperature calculations is the failure of one of the valves controlling the cooling water flow for the PCS. Failure of one of these valves would lead to cooling water flow being delivered to the containment vessel through two of three delivery headers. This results in reduced cooling flow for PCS operation. However, only one flowpath is necessary to meet containment cooling requirements and only one flowpath is assumed in the containment integrity analyses.

The containment integrity analyses for the AP1000 employ a multivolume lumped parameter model to study the long-term containment response to postulated LOCA and MSLB accidents.

The analyses presented in this section are based on assumptions that are conservative with respect to the containment and its heat removal systems, such as minimum heat removal, and maximum initial containment pressure.

The minimum containment backpressure used in the PXS analysis is discussed in Section 9D.4.

9D.1.2 Design Features

The reactor coolant loop is surrounded by structural walls of the containment internal structures. These structural walls are a minimum of 0.76 meter (2-feet - 6-inches) thick and enclose the reactor vessel, steam generators, reactor coolant pumps, and the pressuriser.

The containment vessel is designed and constructed in accordance with the ASME Code, Section III, Subsection NE, Metal Containment, as described in Appendix 10K.

Containment and subcompartment atmospheres are maintained during normal operation within prescribed pressure, temperature, and humidity limits by means of the VCS, and the central chilled water system (VWS). The recirculation system cooling coils are provided with chilled water for temperature control. The filtration supply and exhaust subsystem can be utilised periodically to purge the containment air for pressure control. Periodic inspection and maintenance verify functional capability.

9D.1.3 Design Evaluation

The WGOTHIC computer code (Reference 9D-6) is a computer programme for modelling multiphase flow in a containment transient analysis. It solves the conservation equations in integral form for mass, energy, and momentum for multicomponent flow. The momentum

conservation equations are written separately for each phase in the flow field (drops, liquid pools, and atmosphere vapour). The following terms are included in the momentum equation: storage, convection, surface stress, body force, boundary source, phase interface source, and equipment source.

To model the passive cooling features of the AP1000, several assumptions are made in creating the plant decks. The external cooling water does not completely wet the containment shell; therefore, both wet and dry sections of the shell are modelled in the WGOTHIC analyses. The analyses use conservative coverage fractions to determine evaporative cooling as explained in Chapter 7 of Reference 9D-6. The analyses conservatively assume that the external cooling water is not initiated until 400 seconds into the transient, allowing time to initiate the signal and to fill the headers and weirs and to develop the flow down the containment side walls. The effects of water flowing down the shell from gravitational forces are explicitly considered in the analysis.

The containment initial conditions of pressure, temperature, and humidity are provided in Table 9D.1-2. The WGOTHIC containment evaluation model is presented in Reference 9D-9.

For the LOCA events, two double-ended guillotine reactor coolant system pipe breaks are analysed. The breaks are postulated to occur in either a hot or a cold leg of the reactor coolant system. The hot leg break is limiting during the blowdown phase of the accident, and is only analysed for this time period. The cold leg break is the most limiting scenario after the blowdown, and is analysed for the long term containment response. The cold leg break analysis includes the long term contribution to containment pressure from the sources of stored energy, such as the steam generators. The LOCA mass and energy releases described in subsection 9D.2 are used for these calculations.

For the MSLB event, a double-ended pipe rupture is analysed at several initial power levels with the WGOTHIC code. The MSLB mass and energy releases described in subsection 9D.3 are used for these calculations.

Table 9D.1-4 summarises the required volume of steel inside containment to validate the heat sink input and methodology for the WGOTHIC containment analyses. It includes requirements for analyses that minimise heat sinks (the peak containment pressure analyses) and ones that maximise heat sinks (the minimum containment pressure analyses).

The methodology for calculating the internal containment heat sink data used in the WGOTHIC analyses is presented in Reference 9D-6, Section 13. Heat sinks include both metallic and concrete structures. Table 9D.1-5 lists the heat sinks that are credited for heat transfer in the containment evaluation model for peak containment pressure analyses. The physical properties of the heat sink materials are presented in Table 9D.1-3. These properties are inputs to the containment peak pressure evaluation, consistent with the methodology specified in Reference 9D-6, Section 13, including:

- The thermal conductivity and volumetric heat capacity of all steel materials are reduced by 10% per the ASME standard to account for variability of alloy content
- The thermal conductivity of inorganic zinc is reduced by a factor of two relative to the minimum test requirement
- Emissivity is reduced by 10%

All carbon steel and concrete heat sinks inside containment are modelled with a coating of epoxy on the exposed surface. The containment vessel is modelled with an inorganic zinc coating inside and outside containment. The containment vessel below the operating deck has both an inorganic zinc coating and an epoxy top coating.

The peak containment pressure and temperature results of the LOCA and MSLB postulated accidents are provided in Table 9D.1-1. The peak value is the maximum of any location within the multi-node WGOTHIC model.

The containment pressure response for the peak pressure steam line break case is provided in Figure 9D.1-1. The containment temperature response for the peak temperature steam line break case is provided in Figure 9D.1-2.

The containment pressure and temperature responses to a double-ended cold leg guillotine are presented in Figures 9D.1-3 and 9D.1-4 for the first 5000 seconds which shows the peak portion of the containment transients and Figures 9D.1-5 and 9D.1-6 for the 3 day transients. The containment pressure and temperature response to a double-ended hot leg guillotine break are presented in Figures 9D.1-7 and 9D.1-8. The plotted parameters are the total pressure and vapour temperature at the location of the break.

A separate analysis for the double-ended cold leg guillotine LOCA event, without considering heat conduction from the dry to wet section, results in somewhat higher containment pressure in the long term, but still below 50 percent of design pressure at 24 hours. This separate analysis confirms the assumption in subsection 9.6.4.2.2 of reducing the containment leakage to half its design value at 24 hours.

The instrumentation provided outside containment to monitor and record the containment pressure and the instrumentation provided inside containment to monitor and record temperature are found in Chapter 19.

9D.2 Mass and Energy Release Analyses for Postulated Pipe Ruptures

The section describes the methodology used to determine the mass and energy releases for the containment pressure and temperature calculations using the WGOTHIC code (Reference 9D-6) (referred to as the long term analysis). These releases are used for the containment integrity analysis in subsection 9D.1.

The containment system receives mass and energy releases following a postulated rupture of the reactor coolant system or a postulated rupture of the main steam line within containment.

9D.2.1 LOCA Long Term Mass and Energy Release Data

The LOCA release rates are calculated for pipe failure at two locations: the hot leg and the cold leg. These break locations are analysed for long-term transients. Because the initial operating pressure of the reactor coolant system is approximately 15.51 MPa (2250 psi), the mass and energy are released extremely rapidly when the break occurs. As the water exits from the broken pipe, a portion of it flashes to steam because of the differences in pressure and temperature between the reactor coolant system and containment. The reactor coolant system depressurises rapidly since break flow exits from both sides of the pipe in a DEG severance.

A long term LOCA analysis calculation model is typically divided into four phases: blowdown, which includes the period from the accident initiation (when the reactor is in a steady-state full power operation condition) to the time that the broken loop pressure equalises to the containment pressure; refill, which is the time from the end of the blowdown to the time when the PXS refills the vessel lower plenum; reflood, which begins when the water starts to flood the core and continues until the core is completely quenched; and post-reflood, which is the period after the core has been quenched and energy is released to the reactor coolant system primary system by the reactor coolant system metal, core decay heat, and the steam generators.

The long-term analysis considers the blowdown, reflood, and post-reflood phases of the transient. The refill period is conservatively neglected so that the releases to the containment are conservatively maximised.

The AP1000 long-term LOCA mass and energy releases are predicted for the blowdown phase for postulated double ended cold leg guillotine (DECLG) and double ended hot leg guillotine (DEHLG) breaks. The blowdown phase mass and energy releases are calculated using the NRC approved SATAN-VI computer code (Reference 9D-1). The post blowdown phase mass and energy releases for the postulated DECLG break are calculated considering the energy released from the available energy sources described below. The energy release rates are conservatively modelled so that the energy is released quickly. The higher release rates result in a conservative containment pressure calculation.

The LOCA mass and energy releases to calculate a peak containment pressure are documented in Reference 9D-10.

9D.2.1.1 Mass and Energy Sources

The following are accounted for in the long-term LOCA mass and energy calculation:

- Decay heat
- Core stored energy
- Reactor coolant system fluid and metal energy
- Steam Generator fluid and metal energy
- Accumulators, CMTs,, and the IRWST fluid energy
- Zirconium-water reaction.

The methods and assumptions used to release the various energy sources during the blowdown phase are given in Reference 9D-1.

The following parameters are used to conservatively analyse the energy release for maximum containment pressure:

- Maximum expected operating temperature
- Allowance in temperature for instrument error and dead band
- Margin in volume (+1.4 percent)
- Allowance in volume for thermal expansion (+1.6 percent)
- 100 percent full power operation
- Allowance for calorimetric error (+1.0 percent of full power)
- Conservatively modified coefficients of heat transfer
- Allowance in core stored energy for effect of fuel densification
- Margin in core stored energy (+15.0 percent)
- Allowance in pressure for instrument error and dead band
- Margin in steam generator mass inventory (+10.0 percent)
- One percent of the Zirconium surrounding the fuel is assumed to react.

9D.2.1.2 Description of Blowdown Model

A description of the SATAN-VI model that is used to determine the mass and energy released from the reactor coolant system during the blowdown phase of a postulated LOCA is provided in Reference 9D-1. Significant correlations are discussed in this reference.

9D.2.1.3 Description of Post-Blowdown Model

The remaining reactor coolant system and SG mass and energy inventories at the end of blowdown are used to define the initial conditions for the beginning of the reflood portion of the transient. The broken and unbroken loop SG inventories are kept separate to account for potential differences in the cooldown rate between the loops. In addition, the mass added to the reactor coolant system from the IRWST is returned to containment as break flow so that no net change in system mass occurs.

Energy addition due to decay heat is computed using the 1979 ANS standard (plus 2 sigma) decay heat table from Reference 9D-1. The energy release rates from the reactor coolant system metal and steam generators are modelled using exponential decay rates. This modelling is consistent with analyses for current generation design analyses that are performed with the models described in Reference 9D-1.

The accumulator, CMT, and IRWST mass flow rates are computed from the end of blowdown to the time the tanks empty. The rate of reactor coolant system mass accumulation is assumed to decrease exponentially during the reflood phase. More CMT and accumulator flow is spilled from the break as the system refills. The break flow rate is determined by subtracting the reactor coolant system mass addition rate from the sum of the accumulator, CMT and IRWST flow rates.

Mass which is added to, and which remains in, the vessel is assumed to be raised to saturation. Therefore, the actual amount of energy available for release to the containment for a given time period is determined from the difference between the energy required to raise the temperature of the incoming flow to saturation and the sum of the decay heat, core stored energy, reactor coolant system metal energy and SG mass and metal energy release rates. The energy release rate for the available break flow is determined from a comparison of the total energy available release rate and the energy release rate assuming that the break flow is 100-percent saturated steam following IRWST draindown. Saturated steam releases maximise the calculated containment pressurisation.

9D.2.1.4 Single Failure Analysis

The assumptions for the containment mass and energy release analysis are intended to maximise the calculated release. A single failure could reduce the flow rate of water to the RCS, but would not disable the passive core cooling function. The effects of a single failure are taken into account in the containment analysis of subsection 9D.1.

9D.2.1.5 Metal-Water Reaction

Consistent with 10 CFR 50, Appendix K criteria, the energy release associated with the zirconium-water exothermic reaction has been considered. The LOCA peak cladding temperature analysis, presented in Chapter 9, demonstrates compliance with the Appendix K criteria demonstrates that no appreciable level of zirconium oxidation occurs. This level of reaction has been bounded in the containment mass and energy release analysis by incorporating the heat of reaction from 1 percent of the zirconium surrounding the fuel. This exceeds the level predicted by the LOCA analysis and results in additional conservatism in the mass and energy release calculations.

9D.2.1.6 Additional Information Required for Confirmatory Analysis

System parameters and hydraulic characteristics needed to perform confirmatory analysis are provided in Table 9D.2-1 and Figures 9D.2-1 through 9D.2-4.

9D.3 Mass and Energy Release Analysis for Postulated Secondary-System Pipe Rupture Inside Containment

Steam line ruptures occurring inside a reactor containment structure may result in significant releases of high-energy fluid to the containment environment, possibly resulting in high containment temperatures and pressures. The quantitative nature of the releases following a steam line rupture is dependent upon the configuration of the plant steam system, the containment design as well as the plant operating conditions and the size of the rupture. This section describes the methods used in determining the containment responses to a variety of postulated pipe breaks encompassing variations in plant operation.

The steam line break mass and energy releases to calculate a peak containment pressure are documented in Reference 9D-11.

9D.3.1 Significant Parameters Affecting Steam Line Break Mass and Energy Releases

Four major factors influence the release of mass and energy following a steam line break: steam generator fluid inventory, primary-to-secondary heat transfer, protective system operation and the state of the secondary fluid blowdown. The following is a list of those plant variables which have significant influence on the mass and energy releases:

- Plant power level
- Main feedwater system design
- Startup feedwater system design
- Postulated break type, size, and location
- Availability of offsite power
- Safety system failures
- Steam generator reverse heat transfer and reactor coolant system metal heat capacity.

The following is a discussion of each of these variables.

9D.3.1.1 Plant Power Level

Steam line breaks are postulated to occur with the plant in any operating condition ranging from hot shutdown to full power. Since steam generator mass decreases with increasing power level, breaks occurring at lower power generally result in a greater total mass release to the containment. Because of increased energy storage in the primary plant, increased heat transfer in the steam generators and additional energy generation in the nuclear fuel, the energy released to the containment from breaks postulated to occur during power operation may be greater than for breaks occurring with the plant in a hot shutdown condition. Additionally, steam pressure and the dynamic conditions in the steam generators change with increasing power. They have significant influence on the rate of blowdown from the break following a steam break event.

Because of the opposing effects of changing power level on steam line break releases, no single power level can be pre-defined as a worst case initial condition for a steam line break event.

Therefore, several different power levels (101%, 70%, 30%, 0%) spanning the operating range as well as the hot shutdown condition are analysed.

9D.3.1.2 Main Feedwater System Design

The rapid depressurisation that occurs following a rupture may result in large amounts of water being added to the steam generators through the main feedwater system. Rapid closing isolation valves are provided in the main feedwater lines to limit this effect. The piping layout downstream of the isolation valves determines the volume in the feedwater lines that cannot be isolated from the steam generators. As the steam generator pressure decreases, some of the fluid in this volume will flash into the steam generator, providing additional secondary fluid that may exit out the rupture. This unisolated feedwater mass between the steam generator and isolation valve is accounted for within the results in subsection 9D.3.3.2. The assumed unisolable volume bounds the volume to either the feedwater control valve or the feedwater isolation valve on the faulted loop, so that no additional feedwater mass could be postulated due to a single failure of one of the valves.

The feedwater addition that occurs prior to closing of the feedwater line isolation valves is conservatively calculated based on the depressurisation of the faulted steam generator, and assuming that the feedwater control valve is fully open in response to the increased steam flow rate.

9D.3.1.3 Startup Feedwater System Design

Within the first minute following a steam line break, the startup feedwater system may be initiated on a low steam generator water level signal in combination with low main feedwater flow. The addition of startup feedwater to the steam generators would increase the secondary mass available for release to the containment through the steam line break. If the actuation signal occurs, maximum startup feedwater flow to the faulted steam generator is conservatively assumed until automatically terminated on a low RCS T_{cold} signal.

9D.3.1.4 Postulated Break Type, Size and Location

The steam line break is postulated as a full double-ended pipe rupture immediately downstream of the integral flow restrictor on the faulted steam generator. The forward break flow from the faulted steam generator is limited by the flow restrictor area (0.13 m^2 (1.4 ft^2)). The faulted steam generator is unisolable from the break location, and the forward break flow continues until the steam generator is empty. The reverse break flow consists of the initial steam within the steamline piping and steam that comes from the intact steam generator. The reverse break flow continues until MSIV closure. The modelling of the reverse break flow does not differentiate the location of the MSIVs, and all steam that has exited the intact steam generator prior to MSIV closure is assumed to be released out the break. This bounds the possible effects of an MSIV failed open.

No liquid entrainment is credited in the break effluent from the double-ended pipe rupture. The release of dry saturated steam from the largest possible break size maximises the mass and energy release to the containment.

9D.3.1.5 Availability of Offsite Power

The effects of the assumption of the availability of offsite power are enveloped in the analysis.

Offsite power is assumed to be available where it maximises the mass and energy released from the break because of the following:

- The continued operation of the reactor coolant pumps until automatically tripped as a result of CMT actuation. This maximises the energy transferred from the reactor coolant system to the steam generator.

- The continued operation of the feedwater pumps and actuation of the startup feedwater system until they are automatically terminated. This maximises the steam generator inventories available for release.

- The AP1000 is equipped with the passive safeguards system including the CMT and the PRHR heat exchanger. Following a steam line rupture, these passive systems are actuated when their setpoints are reached. This decreases the primary coolant temperatures. The actuation and operation of these passive safeguards systems do not require the availability of offsite power.

  When the PRHR is in operation, the core-generated heat is dissipated to the IRWST via the PRHR heat exchanger. This causes a reduction of the heat transfer from the primary system to the steam generator secondary system and causes a reduction of mass and energy releases via the break.

Thus, the availability of ac power maximises the mass and energy releases via the break. Therefore, blowdown occurring with the availability of offsite power is more limiting than cases where offsite power is not available.

9D.3.1.6 Safety System Failures

The calculation of the mass and energy release following a steam line rupture is done to conservatively bound the possible increase of mass release due to safety system failures. Two failures, which are bounded are:

- Failure of one main steam isolation valve, as discussed in subsection 9D.3.1.4
- Failure of one main feedwater isolation valve, as discussed in subsection 9D.3.1.2

9D.3.1.7 Steam Generator Reverse Heat Transfer and Reactor Coolant System Metal Heat Capacity

Once steam line isolation is complete, the steam generator in the intact steam loop becomes a source of energy that can be transferred to the steam generator with the broken line. This energy transfer occurs through the primary coolant. As the primary plant cools, the temperature of the coolant flowing in the steam generator tubes drops below the temperature of the secondary fluid in the intact unit, resulting in energy being returned to the primary coolant. This energy is then available to be transferred to the steam generator with the broken steam line.

Similarly, the heat stored in the metal of the reactor coolant piping, the reactor vessel, and the reactor coolant pumps is transferred to the primary coolant as the plant cooldown progresses. This energy also is available to be transferred to the steam generator with the broken line. Energy from the metal of the faulted steam generator is also transferred to the fluid in the faulted steam generator as the fluid temperature drops below the metal temperature.

The effects of the reactor coolant system metal, the steam generator metal, and the energy in the fluid from the intact steam generator are included in the results presented.

9D.3.2 Description of Blowdown Model

The steam line blowdown is calculated with the LOFTRAN code (Reference 9D-3) which has been modified to include simulation of the AP1000 passive residual heat removal heat exchanger, core makeup tanks, and associated protection and safety monitoring system actuation logic. Documentation of the code changes for the passive models is provided in Reference 9D-7. The methodology for the steam line break analysis is based on Reference 9D-2. The applicability of the LOFTRAN code to AP1000, and the applicability of the methodology used to analyse the steam line break blowdown are discussed in Reference 9D-8.

9D.3.3 Containment Response Analysis

The WGOTHIC Computer Code (Reference 9D-6) is used to determine the containment responses following the steam line break, which is described in subsection 9D.1.

9D.3.3.1 Initial Conditions

The initial containment conditions are discussed in subsection 9D.1.3.

9D.3.3.2 Mass and Energy Release Data

Using References 9D-2, 9D-3, 9D-7 and 9D-8 as a basis, mass and energy release data are developed to determine the containment pressure-temperature response for the spectrum of cases analysed. Table 9D.3-1 provides nominal plant data used in the steamline break mass and energy releases determination.

9D.3.3.3 Containment Pressure-Temperature Results

The results of the containment pressure-temperature analyses for the postulated secondary system pipe ruptures that produce the highest peak containment pressure and temperature are presented in subsection 9D.1.3.

9D.4 Minimum Containment Pressure Analysis for Performance Capability Studies of Emergency Core Cooling System (PWR)

An analysis is performed to establish a minimum containment pressure boundary condition applied to the WCOBRA/TRAC code for the cold leg guillotine break for the ECCS analysis presented in subsection 9.6.4. A single-node containment model is used with the WGOTHIC computer code to assess the containment pressure response. The calculated containment backpressure is provided in Figure 9D.4-1.

Minimum containment pressure analyses are also performed to provide the containment backpressure boundary condition for small-break LOCA (See Section 9.6.5) and post-LOCA long-term cooling analyses (see Section 9.6.6). A multi-node WGOTHIC containment model described in Section 13.8 of WCAP-15846 (Reference 9D-6) is used.

9D.4.1 Mass and Energy Release Data

The mathematical models which calculate the mass and energy releases to the containment are described in subsections 9.6.4 and 9.6.5. A break spectrum analysis is performed (see references in subsections 9.6.5 and 9.6.5) that considers various break sizes and Moody discharge coefficients for the double-ended cold leg guillotines and splits. Mixing of steam and accumulator

water injected into the vessel reduces the available energy released to the containment vapour space, thereby minimising calculated containment pressure.

9D.4.2 Initial Containment Internal Conditions

Initial containment conditions were biased for the emergency core cooling system backpressure analysis to predict a conservatively low containment backpressure. Initial containment conditions include an initial pressure of 0.100 MPa (14.5 psia), initial containment temperature of 32.2°C (90°F), and a relative humidity of 100 percent. An air annulus temperature of -17.8°C (0°F) is assumed. The initial through-thickness metal temperature of the containment shell is assumed to also be -17.8°C (0°F).

9D.4.3 Other Parameters

Containment parameters, such as containment volume and passive heat sinks, are biased to predict a conservative low containment backpressure. The containment volume used in the calculation is conservatively set to 1.05 times the free volume of the AP1000 containment Evaluation Model. Containment internal heat sinks used heat transfer correlations of 4 times Tagami (Reference 9D-4) during the blowdown phase followed by 1.2 times Uchida (Reference 9D-5) for the post-blowdown phase. Passive heat sink surface areas were increased by a factor of 1.35 relative to the heat sinks developed for the peak containment evaluation model as described in Section 13 of Reference 9D-6. Material properties were biased high (density, conductivity, and heat capacity). No air gap was modelled between the steel liner and base concrete of jacketed concrete heat sinks. The outside surface of the containment shell was maintained at -17.8°C (0°F) throughout the calculation. To further minimise containment pressure, containment purge was assumed to be in operation at time zero and air is vented through both the containment purge supply and exhaust lines until the isolation valves have fully closed. These valves were modelled to close after the high-2 containment pressure setpoint was reached.

	149°C/300°F	14.5/8.4	37.4/55.8	N/A

Notes:

1. Emissivity is only credited outside containment

Table 9D.1-4. Plant Requirements for Metal Heat Sinks Inside Containment

Region	Metal Volume [m^3 (ft^3)] (minimum – maximum)
Above the operating deck	133.9 – 205.7 (4,730 – 7,264)
Inside SG/Pressuriser compartments	28.37 – 47.46 (1,002 – 1,676)
Below the operating deck	148.2 – 234.9 (5,232 – 8,296)
Total	326.81 – 488.07 (11,541 (3) - 17,236)

Notes:

1. Does not include the containment vessel.
2. Only includes structures and equipment that are typically less than or equal to containment ambient temperature.
3. The total minimum volume includes an additional 16.3 m^3 (577 ft^3) of metal inside containment.

Table 9D.1-5 (Sheet 1 of 3). Heat Sinks Credited in the Peak Containment Pressure Analyses

Description	Material	Surface Area [(m^2)/(ft^2)]	Metal Volume [(m^3)/(ft^3)]	Metal Effective Thickness [(cm)/(in)]
Above the Operating Deck				
Containment vessel above the operating deck	Carbon Steel A	5,851.8/62,988	254.5/8,986	4.128/1.625 and 4.445/1.750

VXS	annex/auxiliary building nonradioactive ventilation system
WGS	gaseous radwaste system
WLS	liquid radwaste system
ZAS	main generator system
ZOS	onsite standby power system

10 REACTOR FAULTS PROBABILISTIC SAFETY ASSESSMENT AND SEVERE ACCIDENT ANALYSIS

10.1 Introduction

This chapter summarises the results of the AP1000 reactor probabilistic safety assessment (PSA) that are needed within the Pre-Construction Safety Report (PCSR). In addition, it supports and justifies the uses made of those results within the PCSR by doing the following:

- Stating the key assumptions on which the PSA is based.
- Describing the sources of information used in producing the PSA.
- Discussing the uncertainties in the results arising from scope limitation, methodology, assumptions, and other causes, and showing that they do not affect the conclusions being drawn from the results.
- Describing the forward programme for development of the PSA to the level needed for licensing and operation of individual units.

This chapter lists the areas of severe accident analysis that were performed for AP1000 plant and summarises the treatment in the PSA of severe accident phenomena. Severe accidents are defined as those fault sequences involving significant core damage and/or the potential for dose release in excess of design basis limits ((100 mSv (10 rem) offsite or 500 mSv (50 rem) onsite (Reference 10.1)).

10.1.1 Background and Overview

The AP1000 PSA was developed to support the application for United States (US) Design Certification of the AP1000 nuclear plant. The AP1000 design is based extensively on the AP600 standard nuclear plant that received US Design Certification in December 1999. The AP600 PSA, which was reviewed by the US Nuclear Regulatory Commission (NRC) in detail during the seven-year review of the AP600, is used as the starting point for the AP1000 PSA. Since the configuration of the AP1000 reactor and Class-1 systems is the same as the AP600, the AP600 PSA is used as the basis of the AP1000 PSA with relevant changes implemented in the model to reflect the AP1000 design changes. Additional AP1000 plant specific thermal-hydraulic (T-H) analyses are performed in order to determine the system success criteria. The core damage frequency (CDF) and large release frequency (LRF) are calculated for internal events. Selected internal hazard events and shutdown models are also quantitatively assessed to derive plant insights and plant risk conclusions. Seismic events are assessed using a margin approach to derive plant insights and plant risk conclusions. Other external hazards are evaluated with a qualitative approach.

The purpose of the PSA is to demonstrate that the risk goals are met and to provide inputs to the optimisation of the AP1000 design. As in the AP600, the PSA is being performed interactively with the design, analysis and operating procedures. The historical use of PSA and severe accident analysis to inform the AP1000 design is provided in APPENDIX 10A, Section 10A.1. Section 10A.2.2 shows that there were numerous design improvements made to the AP600 based on PSA insights. Section 10A.2.3 also shows that there were fewer, less significant, plant improvements made to the AP1000 plant based on PSA insights. Note that the very low risk of the AP600 plant has been maintained in the AP1000 plant. Insights from the analysis are provided discussing the effect on the PSA of differences between the AP600 and the AP1000 nuclear power plant (NPP) designs.

10.1.2 How the Reactor Probabilistic Safety Assessment Results Are Used Within the Pre-Construction Safety Report

The PSA is part of the fault and accident assessment for the AP1000 design. An overview of the entire assessment process is given in Chapter 8. The PSA results have been used in the PCSR to demonstrate the compliance with the Office for Nuclear Regulations (ONR) numerical targets and in the demonstration that the overall risks from planned operation of the reactor are as low as reasonably practicable (ALARP). Compliance with the quantitative targets is demonstrated in Chapter 14, where the risks and the frequencies of reactor accidents in different dose bands, as calculated in the PSA, are added to the corresponding quantities for non-reactor faults calculated in Chapter 9, and the totals compared with the targets.

The ALARP arguments made in Chapter 14 make use of the PSA results and analysis, both through the identification of design alternatives based on PSA insights (Section 14.6.3) and through the evaluation of alternatives on the basis of risk. The design alternatives considered include not only Level 1 measures to reduce CDF, but also the severe accident mitigation design alternatives (SAMDAs) aimed at reducing the size and frequency of releases following core damage (Section 14.7.3).

In addition, the estimated frequencies of different reactor initiating events (IEs) are included in the Fault Schedule (Appendix 8A), and are used in Chapter 9 in combination with design basis dose assessments to demonstrate compliance with the quantitative dose-frequency target for design basis accidents (DBAs) (Target 4).Finally, the spread of risk across the different types of reactor accidents is used in this chapter to demonstrate the well-balanced nature of the reactor design, with no particular accident providing a disproportionate share of the overall risk.

10.1.3 Documentation

The at-power internal events model has been updated since APP-GW-GL-022 (Reference 10.1). The updated at-power internal events model is summarized in this chapter. Results given in this chapter reflect these updates.

In addition, the fuel damage frequency from fuel pool faults was determined in UKP-GW-GL-743 (Reference 10.2). The fuel pool risk assessment is presented in Section10.19.

10.1.4 Scope and Exclusions

The updated PSA consists of a Level 1 and Level 2 analysis. The Design Reference Point (DRP) for the updated at-power Internal Events PSA corresponds with Revision 17 of the DCD.

The Level 1 analysis includes:

- Internal IEs evaluation
- Event tree and success criteria analyses
- Plant systems analysis using fault tree models
- Common cause failure and human reliability analyses
- Data analysis
- Fault tree and event tree quantification to calculate the core damage frequency

The Level 2 analysis includes:

- An evaluation of severe accident phenomena and fission product source terms
- Modelling of the containment event tree and associated success criteria
- Analysis of hydrogen burning and mixing

The Level 3 analysis for offsite dose evaluation was determined in APP-GW-GL-022 (Reference 10.1). This assessment has not been updated based on the updated at-power internal events PSA.

The low power and shutdown (LPSD) PSA was determined in APP-GW-GL-022 (Reference 10.1). This assessment has not been updated based on the updated at-power internal events PSA.

Area events and external events analyses, which have been updated based on the updated at-power internal events PSA, include:

- Internal fire assessment
- Internal flooding assessment
- External hazards qualitative screening assessment

The seismic margin assessment was determined in APP-PRA-GSC-027 (Reference 10.78). This assessment has not been updated based on the updated at-power internal events PSA.

The PSA does not address faults involving fuel-handling or other sources of radioactivity outside the reactor core.

The fuel damage frequency from fuel pool faults was determined in UKP-GW-GL-743 (Reference 10.2). This reference has not been updated based on the updated at-power internal events PSA.

10.2 Internal Initiating Events

10.2.1 Overview of IE Analysis Methodology

An IE is defined as an event which perturbs the steady state operation of the plant by challenging plant control and Class-1 systems whose failure could potentially lead to core damage or release of airborne fission products. The IEs described in this section are limited to the internal IEs that occur either as a result of equipment failures or operator action errors while performing tests, maintenance, or other task requirements. These internal IEs may cause a sequence of accident events during plant power operation that may lead to a core damage state. Initiating events are categorized into two different types: Loss of Coolant Accident (LOCA) and Transients.

LOCAs are accidents involving the rupture or failure of the Reactor Coolant System (RCS) boundary including piping, valves, pressure vessel, and interconnecting systems. The LOCAs consider loss of primary coolant inventory inside and outside the containment structure. LOCAs in the containment building are grouped into categories based on the rate of primary coolant loss that can be expressed as the size of the break. Large LOCA, medium LOCA, small LOCA, RCS leakage, safety injection line break, core makeup tank (CMT) line break, and passive residual heat removal (PRHR) tube rupture are considered as events where

equipment can mitigate core damage. Vessel ruptures beyond the core cooling system capability are considered as non-coolable events. Inadvertent valve opening events, such as spurious actuation of the Automatic Depressurization System (ADS) valves, are treated explicitly as inside containment LOCAs. LOCAs that may divert RCS coolant outside containment are segregated into steam generator tube rupture (SGTR) and interfacing system LOCA (ISLOCA) categories. Each of these initiators affects the plant and the event sequence differently and, therefore, is addressed separately.

Transient events disrupt normal plant operation sufficiently to cause a reactor trip and require decay heat removal, but do not directly result in a LOCA. NUREG/CR-3862 (Reference 10.21) classifies the abnormal events leading to pressurized water reactor (PWR) plant challenges into categories. These categories presented along with categories from NUREG/CR-5750 (Reference 10.22) and NUREG/CR-6928 (Reference 10.15) are generally applicable to existing PWR plants. The secondary side breaks upstream and downstream of the main steam line isolation valves and the main steam line stuck-open safety valve are considered as transients because the primary circuit remains intact during these events.

Events that only may occur during hot standby, hot shutdown, cold shutdown, and refuelling are not considered in this section. IEs due to internal fires or floods, and external events are not considered in this section.

For the initial condition, full-power operation, the plant transient condition will result in a reactor trip and challenge the Class-1 systems. Additionally, technical specification violations that require a shutdown in less than 8 hours are included as an IE. In less sudden transients, such as controlled power reductions that do not induce trips, there is a high probability that plant operators will affect an orderly plant shutdown without Class-1 system actuation. Orderly or controlled shutdowns, such as technical specification required shutdowns where the completion time is longer than 8 hours, are not considered IEs since they do not challenge the plant Class-1 systems.

Initiating event analysis is carried out in the following sequence of steps:

- Identification of candidate events
- Quantification of IE frequencies
- Grouping of candidate IEs

10.2.1.1 Identification of Candidate Events

There are two methods used to identify potential IEs. The first is to review reactor operating experience. In this approach, both industry and plant specific operating experiences are reviewed and classified to enumerate the plant trips and IEs that have actually occurred. Both the industry and the NRC have sponsored generic industry surveys of this experience. These surveys as well as plant specific data are reviewed and factored into the evaluation. Since there is no AP1000 plant operating experience available at this time, only generic operating experience can be reviewed.

In addition to reviewing operating experience, a systematic evaluation of plant systems was performed to identify IEs resulting from equipment failures. System engineer interviews were also conducted to review system and equipment failures that could result in an IE.

10.2.1.2 Quantification of Initiating Event Frequency

Initiating event frequency (IEF) data can be obtained directly from a generic data source or quantified by using fault-tree modelling. Fault-tree modelling is typically used for the quantification of support system initiating events (SSIEs). There are some unique IEs where generic data is not representative of the AP1000 plant design and does not result in the loss of a support system. In these cases, alternative methods for IEF quantification are utilized and documented. The following subsections identify the methods for generating IEFs.

10.2.1.2.1 Single Basic Event Initiators

Single Basic Event IEFs can be calculated using generic and/or plant-specific data and are incorporated into the model as a single basic event. Since there is no operational history available for AP1000 plants, only generic data is available and utilized to determine IEFs.

The primary data source for generic IEFs is NUREG/CR-6928 (Reference 10.15). Alternate data sources are used and documented if a given frequency is not available in the primary data source or if an alternate data source is more relevant for a given event than the primary data source. Justification for the use of an alternate data source is documented in the IE analysis.

All single basic event initiators shall be in units of reactor operating state year. The plant availability factor (PAF) is modelled as a basic event in the linked internal events model.

10.2.1.2.2 Support System Initiating Event Frequency

An SSIE occurs when the loss of a normally operating system results in an IE and can adversely affect one or more systems used to mitigate the IE. Loss of a support system can lead to an immediate reactor trip or a delayed reactor trip due to the consequential loss of a mitigating system. Loss of a support system that does not generate an immediate reactor trip but could result in an administrative shutdown due to a technical specification violation is not considered to be an IE and can be screened. Support system IEs are quantified using a fault tree analysis method consistent with the Electric Power Research Institute (EPRI) SSIE guidance (Reference 10.23).

10.2.1.2.3 Interfacing System Loss of Coolant Accident (ISLOCA) Event Frequency

ISLOCA refers to LOCAs outside of the containment. This type of LOCA challenges the ability to achieve a safe stable state, because the RCS inventory losses are outside containment. ISLOCAs are typically initiated by the failure of multiple pressure isolation devices in a line connected to the RCS that penetrates the containment and interfaces with low pressure piping outside containment. The failure of a high to low pressure interface at full power would result in overpressurization and potentially the subsequent failure of the low pressure system piping or components (e.g., heat exchanger tubing, pump seals, etc.). ISLOCA IE analysis can be broken down into two tasks. The first task is the identification of potential ISLOCA pathways and the second task is to quantify the IE frequency for each non screened path from task one. The ISLOCA event identification and quantification methods are consistent with the guidance provided in Reference 10.24. ISLOCAs for each pathway is quantified to generate an IEF.

10.2.1.2.4 Special Initiating Events – Others

There are some unique IEs where generic data is not representative of the AP1000 plant design and the event is not due to of a loss of a support system or an ISLOCA event. In these

cases, alternative methods for frequency calculations are utilized and documented. Relevant data from other generic sources are reviewed for applicability to the design and operation of the AP1000 plant. If generic data is not available, an IEF may be calculated using a fault tree analysis method similar to the support systems IE quantification. This method should address all possible impacts of common cause failures and should not include the contribution due to loss of a support system already quantified.

10.2.1.3 Grouping of Candidate Initiating Events

IEs are combined or grouped to maintain the number of event trees and event sequences to a manageable size and to facilitate quantification. Combining events into a common group is performed based on the similarity of plant response, success criteria, timing, and impact on mitigating systems. Each IE was reviewed using a structured and systematic process to support the grouping of initiators.

10.2.2 Identification of AP1000 Plant Initiating Events

10.2.2.1 Review of Generic Initiating Event Categories

A review was performed of the IEs identified in NUREG/CR-3862 (Reference 10.21), NUREG/CR-5750 (Reference 10.22), and NUREG/CR-6928 (Reference 10.15) to determine if they were applicable to the AP1000 plant design.

10.2.2.2 Review of AP1000 Plant Systems

A systematic evaluation of AP1000 plant systems was performed to identify IEs resulting from equipment failures.

A review for multi-unit IEs was performed. The Raw Water System (RWS) is the only shared system in the AP1000 plant; however it is not modelled as an SSIE. A loss of offsite power (LOOP) affecting multiple units at one site is the only IE identified for multi-unit impact. Note that the impact of a multi-unit LOOP IE is not currently evaluated for the AP1000 plant PSA.

In addition to the initiators from Section 10.2.2.1 that are applicable to the AP1000 plant, the following IEs were identified:

- Spurious Actuation of the ADS
- Spurious In-containment Refuelling Water Storage Tank (IRWST) Actuation
- CMT, Direct Vessel Injection (DVI), and PRHR Line Breaks
- PRHR Tube Rupture
- Reactor Vessel Rupture
- Loss of Additional Support Systems which result in Loss of Component Cooling Water System (CCS), (Loss of Heating, Ventilation, and Air Conditioning (HVAC) to the CCS Pump Room, and Loss of Central Chilled Water High Capacity System (HCS))

The following Protection and Safety Monitoring System (PMS) and Diverse Actuation System (DAS) actuation functions require further evaluation for the general transient category:

- PMS Actuation Functions
  - IRWST Injection
  - Containment Recirculation
  - CMT Injection
  - ADS Actuation
  - PRHR Actuation
  - Passive Containment Cooling Actuation
- DAS Actuation Functions
  - CMT Injection
  - PRHR Actuation
  - Passive Containment Cooling Actuation

The following IEs are typically included in operating plant PSAs but do not apply to AP1000:

- Startup of an inactive reactor coolant pump (RCP) - all RCPs are normally running while at-power.
- Failure of a pressuriser power-operated relief valve (PORV) - the AP1000 plant design does include a pressuriser PORV.
- RCP seal LOCA - the AP1000 plant RCPs are canned-motor pumps and do not have a seal around the motor shaft.

10.2.3 Initiating Events Modeled in the PSA

Table 10-1 provides a summary of the updated IEFs in units of per reactor operating state year for the AP1000 plant PSA. The IE frequencies are also provided in per reactor year in Table 10-1. The per reactor year frequencies in Table 10-1 were calculated by hand using the PAF (assumed to be 0.93). Where applicable, the associated comprehensive automated fault tree analysis software (CAFTA) database variable name or top event is also provided in Table 10-1. Each IE basic event is used in the quantification model in units of per reactor operating state year or SSIE tree. Each IE is multiplied by a PAF basic event to convert from per units of reactor operating state year to units of per reactor year in the linked model.

10.2.3.1 Large LOCA (Break size 22.86 cm (9 inches) diameter or greater)

The large LOCA event is defined as all RCS ruptures with break sizes sufficient to produce a depressurization of the RCS that allows gravity injection from the IRWST. The break size corresponding to this category is a 22.86 cm (9 inches) equivalent diameter or larger break (excluding “vessel rupture event”). The IEF for a large LOCA was calculated from the exceedance frequencies derived from the expert elicitation process documented in NUREG-1829 (Table 7.19 of Reference 10.27). AP1000 plant specific break size exceedance frequencies are interpolated from the known points in NUREG-1829 Table 7.19 using the power law fit method (Reference 10.25). For the AP1000 plant large LOCA category, the break size is greater than a given AP1000 plant effective break size; therefore, the LOCA IEF

is equal to the mean exceedance frequency for that particular AP1000 plant effective break size. Table 10-1 documents the resulting large LOCA IEF.

10.2.3.2 Medium LOCA (Break size between 10.16 and 22.86 cm (4 inches and 9 inches diameter)

The medium LOCA event is defined as all RCS ruptures with break sizes insufficient to depressurize the RCS to allow gravity injection, but sufficient to depressurize the RCS to the Normal Residual Heat Removal System (RNS) operating pressure without operation of the ADS. The break size corresponding to this category is less than 22.86 cm (9 inches) and greater than or equal to 10.16 cm (4 inches) equivalent diameter. On the basis of piping size, the range of this category includes safety injection (SI) line breaks and CMT line breaks. However, because the mitigating systems' response for these break categories is different than that for a medium LOCA, SI and CMT line breaks are evaluated using separate event trees. The IEF for a medium LOCA was calculated from the exceedance frequencies derived from the expert elicitation process documented in NUREG-1829 (Table 7.19 of Reference 10.27). AP1000 plant specific break size exceedance frequencies are interpolated from the known points in NUREG-1829 Table 7.19 using the power law fit method (Reference 10.25). For the medium AP1000 plant LOCA category, the break size ranges are between two given AP1000 plant effective break sizes; therefore, the LOCA IEF is calculated as the difference of the mean exceedance frequencies for those particular AP1000 plant effective break sizes. Table 10-1 documents the resulting medium LOCA IEF.

10.2.3.3 Small LOCA (Break size between 0.95 cm (3/8 inch) and 10.16 cm (4 inches diameter)

The small LOCA is defined as all RCS ruptures with break sizes less 10.16 cm (4 inches) equivalent diameter and greater than those producing leakage that can be made up by the Chemical and Volume Control System (CVS) (about 0.95 cm (3/8 inch) equivalent diameter, which corresponds to a break flowrate of approximately 6.3 L/sec (100 gallons per minute). The IEF for a small LOCA was calculated from the exceedance frequencies derived from the expert elicitation process documented in NUREG-1829 (Table 7.19 of Reference 10.27). AP1000 plant specific break size exceedance frequencies are interpolated from the known points in NUREG-1829 Table 7.19 using the power law fit method (Reference 10.25). For the small AP1000 plant LOCA category, the break size ranges are between two given AP1000 plant effective break sizes; therefore, the LOCA IEF is calculated as the difference of the mean exceedance frequencies for those particular AP1000 plant effective break sizes. Table 10-1 documents the resulting small LOCA IEF.

10.2.3.4 RCS Leak (Break size less than 0.95 cm (3/8 inch diameter)

The RCS Leak is defined as all RCS ruptures with break size less than 0.95 cm (3/8 inch) equivalent diameter (i.e., leaks that can be made-up by the CVS, which corresponds to a break flowrate of approximately 6.3 L/sec (100 gpm). The CVS is designed to make up RCS leaks of 6.3 L/sec (100 gpm) or less. If the CVS fails, the pressuriser water level will decrease and the event will proceed as a small LOCA. The RCS Leak IEF was determined by a review of generic industry data from NUREG/CR-6928 (Reference 10.15) for a very small LOCA. The NUREG/CR-6928 IE name for this event is IE-VSLOCA. Table 10-1 documents the RCS Leak IEF.

10.2.3.5 Spurious Actuation of the Automatic Depressurization System – ADS Stages 1-3

A spurious actuation of ADS Stages 1-3 occurs when any combination of ADS Stages 1-3 valves spuriously operate and open a flow path from the RCS into the IRWST. The frequency

for spurious actuation of the ADS Stages 1-3 MOVs is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.6 Spurious Actuation of the Automatic Depressurization System – ADS Stage 4

Spurious actuation of the ADS Stage 4 is defined as an inadvertent opening of one or more ADS Stage 4 valves. The frequency for spurious actuation of the ADS Stage 4 squib valves is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.7 Spurious IRWST Actuation

Spurious actuation of the IRWST is defined as an inadvertent opening of one or more IRWST squib valves. The frequency for spurious actuation of the IRWST squib valves is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.8 Core Makeup Tank Line Break

Each CMT line break is defined as all ruptures occurring in one of the lines connecting the CMT to the reactor coolant cold legs. On the basis of break size, this category is classified as a medium LOCA, but it is modelled in a different event tree from the medium LOCA because only one of the CMTs is available for mitigation, with no other systems being impacted. The CMT line break event frequencies are based on system piping information and are calculated using EPRI pipe rupture frequencies (Reference 10.28). The result is documented in Table 10-1.

10.2.3.9 Direct Vessel Injection Line Break

Each DVI line break is defined as all ruptures occurring in one of the safety injection trains and includes the DVI lines and the lines that connect the CMT, accumulator, IRWST, and the RNS injection line to the DVI lines. The DVI line break event frequencies are based on system piping information and are calculated using EPRI pipe rupture frequencies (Reference 10.28). The result is documented in Table 10-1.

10.2.3.10 Passive Residual Heat Removal Line Break

The PRHR line break event is defined as all ruptures occurring in the line connecting the reactor coolant hot leg to the PRHR heat exchanger and the lines connecting the PRHR heat exchanger to the reactor coolant cold leg. The PRHR line break event frequency is based on system piping information and is calculated using EPRI pipe rupture frequencies (Reference10.28). The result is documented in Table 10-1.

10.2.3.11 Passive Residual Heat Removal Tube Rupture

This category includes events in which a single PRHR heat exchanger tube has a complete circumferential rupture. If CVS operation or PRHR isolation fails, the PRHR tube rupture event progression is similar to that for a small LOCA. Based on the ratio of PRHR tubes to steam generator tubes, the frequency of PRHR tube rupture event is expected to be at least 29 times lower than the frequency of an SGTR. The frequency of an SGTR event, based on pressurized water reactor (PWR) generic industry data from NUREG/CR-6928 (Reference 10.15), is 3.54E-03 event per reactor operating year. The PRHR Tube Rupture

frequency was calculated by dividing the SGTR IEF in units of per reactor operating year by a factor of 29. The resulting PRHR tube rupture IEF is documented in Table 10-1.

10.2.3.12 Reactor Vessel Rupture

Reactor vessel rupture is defined as the random failure of the reactor vessel, resulting in a LOCA size/location that exceeds the passive core cooling system capability. The frequency of 2.90E-08 events per reactor year for vessel rupture is from Reference 10.26. This frequency was converted to reactor operating state year by dividing by an assumed industry average plant availability factor of 0.90. The resulting reactor vessel rupture IEF is documented in Table 10-1.

10.2.3.13 Steam Generator Tube Rupture

An SGTR event is defined as a rupture of one or more than one steam generator tubes, either as an IE (e.g., tube rupture due to high cycle fatigue or loose parts) or as a consequence of other IEs (i.e., a main steam line break or stuck-open main steam line safety valve). The SGTR IEF was determined by a review of generic industry data from NUREG/CR-6928 (Reference 10.15). The NUREG/CR-6928 IE name for this event is IE-SGTR (PWR). The generic data is applicable for the AP1000 plant, due to the similarity of the AP1000 plant steam generator design to the PWR legacy plant steam generator design on which NUREG/CR-6928 data is based. Table 10-1 documents the SGTR IEF.

10.2.3.14 Interfacing Systems LOCAs

The ISLOCA refers to a LOCA through a line connected to the RCS in which RCS inventory bypasses containment. The ISLOCA is typically initiated by the failure of pressure isolation devices in a line connected to the RCS that penetrates the containment and involves low pressure piping outside containment.

Seven ISLOCA scenarios were identified and modelled using the CAFTA fault tree approach following guidance in Reference 10.24. The seven ISLOCA scenarios and their respective containment penetration identifiers are:

- CCS RCP external heat exchanger (HX) Outlet Line, penetration P04
- CVS Spent Resin Sluice Line, penetration P05
- CVS Normal Makeup Line, penetration P07-N
- CVS passive core cooling system (PXS) Header Makeup Line, penetration P07-P
- CVS Zinc Injection Line, penetration P08
- RNS Suction Line, penetration P19
- RNS DVI Injection Line, penetration P20

The resulting ISLOCA IEFs are documented in Table 10-1.

10.2.3.15 Contribution to LOCA Event Frequencies by Other Initiating Events

Consequential LOCA due to other IEs are analysed with the event tree for the corresponding IEs. For example, during a reactor trip with a loss of secondary side cooling and loss of the PRHR system the RCS can pressurize to the RCS safety valves set point. After the safety valves are challenged, there is a possibility that the safety valves will fail to reseat. This could lead to a LOCA event. A review of LER events under the category of stuck open safety relief valve was performed. All events reviewed were a result of a safety valve failing to reseat/leaking after a test or a self-revealing maintenance error while returning to power. Therefore, a stuck open safety relief valve is not addressed as a separate IE but is addressed as a consequence if the safety valves are lifted and fail to reseat in the event tree for events where the safety valves' opening set point could be reached.

The AP1000 plant RCPs are canned-motor pumps. Primary coolant circulates between the stator and rotor for cooling. A seal around the motor shaft is not necessary; therefore, the design is not susceptible to RCP seal LOCAs due to loss of cooling and injection.

10.2.3.16 PMS Spurious PRHR Actuation

Spurious opening of the PRHR valves will result in a cooldown event to the RCS resulting in a possible reactor trip. PMS PRHR actuation will also directly cause a reactor trip. The frequency for spurious opening of the PRHR air-operated valves (AOVs) (PXS-PL-V108A/B) is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.17 PMS Spurious CMT Actuation

Spurious opening of the CMT injection valves could result in borated water entering the core and could result in a reactor trip. The frequency for spurious opening of the CMT injection AOVs (PXS-PL-V014A/B or PXS-PL-V015A/B) is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.18 Spurious IRWST Recirculation

Spurious opening of the recirculation valves could drain the IRWST into containment. If any of the IRWST squib valves indicate that they are open, then the operators are directed to start a shutdown of the reactor. This manual shutdown of the reactor is maintained as a potential reactor trip. The frequency for spurious opening of the IRWST recirculation squib valves (PXS-PL-V118A/B or PXS-PL-120A/B) is generated by a special initiator fault tree over a one year mission time. The result is documented in Table 10-1.

10.2.3.19 General Transient Sub-Groups

The general transient IEF from NUREG/CR-6928 (Reference 10.15) is 7.51E-01 per reactor operating state year. The NUREG/CR-6928 IE name for this event is IE-TRAN (PWR). The same event categorization in NUREG/CR-5750 (Reference 10.22) was also used for the development of the frequencies in NUREG/CR-6928.

To address the dependency a General Transient (GTRAN) IE could have on mitigating equipment, sub-grouping is required. Initiators that generate a safeguards signal or fail operation of main feedwater (MFW) should be separated from events that do not impact the ability for MFW to provide decay heat removal during an event.

To achieve this separation, a review of general transient events was performed so the frequency could be fractioned into sub-groups. Note that the IEs unique to the AP1000 plant, identified in Section 10.2.2.2, have been excluded from the sub-grouping since there is no applicable generic category. The three groups and the corresponding number of events identified from NUREG/CR-5750 applicable categories are as follows:

- General Transient with Main Feedwater (717 events)
- General Transient without Main Feedwater (433 events)
- General Transient with Safeguards Actuation Signal (S Signal) (34 events)

The fraction of the number of events for each sub-group over the total number of events (1184 events) was then multiplied by the GTRAN IEF from NUREG/CR-6928 provided above. The resulting frequency for each GTRAN IE sub-group is documented in Table 10-1.

10.2.3.20 Total Loss of Main Feedwater

This category includes those events in which the MFW flow to both steam generators is lost or isolated as an IE, leading to a reactor trip (including the primary and secondary power mismatch and the events that generate a safeguards actuation). The total loss of main feedwater IEF was determined by a review of generic industry data from NUREG/CR-6928 (Reference 10.15). The NUREG/CR-6928 IE name for this event is IE-LOMFW. Table 10-1 documents the total loss of MFW IEF.

10.2.3.21 Total Loss of Condenser Heat Sink

This category includes those events that result in loss of the condenser as a heat sink. This category includes inadvertent closure of all main steam isolation valves (MSIVs), loss of condenser vacuum, and unavailability of the turbine bypass. The total loss of condenser heat sink IEF was determined by a review of generic industry data from NUREG/CR-6928 (Reference 10.15). The NUREG/CR-6928 IE name for this event is IE-LOCHS (PWR). Table 10-1 documents the total loss of condenser heat sink IEF.

10.2.3.22 Total Loss of Component Cooling Water

This category consists of the complete loss of CCS flow due to either an operator error or a mechanical failure. Loss of CCS causes loss of RCP flow, which results in a reactor trip. The frequency for loss of CCS is generated by an SSIE fault tree over a 1 year mission time. The result is documented in Table 10-1.

10.2.3.23 Total Loss of Service Water System

This category consists of the complete loss of Service Water System (SWS) flow due to either an operator error or a mechanical failure. Loss of SWS results in loss of CCS. The frequency for loss of SWS is generated by a support system IE fault tree over a 1 year mission time. The result is documented in Table 10-1.

10.2.3.24 Total Loss of Compressed and Instrument Air System

The complete loss of the Compressed and Instrument Air System (CAS) causes the feedwater flow control valves to close resulting in a turbine trip/reactor trip. The loss of CAS also causes full opening of the startup feedwater (SFW) regulating valves, closure of both MSIVs and/or loss of PORV availability, and opening of the CMT valves and PRHR valves. The frequency for loss of CAS is generated by an SSIE fault tree over a 1 year mission time. The result is documented in Table 10-1.

10.2.3.25 Loss of Medium Voltage ac Power

This category includes loss of a Main alternating current (ac) Power System (ECS) ac bus due to either an operator error or a mechanical failure that could generate a reactor trip. Loss of a 6.9 kilo volt (KV) bus could result in a reactor trip due to loss of an RCP or loss of equipment supporting feedwater operation. All of the ECS buses were reviewed for possible failure modes leading to IEs. The IEF for loss of medium voltage ac power is from NUREG/CR-5750 (Reference 10.22, Table D-11, category C1). Table 10-1 documents the loss of medium voltage ac power IEF.

10.2.3.26 Loss of Low Voltage direct current (dc) Power

Loss of certain Class 1 DC and Uninterruptible Power Supply System (IDS) Class 1 dc buses can generate a reactor trip. IDS consists of the redundant Class 1 DC and ac uninterruptible power supply (UPS) power distribution systems feeding Class-1 loads. IDS provides uninterruptable power for the plant instrumentation, control, monitoring, and other vital functions required for plant startup, normal operation, and normal or emergency shutdown of the plant. All of the IDS buses were reviewed for possible failure modes leading to IEs. The frequencies for loss of IDS are generated by SSIE fault trees over a 1 year mission time. The loss of low voltage power IEF was calculated by hand by adding together the individual IDS bus IEFs. The result is documented in Table 10-1.

10.2.3.27 Loss of HVAC to the CCS Pump Room

This category consists of the complete loss of room cooling to the CCS pump room due to failure of the Turbine Building Ventilation System (VTS) South Bay Equipment Area HVAC Subsystem. Loss of room cooling to the CCS pumps results in loss of CCS. Loss of CCS causes loss of reactor coolant pump flow, which results in a reactor trip. The frequency for loss of HVAC to the CCS pumps is generated by an SSIE fault tree over a 1 year mission time. The result is documented in Table 10-1.

10.2.3.28 Loss of Central Chilled Water System HCS

This category consists of the loss of the common flow path of the Central Chilled Water System HCS which supports HVAC load to the room where the CCS pumps are located. Loss of central chilled water to this HVAC load would result in loss of room cooling to CCS pumps. Loss of room cooling to the CCS pumps results in a reactor trip. The frequency for loss of Central Chilled Water HCS is generated by an SSIE fault tree over a 1 year mission time. The result is documented in Table 10-1.

10.2.3.29 Total Loss of Offsite Power

A LOOP event is defined as an event that results from a loss of the offsite grid power (loss of the grid itself and failures of equipment that tie the plant to the grid). The total LOOP IEF was determined by a review of generic industry data from NUREG/CR-6928 (Reference 10.15). The NUREG/CR-6928 IE name for this event is IE-LOOP. Table 10-1 documents the total LOOP IEF.

10.2.3.30 Steam Line Break Downstream of the MSIVs

This category includes breaks in the main steam lines downstream of the MSIVs. The steam generator can be quickly isolated from the breaks without significant steam generator depressurization. To maximize their effect, all secondary side piping breaks are assumed to be large breaks. This is conservative because smaller breaks cause less severe scenarios with much longer times for operator actions.

The primary generic data source (Reference 10.15) does not include steam line break (SLB) outside containment frequencies. The SLB downstream of the MSIVs IEF was determined by a review of generic industry data from NUREG/CR-5750 (Reference 10.22) SLB outside containment category. A portion of the main steam line is outside containment but upstream of the MSIVs, and therefore is not isolatable. A review of the event reports identified in Table D-5 of NUREG/CR-5750 was performed for the SLB outside containment category (K1). All of the events that occurred were downstream of the MSIVs and were isolatable leaks or breaks. Table 10-1 documents the SLB downstream of MSIVs IEF.

10.2.3.31 Steam Line Break Upstream of the MSIVs

This category includes breaks in the main steam lines upstream of the MSIVs, breaks in the main feedwater lines downstream of the feedwater isolation valves, and SFW line breaks downstream of the SFW isolation valves. In these cases, the faulted steam generator cannot be isolated from the breaks. These breaks result in complete steam generator depressurization. To maximize their effect, all secondary side piping breaks are assumed to be large breaks. This is conservative because smaller breaks cause less severe scenarios with much longer times for operator actions.

The primary generic data source (Reference 10.15) does not contain information to support steam line break inside containment frequencies. SLB upstream of the MSIVs IEF was determined by a review of generic industry data from NUREG/CR-5750 (Reference 10.22) SLB inside containment. The NUREG/CR-5750 IE category for this event is K3. Table 10-1 documents the SLB upstream of MSIVs IEF.

10.2.3.32 Feedwater Line Break

This category includes breaks outside containment in the MFW lines upstream of the feedwater isolation valves, in the SFW line upstream of the SFW isolation valves, and in the condensate line that contains main turbine working fluid at or above atmospheric saturation conditions. The primary generic data source (Reference 10.15) does not contain information to support feedwater line break frequencies. The feedwater line break IEF was determined by a review of generic industry data from NUREG/CR-5750 (Reference 10.22, Table D-11). The NUREG/CR-5750 IE category for this event is K2. Table 10-1 documents the feedwater line break IEF.

10.2.3.33 Anticipated Transient without Trip (ATWT)

An ATWT event is defined as one in which the reactor trip should occur but mechanical failure of the rod control system or failure of the PMS system prevents dropping of the control rods into the core. The failure probability of the automatic and manual reactor trip is used in ATWT frequency calculation.

10.2.4 Grouping of AP1000 Plant Initiating Events

IE groups are events that have similar plant response, success criteria, timing, impact on mitigating systems, and effect on operators. To identify events with similar plant responses, the high level functions of reactivity control, RCS inventory control, RCS overpressure control, and reactor core decay heat removal were used. Table 10-2 includes a summary of the IE grouping results.

10.2.4.1 Grouping of LOCAs

Initiating events that require RCS inventory control as a primary mitigation function are defined as LOCAs. The break sizes for large, medium, small, and RCS leak were based on the thermo – hydraulic response of the AP1000 plant. No mitigation equipment is credited for the reactor vessel rupture IE. Since the RCS LOCA breaks size categories are based on the differences in the impact on mitigation equipment it is not appropriate to group any of the RCS LOCAs.

Breaks in the passive Class-1 systems connected to the RCS (CMT, DVI, and PRHR) could impact the ability of that system to perform its mitigation function. Opening of the ADS Stages 1-3 valves results in a different plant response than opening the ADS Stage 4 valves. Based on the differences in the impact on mitigation equipment none of the passive Class-1 system LOCAs were grouped.

Unlike the breaks in the RCS and breaks in the passive Class-1 systems connected to the RCS, SGTR and ISLOCA events could result in bypassing the containment. Credit for isolation of the break may also be possible for SGTR and ISLOCA events. Due to the potential for bypassing containment, the differences due to the impact of the IE on mitigation equipment and the expected operator response, grouping of ISLOCAs with SGTR is not recommended. No mitigation equipment is credited for non isolatable ISLOCA IEs.

In summary, none of the LOCA IEs were grouped except for the ISLOCA IEs and PRHR tube rupture with small LOCA. Table 10-2 lists all the LOCA IEs which are modelled in specific event trees. For each IE group, a corresponding event tree is developed except for non isolatable ISLOCA, PRHR tube rupture, and vessel rupture initiation events.

10.2.4.2 Grouping of Transients

IEs that do not require RCS inventory control as a primary mitigation function are defined as transient events. The IEs which are identified as general transients with safeguards and without safeguards all have the same expected emergency operating procedures (EOPs) to be entered by the operators. These initiators are grouped into two different categories since PRHR actuation following a safeguards signal will result in isolation of SFW and MFW. Loss of compressed air and loss of low voltage power can result in actuation of PRHR and the CMTs due to loss of power or air to the normally energized PXS AOVs. Within the general transient without MFW group there are several IEs that should not credit MFW. For example, transients due to loss of SWS or loss of CCS would result in loss of MFW.

Loss of offsite power was not grouped with the general transient events to support model development and review. It is important to understand what sequences can lead to station blackout events. Breaks in the steam lines and feedwater lines can result in rapid depressurization of the secondary side and a cooldown of the RCS. This cooldown causes an increase in reactivity and requires additional boron to be added into the RCS to mitigate the event. These events were grouped by the ability to isolate the blowdown of the steam generators.

10.3 Accident Sequence Analysis

10.3.1 Method Discussion

The Accident Sequence Analysis develops the plant response to an IE based on the operator action and system response to specific initiators. This Accident Sequence model and event tree structure includes operator actions, mitigating systems, and phenomena that can alter the accident sequence progression. The event tree structure is based on expected plant response, the EOPs, information from the safety analyses in Chapter15 of the PCSR, and insights from the previous AP1000 plant PSA model. The Success Criteria Analysis, as summarized in Section 10.4, supports the individual accident sequence paths including the functional success, mission times, and human error probability (HEP) time windows. Based on the event tree and Success Criteria models, the core damage paths are binned into a plant damage state to facilitate the Level 1/Level 2 model interface.

10.3.2 Event Tree Models

The event tree models are summarized in the following sections for each IE group. The IE groups from Table 10-2 are listed with their corresponding event tree names in Table 10-3. Table 10-4 through Table 10-28 provide descriptions for each event tree.

In the event tree descriptions, if an operator action can be taken to actuate equipment following a signal failure, then the appropriate procedure and operator action identifier are listed at the beginning of the top event description.

Plant Damage States (PDSs) for core damage sequences are defined in Section 10.10.1.

10.3.2.1 Large Loss of Coolant Accident

The LLOCA includes RCS pipe breaks inside containment with sizes sufficient to produce a depressurization of the RCS that allows gravity injection from the IRWST. The break size range for LLOCA is 22.86 cm (9 inches) up to a double-ended rupture of the hot leg. The event tree model that addresses the plant response to an LLOCA IE is LLOCA. The event tree top events are described in Table 10-4.

10.3.2.2 Medium Loss of Coolant Accident

The MLOCA event includes breaks in the RCS contained inside containment with sizes that are smaller than LLOCAs (the upper bound of MLOCAs) and larger than small LOCAs (SLOCAs) (the lower bound of MLOCAs). The MLOCA event is defined as all RCS ruptures with break sizes sufficient to allow the automatic actuation of ADS Stage 4 without the operation of the ADS Stages 1-3, and ruptures in which there is sufficient pressure decrease and time to initiate the RNS if the IRWST injection fails. In addition, void formation in the core is not sufficient to shut down the reactor; therefore, reactor trip is also required. The break size range for MLOCA is 10.16 cm (4 inches) to less than 22.86 cm (9 inches). The event tree model that addresses the plant response to an MLOCA IE is MLOCA. The event tree top events are described in Table 10-5.

10.3.2.3 Small Loss of Coolant Accident

SLOCA events are characterized by breaks in the RCS with sizes between 0.95 cm (3/8 inch) and less than 10.16 cm (4 inches). These events consist of RCS breaks having a size greater than those producing leakage that can be made up by the CVS but less than that required to depressurize the RCS sufficiently without PRHR or ADS Stages 1-3 before ADS Stage 4 can automatically open. The event tree model that addresses the plant response to an SLOCA IE is SLOCA. The event tree top events are described in Table 10-6.

10.3.2.4 RCS Leak

The RCS leakage event includes leak rates less than the flow from a 0.95 cm (3/8 inch) break (less than approximately 6.3 L/sec – 100 gpm). Typical examples of small line breaks include failed instrument process lines or tubing. The CVS is designed to make up RCS leaks of 6.3L/sec (100 gpm) or less. This function allows the plant to be taken to cold shutdown conditions without the use of Class-1 makeup systems. The controlled plant shutdown is not modelled, but if the CVS system fails, the pressuriser level will decrease and the event will proceed as a slower version of a small LOCA. This is modelled in the event tree. The event tree model that addresses the plant response to an RCS Leak IE is LEAK. The event tree top events are described in Table 10-7.

10.3.2.5 Spurious ADS Stages 1-3 Actuation

A spurious actuation of ADS Stages 1-3 occurs when any combination of ADS Stages 1-3 valves spuriously operate and open a flow path from the RCS into the IRWST. The lower bound of this initiator would be the actuation of only one ADS Stage 1 valve. The upper bound of this initiator would be the actuation of both trains of ADS Stages 1-3 valves. The most likely cause of a spurious ADS Stages 1-3 actuation would occur because of a spurious PMS signal. This spurious signal would actuate one train of ADS Stage 1, and then actuate the remaining ADS Stages 2-3 valves on that train with the appropriate time delay. The ADS Stage 1 valves are 10.16 cm (4 inches) and the Stages 2 and 3 valves are 20.32 cm (8 inches). Given the range of the equivalent break sizes that could occur, this could behave similar to an MLOCA or an LLOCA. Success Criteria Analysis demonstrates that with all six ADS Stages 1-3 valves spuriously opening, the event behaves like an MLOCA. This is the basis for the event tree development. The event tree model that addresses the plant response to a spurious ADS Stages 1-3 IE is SPADS13. The event tree top events are described in Table 10-8.

10.3.2.6 Spurious ADS Stage 4 Actuation

The spurious actuation of one or more ADS Stage 4 valves is modelled for this IE. The most realistic scenarios for spurious actuation are one ADS Stage 4 valve, both ADS Stage 4 valves in the same compartment, or all four ADS Stage 4 valves actuating. The piping to the ADS Stage 4 valves has a nominal diameter of 35.56 cm (14 inches); however, the flow is limited by the squib valve internal flow area. The minimum internal diameter for the ADS Stage 4 line from the line reducer to the squib valve (RCS-PL-V004A) is 23.47 cm (9.24inches) based on the squib valve. This is slightly above the diameter cutoff for a Medium LOCA (less than 22.86 cm (9 inches); however, there is uncertainty concerning the piping response as a result of the spurious actuation, and it is judged that the resulting transient will act similar to a Medium LOCA. For more than one ADS Stage 4 valve, the flow would correspond to an LLOCA. The event tree model that addresses the plant response to a spurious ADS 4 IE is SPADS4. The event tree top events are described in Table 10-9.

10.3.2.7 Spurious IRWST Actuation

The spurious actuation of one or more IRWST squib valves is modelled for this IE. The scenarios for spurious actuation are one to all four IRWST squib valves actuating. The spurious actuation of one or more IRWST squib valves causes a pressure transient in the piping and exposes the piping and check valves upstream of the squib valves to RCS pressure. If the check valve upstream of the squib valve fails, the result is a LOCA into the IRWST. Due to the transient, there is a possibility that the piping pressure boundary could fail resulting in a DVI LOCA with early draining of the IRWST. It is assumed that the pipe pressure boundary remains intact if the check valve remains closed. For this event, even when the pressure boundary integrity is maintained and the check valve remains closed, there is a 0.32 cm (1/8”) diameter hole in the check valve for pressure balancing so the consequence would be an RCS leak into the IRWST. The event tree model that addresses the plant response to a spurious IRWST actuation IE is SPIRWST. The event tree top events are described in Table 10-10.

10.3.2.8 CMT Line Break

This event is a failure in the piping leading to or from either CMT. This includes the piping from the Loop 2 cold legs to the CMTs and from the CMTs to the normally closed isolation valves (PXS-PL-V014A, V014B, V015A, V015B) upstream of the DVI line. The piping has a nominal diameter of 20.32 cm (8 inches). The unique feature of a break in the CMT piping is that it could range from an RCS Leak to an MLOCA with the one CMT disabled, especially for the larger break sizes. At some point, the smaller break sizes would not fail the function of the CMT but may degrade it. These breaks would not be substantially different from SLOCAs in other parts of the primary loop. Therefore, this event focuses on the larger break sizes that disable the function of one CMT. The event analysed is an MLOCA break in the piping to or from a CMT. The event tree top events are described in Table 10-11.

10.3.2.9 DVI Line Break LOCA

The DVI lines are a nominal 20.32 cm (8 inches in diameter). Each DVI line has a flow venturi built into the nozzle at the RV which is designed to limit the flow out of the vessel for a DVI line break. The venturi has an inside diameter of 10.16 cm (4 inches) making this equivalent to the low end of the MLOCA break size range. Therefore, the DVI line break can be classified as an MLOCA event, but some considerations must be made for the event progressing as an SLOCA or RCS Leak. The event tree model that addresses the plant

response to a DVI line break IE is DVILB. The event tree top events are described in Table 10-12.

10.3.2.10 PRHR Line Break

This event is a failure in the piping from the RCS Loop 1 hot leg to the PRHR heat exchanger or from the PRHR heat exchanger to the Loop 1 steam generator (SG). This piping has a nominal diameter of 35.56 cm (14 inches), and one section has a nominal diameter of 45.72 cm (18 inches). The unique feature of a break in the PRHR piping is that it could range from an RCS Leak to an LLOCA with the PRHR function disabled, especially for the larger break sizes. At some point, the smaller break sizes would not fail the function of the PRHR heat exchanger but may degrade it. These breaks would not be substantially different from SLOCAs in other parts of the primary loop. Therefore, this event focuses on the larger break sizes that disable the function of the PRHR. The event analysed is a medium to large break in the piping to or from the PRHR heat exchanger. The event tree model that addresses the plant response to a PRHR line break IE is PRHRLB. The event tree top events are described in Table 10-13.

10.3.2.11 PRHR Tube Rupture

This event is a failure of a single PRHR heat exchanger tube ranging from a small leak up to a complete circumferential tube rupture. As soon as the event initiates, the PRHR heat exchanger inlet pipe temperature begins to increase up to a value at which an alarm in the main control room is actuated. If the leak rate (as indicated by RCS mass balance) is less than the technical specification limit, the plant can continue to operate. If the leak exceeds the technical specification limit, the plant will be shut down to repair the leak. If a complete rupture of a PRHR heat exchanger tube occurs, the RCS transient is fast enough that the reactor is expected to trip and safety injection actuated before the operators are able to isolate the PRHR heat exchanger.

During a PRHR tube rupture event, decay heat removal using PRHR is credited based on the Success Criteria Analysis. This means that the PRHR tube rupture event can be modelled as a SLOCA; therefore, a separate event tree is not required.

10.3.2.12 Steam Generator Tube Rupture

The SGTR initiator covers a range of faults from a single tube double-ended guillotine rupture up to and including a five-tube double-ended guillotine rupture. After reactor trip, the ruptured SG is isolated and the RCS is cooled down and depressurized to stop the flow of RCS coolant into the secondary side of the ruptured SG. The MFW pumps are tripped on an S signal; therefore, they are not credited for this event. The event tree model that addresses the plant response to a SGTR IE is SGTR. The event tree top events are described in Table 10-14.

10.3.2.13 ISLOCA – CVS Spent Resin Sluice Line, CVS Makeup Line, or CVS Zinc Injection Line

Section 10.2 documents the analysis performed to identify ISLOCA events. Of the ISLOCA pathways identified, three have the capability of being isolated, thus terminating the LOCA outside containment. The three are the CVS spent resin sluice line, the CVS makeup line, and the CVS zinc injection line. The other ISLOCA pathways identified cannot be isolated and are modelled as going directly to core damage. The event tree model that addresses the plant

response to an ISLOCA IE is ISL-CVS. The event tree top events are described in Table 10-15.

10.3.2.14 General Transient with Safeguards Actuation

A spurious S signal causes a reactor trip and will also result in a trip of the MFW pumps. At the beginning of this IE, the RCS and secondary sides are intact. The decay heat removal systems available are the PRHR System, SFW System, and RCS depressurization using the ADS with IRWST/RNS injection and recirculation. The MFW pumps are tripped on an S signal; therefore, they are not credited for this event. The event tree model that addresses the plant response to a general transient with an S signal IE is GTRAN-WS. The event tree top events are described in Table 10-16.

10.3.2.15 General Transient, No Safeguards Actuation

This category of events includes transients that cause a reactor trip without an S signal in conjunction with the reactor trip. At the beginning of the IE, the RCS and secondary sides are intact. The decay heat removal systems available are the MFW System, SFW System, PRHR System, and RCS depressurization using the ADS with IRWST/RNS injection and recirculation. The event tree model that addresses the plant response to a general transient (no initial safeguards signal) IE is GTRAN. The event tree top events are described in Table 10-17.

10.3.2.16 Loss of Offsite Power

The LOOP event applies to a transient event that begins with the loss of electrical power from the plant switchyard (loss of the grid itself or failures of equipment that tie the plant to the grid). Restoration of the grid within the PSA time period is not modelled. The passive Class-1 systems need only battery power to actuate. Class 1 250 Vdc divisions A and D battery banks and one of the battery banks in divisions B and C are designated as 24-hour battery banks and provide power to the loads required for the first 24 hours following a loss of all ac power event. The second battery banks in divisions B and C, designated as the 72-hour battery banks, are used for those loads requiring power for 72 hours following the same event.

In addition, systems powered by the standby diesel generators (DGs) are modelled. Note that the MFW pumps are not powered by the standby DGs. A LOOP, with the subsequent failure of both trains of onsite ac power, is a station blackout (SBO) event. For an SBO, only dc power is available from the batteries; therefore, only the passive Class-1 systems can be actuated.

The event tree model that addresses the plant response to a LOOP IE is LOOP. The event tree top events are described in Table 10-18.

10.3.2.17 SLB Downstream of the MSIVs

This IE group includes breaks in the main steam lines downstream of the MSIVs, and breaks in the MFW lines upstream of the feedwater isolation valves (FWIVs). In both events, both SGs can be isolated from the breaks.

SFW is not modelled for this event. PRHR will be actuated on SG level signals for the secondary side breaks in this group. If SFW is operating along with PRHR, then combining their operation with the cooldown from the steam line break would most likely result in an RCS Low Tcold signal. This signal isolates SFW. Therefore, to cover all of the secondary

break cases in this group and to address the possibility that the secondary side break could cause a harsh environment and disable SFW, SFW is not modelled.

The event tree model that addresses the plant response to a steam line break downstream of the MSIVs IE is SLBD. This event tree is also used for a pipe break upstream of the FWIVs. The event tree top events are described in Table 10-19.

10.3.2.18 SLB Upstream of the MSIV

This IE group includes breaks of the main steam lines upstream of the MSIVs, breaks of the MFW lines downstream of the FWIVs, and SFW line breaks downstream of the SFW isolation valves. In these events, the faulted SG cannot be isolated from the break. Successful operation of the isolation valves does not prevent the faulted SG from blowing down; however, it does prevent blowdown of both SGs. The event tree model that addresses the plant response to a steam line break upstream of the MSIVs IE is SLBU. The event tree top events are described in Table 10-20.

10.3.2.19 Spurious IRWST Recirculation

A spurious opening of the PXS recirculation valves can start draining the IRWST inventory to the reactor cavity. A low IRWST level alarm provides a cue for the operator to take action to isolate IRWST injection valves. If any of the IRWST squib valves indicate that they are open, then the operators are directed to start a shutdown of the reactor. This manual shutdown of the reactor is maintained as a potential reactor trip. If the reactor is not manually shut down, there is a potential that the normal plant operation may be challenged due to the increased water level in the reactor cavity and sump. This IE mode includes the likelihood of any one recirculation valve opening and the likelihood of a common cause event resulting in all recirculation valves opening. The event tree model that addresses the plant response to a spurious IRWST recirculation IE is SPRECIRC. The event tree top events are described in Table 10-21.

10.3.2.20 Transfer Tree ATWT – Loss of MFW

The ATWT precursors encompass a spectrum of IEs and ensuing plant transient progressions. This ATWT category applies to those transient precursors where the MFW is lost as a part of the IE. The event tree model that addresses the plant response to an ATWT with loss of MFW IE is ATWT-LMFW. The event tree top events are described in Table 10-22.

10.3.2.21 Transfer Tree ATWT – MFW Available

The ATWT precursors encompass a spectrum of IEs and ensuing plant transient progressions. This ATWT category applies to those transient precursors where the MFW is available at the beginning of the IE. The event tree model that addresses the plant response to an ATWT with MFW IE is ATWT. The event tree top events are described in Table 10-23.

10.3.2.22 Transfer Tree LOCA – No Trip

Reactor trip is required in all of the LOCA event trees except LLOCA. If reactor trip fails, the LOCA event is transferred to the LOCA no trip event tree. This event tree covers various size LOCAs at various locations in the RCS, CMT, ADS, and DVI lines. Therefore, a bounding approach is taken with regard to systems and components modelled for successful plant shutdown. The event tree model that addresses the plant response to a LOCA event without a reactor trip is LOCA-NOTRIP. The event tree top events are described in Table 10-24.

10.3.2.23 Transfer Tree LOCA – Secondary Side Fault

The LOCA secondary side fault event tree is used to address certain LOCA IEs in which the secondary side failed either because the SG safety valves, SG PORVs, and turbine bypass valve failed to open resulting in a pressure boundary failure or because the SG safety valves, SG PORVs, or turbine bypass valve failed to reclose after opening, or turbine trip failed. The event becomes a LOCA with a secondary side failure. The event tree model that addresses the plant response to a LOCA event with a secondary side failure is LOCA-SSFAULT. The event tree top events are described in Table 10-25.

10.3.2.24 Transfer Tree SGTR – No Trip

This event tree addresses an SGTR without reactor trip. Because reactor trip has failed, a CMT is required to shut down the reactor. Based on the ATWT analyses and success criteria, turbine trip and secondary side pressure relief are addressed for this event. The event tree model that addresses the plant response to a SGTR event without a reactor trip is SGTR-NOTRIP. The event tree top events are described in Table 10-26.

10.3.2.25 Transfer Tree SLBD – General Transient

This event tree addresses a secondary side line break downstream of the MSIVs (or upstream of the FWIVs) with successful reactor trip and successful isolation of the break so that no further SG inventory is lost through the break. This changes the event after the initial SG blowdown to one very similar to a reactor trip without MFW. The secondary side PORVs and safety valves are not expected to be challenged for this event. The event tree model that addresses the plant response to this event is SLBD-GTRAN. The event tree top events are described in Table 10-27.

10.3.2.26 Transfer Trees for Long Term Cooling

The long term cooling event trees are transfer trees used to assess long term containment cooling for successful Level 1 sequences in which decay heat is being removed from the RCS by either containment sump recirculation or the PRHR. There are two transfer trees; LTC and LTCP. These transfer trees evaluate electric power, containment isolation, and containment cooling for those sequences that are successful in the shorter term with RCS cooling from either the PRHR heat exchanger or containment sump recirculation. These sequences depend on long term cooling from the containment shell for success. In addition, the LTCP event tree includes credit for SFW for RCS cooling upon failure of PRHR cooling. The event tree models that address the plant response to these events are LTC and LTCP. The event tree top events are described in Table 10-28.

10.4 Success Criteria Analysis

10.4.1 Introduction

The success criteria defines the AP1000 plant specific measures of success and failures which support the accident sequence analysis, systems analysis, human reliability analysis, and Level 2 analysis.

10.4.2 Definitions

Core Damage: Uncovery and heatup of the reactor core to the point at which prolonged oxidation and severe fuel damage are anticipated and involve enough of the core, if released, to result in offsite public health consequences. Core damage is defined from the MAAP4 code as having TCRHOT > 982.2 °C (1800 °F). TCRHOT specifies the peak core node temperature.

Mission Time: The time period that a system or component is required to operate in order to successfully perform its function. AP1000 plant system models for core cooling, reactivity and decay heat removal have mission times of 24 hours. The Passive Containment Cooling System (PCS) model has a mission time of 72 hours.

Safe Stable State: A plant condition, following an IE, in which RCS conditions are controllable at or near desired values.

10.4.3 Computer Codes Used

CENTS

CENTS (Reference 10.29) is an interactive, high fidelity computer code for simulation of the Nuclear Steam Supply System (NSSS). It calculates the transient behaviour of Combustion Engineering (CE) and Westinghouse designed PWRs for normal and abnormal conditions, including accidents. CENTS determines the core power and heat transfer throughout the NSSS. It also computes the thermal-hydraulic (T-H) behaviour of the reactor coolant in the primary and secondary systems. It includes the primary and secondary control systems and the balance-of-plant fluid systems.

CENTS is designed to support engineering, operations, and training functions. It supports evaluation of plant behaviour for accidents, operator actions, design, and scoping studies. It is licensed for safety analyses of PWRs. In addition, it may be used for NSSS simulations supporting optimization, procedure preparation or evaluation, determining success paths for PSA events, training, etc. The code simulates a wide range of variations in plant state, from steady state conditions to severe accidents. It provides a full range of interactions between the analyst, the reactor control systems, and the NSSS. It also allows analysis of multiple failures and the effects of operator intervention or mistakes. Examples of transients run with CENTS include: steady state, power change, pump trip, overcooling or undercooling, loss of feedwater, steam line break, feedwater line break, steam generator tube rupture, anticipated transient without scram, loss of coolant accident, letdown line break, control rod ejection, and malfunctions of the various plant components and control systems.

LOFTRAN

The LOFTRAN program (Reference 10.30) is used for studies of transient response of a pressurized water reactor system to specified perturbations in process parameters. LOFTRAN simulates a multi-loop system by a model containing a reactor vessel, hot and cold leg piping, steam generator (tube and shell sides), and pressuriser. Operation of the pressuriser heaters, spray, and safety valves are also modelled in the program. Point model neutron kinetics and the reactivity effects of the moderator, fuel, boron, and control rods are included. The secondary side of the steam generator uses a homogeneous, saturated mixture for the thermal transients and a water level correlation for indication and control. The protection and safety monitoring system is simulated to include reactor trips on high neutron flux, overtemperature ΔT, high and low pressure, low reactor coolant system flow, and high pressuriser level.

Control systems are also simulated, including rod control, steam dump, feedwater control, and pressuriser level and pressure control. The emergency core cooling system, including the accumulators, is also modelled.

For the AP1000 plant design, the LOFTRAN code allows the simulation of the PRHR heat exchanger, CMTs, and associated protection and safety monitoring system actuation logic.

MAAP4.0.7

The Modular Accident Analysis Program version 4.0.7 (Reference 10.31) is a computer code that simulates the response of light water reactor (LWR) power plants during accidents. Given a set of IEs and operator actions, MAAP4 predicts the plant's response as the accident progresses. MAAP4 possesses a dynamic benchmarking capability to ensure the code is consistent with major experiments and plant transient experiences.

The following are limitations to MAAP4:

- Core Flow Reversal in LLOCA – For break sizes ≥ 25 cm (10 inches), the flow in the core could initially reverse. MAAP4 does not model the flow reversal. There are other situations in the initial phase of the transient that MAAP4 does not model, including: steam binding, departure from nucleate boiling, detailed condensation on safety injection flow. The results of the code during the flow reversal time are not used in this analysis. Break sizes considered in the MAAP4 analysis are limited to 22.86 cm (9 inches) or less.

- Water Momentum Equation – MAAP4 does not have a complete water momentum equation for the primary system or the steam generator; the core voiding and the general two-phase distribution in the RCS during blowdown and reflood requires a fully-posed momentum equation. In the smaller LLOCAs, reflood does not occur, so the momentum equations are not needed. However, in the case of the larger LLOCAs, the design basis safety analysis will be used as a conservative estimate.

- PRHR Steam Condensate Rate – MAAP4 does not accurately model the steam condensation in the PRHR tubes. Heat removal rate through PRHR becomes time step dependent when the RCS water and steam are separated. It leads to excessively small heat removal if used with a small time step.

- Neutronics Model – MAAP does not contain a neutronics model or chemical addition model; therefore, there is no core feedback. For initiators which cause reactivity changes other than nominal decay heat, the success criteria must be developed with other codes. For example, for ATWT initiators, the success criteria were determined using LOFTRAN.

- Piping Break Locations – MAAP4 does not model RCS mixing when a LOCA has stabilized and natural circulation has been established. Analyses performed on the LLOCA show no difference between break locations on the top or the bottom of the hot leg (HL) and cold leg (CL) of the RCS piping.

- Global Pressure Model – Pressure and average water and gas temperatures are calculated via subroutine PTCAL. PTCAL computes the average gas temperature and system pressure by combining all control volumes together. The primary advantage of this method eliminates the numerical stiffness which occurs if the pressure was calculated in each small control volume.

- Simplified RCS Nodalization – Because MAAP4 has a simplified RCS nodalization (i.e., lumped cold leg nodes, no DVI nodes, no CMT nodes, no PRHR nodes), the MAAP4 T-H response for special LOCAs may be predicting non conservative results. Therefore, the event tree structure and the success criteria for special LOCA initiators have been determined via engineering judgment, and there are very few MAAP analyses for the special LOCA cases.

10.4.4 Methodology

The success criteria are determined for the event tree top node paths; they are defined as the minimum requirements per top event that fulfil the basic function which prevents core damage. The basic mitigating functions and their associated systems are:

- Reactivity Control
  - Plant Control System
  - Protection and Monitoring System
  - Diverse Actuation System
  - Chemical and Volume Control System
  - Core Makeup Tanks
- RCS Overpressure Control
  - Pressuriser size (larger than operating plants)
  - Pressuriser Safety Valves
  - Automatic Depressurization System
  - Passive Residual Heat Removal
- RCS Inventory Control
  - Chemical and Volume Control System
  - Core Makeup Tanks
  - Automatic Depressurization System
  - Normal Residual Heat Removal System
  - Accumulators
  - IRWST Gravity Injection and Recirculation
- Reactor Core Decay Heat Removal
  - Main Feedwater
  - Startup Feedwater
  - Secondary Side Pressure Relief (condenser or power-operated relief valve and main steam line safety valves)
  - Passive Residual Heat Removal
  - Normal Residual Heat Removal System
- Containment Cooling
  - Normal Containment Heat Removal (fan coolers)
  - Passive Containment Cooling

– Normal Residual Heat Removal

The minimum requirements can be met by combinations of systems (PXS, CVS, RNS, etc.), structures (containment, etc.), components (MOVs, AOVs, HXs, etc.), and/or automatic actuations or human actions (completed operator actions within the specified time window).

The methodology for the analyses can be divided into two distinct types: distinct initiators with detailed T-H results or similar initiators with modified success criteria and T-H results. For example, the MLOCA initiator is a distinct initiator with a specified response. The MAAP4 T-H results for all MLOCA success paths are determined along with the human reliability analysis (HRA) supporting information. This approach was taken for all of the IEs analysed with MAAP4. In contrast, the DVI line break LOCA is evaluated based on other LOCA results with the basis for the event tree and success criteria development defined.

Engineering judgement has been used for the following IEs: PRHR Tube Rupture, CMT Line Break, PRHR Line Break, Spurious Actuation ADS Stages 1-3, Spurious Actuation ADS Stage 4, Spurious IRWST Injection Actuation, DVI Line Break, and Spurious Containment Recirculation. Engineering judgement is used for these sections either to bound the event by other events or because the MAAP4 model lacks the detailed modelling components to accurately represent these “special LOCAs.”

The results of the T-H analyses are used to confirm the success paths of the event trees and the minimum required amount of mitigation equipment as presented in the Accident Sequence Analysis Sections 10.3.2.1 through 10.3.2.26, and define the time windows for operator actions.

10.4.5 Assumptions

The Success Criteria specific assumptions identified in the development of this model are:

1. When two or more ADS Stage 4 valves are required, it is assumed that at least one valve is required to open on the non-pressuriser loop. ADS stage 4 valves are less effective connected to the HL with the pressuriser. MAAP has a global RCS pressure model and lumped RCS nodalization which is not able to capture the injection gap phenomena. By operating at least 1 valve on the non-pressuriser loop, the phenomenon is avoided. Two ADS Stage 4 valves opening on the non-pressuriser loop will perform like one valve open on each loop.

2. A conservative 25 percent containment condensate bypass (bypassing the IRWST) is assumed for all cases unless otherwise noted.

3. CVS is assumed to automatically provide injection during RCS cool down events where the pressuriser level is expected to decrease. Current CVS design/operation will isolate CVS injection with a coincident Safeguards Signal and PZR High-1 level. Success criteria will model the CVS as follows: During an RCS cool down event, CVS will automatically ‘arm’ 1 pump and isolate the Demineralized Water Storage Tank given a Safeguards Signal. CVS will maintain the PZR level between Low-2 and Low-1, injecting water from the BAST. CVS will begin injecting when the PZR reaches Low-2. This configuration allows for automatic CVS injection should the initial PZR level be above High-1 when the Safeguards Signal is generated.

4. The SGTR HRA time windows are developed based on a single tube rupture because the expected initiator affects a single tube. Additionally, this is consistent with the design basis analysis which determines the SG margin to overfill.

10.4.6 Determination of LOCA Break Sizes

LLOCA:

The LLOCA represents breaks that are greater than or equal to a 22.86 cm (9 inches) equivalent diameter on a main coolant loop or connected line. This break size is chosen based on the ability to provide adequate PXS injection without the use of ADS assuming containment isolation operates normally. A 22.86 cm (9 inches) break size adequately depressurizes the RCS to allow for gravity injection without additional ADS. 20.32 cm (8 inches) break size cases do not allow for sufficient depressurization through the break, and the pressure head for gravity injection is not able to overcome the RCS pressure. The capability of core cooling for a 22.86 cm (9 inches) break and larger is verified by MAAP4 analyses. There are no operator actions associated with this IE in the short term because the event is fast acting; however, time for operator actions exists during recirculation.

Depressurization is not required through the ADS Stage 4 valves to allow gravity injection; however, ADS Stage 4 is required to support long term containment recirculation. The break allows for sufficient depressurization to allow gravity injection, and the PMS signals are required to actuate gravity injection from the IRWST. CMT level setpoints correspond to a series of PMS signals which actuate ADS Stages 1-3, ADS Stage 4, and gravity injection from the IRWST. In support of the LLOCA success path, one of two IRWST lines is required. One of four recirculation lines is required to support the LLOCA-001 success path.

The reduced containment pressure from successful PCS cooling of containment combined with the containment isolation failure produce a conservatively low pressure condition for PXS core cooling. In the passive plant, the RCS and containment pressures are strongly coupled following ADS actuation. At higher system pressure, the steam/water enthalpy is greater and allows the RCS to vent more effectively. More energy is released through the break and ADS at any given venting flowrate, resulting in a lower pressure differential and more efficient PXS injection and recirculation. Therefore, PCS cooling and containment isolation failure produce a lower system pressure and create a more challenging condition for passive core heat removal.

Sensitivities were run to explore different break locations. Results from these sensitivities revealed that breaks at different locations resulted in similar hottest core node temperatures.

MLOCA:

The MLOCA represents a break on a main coolant loop or connected line that is between 22.86 cm (9 inches) and 10.16 cm (4 inches) in diameter or equivalent. The bottom end of the MLOCA range has been determined by the ability of the break by itself to depressurize the RCS below 4136.85 kPa (600 psia) with the 10.16 cm (4 inches) break size to allow for successful ADS Stage 4 actuation.

The MLOCA analyses confirm the success paths of the MLOCA event tree. ADS is required for adequate RCS depressurization to allow for gravity injection or RNS injection. ADS is also required to provide a long term vent pathway.

The MLOCA cases have been run with PCS and containment isolation failure as described for LLOCA as that has been determined most limiting.

SLOCA:

The SLOCA represents a break on a main coolant loop or connected line that is between 0.95 cm (3/8 inch) to 10.16 cm (4 inches) in diameter or equivalent. The bottom end of the SLOCA has been determined by the ability of CVS to make up lost coolant from a 0.95 cm (3/8 inch) break. The CVS provides makeup for RCS leaks up to 0.95 cm (3/8 inch) diameter within the reactor coolant pressure boundary. The upper bound is determined by the bottom end of the MLOCA.

The SLOCA analyses confirm the success paths of the SLOCA event tree. PRHR is able to provide heat removal during a SLOCA and has been credited. ADS is required for adequate RCS depressurization to allow for gravity injection or RNS injection. ADS is also required to provide a long term venting pathway.

The SLOCA cases have been run with PCS as described for LLOCA and MLOCA that have been determined most limiting. 0.95 cm (3/8 inch) to 10.16 cm (4 inches) cases behave differently and the operator action windows for RNS are limited by the 10.16 cm (4 inches) break size. No clear criteria has been identified to create more specific LOCA categories from the SLOCA break range.

10.4.7 Determination of HRA Time Windows

The following information was developed to support the HRA analysis:

- Description of operator action
- Initiator
- Cue for operator action
- Time of cue with respect to time zero (Tdelay)
- Irreversible damage state
- Time of irreversible damage state with respect to time zero (TSW)
- References for cue, irreversible damage state, and MAAP run

The MAAP4 cases run have been designed to determine the most limiting scenarios to be used as inputs for the HRA. Specifically, maximum RCS depressurization, minimum injection along with the correct equipment configuration is modeled to capture the most challenging operator action timeframes. The operator time windows are presented in Table 10-32.

10.4.8 Analyses and Results

10.4.8.1 Large LOCA

The LLOCA initiator has been previously analyzed with design basis accident analysis codes. The MAAP4 code is limited in its ability to correctly model plant response for break sizes above a 22.86 cm (9 inches) equivalent diameter break during core reflood and blowdown; therefore, the minimum equipment required for the LLOCA has been taken from the DBA analysis. The MAAP cases in this analysis are confirmation runs performed for completeness of the documentation of the success criteria.

The only success path on the LLOCA event tree is LLOCA-001. Each case that was analyzed was performed conservatively with one accumulator, two CMTs, two ADS Stage 4 valves for a long term vent path, one PXS injection valve open, one PXS recirculation valve open, successful PCS water cooling and a 55.88 cm (22 inches) equivalent diameter containment

isolation failure, unless otherwise noted. The equipment assumptions for the LLOCA analysis are based on the combination of equipment that results in the minimum equipment configuration scenario to successfully mitigate a LLOCA. The minimum break size provides the least pressure relief from the break during the injection phase.

The minimum LLOCA break size is a 22.86 cm (9 inches) equivalent diameter break as determined by the smallest break size that is able to remove energy from the primary system while keeping the peak core temperature below 982.2˚ C (1800˚ F) (TCRHOT < 1800˚ F) during PXS injection without any additional depressurization from ADS. The break size was determined assuming successful containment isolation. Sensitivity analyses were performed to ensure that the 22.86 cm (9 inches break) would allow sufficient injection to keep the core below 1800˚F. For confirmatory purposes, 25.4 cm (10 inches) and 20.32 cm (8 inches) break size cases were run to verify that a 22.86 cm (9 inches) break is the lower bound for the LLOCA.

At least one accumulator is required for reactor vessel reflooding following a LLOCA IE. Automatic actuation of the ADS valves is required as manual ADS actuation is not credited in the LLOCA. The break size is sufficient for allowing PXS injection without additional ADS; however, a minimum of two ADS Stage 4 valves are required for long term core cooling.

The successful mitigation of the LLOCA requires successful opening of a PXS injection valve. The manual action to align RNS injection is not credited for the LLOCA. PXS injection is initiated on the same PMS signal as ADS Stage 4 and is driven by the head of water between the IRWST water level and the mixture level in the HL. Additionally, as the injection water boils in the core, the two-phase mixture has a lower density, and the density difference provides additional driving head for PXS injection.

For success, one out of four injection lines must be available, and one of four recirculation lines must be available in any combination of trains.

The MAAP4 analyses verifying the 22.86 cm (9 inches) break were run with PCS water cooling and containment isolation failure. PCS cools the shell around containment, resulting in lower containment pressures. The likely containment failure is of two 40.64 cm (16 inches) diameter valves and has been simulated. Cases run show that low system pressure results in the limiting scenario for PXS injection. These cases also demonstrate that the AP1000 can tolerate failure to isolate the containment and maintain sufficient water inventory to support long term core cooling.

10.4.8.2 Medium LOCA

The success paths for MLOCA are presented in the MLOCA event tree. Each success criteria analysis case for MLOCA has been analyzed with PCS in operation with 25 percent condensate bypass. Each case assumes a 55.88 cm (22 inches) equivalent diameter containment isolation failure, and the success criteria has been determined from this limiting set of conditions. The cases have been run for the upper and lower bound break sizes which are 22.86 cm (9 inches) and 10.16 cm (4 inches), respectively. All success paths assume a hot leg break located at the piping centerline. The upper end of the break range was determined by the lower end of the LLOCA. The lower end of the MLOCA break range has been determined by the 10.16 cm (4 inches) break size's ability to depressurize the RCS below 4136.85 kPa (600 psia) allowing successful ADS Stage 4 operation. 15.24 cm (6 inches) break sizes were also analyzed. These cases also demonstrate that the AP1000 can tolerate failure to isolate the containment and maintain sufficient water inventory to support long term core cooling.

The MLOCA requires ADS Stages 1-3 to actuate to depressurize the RCS for successful RNS injection. ADS Stages 1-3 also cue the operators to manually put RNS in service. ADS Stage 4 must operate to vent the RCS to allow for PXS injection and continued long term recirculation. ADS Stages 1-3 are not required for successful actuation of ADS Stage 4 as the break size will adequately depressurize the RCS. ADS Stages 1-3 can be actuated through Condition 1 or Condition 2. Condition 1 is defined as the setpoints designed in automatic PMS, which actuate ADS. Condition 2 is defined as when the level in the hot leg of the RCS reaches 16.1 percent.

RNS is manually put in service on the cue for ADS Stages 1-3. ADS Stages 1-3 cues are given in the appropriate cases to determine the time that RNS is to be aligned. The success cases assume that RNS is put in service when the ADS Stages 1-3 cue is met.

Pressuriser safety valves (SVs) may potentially stick open during their operation; because of this, any stuck open pressuriser SV in initiators other than MLOCA will transfer to the MLOCA event tree. When fully open, the SV's flow area is approximately equivalent to the break size covered in the MLOCA initiator. When an SV does not seat, it will continue to vent and depressurize the RCS just as a MLOCA would. It is for this reason that stuck open pressuriser SVs will be transferred to the MLOCA event tree. This is considered bounding as the pressuriser SVs may stick only partially open.

10.4.8.3 Small LOCA

The success paths for SLOCA are presented in the SLOCA event tree. Each case has been analyzed with PCS in operation with 25 percent condensate bypass. Each case models a 55.88cm (22 inches) equivalent diameter containment isolation failure, and the success criteria has been determined from this limiting set of conditions. The cases have been run for the upper and lower bound break sizes which are 10.16 cm (4 inches) and 0.95 cm (3/8 inches), respectively. All success paths have been run on the hot leg, where the break is located on the piping centerline. The upper end of the break range was determined by the lower end of the MLOCA. The lower end of the SLOCA break range has been determined by the ability of CVS to make up lost coolant from a 0.95 cm (3/8 inch) break. These cases also demonstrate that the AP1000 can tolerate failure to isolate the containment and maintain sufficient water inventory to support long term core cooling.

The SLOCA requires that ADS Stages 1 3 operate to depressurize the RCS to allow for gravity or RNS injection. The equipment setpoints and associated actuations for the SLOCA are the same as the MLOCA initiator.

RNS is manually put in service on the cue for ADS Stages 1-3. ADS Stages 1-3 cues are given in the appropriate cases following to determine the time that RNS is to be aligned. The success cases assume that RNS is put in service when the ADS Stages 1-3 cue is met. 10.16 cm (4 inches) cases do not see any benefit from PRHR; however, 0.95 cm (3/8 inch) breaks benefit where the RCS is depressurized, and time to core damage is extended. A 5.08 cm (2 inches) break size was also analyzed.

10.4.8.4 RCS Leak

This initiator is an RCS LOCA, 0.95 cm (3/8 inch) and smaller, which is in the nominal CVS pump makeup capacity of 6.3 L/sec (100 gpm).

If CVS and borated inventory is available, this accident can be mitigated with a controlled plant shutdown without the use of Class 1 equipment within the time described in the technical specifications.

In the event that CVS is unavailable, there will be continual RCS inventory losses. When PRHR is available to remove decay heat, its availability provides more long term success paths. In injection mode, the CMT level drops and ADS Stages 1-3 and ADS Stage 4 actuation will occur. Otherwise, the accumulators will inject and ADS Stages 1-3, and ADS Stage 4 must be actuated manually. The IRWST provides gravity injected RCS inventory makeup after the ADS Stage 4 squib valves open; RNS pumped injection provides an alternative means for RCS makeup. When the IRWST level drops, recirculation is required via passive recirculation or RNS pumped recirculation. All LEAK event tree success paths were analyzed and confirmed using the upper bound RCS leak size.

10.4.8.5 General Transients with Safeguards Actuation

This initiator is a reactor trip coincident with a Safeguards Signal. Safeguards actuation provides automatic CMT actuation, PRHR actuation, and main feedwater isolation. For successful mitigation of general transient sequences, decay heat removal is required from either SFW or PRHR.

This analysis bounds general transient events that experience a failure of MFW and/or SFW by analyzing cases that model a total loss of feedwater. A total loss of feedwater event bounds the thermal hydraulic response of general transient initiators with failures of feedwater. During a total loss of feedwater event, the SG dries out during at power operation. However, during a general transient initiator with failed MFW and/or SFW, the reactor trips and SG dry out follows. So, at the time of reactor trip, there is significantly less SG inventory in the total loss of feedwater case as compared to the general transient case.

In the event that decay heat removal is unavailable, the RCS will lose the ability to transfer heat and begin to heat up. As the RCS temperature and pressure increase, the pressuriser SVs will lift and cause an RCS inventory loss. This helps the CMT recirculation and injection driving force. In recirculation mode, the CMTs provide borated water to the reactor vessel for RCS inventory and reactivity control. In injection mode, the CMT level drops and ADS Stages 1-3 and ADS Stage 4 actuation will occur. The IRWST provides gravity injected RCS inventory makeup after the ADS Stage 4 squib valves open; pumped RNS injection provides an alternative means for RCS makeup. When the IRWST level drops, recirculation is required via passive recirculation or pumped RNS recirculation.

The success paths of the general transients with safeguards actuation (GTRAN-WS) event tree are analyzed and confirmed. In all cases, reactor trip is successful, the secondary side is not faulted, and the pressuriser SV lifts but does not stick open. The interaction between SFW and PRHR is addressed in this analysis. Each sequence has been analyzed with PCS in operation and 25 percent condensate bypass and a 55.88 cm (22 inches) diameter containment isolation failure. The success criteria have been determined from this limiting set of conditions. These cases also demonstrate that the AP1000 can tolerate failure to isolate the containment and maintain sufficient water inventory to support long term core cooling.

10.4.8.6 General Transients without Safeguards Actuation

This initiator is a reactor trip without a Safeguards Signal. In this event tree, MFW is available to the SGs. For successful mitigation of general transient sequences, decay heat removal is required from MFW, SFW, or PRHR.

This analysis bounds general transient events that experience a failure of MFW and/or SFW by analyzing cases that model a total loss of feedwater. A total loss of feedwater event bounds the thermal-hydraulic response of general transient initiators with failures of

feedwater. During a total loss of feedwater event, the SG dries out during at power operation. However, during a general transient initiator with failed MFW and/or SFW, the reactor trips and SG dry out follows. So, at the time of reactor trip, there is significantly less SG inventory in the total loss of feedwater case as compared to the general transient case.

Consistent with the system model, MFW pumps receive supply from the condenser. The condenser receives discharged steam from the SG and produces condensate. Therefore, there is a continuous supply of condensate for the MFW pumps. MAAP4 does not have the capability to model this feature; to mimic this setup, an additional condensate storage tank (CST) mass inventory is added when the CST reaches an arbitrarily low value.

In the event that decay heat removal is unavailable, the RCS will lose the ability to transfer heat and begin to heat up. As the RCS temperature and pressure increase, the pressuriser SVs will lift and cause an RCS inventory loss. This helps the CMT recirculation and injection driving force. As the CMTs inject into the RCS and their level decreases, the ADS Stages 1-3 and ADS Stage 4 actuation will occur. The IRWST provides gravity injected RCS inventory makeup after the ADS Stage 4 squib valves open; pumped RNS injection provides an alternative means for RCS makeup. When the IRWST level drops, recirculation is required via passive recirculation or pumped RNS recirculation. The interaction between SFW and PRHR is addressed in this analysis.

The success paths of the general transients without the safeguards actuation (GTRAN) event tree are analyzed and confirmed. In all cases, reactor trip is successful, the secondary side is not faulted, and the pressuriser SVs lift but do not stick open.

10.4.8.7 Steam Generator Tube Rupture

An SGTR can occur as an initiator or as an induced event from a different initiator. During an SGTR, RCS inventory is transferred through the tube rupture and into the SG secondary side. In general, the AP1000 plant design operating philosophy requires limiting the primary to secondary leakage and minimizing the radiological releases following a SGTR. Success for this initiator is defined as the termination of tube rupture break flow and prevention of core damage.

When ruptured SG isolation is successful (based on SG level setpoints) and decay heat removal is available, the RCS pressure is balanced and SGTR break flow is terminated and remains in the ruptured SG. If isolation is failed, or there is no decay heat removal, then RCS depressurization via the ADS valves helps reduce the inventory losses. This allows for recirculation to be credited when ruptured SG isolation fails.

The success criteria is valid for a single detectable tube leak up to five double-ended guillotine (DEG) tube ruptures. For the SGTR event tree success paths reactor trip is successful. SFW has been modeled in each of the cases to minimize the time for SG overfill; this way the accident progression is not changed; however, the timeline of events is moved up to be within the 24 hour mission time. Cases which include SFW as a mitigating system will also be modeled with a cooldown via the secondary side at a rate of 37.7˚ C/hr (100˚ F/hr). The interaction between SFW and PRHR is addressed in this analysis. Top event I&I involves manual identification and isolation of the ruptured steam generator. Top event OFILL isolates CVS and SFW flow to the steam generators. The success paths of the SGTR event tree are analyzed and confirmed.

10.4.8.8 Steam Line Break

Steam line break represents a DEG break on the secondary steam line. The break size is limited by the area of the venturi flow limiting insert at the top of the SG. The steam line break area has been defined by this restrictor, which is 0.13 square meter (1.4 square feet).

An SLB requires boration of the RCS to maintain core subcriticality. MAAP4 is not capable of modelling criticality; and therefore, the first 1,000 seconds of each case has been modelled by CENTS which has a criticality model and can determine any return to power after the break. Based on the CENTS runs, the return to power cases (<25percent of total power) do not result in core damage. The success criteria have been determined from cases that have acceptable return to power events which quickly turn around and stabilize with subcritical conditions.

The CENTS model has generated a bounding total power curve for the first 1,000 seconds of an SLB. The bounding total power curve accounts for the decay heat from reactor trip as well as the short return to criticality at the beginning of the accident. This return to power occurs almost immediately after reactor trip, and subsides a few hundred seconds into the accident as seen in the CENTS analysis. It is important that boration from the fast acting CMTs is introduced to the reactor immediately following reactor trip to shut the reactor down. The MAAP4 analyses incorporate the total power curve from CENTS to determine the minimum set of equipment required for an SLB.

The SLB initiator does not include any success paths that require manual actuation of ADS (via Condition 2). The return to power that is modelled in these cases is so great that the boration required to shut down the reactor must come immediately after the reactor trips, via the CMT or CVS. ADS Stages 1-3 (actuated via the low hot leg level) are unable to depressurize the RCS in time for the accumulators to mitigate the return to power.

Each sequence has been analysed with PCS in operation, 25 percent condensate bypass and a 55.88 cm (22 inches) diameter containment isolation failure. Both the SLB upstream and downstream of the MSIVs are modelled so that they vent the break effluent inside containment. Break locations that discharge to the containment or the environment are not expected to have a significant impact on results. Containment isolation failure results in the more conservative approach for determining the long term success of each case. MAAP detects low steam line pressure (which would result in SG isolation) about 13 seconds after the steam line break. For consistency, the cases have been designed so that SG isolation (if required) will occur 15 seconds after the SLB. The success criteria have been determined from this limiting set of conditions. The success paths of the SLBU and SLBD event trees are analyzed and confirmed.

10.4.8.9 Interfacing System LOCA

An Interfacing System LOCA is a break outside containment in an auxiliary system that interacts with the reactor coolant system. If the break is not isolated, the result is a loss of reactor coolant and emergency cooling water outside containment. The unmitigated loss of coolant outside containment may lead to core damage and a direct release to the environment. If isolation of the break is successful, the ISLOCA may then be successfully mitigated by the Class-1 and non-Class 1 systems of the plant. This analysis is based on (and uses scenario information from) the break pathways identified in the ISLOCA analysis.

The ISLOCA cases act like general transients after the breaks have been isolated. Therefore, the cases reference the general transient sections. All of the sequences for ISLOCA have been analyzed with PCS in operation and 25 percent condensate bypass, as well as a 55.88 cm (22 inches) equivalent diameter containment isolation failure. The interaction between SFW and PRHR is addressed in this analysis. Each of the ISLOCA pathways is described along with its corresponding success case.

CVS Spent Resin Sluice Line (P05)

In the event of a CVS spent resin sluice line over pressurization, the low pressure piping located outside of containment just before the WSS Spent Resin Tank may fail, resulting in an ISLOCA. The line is 5.08 cm (2 inches) in diameter and passes through containment penetration P05. Successful mitigation in these cases requires automatic or manual isolation on the Safeguards Signal; otherwise, the sequence will proceed to core damage and large release. Therefore, each of the success paths includes successful isolation at the time of the Safeguards Signal. The success criteria for each ISL-CVS event tree success path are analyzed and confirmed.

CVS Normal, CMT and Accumulator Makeup Lines (P07)

In the scenario where the CVS normal, CMT or accumulator makeup lines over pressurize (through containment penetration P07), the low pressure piping and makeup suction header outside containment may fail resulting in an ISLOCA. A 7.62 cm (3 inches) diameter line runs through containment penetration P07. This ISLOCA has the same event tree as the CVS Spent Resin Sluice Line. Successful mitigation in these cases requires automatic or manual isolation on the Safeguards Signal; otherwise, the sequence will proceed to core damage and large release. Therefore, each of the success paths includes successful isolation at the time of the Safeguards Signal. The success criteria for each ISL-CVS event tree success path are analyzed and confirmed.

CVS Zinc Injection Line (P08)

The zinc injection package continuously adds liquid zinc acetate solution through containment penetration P08 during normal power operation. A positive displacement pump accommodates the variations in operating pressures at the injection point. Upon failure of the positive displacement pump, a potential ISLOCA scenario will result from external leakage of the containment isolation valve outside containment or the failure of the zinc addition pump discharge check valve and external leakage of the pump. The HRA has been bounded by the previous ISLOCA pathway (P07). The success criteria for each ISL-CVS event tree success path are analyzed and confirmed.

10.4.8.10 Loss of Offsite Power

A LOOP initiator occurs when offsite ac power is lost to the reactor and its associated mitigation equipment. This analysis does not credit turbine runback.

Under normal operation, passive equipment is powered from the Class 1 250V dc batteries. For LOOP initiators, the only condition that changes is what powers the batteries. When ac power is available, the ac source is supplying power to the battery chargers, which allows the batteries to maintain charge while supplying the loads. When ac power is not available, the batteries are sufficiently sized to supply 24 hours of indication and control to Class 1 equipment. During LOOP initiators, active equipment is loaded on the SDG and supplied power from those sources.

The LOOP event tree structure and success criteria are similar to the general transient event tree, and when a secondary side fault occurs the event transfers to the SLBU event tree. The only exceptions to the information presented in these sections are ac power availability and use of PRHR. The availability of ac power and, therefore, the power source for active systems and the treatment of the passive system battery power is a difference from the general transient tree.

When a LOOP initiator occurs and the SDGs are unavailable, the plant is in SBO conditions. Because the active systems rely on the SDGs as their power source, in this scenario, the active systems are disabled. The passive systems are powered from the Class 1 batteries, which provide 24 hours of power for reactor trip and ESFAC (Engineering Safety Features Actuation Cabinets) actuation.

There is a cumulative timer, which measures the time the ac power source is unavailable; this monitors the SBO accident length. Shortly before the timer is fulfilled (at approximately 22 hours), the ADS Stage 4 and IRWST gravity injection line squib valves are fired. Based on the MAAP4 results, ADS Stages 1-3 are not required to reduce the RCS to pressures lower than 4136.85 kPa (600 psia). If the cumulative timer is disabled as is recommended in the operating procedures, then PRHR is the only system required for mitigation of this accident. PRHR serves as both decay heat removal and RCS depressurization for this accident scenario. The interaction between SFW and PRHR is addressed in this analysis. The success criteria for each LOOP event tree success path are analyzed and confirmed.

10.4.8.11 PRHR Tube Rupture

During a PRHR tube rupture, the PRHR tube is leaking RCS inventory into the IRWST. This initiator represents a detectible leak up to a single DEG break. For smaller PRHR HX tube leaks, the temperature instruments in the PRHR or IRWST will identify that hot water is leaking out of the RCS. During larger breaks of the PRHR HX tubes, the reactor will trip on low pressuriser pressure/level. As a complication of reactor trip, the secondary side relief valves lift and are expected to reclose. If the valves remain open, this initiator is treated with the secondary side fault initiators.

When PRHR HX isolation is not successful, the transient break flow continues and the resulting mitigation is similar to a SLOCA. These success paths require initial inventory control using either the CMTs or accumulators. As this accident progresses, the CMT or RCS levels will drop and ADS Stages 1-3 actuation can occur either automatically or manually. After ADS Stages 1-3 actuations occur, the ADS Stage 4 valves, IRWST gravity injection and recirculation will follow. Instances when ADS Stage 4 depressurization or IRWST gravity injection is not successful, RNS injection and pumped recirculation can provide long term RCS inventory control.

This analysis does not credit CVS as an RCS inventory source. The PRHR tubes are 1.91 cm (3/4 inch), which is greater than the CVS capability. Crediting CVS in this initiator only prolongs the time of reactor trip from low pressuriser pressure/level. CVS does not support long term normal operation with a single DEG PRHR tube rupture.

This analysis does not credit PRHR HX isolation. On the upper bound break size of the accident progression, the RCS transient is fast enough that the reactor is expected to trip, and Safeguards Signal is actuated before the operators are able to isolate the PRHR HX. There is less than 5 minutes to isolate the PRHR HX.

During a PRHR tube rupture event PRHR performance is expected to be maintained. Sensitivity cases were run with a design basis T-H code to demonstrate continual PRHR performance during a tube rupture event. Since this tube rupture break size could be a small leak up to a double ended break of a 1.91 cm (3/4 inch) tube, this event is grouped with Small LOCA since CVS makeup is not sufficient at the upper end of the break size. This IE can therefore be grouped as a small LOCA event.

10.4.8.12 CMT Line Break

A CMT line break occurs upstream of the CMT isolation valves (PXS-V014A/B and PXS-V015A/B) on the discharge line and downstream of the T-connection for the RCS CL and the CMT balance line.

When a CMT line break occurs on the discharge line, the initial CMT inventory will drain down. Following CMT drain down from a discharge line break or when a CMT line break occurs on the balance line, RCS inventory will be lost through the normally open valves PXS-V002A/B and/or ruptured area via the CL.

Because these line sizes are nominally 20.32 cm (8 inches), the upper bound break size of this event is based on the MLOCA tree. On the lower end of the break sizes, it is similar to the success paths of lower bound of RCS Leaks. It is acceptable to not include PRHR as a mitigation feature because in these cases, PRHR removes decay heat and decreases the RCS pressure. But there are still success paths without PRHR modelled in the LEAK event tree. Therefore, this initiator uses a combination of success paths from MLOCA (for the upper bound requirements) and RCS Leak (for the lower bound requirements) for the CMTLB event tree. As part of the initiator, one CMT's inventory is lost. The CMT success criteria must be reduced to one out of one available CMT.

10.4.8.13 PRHR Line Break

A PRHR line break occurs upstream of the PRHR HX inlet up to the T-connection with the RCS HL and downstream of the PRHR HX outlet to the SG CL plenum. This analysis disables the heat removal capability of PRHR for any break size in the PRHR lines. Although this is conservative, PRHR is not credited as a mitigation feature of this initiator.

At the upper bound of this initiator, a DEG of the 45.72 cm (18 inches) pipe could occur. On the other hand, at the lower bound of this initiator, a break equivalent to an RCS leak could occur. In order to develop success criteria that are valid for the entire break range, the LLOCA event tree was altered to include the necessity of reactor trip and depressurization from ADS Stages 1-3 to mitigate the smaller break sizes. Additionally, only the PXS automatic features are considered in the PRHRLB event tree as consistent with LLOCA. The PRHR line break accident progression credits only the recirculation operator action.

10.4.8.14 Spurious Actuation ADS Stages 1-3

Spurious ADS Stages 1-3 initiators occur when any combination of ADS Stages 1-3 valves spuriously operate and provide depressurization from the RCS into the IRWST. It is expected that most actuations will occur with a spurious PMS signal to one train, which would begin with the ADS Stage 1 actuation and remaining ADS Stages 2-3 valves with the appropriate time delay. However, this analysis must consider an upper and lower bound spurious actuation. The lower bound of this initiator would be the actuation of only one ADS Stage 1 valve. The upper bound of this initiator would be the actuation of both trains of all ADS

Stages 1-3 valves. The actuation of any ADS stage 1-3 valve is very unlikely due to PMS interlocks and a diverse blocker.

The event tree structure of this initiator is based on the MLOCA event tree with adjusted success criteria for ADS Stages 1-3 depressurization. For this initiator, reactor trip is required for reactivity control. Following reactivity control, the RCS also needs inventory control from any one of the CMTs or accumulators. Depending on how many ADS valves opened as part of the initiator, more ADS valves may need to open to provide depressurization to reduce the RCS pressure to less than 4136.85 kPa (600 psia) for ADS Stage 4 actuation. ADS Stage 4 actuation is followed by IRWST passive gravity injection and recirculation or RNS pumped injection and recirculation.

Based on MAAP4 runs, the spurious ADS Stages 1-3 initiator can be appropriately treated as a MLOCA with adjusted success criteria based on the SPADS13 event tree structure. The RCS pressure decrease from the spurious ADS Stages 1-3 initiator is within the range of RCS pressure from a traditional HL or CL MLOCA break.

10.4.8.15 Spurious Actuation ADS Stage 4

The spurious ADS Stage 4 initiator occurs when one or more ADS Stage 4 valves operate and open during at-power conditions. This IE has complicating factors associated with the plant response of this initiator mainly from the potential for local pipe and valve damage. The actuation of any ADS Stage 4 valve is very unlikely due to PMS interlocks and a diverse blocker.

The top portion of the SPADS4 event tree (greater than one valve spuriously operates) uses LLOCA success criteria requirements, and the bottom portion (one valve spuriously operates) uses MLOCA success criteria. There are no MAAP4 supporting T-H cases to determine the success criteria requirements for this initiator.

When two ADS Stage 4 valves spuriously operate, one valve on the opposite loop is required to meet the depressurization success criteria, and the signal for IRWST gravity injection must be provided. When four ADS Stage 4 valves spuriously operate, the depressurization success criteria is met; however, the IRWST gravity injection signal must be generated. When one ADS Stage 4 valve spuriously operates, one valve on the opposite loop is required to meet the depressurization success criteria and the signal for IRWST gravity injection must be provided.

A spurious actuation of one ADS Stage 4 valve can create an accident equivalent to a LLOCA. The opening of a valve at full RCS pressure may not work as intended. It is because of this phenomenon that the depressurization has been demonstrated with a MAAP4 run to clarify that one fully opened ADS Stage 4 valve will depressurize the RCS in about 300 seconds. With one ADS Stage 4 valve spuriously operating along with two accumulators the RCS depressurizes rapidly to nearly 689.5 kPa (100 psia).

10.4.8.16 Spurious IRWST Injection Actuation

The spurious IRWST injection valve initiator occurs when one or more IRWST gravity injection squib valves operate during at-power conditions. This IE has several complicating factors associated with the plant response of this initiator (the potential for local pipe and valve damage). There are no MAAP4 supporting T-H cases to determine the success criteria requirements for this initiator. The actuation of any IRWST injection valve is very unlikely due to PMS interlocks and the diverse blocker.

The top non-core damage path on the SPIRWST event tree (two or more valves spuriously operate) requires four out of four injection check valves to remain intact and closed after spurious actuation of the IRWST gravity injection squib valves. This path transfers to the SLOCA event tree because of pressure balancing holes in the check valves.

The bottom non-core damage paths on the SPIRWST event tree (one out of four valves spuriously operates) requires one out of one gravity injection check valve to remain intact and closed after there is spurious actuation of the IRWST squib valves on that line. If the gravity injection check valve remains intact and closed, the path transfers to the LEAK event tree. If the gravity injection check valve fails to remain intact or closed, this event is treated as a DVILB since it could result in a LOCA with loss of one injection pathway.

10.4.8.17 DVI Line Break

A DVI line break occurs upstream of the RV inlet and downstream of the CMT isolation valves, the accumulator check valves, the IRWST injection lines, and the RNS injection lines. This break range can be on the upper end, a DEG of the 20.32 cm (8 inches) portion of the line but limited by the 10.16 cm (4 inches) venturi in the RV inlet nozzle, or on the lower end, an RCS leak.

When this initiator occurs and RCS inventory is lost through the DVI line, reactor trip is required for reactivity control. RCS inventory is replaced from either the CMTs or the accumulators. In order to provide long term core cooling, the ADS Stages 1-3 valves provide depressurization to reduce the RCS pressure to less than 4136.85 kPa (600 psia) for ADS Stage 4 actuation. ADS Stage 4 actuation is followed by IRWST passive gravity injection and recirculation. Neither RNS injection nor RNS recirculation are credited in this analysis.

10.4.8.18 Spurious Containment Recirculation

The spurious containment recirculation initiator occurs when one PXS recirculation valve or a common cause failure event of all PXS recirculation valves open. Spurious actuation of the PXS recirculation squib valves can drain the IRWST inventory to the reactor cavity. The PXS recirculation line configuration includes two cavity flooding lines. Two of the four lines have a squib valve and an open motor-operated valve (MOV) in series. The other two recirculation lines have a squib valve in series with a check valve that prevents the IRWST from draining through them. Engineering judgement was used to support the success criteria. There are limited MAAP4 supporting T-H cases to determine the success criteria requirements for this unique initiator.

If the operator successfully isolates the IRWST recirculation valves within 30 minutes of the low IRWST level alarm, then the IRWST level remaining will support PRHR cooling and IRWST injection and recirculation. If the reactor trip is successful, main feedwater or startup feedwater could provide RCS cooling. A safeguards signal is not anticipated due to the inventory drained to the sump. The potential containment pressure increase due to external reactor vessel cooling (water in the cavity and the in-vessel retention design feature) is expected to be maintained lower than the containment isolation setpoint.

MAAP4 results of this analysis looked at the spurious opening of both recirculation lines opening at time 0 and isolation of the recirculation pathway after 30 minutes. After reactor trip, the run did not credit SFW or MFW for decay heat removal. PRHR was actuated on low steam generator level. CMT actuation with RCP trip occurs on low pressuriser pressure. With the RCPs tripped, there is decreased PRHR decay heat removal and the pressuriser safety valves open for a time until the decay heat subsides. With PRHR operating, successful

IRWST recirculation isolation, and successful opening and closure of the pressuriser safety valves, this event can be treated like a general transient with safeguards (safeguards signal is anticipated due to PRHR actuation on low pressuriser pressure). In the GTRAN-WS event tree, decay heat removal systems available are PRHR system, SFW system, and RCS depressurization using the ADS with IRWST/RNS injection and recirculation.

If the pressuriser safety valves stick open, the success criteria are based on the MLOCA plant response. This potential event was analysed with MAAP4. The analysis shows that based on the timing of passive injection and recirculation, a minimum of 3 out of 4 ADS Stage 4 valves are required for successful passive injection and long term core cooling by the PXS system following RCS depressurization. Gravity injection is successful if the water head in the IRWST is sufficient to overcome the friction losses and pressure drop across the piping, core, and ADS Stage 4 lines that develop from venting the two-phase steam and water flow produced by the decay heat boiling in the core. The ADS Stage 4 requirements are a function of decay heat, the time to start of injection, the time to start recirculation, and the reduced IRWST level at injection.

If the IRWST recirculation valve is isolated within 30 minutes and the reactor is not successfully tripped, the sequence is maintained as a sequence because the operators are directed to initiate a plant shutdown due to a technical specification requirement. If the reactor does not successfully trip, then the sequence can be treated as an ATWT event.

If the IRWST recirculation is not isolated and the reactor is not successfully tripped, the sequence is assigned as a core damage event. In this potential ATWT event, PRHR and passive injection is degraded due to the drained IRWST condition.

If IRWST recirculation isolation is not successful, then the IRWST will continue to drain to the reactor cavity and containment sump. Because IRWST inventory is needed to support heat removal systems like PRHR and RCS depressurization using the ADS with IRWST/RNS injection and recirculation, only the secondary side heat removal systems are credited.

10.4.8.19 Anticipated Transient Without SCRAM

The ATWT initiator occurs for a spectrum of IEs which are expected to result in a reactor trip and it does not occur. Note that DAS provides a backup means of removing power from the CRDMs to provide for control rod insertion. In order to mitigate this event the reactor power must be reduced without rod insertion. In addition, the maximum RCS pressure must be limited. Providing these two functions are interrelated.

The success criteria is the RCS pressure must remain less than 220.63 Bar (3200 psig). Limiting the RCS pressure to this value without rod insertion requires that the core power production be rapidly reduced to levels that can be removed by the MFW, SFW or PRHR. This power reduction is accomplished by:

- Reactor coolant temperature rise and associated negative reactivity feedback
- Tripping of the RCPs and associated void formation in the core

In the longer term, boron is required to completely shut down core power generation. For this function CMT operation is credited. Note that when the CMTs are actuated, the RCPs are also tripped which is important in reducing the power. In an ATWT, the CMTs will operate in a water recirculation mode.

For this specific initiator, MFW, SFW or PRHR are available for heat removal. For immediate boration CVS is not credited because there is not enough time to complete the operator action to align the system.

The interaction between SFW and PRHR is addressed in this analysis. The LOFTRAN code with its ability to model reactivity changes was used for the success criteria runs. The success criteria for each ATWT event tree success path are analyzed and confirmed.

10.4.8.20 ATWT – Loss of Main Feedwater

This event is similar to the ATWT event described in Section 10.4.8.19 except that the IE involved a loss of MFW. For this specific initiator, SFW or PRHR is available for heat removal. Otherwise, the success criteria are the same as in Section 10.4.8.19.

10.4.8.21 Long Term Cooling Analysis

The long term cooling event trees are transfer trees used to assess long term containment cooling for successful Level 1 sequences in which decay heat is being removed from the RCS by either containment sump recirculation or the PRHR. The Level 1 success criteria analysis has confirmed that these cases mitigate core damage for the first 24 hours (reaching a safe, stable state), and this analysis determines the equipment configurations that will allow for successful continued long term core cooling for at least 3 days from the start of an accident. For each case analysed, the equipment required to mitigate each accident in the short term (<24 hours) has successfully operated, and the long term heat removal ability is determined and analysed.

PCS water actuation is modelled in the cases in this analysis; the actuation setpoint used is the high containment pressure setpoint. In containment isolation failure cases where the containment pressure setpoint was not met, the containment temperature setpoint was used to actuate PCS water. Containment will eventually reach this setpoint as demonstrated in the SGTR cases where CI is failed and PCS is required to actuate.

Success is determined by a sump level analysis and by an analysis for extended PRHR cooling. Each case that uses ADS must maintain a sump water level that is above the minimum level during recirculation operation to be considered successful. This minimum water level ensures that recirculation of water through the sump is possible. For the total loss of feedwater (TLFW) cases which analyse PRHR cooling, success is based off the PRHR HX's ability to provide cooling during each case. Each case has been run for 5 day duration to determine if a case is successful for a minimum of 3 days and to determine if a case is successful past the 3 day time frame. Success using PRHR requires that the RCS temperature does not exceed 253 ˚ C (488˚ F) before 72 hours.

Representative MAAP4 runs were made for the following events:

- Large LOCA
- DVI Line Break
- TLFW
- Steam Line Break Upstream of the MSIVs
- SGTR

The success paths of the LTC and LTCP event trees are analyzed and confirmed.

10.5 Systems Analysis

10.5.1 Fault Tree Guidelines

The Systems Analysis documentation and fault trees were developed based on consistent guidance. This section aims to summarize those guidelines.

10.5.1.1 Basic Event Parameters

A basic event's failure probability or unavailability is determined by identifying the failure modes for the component and by assigning failure rates to the failure modes from the Master Type Code Table.

Demand failure probabilities for equipment, which must start or change state, are calculated using the failures per demand value multiplied by the number of demands required (Calculation Method (Type) 1). Operating equipment basic event failure probabilities are calculated using the failure rate multiplied by the mission time (Calculation Method (Type) 3), and standby equipment basic event probabilities are calculated using the failure rate multiplied by the exposure time divided by 2 plus the mission time (Calculation Method (Type) 5).

The calculation of component failure probabilities is summarized by the following examples for each method:

- Calculation Method (Type) 1: A normally closed, MOV, which is required to pass flow, may fail to open on demand.

- Calculation Method (Type) 3: A pump, which is required to run in order to mitigate an event, may fail to run for the mission time.

- Calculation Method (Type) 5: A standby, normally open, MOV, which is required to pass flow, may have transferred closed during the period of time between the previous test and the IE, or the mission time.

Instead of the calculation method (type) in CAFTA, the equation field is used with the equations corresponding to the calculation methods discussed above.

10.5.1.2 Exposure Times

Many components that need to be included in the model are normally in a standby mode; that is, they are not used until required. Often such components are assumed to have a failure rate (i.e., failure per hour) while in standby mode. Standby components are usually subjected to periodic testing. The time between tests is the length of time the component is exposed to failure without detection, and hence the term "exposure time."

For support system trains that are normally rotated during at-power operation, an exposure time will be used that is the time, or representative of the time, the component is exposed to failure without detection. This exposure time for support systems that are normally rotated is the time period between rotating pump trains. Pump trains are assumed to be rotated every two weeks. This is consistent with current plant practices.

10.5.1.3 Mission Times

The mission time is the time period that a system or component is required to operate in order to successfully perform its function. Success is defined as the plant reaching a safe, stable plant condition after the IE. The timing required to reach a safe, stable state is established by Success Criteria.

Each core damage event tree is modelled through a time frame of up to 24 hours. This time frame is selected to be consistent with the commonly accepted PRA practices, in which it is postulated that an event sequence will reach steady state conditions which will change very slowly at that time. Also assumed is the possibility of numerous and diverse recovery actions (which are not credited in the cutsets) that can be undertaken in such a time frame to further mitigate the event. Another aspect of this time frame is that it covers the actuation of all expected mitigation functions/systems needed for avoiding core damage.

Likewise, some systems required to maintain containment integrity are modelled through a 72 hour mission time.

Additionally, when developing an IE system model, a mission time of 1 year (8760 hours) is used for the initial fault to obtain an annual frequency of failure, and 72 hours is used for subsequent faults.

10.5.1.4 Naming Convention

A standard naming convention is used throughout the model. For failure basic events (component failures), the normal basic event name shall follow the convention:

SYS-SCT-CFM-XXX

where,

SYS is the unique three letter system code identified for the AP1000 plant

SCT is the specific component type from NUREG-6928 (Reference 10.15)

CFM is the component failure mode (note that TAM is used as the Test and Maintenance Identifier)

XXX is the unique component identifier

There are several unique expansions to the naming convention such as for C&I systems and electrical systems.

For a support system IE fault tree, a “-IE” or “-ST” designator is added to the end of the basic event ID to indicate basic events with a mission time of 8760 hours or 72 hours, respectively.

A standard naming convention is also used for gate names. The gate naming convention is broken into parts:

- Top Logic Names
- System Tops
- System Gates

Common cause and flag names also follow a standard naming convention using identifiers including “CCF-” and “FL-”, respectively.

10.5.1.5 Failure Modes

Failure modes for Systems Analysis are considered to:

- Include active and passive failures affecting system operability (as identified in the system success criteria). Active failures typically affect pumps, valves, relays and air compressors. Passive failures typically affect heat exchangers, valves not required to change position, and tanks.

- Exclude beneficial failures (e.g., failure of an instrument in such a fashion as to generate a required actuation signal). This failure should not be included unless omission would distort the results.

- All applicable failure modes for components on a main flow path shall be modelled.

10.5.1.6 Common Cause Failures

Failure of multiple components of similar manufacture and function due to common cause are potentially significant contributors to system failure and should be accounted for during system analysis. These types of failures are represented in fault trees as common cause failure (CCF) basic events. CCF can result in failure of a system when identical, non-diverse, and active components are used to provide redundancy. A component common cause group (CCCG) shall be defined for these cases, and basic events representing failure of two or more components due to CCF shall be incorporated into the fault tree.

The identification of CCCGs shall be performed by focusing on components that share one or more of the following criteria:

- Same design
- Same hardware
- Same function
- Same installation
- Same maintenance
- Same procedures
- Same system/component interface
- Same environment

Common cause failures are discussed in detail in Section 10.8.

10.5.1.7 Test and Maintenance

The component unavailability due to testing and maintenance, where applicable, is determined as follows:

- Based on the system Piping and Instrumentation Diagram (P&ID) and the test and maintenance procedures, the system alignment for each of the test and maintenance activities is determined. Then, it is determined whether the test requires that a component be placed in a position, which makes the component unavailable.

- For each component placed into a non-safety position, both the unavailability during testing or maintenance is modelled.

- Particular attention is given to identifying components that are isolated to facilitate maintenance of another component. An example is the closure of manual valves to perform pump maintenance.

10.5.1.8 Flow Diversions and Piping Failures

Flow paths that can divert the system fluid from the intended destination shall be evaluated to determine if they should be modelled as a failure mode.

Both active and passive components shall be considered. If necessary, piping will be modelled on a functional basis.

10.5.1.9 Mutually Exclusive

Often two events may appear in a cutset that could not occur simultaneously. To address mutually exclusive events, combinations are identified and the non-applicable cutsets are removed.

10.5.1.10 Recovery

The repair of hardware failures is not modelled in the AP1000 plant PRA except where the probability of repair is justified through an adequate analysis or examination of data.

The manual actions required to bypass failed systems or recover malfunctioning equipment are modelled as described in the HRA Section 10.6.

10.5.2 Passive Core Cooling System

10.5.2.1 System Description

The PXS consists of a PRHR heat exchanger, two accumulators, two CMTs, an IRWST, and associated valves, piping, and instrumentation. The ADS is actually a subsystem of the RCS; however, it is discussed here because of its relationship with the passive core cooling system. Additionally, the RCP breakers, which are part of the ECS, are discussed here for CMT actuation.

The RCS injection subsystem consists of CMTs, accumulators, and IRWST and associated valves, piping, and instrumentation. The safety injection from these three injection sources, as well as the containment recirculation flow paths, have a common discharge through the two DVI lines and into the reactor DVI nozzles. The DVI nozzles have a venturi shape, which reduces the loss of reactor coolant in case of a break of the DVI line, and minimizes the unrecovered pressure loss during PXS injection.

The CMTs provide RCS makeup and boration for LOCAs and non-LOCAs when the normal makeup system is unavailable or insufficient. Located inside containment, above the reactor coolant loops, two CMTs during normal operation are completely filled with cold borated water. The boron concentration in these tanks is slightly higher than in the accumulators or IRWST, and therefore the tanks provide adequate shutdown margin for safe shutdown events. The CMTs are connected to the RCS through a discharge line and a cold leg inlet pressure balance line (cold leg 2A and 2B). The pressure balance line is normally open to maintain the CMTs at RCS pressure which prevents water hammer upon initiation of CMT injection. The pressure balance line or inlet line contains a normally open MOV. The discharge line of the CMT includes two normally closed, parallel air-operated isolation valves that fail open on a loss of air or electrical power. Downstream of the parallel AOVs, the discharge line contains two in line, nozzle check valves in series, a normally open manual valve, and an orifice which is provided to allow for tuning of the CMT injection flowrate prior to initial startup. Between the check valves and the orifice is the connection from the RNS pumps to provide injection to the RCS. The CMT discharge check valves are normally full open. The purpose of the check valves in series is to prevent reverse flow from the accumulators through the CMT.

Two accumulators contain borated water and a compressed nitrogen cover gas to provide rapid injection to the RCS through each DVI line. Each accumulator discharges through a normally open MOV and two normally closed tilt-disc check valves in series. Between the MOV and the check valves is an orifice to provide tuning of the injection flow. The check valves isolate the accumulators from the RCS during normal operation.

The IRWST, located in the containment slightly above the RCS loop piping, contains cold borated water and three separate screens at the bottom. A cross-connect pipe connects all three screens to distribute flow. The area of the third screen (C) is equal to the total size of the other screens (A and B). With the addition of the cross-connect pipe, clogging of any one screen would not fail the function of the IRWST to deliver flow to the gravity injection lines. The IRWST is connected to the RCS through two gravity injection lines, with each line connecting to a DVI line. Each gravity injection line contains a normally open MOV and four isolation valves. The isolation valves are in two parallel paths, each path with one squib valve backed up by an upstream check valve. The check valve prevents a LOCA in the case of an inadvertent opening of a squib valve. The containment recirculation lines are connected to an associated gravity injection line. The containment recirculation lines have two parallel paths. One path contains a squib valve backed up by an upstream check valve, and the other path contains a squib valve backed up by an upstream normally open MOV. The path with the MOV can also be used to dump the IRWST water into containment in the case of a complete failure to cool the core.

A number of vents are provided in the roof of the IRWST around the side of the IRWST adjacent to the containment wall and next to the SG compartment. Most of the vents are designed to vent steam from the IRWST to the containment. These vents open on small pressure differentials to limit the pressure differential with the containment during accidents, such as a LOCA. This venting prevents overpressurization of the IRWST and provides a path to vent steam released by the spargers or generated by PRHR HX operation into the

containment atmosphere. A few vents are designed to vent steam from the containment to the IRWST. These vents prevent excessive external pressurization of the IRWST. Vents located near containment have hoods to direct hydrogen produced during a severe accident away from containment, and these vents have a higher opening differential pressure than other vents to preferentially cause other vents away from containment to open first.

The IRWST gutter line return contains two AOVs in series which fail closed on a loss of air or control power. Under normal operating conditions, both valves are open and excess condensate on the inside of containment shell collects, and the condensate is sent to the liquid radwaste containment sump. The condensate collected during normal operation is directed to the waste sump to prevent adverse conditions in the IRWST chemistry. When the PRHR HX activates, the valves close. This closure isolates the sump, and during an accident scenario the steam is condensed by the PCS and collected by the gutter and drained back to the IRWST. Failure to close two out of two IRWST gutter AOVs (series arrangement) would fail the PRHR function for scenarios where the RCS pressure boundary is intact, such as for a loss of main feedwater or SGTR event but not for a LOCA. Recovery of the condensate within several hours would maintain the PRHR HX heat sink for an indefinite period of time. In LOCA scenarios, the PRHR function is only required for short periods of time (only needed in a few scenarios before ADS is actuated) such that collecting condensate is not required.

The emergency core decay heat removal subsystem consists of the PRHR HX and associated valves, piping, and instrumentation. The PRHR HX is located in the IRWST which then becomes the heat sink for the HX. The HX consists of c-tubes connected at the top (inlet) and bottom (outlet) to a tubesheet and channel head that is mounted on the IRWST wall. The PRHR HX is connected to the RCS through a normally open inlet line from one RCS hot leg (hot leg 1), which contains a normally open (MOV. This is a shared line with the ADS Stage 4 valves on hot leg 1. The outlet line connects to the associated steam generator (SG) (SG 1) cold plenum. This line contains two normally closed AOVs in parallel that open on a loss of air or electric power. These valves open in response to an S Signal. The discharge line also contains a normally open manual valve downstream of the parallel AOVs. The alignment of the PRHR maintains the HX full of reactor coolant at RCS pressure and prevents water hammer upon PRHR initiation. The HX is located above the RCS loops to induce natural circulation if the RCPs are not available.

The ADS consists of four different valve stages that open sequentially to reduce RCS pressure so that long term cooling can be provided to the RCS. For ADS Stages 1-3, each valve stage consists of two lines, where each line contains two normally closed valves in series. Each stage line has an isolation valve upstream of a control valve. When ADS is actuated, the isolation valve opens first and is followed by opening of the control valve to initiate and control the flow to the IRWST. Both groups of ADS Stages 1-3 have a common inlet header connected to the pressuriser and a common discharge line connected to one of the two spargers in the IRWST. ADS Stage 4 is arranged in two identical groups and each group discharges separately into one of the two SG compartments above post-accident flood up level. ADS Stage 4 has four lines each with two valves in series, which are a normally open isolation valve in series with a squib valve. The isolation valve, upstream of the squib valve, is an MOV gate valve and is only closed during cold/refuelling shutdowns to perform maintenance or in-service testing on the squib valves.

Each RCP is powered through two Class 1 circuit breakers connected in series: ECS-ES-31, -32; -41, -42; -51, -52; and -61, -62. The circuit breakers' purpose is to satisfy tripping requirement of these pumps. The two breakers in series scheme are to ensure that the RCPs are shut down when tripping signal is initiated. Each RCP breaker receives a separate

signal from the PMS. Only one of the breakers in series receives a redundant signal from the DAS. The RCP trip switchgear room is located in the Auxiliary Building.

10.5.2.2 Assumptions and Sources of Model Uncertainty

The assumptions and uncertainties made in the development of the PRHR system models are as follows:

1. The mission time for Class 1 equipment with position indication in the main control room (MCR) is 24 hours. This length of time is based on the assumption that, if component position indication is provided in the MCR, the verification of that components position is included in the board walkdown procedure.

2. One demand was used in the model for the opening and closing of the IRWST vents. The vents could be cycled more than once in the mission time.

10.5.2.3 System Boundaries for PSA Model

The PXS system boundary consists of a PRHR HX, two accumulators, two CMTs, an IRWST, and associated valves, piping, and instrumentation. The system boundary for this system analysis also includes the DVI line to the reactor vessel boundary. The PRHR draws water from the hot leg (SG 1) and returns to SG 1. The CMTs draw water from the cold legs on loop 2. The boundary of this system analysis does not include the SGs, or parts of the RCS: specifically the reactor vessel, the pressuriser, the hot legs, or the cold legs.

The RCS model includes the ADS Stage 1-4 valves and the pressuriser safety valves.

The RCP breakers, which are part of the ECS, are part of the system boundary for CMT actuation.

In addition for the Level 2 model, four types of IRWST vents are modelled, including hooded vents, vacuum breaker hooded vents, pipe vents, and overflow vents.

10.5.2.4 Common Cause Failures

The PXS system common cause failure groups were determined consistent with the method described in Section 10.8. Unique common cause groups to note:

- Since the PXS gutter valves (PXS-PL-V130A/B) are part of the main flow path (not flow diversion) and therefore risk important to PXS, common cause is considered for fails to remain closed for these valves.

- Accumulator check valves are included in the same group since they are expected to see the same RCS pressure (Group Size of 4 – PXS-PL-V028A/B, PXS-PL-V029A/B).

- ADS Stages 2 and 3 valves are divided into two common cause groups:

  – ADS Stage 2 and 3 Isolation Valves 8” Gate Valves (Group Size of 4 – RCS-PL-V012A/B, RCS-PL-V013A/B)

  – ADS Stage 2 and 3 Control Valves 8” Globe Valves (Group Size of 4 – RCS-PL-V002A/B, RCS-PL-V003A/B)

- ADS Stage 4 Valves 14" Squib Valves (Group Size of 4 – RCS-PL-V004A/B/C/D)
- Recirculation Low Pressure 8" Squib Valves (Group Size of 2 – PXS-PL-V118A, PXS-PL-V118B)
- IRWST/Recirculation High Pressure 8" Squib Valves (Group Size of 6 – PXS-PL-V123A, PXS-PL-V125A, PXS-PL-V123B, PXS-PL-V125B, PXS-PL-V120A, PXS-PL-V120B)
- CMT outlet 8" AOVs (Group Size of 4 – PXS-PL-V014A/B, PXS-PL-V015A/B)
- CMT outlet 8" check valves (Group Size of 4 – PXS-PL-V016A/B, PXS-PL-V017A/B)
- PRHR outlet 14" AOVs (Group Size of 2 – PXS-PL-V108A/B)

10.5.3 Passive Containment Cooling System

10.5.3.1 System Description

The PCS system consists of the passive containment cooling water storage tank (PCCWST), isolation valves, a valve room, a drainage bucket, two trough and weir systems, the containment vessel, Class-1 drains, non-Class-1 drains, the passive containment cooling ancillary water storage tank (PCCAWST), two trains of recirculation pumps, a recirculation heater, an air baffle in the Shield Building, a chimney in the Shield Building, screens on the air inlets and outlets, and connections to the spent fuel pool (SFP), Demineralized Water Transfer and Storage System (DWS), and Fire Protection System (FPS).

The PCCWST is a large tank affixed to the top of the Shield Building. The PCCWST provides a sufficient amount of water for 72 hours of post-DBA containment cooling. Recirculation Pumps, a chemical addition tank, and a recirculation heater keep the PCCWST chemicals and temperature within values determined by technical specifications.

The containment vessel is the heat transfer surface for the PCS. Heat produced inside the containment vessel propagates to the atmosphere via the containment vessel. The containment vessel removes heat from the inside through convection, conduction, and radiation. The PCCWST provides flow to the containment vessel through four pipes. Each pipe penetrates to a different elevation in the PCCWST. The differing elevations of the pipes allow a passive method of flowrate control. The PCCWST also has penetrations for makeup to the SFP and FPS, and a vent to the atmosphere to ensure the water flow out does not cause a vacuum on the inside of the PCCWST and prevent the flow from meeting requirements.

Water flows from the PCCWST to a single header. The header provides flow to three trains of two isolation valves per train. The first set of isolation valves (PCS-PL-V002A/B/C) in each train is a normally open, fail as is, motor-operated gate valve. These valves provide the ability to perform testing and maintenance on the normally closed isolation valves without emptying the PCCWST. The normally open isolation valves receive a confirmatory High-2 containment pressure signal from the PMS. The normally open isolation valves are housed in the temperature controlled Valve Room directly beneath the PCCWST.

Downstream of two of the normally open isolation valves (PCS-PL-V002A/B) are normally closed, fail open, air-operated butterfly valves (PCS-PL-V001A/B). Downstream of one of the normally open isolation valves (PCS-PL-V002C) is a normally closed, fail as is, motor-operated gate valve (PCS-PL-V001C). All three of the normally closed isolation valves (PCS-PL-V001A/B/C) serve the same purpose. The valves isolate the flow of water from the PCCWST until they receive either a High containment temperature open signal from DAS or a High-2 containment pressure open signal from PMS.

10.5.3.2 Assumptions and Sources of Model Uncertainty

The assumptions and uncertainties made in the development of the PCS models are as follows:

1. The PCS troughs and weirs will provide uniform flow over the containment shell and are not subject to failure mechanisms that would prevent this. The troughs and weirs are designed to be filled with water from the distribution bucket and overflow onto the containment shell.

2. Blockage of the air flow inlets is not considered in this analysis. When water flow is available, the containment maximum pressure is not sensitive to air flow blockage.

3. The redundancy associated with the annulus inlet and the flow area associated with the chimney will provide adequate flow during any accident.

10.5.3.3 System Boundaries for PSA Model

The PCS PSA model boundary includes all flow paths from the PCCWST to the containment vessel and alignments for flow to the distribution bucket. Components modelled include tanks, MOVs, AOVs, check valves, pumps, and manual valves.

10.5.3.4 Common Cause Failures

The PCS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.4 Main and Startup Feedwater System

10.5.4.1 System Description

The Main and Startup Feedwater System (FWS) can supply feedwater to the SGs of the Steam Generator System (SGS) through two different flow paths. These flow paths are defined as follows:

- Main feedwater is defined to be feedwater that passes through the SGS main feedwater control valves (MFCVs) (SGS-PL-V250A/B). Main feedwater is always supplied from the deaerator through the main feedwater pumps.

- Startup feedwater is defined to be feedwater that passes through the SGS startup feedwater control valves (SFCVs) (SGS-PL-V255A/B). Startup feedwater can be supplied either from the deaerator through the main feedwater pumps (normal source) or from the condensate storage tank (CST) through the startup feedwater pumps (backup source).

FWS main feedwater piping begins at the outlet connections on the bottom of the Condensate System (CDS) deaerator. Feedwater from the deaerator flows through three individual lines to the suction of each of the three main feedwater pump trains. During normal operation, the deaerator contains saturated water and the height of the water level in the deaerator above the feedwater booster pumps provides the necessary net positive suction head (NPSH) for the pumps.

Three parallel trains of feedwater booster pumps and main feedwater pumps provide the motive power for main feedwater flow. The pump trains are identical in capacity and characteristics. These pumps are fixed speed motor driven and utilize the SGS main feedwater control valves to provide effective feedwater flow control. During normal full load operation, each train provides 33.3 percent of the total feedwater flow. However, with one train out of service the other two trains can provide sufficient flow to maintain power operation at up to 70 percent of full load power.

The startup feedwater pumps and their associated flow paths primarily provide backup feedwater capability in the event the booster/main feedwater pumps or their associated flow paths are lost. The startup feedwater pumps and their associated flow paths perform a defence-in-depth function of decay heat removal after a plant shutdown/trip if the main feedwater pumps are not available, such as during a LOOP event. Although it does mitigate "loss of feedwater" events, this function of the FWS is a non- Class 1system function.

10.5.4.2 Assumptions and Sources of Model Uncertainty

There were no FWS specific assumptions and uncertainties made in the development of this system model.

10.5.4.3 System Boundaries for PSA Model

The FWS consists of three MFW pump trains drawing suction from the deaerator, two SFW pump trains drawing suction from the CST, two trains of high pressure feedwater heaters, and associated valves, piping, and instrumentation. The MFW pumps normally provide flow to the MFCV; however, a cross connect allows the MFW pumps to provide flow to the SFCV if necessary. The SFW pumps provide flow to the SFCV.

10.5.4.4 Common Cause Failures

The FWS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.5 Chemical and Volume Control System

10.5.5.1 System Description

The system functions as a whole to fulfil the requirements of controlling RCS chemistry, purity, and inventory for normal plant operations. The CVS is functionally divided into six different subsystems:

Purification Loop Subsystem

This subsystem includes the regenerative and letdown heat exchangers, a flow restricting orifice, mixed and cation bed demineralizers, reactor coolant filters, and associated valves, piping, and instrumentation. The entire purification loop of the CVS is located inside

containment and provides the direct interface with the RCS. The motive force for the purification loop is the differential head across the RCPs, and continuous purification is provided without operating the CVS Makeup Pumps.

Makeup Subsystem

This subsystem includes the high head makeup pumps and associated suction and discharge piping. The makeup pumps are located outside containment in the Auxiliary Building and take suction from the boric acid storage tank (BAST), the DWS, or a combination of both through a common suction header. The discharge piping from both makeup pumps combines to form a makeup header which connects to the purification loop inside containment downstream of the reactor coolant filters. The makeup pumps are used to supply makeup water to the RCS, to introduce chemicals to the RCS, to fill and pressure test the RCS (after regular refuelling and maintenance outages), and to add borated makeup for auxiliary pressuriser spray and filling auxiliary equipment.

Letdown Subsystem

The letdown subsystem consists primarily of an effluent line off the purification loop downstream of the reactor coolant filters. When delivery of flow to the Liquid Radwaste System (WLS) is necessary, isolation valves are remotely opened to allow for diversion of purification flow through a letdown orifice to significantly drop the pressure to a value compatible with the WLS design. The letdown line functions to reduce RCS inventory during normal plant operations, power changes, startups, and shutdown.

Demineralizer Resin Sluicing and Flushing Subsystem

The demineralizer resin sluicing and flushing subsystem includes various piping flow paths and numerous valves that allow for resin fluidization, sluicing, flushing, and refilling each time a resin bed changeout is required (which typically will happen during each refuelling outage). A resin discharge header is also included to transfer spent resins from each of the demineralizers to the spent resin tanks in the WSS, located outside containment in the Auxiliary Building.

Zinc and Hydrogen Injection Subsystem

The zinc and hydrogen injection subsystem includes both the zinc and hydrogen injection packages. Piping from both the zinc and hydrogen injection packages run from the turbine hall and connect to the purification loop inside containment. The hydrogen injection point is downstream of the regenerative heat exchanger (RHX) shell side outlet line, and the zinc injection point is on the purification return line upstream of the shell side inlet of the RHX. These different injection points allow optimal mixing of the chemicals with the coolant due to the temperatures and pressures at their respective injection sites.

Auxiliary Spray Subsystem

The auxiliary spray subsystem is an additional line with isolation valves that branches off the purification return line downstream of the RHX and supplies fluid flow to the pressuriser spray nozzle when needed.

10.5.5.2 Assumptions and Sources of Model Uncertainty

No CVS specific assumptions were made in the development of this system model.

10.5.5.3 System Boundaries for PSA Model

The CVS PSA model consists of the purification loop, the makeup subsystem, the letdown line containment isolation valves (CVS-PL-V045 and V047), and the zinc injection containment isolation valves (CVS-PL-V092 and V094).

The purification loop includes the purification supply line and return line. The purification loop supply line consists of the purification stop valves (CVS-PL-V001, V002, and V003), the tube side of the regenerative heat exchanger (CVS-ME-01), the letdown heat exchanger (CVS-ME-02), and the in service mixed bed demineralizer (CVS-MV-01A). The purification loop return line includes the shell side of the regenerative heat exchanger (CVS-ME-01) and the purification return line valves (CVS-PL-V080, V081, and V082) which inject water into the RCS via the steam generator.

The makeup subsystem consists of two makeup pump trains (CVS-MP-01A/B) which draw from the BAST (CVS-MT-01) and/or the DWS supply line via a three-way blend control valve (CVS-PL-V115). The common makeup pump discharge header includes a makeup flow control valve (CVS-PL-V157), two makeup discharge header containment isolation valves (CVS-PL-V090 and V091), and other associated valves and piping which inject makeup into the purification return line upstream of the shell side of the regenerative heat exchanger.

10.5.5.4 Common Cause Failures

The CVS common cause failure groups were determined consistent with the method described in Section 10.8. Unique common cause groups to note:

- Common cause is only modelled between two of the three purification stop valves (CVS-PL-V001 and V002) which are redundant. The third isolation valve (CVS-PL-V003) is a diverse valve type.

- The letdown line outside containment isolation valve (CVS-PL-V047) has an air positioner and is diverse from the letdown line inside containment isolation valve (CVS-PL-V045). No common cause is modelled between the valves in this case.

10.5.6 Containment Hydrogen Control System

10.5.6.1 System Description

The Containment Hydrogen Control System (VLS) provides monitoring and control of the hydrogen concentrations inside containment in order to maintain containment integrity against hydrogen detonation. The system performs its functions through the use of three subsystems as discussed below.

Hydrogen Monitoring

This subsystem includes three hydrogen sensors and three pressure sensors that continuously provide hydrogen concentration levels to the main control room via three independent channels in the Plant Control System (PLS). The three hydrogen sensors are located in the upper dome of containment in order to provide a global hydrogen concentration measurement, while the pressure sensors are used to provide pressure compensation to the hydrogen sensors. For accident mitigation, this subsystem is used as a backup to the core exit temperature indication that prompts operators to start the igniters in containment. An elevated containment hydrogen level alarm, coincident with high core exit temperature, will alert the

operators to start the igniters if they have not already done so. Procedures will instruct operators to start the igniters based on core exit temperature alone.

Hydrogen Recombination

The hydrogen recombination subsystem consists of two pairs of passive autocatalytic recombiners (PARs) positioned in containment such that they are able to take advantage of the natural circulation and mixing of the containment atmosphere to optimize their efficiency and remove susceptibility to debris blockage. The PARs are designed to accommodate the relatively slow hydrogen production rate anticipated for a design basis LOCA. The PARs are entirely passive devices relying on the catalytic properties of the material (palladium or platinum) to induce catalytic oxidation of the surrounding hydrogen. Therefore, no power supplies or other supports are required. Additionally, the catalyst is not consumed during operation, nor is it subject to long-term aging degradation.

Hydrogen Ignition

This subsystem contains 66 coil-type hydrogen igniters strategically distributed throughout containment. These igniters are designed to burn hydrogen in containment whenever concentration levels increase rapidly beyond the capacity of the PARs, in order to prevent hydrogen detonation. The igniters are divided into two groups of 33, which are supplied power by separate 220/120V ac distribution panels and backed up by separate dc supplies fed through their respective inverters. Each major area in which the igniters are located includes at least one igniter from each group for redundancy. The igniters are actuated manually through PLS upon indication of core exit temperature greater than 648.9° C (1200° F), which is likely prior to RCS breach. The hydrogen monitoring subsystem discussed above provides backup indication to start the igniters. The DAS provides a diverse means of manually actuating the igniters from the MCR. There are no automatic actuations for this system. All 33 igniters in a group are actuated simultaneously via PLS, and all 66 igniters are actuated simultaneously via DAS.

10.5.6.2 Assumptions and Sources of Model Uncertainty

The VLS specific assumptions and uncertainties made in the development of this system model are as follows:

1. While the igniters are always grouped for redundancy, they are located throughout containment, including relatively isolated areas. The PSA cannot distinguish areas of hydrogen concentration; it can only make the determination that hydrogen is present in containment and the igniters are required for mitigation. Therefore, this success criterion is extended to include each area identified; system success is defined as the successful operation of one igniter in each area. This is conservative modelling since there is some likelihood associated with there being hydrogen in any given area, and the igniters in that area may not be required to mitigate the accident.

2. Though the PARs have no explicit failure modes in the PSA, credit may be taken for their ability to reduce hydrogen levels in containment and forestall or eliminate the need for the igniters. Any credit taken necessarily has some level of model uncertainty associated with it.

10.5.6.3 System Boundaries for PSA Model

The VLS model contains all 66 igniters and associated fuses and circuit breakers between the igniters and the 220/120V ac distribution panels. These fuses are included as protection for the igniters; however, for the purpose of the PSA, if a fuse spuriously breaks contact, the igniter is no longer available for accident mitigation. The panels themselves and associated backup supplies are included in other system models and linked via transfers. The VLS model also includes relays for igniter actuation. The hydrogen monitoring subsystem is not credited in the PSA. The VLS model also does not take credit for the PARs for hydrogen control.

10.5.6.4 Common Cause Failures

The igniter and associated fuse CCF groups are defined by the number of igniters/fuses in each area, and the remaining components are defined with a single group per component type. Because there are a large number of similar components in this system, the VLS CCF groups in the model would become too cumbersome for quantification. The CCF events were injected into the system model and the change in the top event probability (from its value without CCF injected) was used to calculate a beta factor. With this, the CCF was removed from the model, and a basic event that includes the beta factor ($VLS-ALL-CCF-B) was used to raise the system top probability to the value that included CCF.

10.5.7 Normal Residual Heat Removal System

10.5.7.1 System Description

The RNS includes two mechanical trains of decay heat-removal equipment. Each train includes one RNS pump and one RNS heat exchanger located in the Auxiliary Building. The two trains of equipment share a common suction line from the RCS. Each train has a discharge line to return the flow to the RCS through the two PXS DVI lines. The RNS is also interconnected with the IRWST, the SFP, and the CVS to perform support functions. In addition, the RNS includes the piping, valves, and instrumentation necessary for correct system operation.

The portions of the RNS piping that contain reactor coolant outside the RCS pressure boundary valves (RNS-PL-V001A/B, RNS-PL-V002A/B, RNS-PL-V015A/B, and RNS-PL-V017A/B); including those that are outside containment, have a design pressure and temperature high enough that full RCS system pressure is below the ultimate rupture strength of the piping.

The common suction header then branches into two parallel lines, with each line containing two normally closed MOVs in series that serve as reactor coolant pressure boundary valves. This configuration ensures both reliable RCS pressure boundary isolation and decay heat removal initiation by allowing RNS initiation after a single failure of an isolation valve to open, and also by allowing for RNS isolation after a single failure of an isolation valve to close. The isolation valve in each pair closest to the containment penetration also serves as a containment isolation valve. Each RNS/RCS suction isolation valve receives power from a Class 1 power supply (250 Vdc) and is interlocked with RCS pressure to prevent the operator from opening the valve until RCS pressure is below 31 Bar (450 psig), the normal operating pressure of the RNS suction. These valves are also interlocked to prevent them from being opened unless the isolation valves from the IRWST to the RNS pump suction header and from the RNS pump discharge header to the IRWST are closed. This prevents inadvertent

blowdown of the RCS to the IRWST. In addition, the power supply to each valve is blocked at the valve's motor control centre during plant power operations.

Once inside containment, each discharge line contains a check valve which acts as a containment isolation valve. Downstream of the check valve, each discharge line is routed to a PXS DVI line. Note that the PSA model is based on an RNS design in which there is a common discharge header through containment that then branches into two lines, each being routed to a PXS DVI line.

The RNS is capable of providing low pressure makeup from the Spent Fuel Pool Cooling System (SFS) cask loading pit (CLP) and the IRWST to the RCS. The system must be manually initiated by the operator following receipt of an ADS signal. If the RNS is available, it will provide RCS makeup once the pressure in the RCS falls below the shutoff head of the RNS pumps.

10.5.7.2 Assumptions and Sources of Model Uncertainty

The RNS specific assumptions and uncertainties made in the development of this system model are as follows:

1. There is uncertainty associated with the amount of time that the CLP is unavailable while the plant is at-power. The CLP can be unavailable for use by the RNS for accident mitigation due to fuel handling operations. The CLP is assumed to be unavailable 5percent of the time while the plant is at-power.

2. There is uncertainty associated with the response of check valve RNS-PL-V056 during switch over from CLP injection to IRWST injection. Because of RNS pump suction, check valve RNS-PL-V056 may never fully close; therefore, closing of RNS-PL-V056 as a redundant method to isolate the CLP has not been modelled. CLP isolation failure is a concern because, if the CLP is not isolated, the RNS pumps may drain down the CLP and entrain air in the RNS pump suction causing the RNS pumps to fail. Note that MOV RNS-PL-V055 can isolate the CLP and is modelled to do so.

10.5.7.3 System Boundaries for PSA Model

The boundaries for the RNS PSA model include the flow path from the hot leg suction to the DVI lines into the reactor vessel. Also included are connections to the PXS IRWST and the PXS sump as well as the CLP and its connections. For the Level 2 portion of the RNS model, the spent fuel pool and its connections are included in the RNS boundary.

10.5.7.4 Common Cause Failures

The RNS common cause failure groups were determined consistent with the method described in Section 10.8. Unique common cause groups to note:

- Check valves on the DVI lines – these four check valves are broken up into two CCF groups of two because RNS-PL-V017A/B are normal swing check valves, and RNS-PL-V015A/B are stop check valves. This diversity allows these four check valves to be in different common cause groups.

Hot leg suction MOVs – these four MOVs are broken up into two CCF groups of two because valves RNS-PL-V001A/B are subject to RCS pressure, and valves RNS-PL-V002A/B are not. Additionally, valves RNS-PL-V002A/B are containment isolation valves

so they will be tested more frequently than RNS-PL-V001A/B. This diversity allows these four MOVs to be in different common cause groups.

10.5.8 Component Cooling Water System

10.5.8.1 System Description

The CCS is divided into two redundant trains, each including one pump and one heat exchanger. The two pumps take suction from a common return header and the heat exchangers are routed to a common supply header. Each pump discharges to the respective heat exchanger, but a cross-connection at the pump discharge allows for either pump to feed either heat exchanger. The CCS heat exchangers are cooled by the SWS. The CCS heat exchangers are plate type, counterflow heat exchangers.

The CCS supplies cooling water to:

- RCP motor cooling
- RCP variable frequency drive cooling
- RNS heat exchangers (shutdown and refuelling modes only)
- Spent fuel pool cooling
- Condenser cooling for the Central Chilled Water System (VWS) high capacity water-cooled chiller units
- Letdown cooling via the CVS letdown heat exchanger
- Primary Sampling System (PSS) sample heat exchanger cooling
- WLS reactor coolant drain tank heat exchanger cooling
- CVS makeup pump miniflow heat exchanger cooling
- RNS pump seal cooling
- CAS cooling
- CDS condensate pump motor oil cooling

One train of CCS is required for normal operation. The remaining CCS pump is aligned to deliver flow to the operating heat exchanger and is started automatically if the operating CCS pump fails. All loads inside containment can be remotely isolated by automatic closure of motor-operated containment isolation valves in response to a safeguards signal.

10.5.8.2 Assumptions and Sources of Model Uncertainty

No CCS specific assumptions were made in the development of this system model.

10.5.8.3 System Boundaries for PSA Model

The CCS consists of two trains of cooling which consist of pumps, heat exchangers, and associated valves and piping. The CCS surge tank is part of the system boundary which provides makeup to the CCS. The CCS is made of common valves and piping to associated loads. Valves and piping that are part of the CCS which are specific to other systems are modelled with that system.

10.5.8.4 Common Cause Failures

The CCS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.9 Service Water System

10.5.9.1 System Description

Major elements of the SWS include two 100 percent capacity service water pumps, automatic backwash strainers, a two-cell cooling tower with a divided basin and associated piping, valves, controls, and instrumentation. The service water system is arranged into two trains of components and piping. Each train includes one service water pump, one strainer, and one cooling tower cell. Each train provides cooling to one CCS heat exchanger. SWS piping and components are located within the Turbine Building or in the yard area.

Cooled service water exiting from the cooling tower is collected in a concrete storage basin located below the tower structure. The basin is divided into halves, with each half capable of collecting the segregated flow from one tower cell.

Each service water pump provides 100 percent of the required flow to cool the CCS heat exchanger. Both service water pumps are operated simultaneously for increased capacity in order to support outage scheduling (shutdown cooling).

A check valve (SWS-PL-V025A/B) at the discharge of each pump prevents reverse flow through an idle pump during periods when the pump discharge valve is not fully closed. In the event that neither service water pump is operating (e.g., immediately following loss of normal ac power), the check valves minimize system drain down. Each pump discharge isolation valve is an MOV (SWS-PL-V002A/B) and automatically closes after the associated pump is stopped. The discharge MOV must be fully closed to start the associated pump.

The SWS normally operates in one of two basic modes of operation: single train or two trains. The SWS follows the needs of the CCS, and the mode of operation selected for use is chosen to support the current mode of CCS operation.

10.5.9.2 Assumptions and Sources of Model Uncertainty

No SWS specific assumptions were made in the development of this system model.

10.5.9.3 System Boundaries for PSA Model

The boundary of the SWS includes the main flow path of Train A and B from the cooling tower basin, through the pumps, through the CCS heat exchangers, and back to the cooling tower. The main components in the SWS include service water pumps, valves, strainers, screens, cooling tower, and cooling tower fans. The SWS boundary also includes makeup to the cooling tower basin from the RWS.

10.5.9.4 Common Cause Failures

The SWS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.10 Central Chilled Water System

10.5.10.1 System Description

The Central Chilled Water System consists of two subsystems: a High Capacity System (HCS), and a Low Capacity System (LCS). The HCS supplies cooling water to the Radiologically Controlled Area Ventilation System (VAS), Containment Recirculation Cooling System (VCS), Containment Air Filtration System (VFS), Health Physics and Hot Machine Shop HVAC System (VHS), Radwaste Building HVAC System (VRS), VTS, and the Annex/Auxiliary Building Nonradioactive Ventilation System (VXS). The HCS also provides cooling water for the Secondary Sampling System (SSS) sample cooler, the WLS vapour condenser and the Gaseous Radwaste System (WGS) gas cooler. The LCS provides chilled water to defence-in-depth HVAC cooling coils used by the Nuclear Island Nonradioactive Ventilation System (VBS) air handling units and the VAS unit coolers located in the CVS and RNS pump rooms.

High Capacity Subsystem

The high capacity subsystem consists of two 85 percent capacity chilled water pumps, two 15percent capacity chilled water pumps, two 85 percent capacity water cooled chillers , two 15percent air cooled chillers, a chemical feed tank, an expansion tank, and associated valves, piping, and instrumentation. The subsystem is arranged in two parallel mechanical trains with common supply and return headers. Each train includes one 15 percent capacity pump, one 85 percent capacity pump, one 15 percent capacity chiller, and one 85 percent capacity chiller. A cross-connection at the discharge of each pump allows for each to feed a given chiller of matching capacity.

Low Capacity Subsystem

The LCS consists of two 100 percent capacity chilled water trains. Each train consists of a chilled water pump, an air-cooled chiller, an expansion tank, and associated valves, piping, and instrumentation. A common chemical feed tank is connected to both subsystems. The system is arranged in two independent trains with separate supply and return headers. This configuration provides redundancy and independence of trains during the various modes of system operation and satisfies availability requirements. The subsystem configuration provides 100 percent redundancy during normal plant operation and following the loss of offsite power.

10.5.10.2 Assumptions and Sources of Model Uncertainty

No VWS specific assumptions were made in the development of this system model.

10.5.10.3 System Boundaries for PSA Model

The VWS consists of an HCS and an LCS. The HCS consists of two parallel trains of chilled water which feed a common header. Each train consists of an 85 percent capacity water cooled chiller pump, a 15 percent capacity air cooled chiller pump, an 85 percent capacity water cooled chiller package, a 15 percent capacity air cooled chiller package, and associated valves and piping. The VWS expansion tank on the HCS is part of the system boundary which provides makeup to the VWS HCS. DWS makeup to VWS HCS is less than 6.3 L/sec (100 gpm) and therefore is not credited in the model. The VWS is made of common valves and piping to associated HVAC loads. Valves and piping that are part of VWS which are specific to HVAC loads are modelled in the HVAC system.

The LCS consists of two independent trains of chilled water. Each train consists of a 100 percent capacity air cooled pump, a 100 percent capacity air cooled chiller package, and associated valves and piping. The VWS expansion tanks on each LCS train are part of the system boundary which provides makeup to each train of the VWS LCS. DWS makeup to VWS LCS is less than 6.3 L/sec (100 gpm) and therefore is not credited in the model. The VWS is made of common valves and piping to associated HVAC loads. Valves and piping that are part of VWS which are specific to HVAC loads are modelled in the HVAC system.

10.5.10.4 Common Cause Failures

The VWS common cause failure groups were determined consistent with the method described in Section 10.8. Unique common cause groups to note:

Common cause failure was modelled for both the 15 percent capacity portion of HCS and the LCS for air cooled pumps and air-cooled chiller packages due to similar sizing and operation.

10.5.11 Electric Power Distribution Systems (EPS)

10.5.11.1 System Description

The EPS consists of three electrical systems ECS, dc and uninterruptible power supply system (EDS), and IDS, supported by various mechanical and C&I systems. The first tier (ECS) consists of the ac power distribution systems feeding non-Class-1 loads required for unit operation. The second tier (EDS) includes the ac and dc power distribution systems supplying power to permanent non-Class 1 loads, i.e., loads that, due to their specific functions, are generally required to remain operational at all times or when the unit is shut down. The third tier (IDS) consists of the redundant Class 1 dc and ac UPS power distribution systems feeding Class-1 loads. The EPS is supported by transformers in the main generator system (ZAS), two standby DGs in the onsite standby power system (ZOS), and fuel delivery to the ZOS supplied by DOS.

To provide normal power to the plant auxiliary and service loads during normal operation, the station generated power is transmitted to the offsite transmission system with a tap to the three unit auxiliary transformers (UATs): ZAS ET-2A, 2B, 2C. A second ac power supply from the utility grid, or other power source, is provided for reserve power, maintenance, and testing of the equipment through two reserve auxiliary transformers (RATs): ZAS-ET-4A, 4B. The reserve power source is site specific.

The normal ac power supply to the ECS is provided from the station main generator. When the main generator is not available, the preferred plant auxiliary power supply is provided from the switchyard by back-feeding through the main step-up transformer (MSUT) and UATs with the generator breaker open. A reserve source of power is provided through two RATs to the ECS. In case of loss of both normal and preferred power sources as a result of a fault operating the protective relays and devices for the UATs and MSUT concurrent with a turbine generator breaker trip, the automatic bus transfer will be initiated to switch over loads from the UATs to RATs. This automatic switch over is a fast bus transfer backed up by a residual voltage transfer. The fast bus transfer is blocked during plant startup when the auxiliary boiler(s) is in operation.

The ECS is divided into two subsystems; Medium Voltage (MV) and Low Voltage (LV). The MV subsystem contains the 6.9kVac switchgear which provides power for the large ac loads including RCPs, CWS pumps, SWS pumps, CCS pumps, etc. The arrangement of the 6.9kVac 60 Hz buses permits feeding functionally redundant pumps or groups of loads from separate buses and enhances the plant operational flexibility. The 6.9kVac switchgear powers motors larger than 250HP, and the load centre transformers. There are two 6.9kVac switchgear (ECS-ES-1 and ECS ES-2) located in the Annex Building, and five switchgear (ECS-ES-3, 4, 5, 6, 7) located in the Turbine Building.

The LV subsystem begins at the MV 6.9kVac terminals of the load centre transformers, which are powered from the MV portion of the ECS, and ends at the terminals of the 480Vac 60 Hz LCs and is then further broken down into 480Vac 60 Hz MCCs. LCs and MCCs power loads such as motors, heaters, battery chargers, voltage regulating transformers, and lighting transformers.

The ECS also includes two 480Vac 60 Hz Non-Class 1 ancillary ac DGs located in the southeast corner of the Annex Building. These DGs provide power for post-accident monitoring (PAM), MCR lighting, and MCR and C&I room ventilation. The ancillary DGs are used following an extended (more than 72 hour) loss of all normal/preferred, standby, and dc backed electric power sources.

The IDS consists of the redundant Class 1 dc and ac UPS power distribution systems feeding Class-1 loads.

The IDS consists of Class 1 250Vdc and Class 1 120Vac UPS, power distribution subsystems. The IDS is designed such that the critical plant loads required for plant safe shutdown and monitoring are powered when all the onsite and offsite ac power sources at the plant are lost and cannot be recovered for a period of up to 72 hours.

The normal source of power for the Class 1 dc system is the Non-Class 1 ECS. The connection between the Class 1 system and the Non-Class 1 system is made through the battery chargers that serve as isolation devices. If the normal source of ac power is not available, the Class 1 batteries have sufficient capacity for the critical plant loads required for plant safe shutdown for a period of up to 72 hours.

The Class 1 250Vdc subsystem is divided into four independent divisions (A, B, C, and D). Each of these divisions is supplied from dedicated batteries and battery chargers.

Divisions A and D battery banks and one of the battery banks in divisions B and C are designated as 24 hour battery banks and provide power to the loads required for the first 24 hours following a loss of all ac power event or a DBA. The second battery bank in divisions B and C, designated as the 72 hour battery banks, are used for those loads requiring power for 72 hours following the same event.

The Class 1 120Vac, 60 Hz ac UPS provides power to four independent divisions of Class 1 instruments and control power buses. Divisions A and D each consist of one Class 1 inverter associated with C&I DP and a backup voltage-regulating transformer with a DP. Each inverter is powered from its respective 24 hour battery bank SB. Divisions B and C each consists of two inverters, two C&I DPs, and a backup voltage-regulating transformer with a DP shared between the divisions. The 24 hour battery bank SB powers one inverter, and the 72 hour battery bank SB powers the other inverter.

The EDS includes the ac and dc power distribution systems supplying power to permanent non-Class-1 loads i.e., loads that, due to their specific functions, are generally required to remain operational at all times or when the unit is shut down.

The EDS consists of two 125Vdc and 120Vac subsystems and one 250Vdc subsystem. The 125Vdc and 120Vac subsystems represent two separate power supply trains. The 250Vdc subsystem is dedicated to the turbine-generator dc emergency pump motors. The 250Vdc subsystem has only one dc SB bus.

Each 125Vdc subsystem consists of two separate dc SB buses for the Non-Class 1 dc loads. These two buses can be interconnected by a normally open circuit breaker at each distribution bus to enhance the power supply source availability. When the tie breakers between two buses are closed, the selection of loads to be powered is administratively controlled to stay within the battery rating. Each of the two 125Vdc subsystems include two sets of battery chargers, stationary batteries, dc distribution equipment, and associated monitoring and protection devices.

The 480Vac ECS LCs, backed by the ZOS, provides the normal ac power to the battery chargers which provide the dc power for plant operation, and at the same time maintain the associated stationary battery banks on float charge. Battery chargers for 125Vdc EDS1 and EDS3 subsystem are fed by LC ECS-EK-13; battery chargers for 125Vdc EDS2 and EDS4 are fed by LC ECS-EK-23. Both LCs are part of the ECS and DG backed.

10.5.11.2 Assumptions and Sources of Model Uncertainty

No electric power specific assumptions were made in the development of this system model.

10.5.11.3 System Boundaries for PSA Model

The ECS portion of the EPS PSA model includes the ZAS transformers (MSUT, UATs, and RATs), 6.9kVac buses, 480Vac LCs, 6.9kVac to 480Vac LC transformers, 480Vac MCCs, 120Vac DPs, 480Vac to 120Vac DP transformers, and the ancillary DGs. The ECS also accounts for all breakers between the components listed.

The IDS portion of the EPS PRSA model includes battery chargers, 24 and 72 hour batteries, 250Vdc SBs, DPs, and MCCs. The IDS also includes 120Vac UPS components consisting of inverters, static switches, regulating transformers, and 120Vac UPS DPs. The IDS also accounts for all breakers between the ECS and IDS components.

The EDS portion of the EPS PSA model includes battery chargers, 2 hour batteries, 125Vdc SBs, DPs, and MCCs. The EDS also includes 120Vac UPS components consisting of inverters, static switches, regulating transformers, and 120Vac UPS DPs.

The DG portion of the EPS PSA model includes components in the ZOS and DOS. The DOS includes all fuel oil transfer components from the 7 day tank to the 4 hour day tank. Components in the DOS include transfer pumps, strainers, valves, and moisture separators. The ZOS includes the diesel engine and generator, output breaker, air start system, oil/water jacket cooling system, exhaust system, and air intake system.

10.5.11.4 Common Cause Failures

The electric power common cause failure groups were determined consistent with the method described in Section 10.8. Unique common cause groups to note:

- The 6.9kVac and 480Vac breakers were identified as being subject to CCF. The CCF failure modes for breakers include fail to open, fail to close, and spurious operation. The 6.9kVac and 480Vac LC breakers that supply redundant equipment were included in the CCF analysis for ECS in their own respective CCF groups. Feeder breakers for mechanical components were not considered in the ECS because the breaker is within the component boundary of that mechanical component.

- Battery chargers and inverters were identified as being subject to CCF. The CCF failure mode for chargers and inverters is failed to operate. In the IDS there are two group sizes for battery chargers. One group includes four battery chargers for the 24 hour batteries, and the other group includes two chargers for the 72 hour batteries. The inverters follow the same methodology: four inverters for the 24 hour power supplies, and two inverters for the 72 hour supplies. In EDS there is a group of four battery chargers and a group of four inverters.

10.5.12 Containment Isolation

10.5.12.1 System Description

The Containment System (CNS) isolation system provides the Class 1 system function of containment isolation for containment boundary integrity and provides a barrier against the release of fission products to the atmosphere. The containment isolation system utilizes manual valves, check valves, relief valves, AOVs, and MOVs to isolate the containment atmosphere from the environment outside.

Some penetrations do not isolate solely on a containment isolation signal (T Signal), these penetrations are addressed below:

CCS – The CCS containment isolation valves (CIVs) isolate on an S Signal rather than a T Signal to maximize routine recovery and economic protection, in the event that the T Signal was generated on manual actuation of the PCS.

CVS (Charging) – The CVS makeup line CIVs will be closed based on the following Category-A signals: (a) High-2 pressuriser level (pressuriser overfill protection), (b) High SG level (SGTR – steam generator overfill protection), (c) S Signal + High pressuriser level (safeguards actuation without makeup requirements), and (d) High-2 containment radiation (core damage source term containment isolation).

RNS – The RNS CIVs are isolated on a High containment radiation signal. The High containment radiation signal indicates an event in which there is core damage, and is therefore a source term requiring containment isolation including RNS. Because the RNS is normally isolated during Modes 1, 2, and 3 and aligned only for shutdown operations, it would typically not require an isolation signal following a DBA from Modes 1, 2, and 3.

SGS Main Steam – The main steam line is isolated on a main steam line isolation signal, indicating either excessive cooldown of the reactor (which might lead to an uncontrolled return to criticality) or a challenge to the integrity of the reactor vessel due to thermal shock. In addition to limiting the reactor cooldown rate, the closure of the CIVs maintains containment integrity by limiting mass and energy addition to the containment.

SGS Main Feedwater – The main feedwater line is isolated on a feedwater isolation signal indicating excessive cooldown of the reactor, which may lead to an uncontrolled return to criticality or a challenge to the integrity of the reactor vessel due to thermal shock. The signal is generated on any condition that generates an S Signal. In addition to limiting the reactor cooldown rate, the closure of the CIVs maintains containment integrity by limiting mass and energy addition to the containment. Finally, isolation prevents overfilling the SGs with possible consequent damage to the steam system and/or turbine.

SGS Blowdown – The PMS limits the potential for SG dryout and limits the loss of the SG inventory as a heat sink under accident or transient conditions. Within the PMS, any set of conditions which initiates the PRHR system operation also isolates the blowdown system.

VFS – The VFS is isolated not only on a T Signal, but also on a High containment radiation signal to provide an immediate response to radioactive releases to containment. In addition to the normal function of the containment filtration system, the VFS vent line also provides vacuum relief capability. The vacuum relief system utilizes the vent line penetration, but performs vacuum relief through separate branch lines. The branch lines contain check valves inside containment which will remain closed during normal operation. Motor operated butterfly valves provide containment isolation on the outboard side of the vacuum relief system. The motor operated butterfly valves are normally closed during all modes of operation, and receive an automatic close signal on a T Signal and High containment radiation signal. These valves receive an open signal on a Low-2 containment pressure signal, which takes priority over containment isolation. This functionality ensures that any event requiring vacuum relief inside containment can be mitigated to protect the containment vessel.

10.5.12.2 Assumptions and Sources of Model Uncertainty

The CNS specific assumptions and uncertainties made in the development of this system model are as follows:

1. Electrical, instrumentation, and spare penetrations are not modelled in this analysis. The penetrations either have no fluid flow and very low differential pressure, or are capped at both ends. The pipe failure data is not detailed enough to represent the failure of piping with very low differential pressure and no flow.

10.5.12.3 System Boundaries for PSA Model

The CNS components credited in this model consist of the inside reactor containment (IRC) isolation valves and the outside reactor containment (ORC) isolation valves for each penetration modelled.

10.5.12.4 Common Cause Failures

The CNS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.13 Compressed and Instrument Air System

10.5.13.1 System Description

The CAS consists of three subsystems: instrument air, service air, and high-pressure air.

Instrument Air Subsystem

Instrument air supplies compressed air for AOVs, dampers, fan inlet guide vane actuators, and pneumatic instruments. Instrument air consists of two 100 percent capacity air-supply trains, which include a compressor package, a dryer package, an air receiver, and associated valves, piping, and instrumentation. Both air receiver discharge lines are connected to the instrument air distribution header. An interconnection is provided between the instrument air system and the service air system. Ball valve (CAS-PL-V017) is normally closed during power operations and during plant shutdown. If an instrument air compressor train fails during power operation, the valve may be opened to allow the service air compressors to back up the remaining instrument air compressor until the failed train is repaired. The instrument air compressors are cooled by the CCS. The instrument air compressor and dryer packages are powered from permanent and non-Class 1 buses that are backed by onsite standby diesel generators. If loss of normal ac power occurs, the "A" instrument air train is powered by the "A" train diesel, and train "B" is powered by the "B" train diesel.

Service Air Subsystem

Service air is supplied at outlets throughout the plant to power air-operated tools. Service air includes two compressor trains, each with a compressor package and an air dryer package. The service air compressor and associated equipment are powered from permanent, non-Class 1 buses. Cooling water is also supplied by the CCS.

High Pressure Air Subsystem

The high-pressure air supplies air to the Main Control Room Emergency Habitability System (VES) and fire-fighting apparatus recharge station. High-pressure air includes an air compressor and filtration package, a receiver package, and supply piping. The high-pressure air compressor package is powered from permanent, non-Class 1 electrical buses. The high-pressure air compressor is air cooled and does not require a cooling water source.

10.5.13.2 Assumptions and Sources of Model Uncertainty

The CAS specific assumptions and uncertainties made in the development of this system model are as follows:

Check valves CAS-PL-V001A/B are modelled using one demand. This was used to represent the swapping of the trains. The normal operation of the compressor starts and stops based on system pressure.

10.5.13.3 System Boundaries for PSA Model

The instrument air subsystem contains two air compressor packages, where each package includes the compressor with ac motor drive, a microprocessor-based controller, lube oil system, inlet air filter, and intercooler with moisture separator, aftercooler with moisture separator, air-side safety relief valves, and a discharge check valve. The compressors receive cooling water from the CCS. The instrument air subsystem also contains two air dryer packages. The purpose of the dryer package is to remove moisture that can damage instruments, controls, system piping, and tools. Each dryer package contains two drying towers, an inlet air prefilter, and an afterfilter. The instrument air subsystem also contains two air receivers, one in each compressor train. The air receivers function to avoid excessive cycling of the air compressor valves and to allow for surge capacity for short periods of time.

10.5.13.4 Common Cause Failures

The CAS common cause failure groups were determined consistent with the method described in Section 10.8.

10.5.14 Protection and Safety Monitoring System

10.5.14.1 System Description

The PMS serves to perform the necessary Category-A signal acquisition, calculations, setpoint comparison, coincidence logic, RT or ESF actuation functions, and component control functions. The PMS serves to achieve and maintain the plant in a safe shutdown condition.

Related sensors and the reactor trip switchgear are, for the most part, four-way redundant for C&I equipment used for reactor trip and Engineered Safety Feature (ESF) actuation functions. This redundancy permits the use of bypass logic so that a division or individual channel out of service can be accommodated by the operating portions of the protection system reverting to two out of three logic from two out of four logic. Four redundant measurements of each variable for reactor trip criteria are obtained by the use of four separate sensors. One measurement is processed by each division.

The Bistable Processor Logic (BPL) is the first level of processing in a safety path. Analogue signals are converted to digital form by analogue-to-digital converters within the division's BPL. Signal conditioning is applied to selected inputs following the conversion to digital form. Following necessary calculations and processing by the BPL, the measurements are compared against the applicable setpoint for that variable. A partial trip signal for a parameter is generated if the channel's measurement exceeds its predetermined or calculated limit. Processing of variables for reactor trip is identical in each of the four redundant divisions of the protection system.

The Local Coincidence Logic (LCL) subsystem acts to initiate a reactor trip or ESF actuation when a pre-determined condition in two out of four independent safety divisions reaches a partial trip or partial actuation state. The LCL also provides for the bypass of trip or actuation functions to accommodate periodic tests and maintenance.

The reactor trip signal from each of the four divisions of the PMS is sent to that division's reactor trip circuit breakers (RTCB). Each division controls two RTCBs. The reactor is tripped when two or more actuation divisions output a reactor trip signal, opening their breakers.

The ESF component control function is implemented with two Integrated Logic Processors (ILPs) and Component Interface Modules (CIMs) that provide a distributed interface between the Class-1 system and the plant operator for control of non-modulating Class 1 plant components. CIMs provide the capability for on/off control of individual Class 1 plant components. The CIMs receive inputs from the ILPs and from the PLS. Non-modulating control relates to the opening or closing of solenoid-operated valves and solenoid-operated pilot valves, and the opening or closing of motor-operated valves and dampers.

10.5.14.2 Assumptions and Sources of Model Uncertainty

The PMS specific assumptions and uncertainties made in the development of this system model are as follows:

1. The model is based on representative signals. The signals modelled for reactor trip include high pressuriser pressure and over temperature delta T (OTDT). Representative reactor trip signals are used based on the previous studies completed for the Pressurized Water Reactor Owners Group (PWROG). It was concluded in these studies that reactor trip actuation signals will be provided by multiple sources (plant parameters) for all initiators. In addition, these automatic actuations are backed up by an operator action to trip the reactor. Given the multiple ways the reactor can be tripped, the divisions are very small contributors to the trip signal unavailability, and the specific signals modelled will not impact the results of the reactor trip signal unavailability analysis.

2. A failure of a single cabinet fan is assumed to lead to only a small increase in cabinet temperature which would not impact the reliability of the components in the cabinet. Each cabinet includes multiple cooling fans located in various locations throughout the cabinet. It is expected that multiple fans would need to fail to cause a significant change in the reliability of the components inside the cabinet.

3. The spurious actuation fault trees modelled in the PMS include single failures that cause a spurious actuation. There is uncertainty in the failure modes identified and modelled for support actuations. For ADS Stages 1-3, two CIMs are modelled for spurious actuation (isolation and control valves). The common cause failures of the software and other modules are modelled as part of the single failure methodology for spurious actuation.

4. The Low-3 Pressuriser Pressure signal is a representative signal used in the containment isolation TOPS (over pressure protection) for long term cooling analysis (LTCA) and Level 2. The signal is representative of the safeguards signal that would occur in Level 1 sequences requiring containment isolation.

5. The IDS power supply and integral cabinet power supply panel are required for successful ILC actuation of the ESF components controlled by the PMS. This dependency on an external power supply and the integral cabinet power supply panel is modelled explicitly in each PMS TOP. However, in cases where the PMS top models the de-energization of a normally energized solenoid-operated valve (e.g., CMT, PRHR, and PCS actuation), the failure of the integral cabinet power supply panel and external power supplies was removed because failure of the power supplies results in the Class-1 components entering their safe state. There are other solenoid-operated valves (SOVs) that may have conservatively modelled the ILP power supply and SOV external power supply that were not felt to be risk significant.

10.5.14.3 System Boundaries for PSA Model

The components and type codes (TCs) included in the PMS PSA model include:

- Component Interface Module CI631 (PMS-CIM-FOP)
- Digital Input Module DI621 (PMS-DIM-FOP)
- Digital Output Module
  - PMS-DO1-FOP Type DO620 (used for PMS-PLS digital interface in the ICP and turbine trip in the LCL)
  - PMS-DO2-FOP Type DO630 (used for reactor trip (RT) model)
- Analogue Input Module
  - PMS-AI1-FOP Type AI687
  - PMS-AI2-FOP Type AI688
- Processor Module PM646A (PMS-PRM-FOP)
- Communication Interface Module (PMS-COM-FOP)
- High Speed Link (PMS-HSL-FOP)
- Safety Remote Node Controller (PMS-SRN-FOP)
- Sensors
  - Pressure (PCS-STP-FOP, RCS-STP-FOP, SGS-STP-FOP)
  - Level (PXS-STL-FOP, RCS-STL-FOP, SGS-STL-FOP)
  - Temperature (RCS-STT-FOP)
  - Neutron Detector (RXS-NDT-FOP)
- Turbine Trip Relays (PMS-RLY-FOP)
- Reactor Trip Breakers (PMS-RTB-FOP)
- Reactor Trip Matrix Termination Unit
  - Shunt Trip (PMS-RST-FOP)
  - UV Trip (PMS-RUV-FOP)
- Squib Valve Termination Unit (PXS-STU-FOP)
- Analogue Output Module
  - PMS-AOM-FOP Type AO650
- Isolation Barrier
  - PMS-IS1-FOP Analogue Output I/I Isolator (Current/Current)
  - PMS-IS2-FOP Analogue Output E/I Isolator (Voltage/Current)
  - PMS-IS3-FOP Digital Output Isolator
  - PMS-IS4-FOP Isolator for Turbine Trip
- Hand Switches on the Primary Dedicated Shutdown Panel and Secondary Dedicated Shutdown Panel (PMS-MSW-FTC)
- Power supplies within each modelled cabinet, including the power supply module, line filter, rectifier, and circuit breakers

10.5.14.4 Common Cause Failures (CCFs)

CCFs for the PMS modules are modelled using a beta factor. The PMS includes relatively large numbers of similar components that should be included together in CCF groups. Application of the alpha-factor method for such large groups would result in a substantial increase in fault tree size and complexity that is not necessary to reflect the contribution of CCF to system failure. Using the beta factor model, only global common cause events that fail all components in a common cause group are included in the model.

The failure of the PMS software is modelled as a single common cause event. Modelling and establishment of CCF groups for sensors are developed and quantified using the alpha factor method. CCF groups are established for redundant sensors based on the specific plant parameter that is being monitored. Unique functions are provided as follows:

- Each core makeup tank includes four level sensors that monitor upper tank level and are included in a CCF group of size eight to cover the sensors in both tanks.

- Similarly, each core makeup tank also includes four level sensors that monitor lower tank level and are included in a separate CCF group of size eight.

- The neutron detectors are also broken into two groups based on upper and lower detectors.

10.5.15 Diverse Actuation System

10.5.15.1 System Description

The DAS is a Class 2 system that provides backup to the PMS. The DAS provides an alternate means of initiating a reactor trip and actuating selected engineered safety features. The DAS was added to the set of AP1000 plant C&I systems to provide a means to mitigate consequences of failure to trip following an ATWT event and reduce the impact on PSA for postulated common-mode failures of PMS.

The DAS uses dedicated sensors to monitor the following six plant parameters independently of the PMS and the PLS:

- SG wide range water level
- Pressuriser water level
- Core exit thermocouple temperature
- RCS hot leg temperature
- Containment operating area temperature
- Rod control motor-generator (MG) set output voltage

In order for a DAS automatic function to be initiated, a digital output from two out of three or one out of two taken twice DAS processors is required. For example, pressuriser water level is monitored by three DAS channels. Each level channel is sent to a different DAS processor. It is necessary for two processors to produce a water level output signal to initiate an RT and CMT actuation. Note that the PSA model is currently based on two out of two logic.

10.5.15.2 Assumptions and Sources of Model Uncertainty

The DAS specific assumptions and uncertainties made in the development of this system model are as follows:

1. The master disable switch located outside the MCR, which is a component in the Operations and Control Centres System (OCS), is not expected to be used or tested at any time during maintenance or operation of the plant.

2. A failure of a single cabinet fan is assumed to lead to only a small increase in cabinet temperature which would not impact the reliability of the components in the cabinet. Each cabinet includes multiple cooling fans located in various locations throughout the cabinet. It is expected that multiple fans would need to fail to cause a significant change in the reliability of the components inside the cabinet. The processor cabinet cooling fans (front and rear doors) failure to provide circulating air when the cabinet is powered results in the cabinet retaining function with no spurious actuation.

10.5.15.3 System Boundaries for PSA Model

The DAS equipment includes the following major components:

- Dedicated sensors
- Two Processor Cabinets
- One DAS Control Panel
- One Squib Valve Controller (SVC) Cabinet

10.5.15.4 Common Cause Failures

No common cause failures were identified for non-electric power distribution DAS equipment located in the Processor Cabinets. Failure modes related to this group of equipment are single failures to the DAS system tops.

Common cause failures for the DAS relays are modelled using a beta factor. The DAS relays and manual switches include a number of similar components that should be included together in CCF groups. Application of the alpha-factor method for such groups would result in a substantial increase in fault tree size and complexity that is not necessary to reflect the contribution of CCF to system failure. Using the beta factor model, only global common cause events that fail all components in a common cause group are included in the model.

Modelling and establishment of CCF groups for sensors were developed and quantified using the alpha factor method for groups up to size eight. CCF groups are established for redundant sensors based on the specific plant parameter that is being monitored.

10.5.16 Plant Control System

10.5.16.1 System Description

PLS performs signal acquisition, calculations, setpoint comparisons, logic calculations, and component control to maintain the plant's systems during all modes of operations. The PLS accepts operator soft control manual commands from the Data Display and Processing System (DDS) and actuates the command if the plant system and control system are in the proper modes. Process variables, component status, and alarm data are generated and processed in the PLS and transmitted to the DDS for presentation and recording. The PLS can control Class 1 components via an optical interface to CIMs in the PMS. The CIM is a Class 1 component that provides command prioritization. The PLS communicates to field devices primarily via Ovation-based input/output (I/O) modules, but also utilizes Profibus and Modbus communications.

The PLS is composed of individual controllers with local and remote I/O. Each controller communicates point data via the Ovation network. Controllers can receive point data from other controllers via the Ovation network, or utilize hardwired communication via I/O.

The PLS performs the following control and monitoring functions:

- Rod position indications
- NSSS control
- Rod control
- Reactor power
- Pressuriser pressure
- Pressuriser level
- Steam generator inventory
- Reactor coolant system inventory
- Turbine steam demand control:
- Tavg
- Steam pressure
- Turbine control and protection
- Fluid systems control
- Balance of plant system control
- Electrical systems control
- Diesel generator control and load sequencing
- Ventilation systems control

PLS functions are implemented with the Emerson Ovation Control System. The system is made up of controllers that communicate with field devices using local and remote I/O modules, Profibus, and Modbus.

10.5.16.2 Assumptions and Sources of Model Uncertainty

The PLS specific assumptions and uncertainties made in the development of this system model are as follows:

1. PLS cabinets PLS-JD-DPU041 through PLS-JD-DPU048 are dual redundant controller cabinets that house two pairs of controllers with each pair acting as a redundant pair. The PLS model does not include the second set due to unavailability of the precise location.

2. A failure of a single cabinet fan is assumed to lead to only a small increase in cabinet temperature which would not impact the reliability of the components in the cabinet. Each cabinet includes multiple cooling fans located in various locations throughout the cabinet. It is expected that multiple fans would need to fail to cause a significant change in the reliability of the components inside the cabinet.

3. HVAC dependencies are not required for PLS. Failure of HVAC to a PLS cabinet room is assumed to lead to a relatively small decrease in component reliability and an insignificant impact on overall risk.

10.5.16.3 System Boundaries for PSA Model

The components and TCs included in the PLS PSA model include:

- Contact Input (Enhanced Compact SOE Input Module) (PLS-CTI-FOP)
- Relay Output Module (PLS-ROM-FOP)
- Analogue Input Module (PLS-AIM-FOP)
- Analogue Output Module (PLS-AOM-FOP)
- Resistance Temperature Detector (PLS-RTD-FOP)
- Processor Module (which includes the NIC card) (PLS-PRM-FOP)
- Profibus (PLS-PFB-FOP)
- IOIC (PLS-IOC-FOP)
- MAU (PLS-MAU-FOP)
- Remote Node Controller (PLS-RNC-FOP)
- Sensors
  - Pressure (STP-FOP-PT)
  - Level (STL-FOP-LT)
  - Temperature (STT-FOP-TE)
  - Flow (STF-FOP-FT)
- Power Distribution Module (PLS-PDM-FOP)
- 24V dc Power Supply (PLS-PWS-FOP)
- Power Line Filter (PLS-PWF-FOP)
- 5V/12V dc PCPS (PLS-CPS-FOP)

10.5.16.4 Common Cause Failures

Common cause failures for the PLS modules are modelled using a beta factor. The PLS includes relatively large numbers of similar components that should be included together in CCF groups. Application of the alpha-factor method to such large groups would result in a substantial increase in fault tree size and complexity that is not necessary to reflect the contribution of CCF to system failure. Using the beta factor model, only a global common cause event that fails all components in a common cause group is included in the model.

The failure of the PLS software is modelled as a single common cause event. Modelling and establishment of CCF groups for sensors are developed and quantified using the alpha factor method. CCF groups are established for redundant sensors based on the specific plant parameter that is being monitored.

10.5.17 Support Systems

A support system is defined as a plant system that affects the operation of two or more other plant systems, whether those systems are front line systems, support systems, or a combination of support and front line systems. Table 10-29 maps mitigating systems (left hand column) to support systems. Table 10-30 maps support systems that are supported by other support systems.

10.6 Human Reliability Analysis

10.6.1 Method Discussion

This section summarizes the HRA for the at-power internal events PSA for the AP1000 plant. The two types of human interactions that are analysed are pre-initiator (Type A) and post-initiators (Type C). The following describes these types of human interactions (HIs).

- Type A or Pre-initiators – This type of HI accounts for latent human interactions that occur during routine activities including testing, maintenance, or calibration activities that are performed before the IE. These actions by plant personnel can affect availability and safety by inadvertently disabling equipment during test and maintenance (T&M). Routine actions considered in the PSA involve restoring a component or flow path to normal configuration after completing the testing, inspection, or maintenance and ensuring that the sensing equipment is correctly aligned and calibrated for automatic response to emergency actuation conditions.

- Type C or Post-Initiators – This type of HI is a dynamic human interaction occurring after initiator occurrence. Operator actions are taken following procedures during a plant accident; plant personnel can operate standby equipment that terminates the accident, and human actions that prevent the termination of the accident fall into this category.

Type B HI includes human actions that can cause an IE (i.e., by committing an error, plant personnel can initiate an accident). Actions that can initiate plant transients are implicitly accounted for in the quantification of IE frequencies to the extent that these human actions are the cause of such events. Plant specific data are used to assign total IE frequencies of which human errors are only one cause.

HRA for pre-initiators is carried out in the following sequence of steps.

1. Identification of specific routine activities that, if not performed correctly, could impact the availability of equipment necessary for a system's PSA function.

2. Screening of routine activities identified that could impact the availability of equipment. None of these screened activities are identified as pre-initiators.

3. Assessment of the probability of pre-initiators and possible dependency between HI.

HRA for post-initiators is carried out in the following sequence of steps.

1. Identification of post-initiators through a review of relevant procedures.
2. Assessment of the probability of post-initiators and possible dependency between HI.

HRA results were documented and quantified using the EPRI HRA Calculator®. This tool is designed to step PSA analysts through the HRA tasks needed to develop and document human failure events (HFEs) and to quantify HEPs.

10.6.2 Analyses and Results

10.6.2.1 Pre-Initiators

The identification and screening of pre-initiators is performed during the systems analyses. Pre-initiators are quantified using the Techniques for Human Error Rate Prediction (THERP) methodology in the EPRI HRA Calculator. Detailed information including applicable procedures, steps, and test or maintenance periodicity are entered into the HRA Calculator for each pre-initiator. Quantification is then performed by selecting the appropriate item from the applicable THERP table.

Table 10-31 provides a summary of all of the calculated HEPs and associated error factors for each of the pre-initiators. Several of the Event IDs were developed for multiple basic events (BEs). This was done for events that impact similar equipment and have a potential error from a similar action. The consequence is the same, and the ability to recover from the error is the same. This grouping is appropriate since the HEPs would be the same if each were analysed separately.

10.6.2.2 Post-Initiators

The identification of post-initiator HFEs was performed in parallel to the PSA systems and accident sequence analyses. As event tree models that represent potential accident sequences were developed, the analyst identified operator actions that are required to be taken to mitigate an accident in accordance with the applicable procedures. Similarly, as fault tree models were developed, the system analysts identified human actions that are required to place equipment in a state necessary to support the applicable success criteria.

The identification of post-initiator HFEs was performed as follows:

- A review of the relevant procedures, including the emergency operating procedures (EOPs), abnormal operating procedures (AOPs), annunciator response procedures, system procedures, and other procedures was performed. The procedures were reviewed in the context of the IE and its associated accident sequences and mitigating systems that were modelled in the PSA.

- During the development of the system fault trees, a review of each system was performed. This included a review of the system function, human interfaces with the system, piping and instrumentation diagrams, dependencies on other systems, etc. This information was used for the identification of HFEs.

Interviews were conducted with procedure writers and plant experts to apply their knowledge and experience to gain insights into the identification of HFEs, confirm that the proposed actions to be included in the PSA are aligned with the operator training and procedures such that the action can be credited, confirm whether the failure to complete the human actions could lead to core damage, and identify potential additional actions that could be credited in the PSA.

Post-initiator HFEs are primarily quantified using the Cause-Based Decision Tree Method (CBDTM)/THERP methodology in the EPRI HRA Calculator, which considers both cognitive and execution errors.

Analysis of cognitive errors takes into account the following factors that could contribute to failure to recognize that an initiator has occurred or incorrect diagnosis:

- Availability of information to the crew
- Effectiveness in getting the attention of the crew
- Possibility of misreading or miscommunication of information
- Clarity of the information provided to the crew
- Likelihood of skipping a step
- Possibility of misinterpreting a step in the procedure
- Misleading logic in the instruction or procedure
- Possibility that the procedure will be deliberately violated

Analysis of execution errors takes into account the following factors:

- Manipulation tasks to implement an action, such as selecting the wrong control on a panel or turning a multi-position switch in the wrong direction or leaving it in the wrong setting
- Availability of confirmatory steps to ensure that the action was successfully performed
- Likelihood of skipping an execution step

Time windows for the operator actions were developed as part of the Success Criteria Analysis. The time windows associated with the HEPs are presented in Table 10-32. Table 10-33 provides a summary of all of the calculated HEPs and associated error factors for each of the post-initiators.

10.6.3 Operator Action Dependency

Dependency analysis is performed on PSA models to address dependencies between multiple HFEs. Dependencies occur between different HFEs that are present in the same cutset. No level of dependency is assigned between pre-initiator actions. All test and maintenance actives identified as possible pre-initiator actions are expected to be performed by different crews at different times. There is also no level of dependence assigned between pre--initiators

and post-initiators actions. These actions are assumed to be performed at different times and by different crews.

The level of dependency is assigned between actions based on a review of if the actions are performed by the same crew, contain common cognitive, occur during the same time, performed within the same location, and the associated stress level. If the actions do not occur within the same time window the level of dependency may vary based on the difference in time. A decision tree is used as a tool to determine the level of dependency to assign. The independent probability for the second HFE in the pair is replaced with a probability based on the level of dependency. These probabilities are 1.0, 0.5, 0.15 and 0.05 for complete, high, medium and low levels of dependency, respectively. The level of dependency is applied using the EPRI HRA Calculator, and is applied during quantification using a recovery rule file.

The dependency analysis was performed on the CDF and large early release frequency (LERF) results of the model in Section 10.20 using the EPRI HRA Calculator tool to generate the combinations of HEPs to be assessed and determine the level of dependency.

10.7 Data Analysis

10.7.1 Method Discussion

The objective of the data analysis is to provide the parameter estimates used in basic event creation which accurately represent the failure mode or unavailability of the component or train. The data analysis ensures that parameters accurately represent the configuration and operation of the plant, that component or system unavailability is accounted for, and that uncertainties in the data are understood and appropriately accounted for. The data analysis is primarily based on the information provided in NUREG/CR-6928 (Reference 10.15).

10.7.2 Identification of Component Types, Failure Modes, and Boundaries

Basic events represent the potential failure modes of components that result in a component failing to perform its intended function. Such basic events include, but are not limited to, a component failing to start, a component failing to run, a component failing when demanded, or a component being out of service due to test or maintenance. The components included in the PSA model are identified during the system analyses. Basic events are then developed to represent component failures and equipment unavailability that contribute to the failure of the system to meet specific success criteria.

In addition to identifying the component types and failure modes represented in the PSA, it is necessary to define component boundaries by specifying what “pieces” or “sub-components” are considered to be represented by the component failure data. These definitions are necessary to assure consistency between the basic events in the system models and the data analysis so that the boundaries of the components are defined identically. For example, all pieces of a motor-operated valve are typically considered to be part of a single “component” when collecting reliability data even though the valve consists of various piece parts (e.g., electric motor, gearbox, limit switches, stem, disc, valve body, etc.) that may be separately identified in the plant maintenance records. PSAs typically do not model failures of every switch, relay, or contact in a control circuit of a component because that type of detail is difficult to obtain from the plant data. Instead, failures of these “pieces” are typically included with actual failures of the components to establish a failure rate.

10.7.3 Component Grouping

The generic component failure data in NUREG/CR-6928 is primarily tabulated by component type (e.g., motor-operated pumps, circuit breakers, etc.). Component grouping is further refined according to mission type (standby or normally operating) and service condition (clean water or raw water) when supported by data. Separate groups were created for chillers, compressors, diesel generators, and fans to differentiate between standby and normally operating components. All components were grouped by system to allow plant-specific data changes in the future. In some cases, representative data must be assigned to component groups that are included in the AP1000 plant PSA model, but have no specific failure data or no specific unavailability test and maintenance data from generic sources.

10.7.4 Generic Component Failure Parameters

This section identifies the type codes used in the AP1000 plant PSA and the applicable generic component failure parameters. Each combination of system, component group, and failure mode was assigned an eleven-character type code. The component failure basic event naming convention uses the first eleven characters of the basic event for the type code. The failure parameters and source information for each type code is stored in the "TC" table of the CAFTA database. As basic events are developed during fault tree construction, CAFTA pulls the applicable information into the "BE" table of the database from the "TC" table when the first eleven characters match a type code. For example, the fault tree model for the PCS includes basic event "PCS-AOV-FTO-V001A," which represents failure of the PCCWST isolation valve PCS-PL-V001A failing to open when demanded. "PCS-AOV-FTO" is the eleven character type code for this component/failure mode combination, and CAFTA uses the failure parameter and source information in the type code table to populate the "BE" table. Type codes with generic failure parameters derived from NUREG/CR-6928 Table 5-1, are listed in Table 10-34 with their description, failure rate, units (Demand or Hour), NUREG/CR-6928 failure mode code, α value, β value, and variance.

Other sources of component failure data were used for type codes not covered in NUREG/CR-6928. These type codes are listed in Table 10-35 along with the associated failure parameter information and sources.

10.7.5 Component and Equipment Unavailability

Test and maintenance activities that remove components and equipment from service and alter the normal configuration of mechanical systems can be significant contributors to the overall unavailability of those systems. AP1000 plant specific planned or unplanned maintenance data is not available. The data analysis used generic unavailability from NUREG/CR-6928. Table 10-36 shows the variables used for unavailability as well as the description, the rate, the event code, the α variable, the β variable, and the variance from NUREG/CR-6928.

Other sources of component unavailability data were used for unavailability not covered in NUREG/CR-6928. These unavailabilities are listed in Table 10-37 along with the associated parameter information and sources.

10.7.6 C&I Data

Reliability analyses were performed for each C&I system as part of the design process to ensure satisfaction of plant availability expectations and PSA safety goals. The data developed for, and used in, the reliability analyses was also used in the PSA.

The reliability analysis for the DAS is documented in Reference 10.38. The reliability analysis includes the DAS component failure rates as well as the values used for the length of surveillance test intervals, probability of detection, and mean time to repair. The values used in the PRA are consistent with the values used in the reliability analysis. The DAS type codes and failure parameters are listed in Table 10-38.

Failure rates for PMS components are provided in Reference 10.39. The reliability analysis for the PMS is documented in Reference 10.40. The reliability analysis also includes the values used for the length of surveillance test intervals, probability of detection, and mean time to repair. The PMS type codes and failure parameters are listed in Table 10-39 (including the failure parameters for spurious PMS component failures).

Spurious actuation of the PMS is modelled in the updated PSA and, therefore, data analyses for these failure modes were considered. The design of the PMS includes an ADS blocking device in each division to prevent spurious actuation of the automatic depression system and IRWST injection due to software CCF. The block can fail in one of two ways. The first failure mode is one where the block fails to be removed and prevent a necessary actuation. The failure rate for this mode is estimated to be approximately [ ] of the total rate and is documented in Reference 10.42. The failure rate for spurious actuation due to a CIM fault was determined based on Reference 10.43 which indicates that approximately [ ] of CIM failures would lead to such an event.

The reliability analysis for the PLS is documented in Reference 10.41. The analysis also includes the component failure rates as well as the values used for the length of surveillance test intervals, probability of detection, and mean time to repair. The values used in the PSA are consistent with the values used in the reliability analysis. The PLS type codes and failure parameters are listed in Table 10-40.

10.8 Common Cause Analysis

10.8.1 Method Discussion

Components of similar manufacture and functions are subject to CCF. Common cause failure can result in failure of a system when identical, non-diverse, and active components are used to provide redundancy. Failure of two or more components in a common cause group can occur if they are of the same design, perform the same function, share the same installation and maintenance procedures, or are located in the same location or environment. In most systems modelled in the PSA, some components meet these criteria for susceptibility to CCF. The CCF groups for each system are identified during system analysis using the methodology described in NUREG/CR-5485 (Reference 10.45). If the component is subject to multiple failure modes, a CCF group is created for each failure mode.

For the AP1000 plant PSA, CCF modelling and establishment of CCF groups was performed in accordance with the guidance in NUREG/CR-5485 (Reference 10.45) and quantified using the alpha factor model. The alpha factors were derived from WCAP-16672-P (Reference 10.46). An exception to this is the application of the beta factor model for the C&I systems and the VLS due to large CCF group size. CCF groups are established for each system, component, and failure mode combination listed in Table 10-41 and Table 10-42 that is included in the AP1000 plant fault tree models.

Due to the unique systems in the AP1000 plant, and the lack of plant-specific experience, generic common cause failure groups are defined in Table 10-42. These common cause

failure groups are included in every system model where CCF is appropriate. The data for these groups is based on the alpha factors from Reference 10.46.

The CCF calculations depend on alpha factors representative of data from observed CCF events. Table 10-43 reports the CCF alpha and beta factors used in the AP1000 plant PSA, as well as their description, value, and source. Some CCF group sizes are larger than the data in the table records. When a group size was larger than the referenced data, the largest group size was used.

10.8.2 Unique Common Cause

10.8.2.1 Common Cause Variables for C&I

The PMS, PLS, and DAS include relatively large numbers of similar components that should be included together in CCF groups although DAS is simpler than the other two systems. In some cases there are dozens of the same component type used in each system. Application of the alpha factor method to such large group sizes is not practical and would result in a substantial increase in fault tree size and complexity that is not necessary to reflect the impact of CCF on system failure.

The C&I beta factor values were originally developed based on a method presented in AnnexD of the international standard IEC 61508-6 (Reference 10.47) as documented in Reference 10.48. Reference 10.50 includes PLS hardware common cause variables for the ovation data network. The data used assumed 12 fan out clusters.

C&I beta factors are summarized in Table 10-44.

In addition to the C&I beta factors used for hardware common cause, the PMS and PLS systems include a software common cause event. A desirable characteristic of the PSA would be to model software failures in a way that is consistent with the basis of how they occur and also within the context that the software is used. However, due to the lack of consensus on software reliability methods, detailed modelling of software failures was not performed for this analysis. In order to account for the potential impact of software errors on the reliability of these systems, a basic event representing failure due to common cause is included in the model for each system. No common mode failure of software between PMS and PLS is modelled because the processors and software in these two systems are from different manufacturers using different designs. Reference 10.49 includes an evaluation of software failures that was used in the PSA. The calculated failure rate is a function of several variables relative to software development. The assumptions for common cause failure of software and common cause failure of software leading to a spurious actuation are documented as areas of model uncertainty in the PSA.

Unique C&I common cause variables are summarized in Table 10-45.

10.8.2.2 Common Cause Variables for Loss of Long Term Core Cooling

PSAs should address the need for containment sump recirculation for a wide range of IEs, including non-LOCA events. Theoretically, any accident sequence that involves containment sump recirculation could have a failure path that involves a loss of long term core cooling due to inadequate gravity driven flow (PXS) or Net Positive Suction Head (NPSH) (RNS) as a result of high sump screen head losses or downstream effects. Considerations for loss of long term cooling were incorporated into the AP1000 plant during the design process and led to the conclusion that this design is less susceptible to debris-induced failure of LTCC. An

expert panel was conducted to assess the estimated probabilities used in the PSA (Reference10.51). The factors are used as common cause basic events in the PSA model. The common cause variables are summarized in Table 10-46.

10.9 Fault Tree and Core Damage Quantification Process

10.9.1 Model Quantification

Quantification of the PSA model was performed using fault tree linking at the following stages of the model building process:

- System level – to generate results for each system top event or support system model
- Accident sequence level – to generate results for each accident sequence
- Total CDF level – to generate overall results for core damage frequency

A brief description of the sequence of steps used to build the integrated model follows:

1. Accident sequence logic was generated from the event trees to create an equivalent fault tree logic model consisting of top events or system logic. Successes are accounted for in each sequence by including the applicable successful tops under an ‘A and not B’ gate.

2. Mitigating system fault tree models were merged into the model. The accident sequence event names match the names of the mitigating system models. In this manner, a system was merged into its proper location in the event sequence.

3. Support system models were merged into the model as required by the mitigating systems. The mitigating system models contain transfer gates whose names match the names of top gates in the support system. In this manner, a support system was merged into its proper location in the model.

10.9.2 Mutually Exclusive

Often two events may appear in a cutset that could not occur simultaneously. For example, maintenance events on separate trains of the same system are typically not allowed by plant technical specifications. Mutually exclusive (MUX) combinations were identified in the Systems Analyses as well as the Level 2 Analysis.

To address mutually exclusive events, combinations were identified and the non-applicable cutsets were removed from the model by means of a mutually exclusive fault tree which includes a branch for standard plant systems and a branch for site-specific systems. The MUX top event was developed using the combinations identified in the aforementioned analyses and then merged into the linked fault tree model with an ‘A and not B’ gate at a sequence organizational gate level.

10.9.3 Flags

Flags are used in the model to define system alignments/configurations, probabilities associated with IEs, and logic markers. The alignment/configuration flags are used to identify the running and standby trains at the time of the IE or to include/eliminate weather related failures such as outside temperature. Alignment/configuration flags can be set for the operating configuration once the plant is operational. For CDF and Level 2 release category

quantification, flag values are based on the fraction of time the component is expected to be running or in standby (or weather related state) during a year of operation.

Flags with the prefix "FL-L2" are used in the Level 2 model.

10.9.4 Event Tree Transfers

In some cases, an accident scenario path may have a transfer to a different event tree as a consequence of the accident progression (e.g., transient with a stuck open pressuriser safety valve transfers to a LOCA scenario). The application of transfers between event trees also reduces the size and complexity of individual event trees. The Accident Sequence Analysis (Section 10.3) identifies where transfers are in the event tree models. When transfers are used between event trees, all sequence logic is maintained. Logic flags are used to identify when a transfer is part of a sequence.

10.9.5 Treatment of Dependencies

Dependencies are addressed using different methods in the AP1000 plant PSA model. Several IE dependencies are addressed during the accident sequence development and documented in the Accident Sequence Analysis (Section 10.3). Initiating event dependencies have also been addressed in the corresponding system models. For support systems that have an SSIE tree, initiator dependencies are addressed using logic in the support system models.

SSIE dependencies are also addressed if the IE could change the possible failure modes for that system. For example, during normal operation one CCS pump is normally running with the other in standby, however, during a LOOP event the running pump would stop and have to restart or the standby pump would have to start. Therefore, the logic under the normal CCS top does not account for the requirement for both pumps to start. To account for this, these system failures that are unique to a LOOP event are modelled under an 'AND' gate with the LOOP initiator.

Support system dependencies are addressed within the system models. Section 10.5.17 provides a summary of the support system dependencies for the AP1000 plant PSA. In addition to IE and system dependencies, the dependency between HFEs is also addressed as summarized in Section 10.6.

10.9.6 Truncation Limitation

A sufficiently low truncation value was determined for the plant-level CDF calculation in order to ensure that significant cutsets and sequences were included in the final results. This was accomplished by initially quantifying the model with a truncation value of 1E-12 and iteratively reducing the truncation value by an order of magnitude until the change in CDF was less than 5 percent. Convergence was demonstrated with a truncation value of 1E-14.

10.9.7 Recoveries

The AP1000 plant passive system designs have very limited dependency on support systems. There is limited benefit from LOOP recovery and support system recoveries. Based on the low contribution to CDF from LOOP IEs and the limited benefit of restoring offsite power, a LOOP recovery factor was not addressed for this model.

10.10 Level 2 Analysis

The Level 2 analysis begins with core damage (CD) sequences from the Level 1 model development. The Level 1 core damage sequences are binned into PDSs that characterize the plant conditions that may impact the severe accident progression from the initiator conditions (high RCS pressure, low RCS pressure, or containment bypass) magnitude of hydrogen generation and release locations, and IRWST water availability.

10.10.1 Plant Damage States for Core Damage Sequences

Categorizing core damage accident scenarios provides a systematic method for interfacing the Level 1 PRA core damage analysis results with the Level 2 PRA severe accident containment integrity analyses. This modelling method provides a direct transfer of all CD sequences that result from Level 1 quantification into the Level 2 model.

A naming convention with a maximum of three-characters has been developed that defines the PDS characteristics for the AP1000 plant. The first character(s) in the naming convention defines the degree of RCS depressurization available from the IE. The second set of characters provided in the PDS name is the availability of the ADS depressurization. The availability of successful ADS is important because it gives information regarding two conditions: (1) how much RCS depressurization has occurred because of ADS actuation and (2) where hydrogen gas will be released from the RCS and accumulate in containment. The final PDS naming criteria is for PXS water availability and distribution in the containment, which is primarily influenced by PXS failures. Table 10-47 summarizes the accident sequence characteristics, initiators, placement of hydrogen generation, and water availability.

10.10.2 Level 2 Recovery and Containment Isolation Event Trees

Through automatic actuations or recovery operator actions in FR-C.1, the PXS and RCS (i.e., ADS) systems can be recovered post CD to support the RCS pressure boundary integrity, in-vessel retention (IVR) or support hydrogen mitigation. These recoveries are treated in Level 2 recovery event trees. The inputs to these trees are the PDSs described in Section 10.10.1, and the recoveries are applied based on the associated system failures in Level 1 (Table 10-48 and Table 10-49).

10.10.3 Magnitude of Release

10.10.3.1 Large Release Definition

This analysis considers containment isolation line sizes greater than 5.08 cm (2 inches) in nominal diameter are large releases from the containment. Additionally, this analysis considers large pre-existing containment leaks (Reference 10.52). Failure of the containment pressure boundary due to severe accident phenomena is classified as a large release.

This analysis also considers unisolated SGTR and ISLOCA core damage events as large releases from the containment. These sequences are treated in the bypass Containment Event Tree (CET).

10.10.3.2 Small Release Definition

This analysis considers that containment isolation line sizes less than or equal to 5.08 cm (2 inches) in nominal diameter are small releases from the containment. Additionally, this analysis considers small pre-existing containment leaks. This analysis also considers SGTR

with success of overfill protection as small releases from the containment. The overfill protection isolates CVS and SFW to both SGs. Additionally; the MFW line to the ruptured SG is isolated on a Safeguards Signal. Because this protection measure isolates flow to and from the ruptured SG but does not automatically close the MSIVs, these releases are considered small.

10.10.3.3 Containment Leakage

Severe accident scenarios that are mitigated such that the containment pressure boundary is intact and has not been pressurized beyond American Society of Mechanical Engineers (ASME) service level C pressure during the severe accident will leak at or less than the design leak rate.

10.10.4 Recovery and Containment Isolation Event Trees

The Level 2 recovery and containment isolation event tree models are described.

10.10.4.1 Is the Containment Isolation Successful?

This top examines the sequences that bypass the containment because of a containment isolation failure or a pre-existing containment crack or tear. It determines the status of containment isolation prior to CD. This top is valid for both the high pressure and low pressure CETs.

Containment isolation is required to prevent fission product releases to the environment after CD. The containment isolation failure provides a direct release pathway from the containment atmosphere to the environment.

A negative response to this question implies either a large or small containment isolation failure has occurred prior to the time of core damage and results in an early release.

10.10.4.2 Are ADS Stages 2-3 Depressurization Available?

This top examines the availability of ADS Stages 2-3 to provide RCS depressurization and a flow path for hydrogen release from the RCS into the IRWST.

The status of ADS Stages 2-3 is determined in one of two ways, either by the Level 1 actuation or by the post CD actuation. Based on the size of the ADS Stage 1 valve and the MLOCA break definition, one out of two ADS Stage 1 valves would be sufficient to reduce the RCS pressure below the main steam safety valve (MSSV) setpoints and thereby mitigate I-SGTR (Assumption 3). However, based on downstream needs (success criteria for IVR), the success criteria for this top is defined by success in the Level 1 or as a recovery of two out of four ADS Stages 2-3 valves.

10.10.4.3 Is ADS Stage 4 Depressurization Available?

This top examines the availability of ADS Stage 4 to provide a continuous RCS depressurization through discharge from the hot legs and into the containment atmosphere facilitating passive IRWST gravity injection, containment sump recirculation, and IVR. ADS Stage 4 also provides an engineered flow path for hydrogen release from the RCS into the containment loop compartments.

The status of ADS Stage 4 is determined in one of two ways, either by the Level 1 actuation or by the post CD actuation. The success criteria for this top are defined by success in the Level 1 or as a recovery of one out of four ADS Stage 4 valves.

10.10.4.4 Is the IRWST Water Injected into the RCS?

This top examines the availability and timing of IRWST water injection into the RCS.

IRWST may be injected before or after core damage. When IRWST gravity injection is successful and ADS Stage 4 is successful, the reactor cavity is flooded with water and the Reactor Vessel (RV) is submerged by the accident progression. Here, core damage is typically a result of the failure of passive recirculation. If IRWST gravity injection fails or ADS Stage 4 fails, the reactor cavity will not be flooded sufficiently to support IVR without a successful FR-C.1 operator action to flood the reactor cavity manually.

Success or failure at this node is determined by the Level 1 actuation or the post CD recovery.

10.10.4.5 Is Recirculation Successful?

This top examines the availability and timing of recirculation maintaining long term core cooling into the RCS from containment sump.

When PXS recirculation from the containment sump is successful, the reactor cavity contains water, and the sump and the IRWST are hydraulically coupled. Condensation water from the containment shell is returned to either the IRWST or the containment sump to maintain the water pool. However, if sump recirculation fails, only water from the IRWST can be injected into the RCS. As the IRWST drains, water head to maintain long term core cooling is lost and core damage occurs.

Success or failure at this node is determined by the Level 1 actuation or the post CD recovery.

10.10.5 Containment Event Tree Tops

The Level 2 containment event tree models are described.

10.10.5.1 No Induced Steam Generator Tube Rupture Occurs?

This top examines the conditions for either pressure induced or thermally induced SGTR. This top is valid for only the high pressure CETs.

Pressure induced SGTR occurs when there is a high differential pressure across the SG tubes, typically when the RCS pressure is at the pressuriser safety valve setpoint and the SG is fully depressurized. Thermally induced SGTR occurs when the RCS pressure is high and the post CD natural circulation conditions heat up the SG tubes.

This top includes the success of the SGS PORVs or MSSVs to operate as designed to relieve pressure when their setpoints are reached and to reclose, and includes the consideration that either a Pressure Induced SGTR (PI-SGTR) or a Thermally Induced SGTR (TI-SGTR) can occur if SGS fails.

TI-SGTR occurs when a creep rupture failure from a high SG tube temperature is predicted during high pressure severe accident conditions. The MAAP4 analysis concluded that a

depressurized secondary side is a prerequisite for TI-SGTR. If the secondary side is pressurized, molten debris relocation to the lower head is predicted to occur well before TI-SGTR and will challenge vessel integrity due to creep failure of the lower head. For SGS failure cases, TI-SGTR occurs before RV integrity challenge. Failure of this top leads to a large early release that bypasses the containment through the I-SGTR. HL creep failure is not predicted to occur prior to TI-SGTR or reactor vessel failure regardless of SGS success. Therefore, hot leg creep rupture failure is not credited for RCS depressurization and mitigation of high pressure phenomena. If the secondary is not depressurized, vessel failure is predicted.

PI-SGTR occurs when a large pressure differential exists across the SG tubes and a flaw exists in the SG tubes which becomes weak and fails under the stress of the pressure. Early in plant life, the SG tubes are considered to be in pristine condition (i.e., no tube flaws) so the probability that a PI-SGTR will occur is zero. TI-SGTR occurs when temperature challenges exist on the SG tubes. Because this plant does not have loop seals, full loop natural circulation is very effective at increasing the heat transfer from the core to the SG tubes and increases the probability of a thermal creep failure. The probability that a TI-SGTR will occur is one for high pressure CD scenarios when SGS fails.

10.10.5.2 Has the PXS Gutter Successfully Aligned?

This top event examines if the PXS gutter valves are successfully aligned. This top is valid for both the high pressure and low pressure CETs.

During injection, the steam in containment condenses on the containment shell and returns to the IRWST through the PXS gutters, slowing the loss of injection. This recirculation of condensate water to the IRWST has a significant effect on IVR by maintaining a flow of debris cooling water to the RV. However, if the gutter valves fail to align to the IRWST, the condensate will not be returned to the IRWST and instead will be directed to the containment sump. In the event of recirculation failure and gutter failure, the IRWST water inventory will be depleted more quickly and the RV will dry out after injection is completed.

This top event is only considered if recirculation has failed after the recovery event tree results (HP2 and LP2). The gutter valve alignment does not need to be considered for recirculation success paths because the IRWST and the containment sump are hydraulically coupled through the recirculation lines so it does not matter if the condensate is returned to the IRWST or the containment sump.

10.10.5.3 Is In-Vessel Retention Successful?

This top examines if the core debris is maintained within the RV and is valid for both the high pressure and low pressure CETs.

IVR is detailed in Section 10.12.2.1.

When molten core debris is relocated to the lower plenum of the RV, the water in the cavity cools the external surface of the RV by nucleate boiling to prevent vessel failure. The two conditions which ensure IVR are RCS depressurization by a minimum of two out of four ADS Stages 2-3 valves or one out of four ADS Stage 4 valves and RV cavity flooding to at least the 99.4 m (98’) elevation prior to the challenge to the vessel integrity. When these conditions are successful, the AP1000 plant RV retains the core debris and prevents the release of molten debris into the containment.

10.10.5.4 No Ex-Vessel High Energy Phenomena Occurs?

This top examines ex-vessel phenomena that can immediately fail the containment at vessel failure. This top is valid for both the high pressure and low pressure CETs.

Ex-Vessel Phenomena is detailed in Section 10.12.2.2.2.

At vessel failure, containment integrity may be challenged immediately by high energy phenomena that occur as a result of debris relocation to the reactor cavity. Ex-vessel steam explosion and High Pressure Melt Ejection (HPME)/Direct Containment Heating (DCH) are evaluated as potential containment failure modes. Steam explosions are postulated to occur in the reactor cavity when the RV fails and debris is ejected from it into water in the reactor cavity. A steam explosion may occur as a result of molten metal and/or oxide core debris mixing and thermally interacting with water. Steam is created at a very high rate, potentially producing a sonic pressure front and dynamic loading on local structures.

A positive response to this top implies that steam explosion does not occur or does not fail the containment integrity. A negative response implies that there is an ex-vessel steam explosion which fails containment.

10.10.5.5 Does the Ex-Vessel Core Debris Spread and Quench?

This top examines the characterizations of the Molten Core Concrete Interaction (MCCI) after RV failure. This top is valid for both the high pressure and low pressure CETs.

Core debris coolability is detailed in Section 10.12.2.5.

If IVR is not successful and the RV fails, the molten core debris will spill from the RV into the reactor cavity and onto the concrete basemat below the RV. The degree of the debris spreading on the cavity floor and potentially into the Reactor Coolant Drain Tank (RCDT) room will depend on the RV failure mode. The global lower head failure mode is expected to spread the debris throughout the cavity and RCDT room. The flow of debris from a localized failure of the lower head would have little momentum, and the spreading is expected to be limited to the reactor cavity octagon.

For either spreading pattern, the molten debris will transfer heat into the concrete floor of the cavity. Over time, the containment floor may be eroded from this molten core and concrete interaction; this phenomenon is referred to as Base Mat Melt Through (BMMT). The probability of basemat failure due to BMMT is investigated for two concrete types, limestone and basaltic. The output of the MCCI analysis is the probability of debris quenching prior to basemat failure and the timing of quench or failure. The model structure applied in the CET was compiled using a decomposition event tree which was converted to a fault tree and included in the Level 2 fault tree model.

10.10.5.6 Is the PCS Water Cooling the Containment Shell?

This top examines the availability of PCS cooling on the containment shell. This top is valid for both the high pressure and low pressure CETs.

The containment atmosphere is cooled by PCS, which condenses the steam in the containment atmosphere onto the containment shell as heat is transferred through the shell to the ambient environment. PCS water is applied to the shell external surface to enhance the cooling by evaporation to the natural circulation air flow through the PCS cooling annulus. Except for pressurization by high energy severe accident phenomena such as a hydrogen

burn, the water-cooled PCS will generally maintain the containment pressure below the design pressure. Water that is condensed on the PCS inner surface is returned to the IRWST through the PXS gutter or to the containment sump if the gutter system is not aligned.

When PCS water cooling is not available, the containment atmosphere will become steam inerted and hydrogen combustion will not be possible unless cooling is restored and steam is condensed from the atmosphere.

This top represents the availability of PCS water which provides containment cooling.

10.10.5.7 Is PRHR Providing Decay Heat Removal?

This top examines the availability of PRHR as the decay heat removal method. This top is valid for only the high pressure CETs.

PRHR provides effective decay heat removal during high pressure scenarios. When PRHR removes decay heat, the IRWST becomes saturated. Steaming in the IRWST will drive the oxygen out of the gas space and along with other conditions (described in Section 10.10.5.11); prevent deflagration to detonation transition (DDT) from occurring in the IRWST.

A positive response to this top shows that PRHR, which prevents hydrogen complications, has been met. However, a negative response to this top shows that the PRHR system is not being used and DDT must be evaluated later in the CET.

10.10.5.8 Can ADS Stage 4 Actuation Mitigate Hydrogen Complications?

This top examines the availability of ADS Stage 4 depressurization to mitigate hydrogen complications in the containment atmosphere by mixing the hydrogen uniformly in the major compartments of the containment. This top is valid for both the high pressure and low pressure CETs.

By design, the ADS Stage 4 valves play an important part in hydrogen mitigation within the containment. ADS Stage 4 provides an engineered flow path for hydrogen release from the RCS into the containment loop compartments where it is mixed in the containment, thereby reducing the complication of diffusion flame against the containment shell and preventing detonable local limits of hydrogen accumulation in small dead ended compartments, such as the IRWST. Mainly, there are two types of hydrogen generation concerns within the AP1000 plant containment: DDT and diffusion flame.

Hydrogen combustion and detonation are detailed in Section 10.12.2.3. This section also includes the conditions and failures leading to potential for DDT.

A positive response to this top implies that the ADS Stage 4 success criteria for actuation which prevents hydrogen complications has been met. However, a negative response to this top implies that the ADS Stage 4 success criteria have not been met and DDT or diffusion flame must be evaluated later in the CET.

10.10.5.9 Are the Hydrogen Igniters Providing Hydrogen Mitigation?

This top represents the availability of the hydrogen igniters (as part VLS) which mitigate hydrogen generation. This top is valid for both the high pressure and low pressure CETs.

A positive response implies that hydrogen igniter system mitigation is available; a negative response implies that the hydrogen igniter system mitigation has failed.

10.10.5.10 No Diffusion Flame Occurs which Fails the Containment?

This top examines if a diffusion flame can occur from ADS Stages 1-3 actuation and hydrogen generation in the IRWST. This top is valid for both the high pressure and low pressure CETs.

Hydrogen combustion and detonation are detailed in Section 10.12.2.3.

If the hydrogen igniters are successfully actuated, a hydrogen plume may be postulated to ignite as a diffusion flame and locally heat the containment pressure boundary if a hydrogen release pathway near the containment pressure boundary is open. A diffusion flame can occur when an inert plume of hydrogen and steam enters an oxygen rich atmosphere. The plume is ignited and burns as a standing flame at the location where the plume enters the oxygen rich compartment. When hydrogen burns at a vent near the containment pressure boundary, a thermal loading on nearby structures by radiation heat transfer and convection is produced.

A positive response to this top implies that a diffusion flame does not occur and the IRWST vents meet their success criteria. However, a negative response to this top implies that a diffusion flame occurs and fails the containment.

10.10.5.11 Containment Does Not Fail during Hydrogen Combustion?

This top examines the survivability of containment given a hydrogen combustion event occurs. This top is valid for both the high pressure and low pressure CETs.

Containment failures due to hydrogen combustion are considered for flame acceleration and deflagration to DDT in the event of igniter failure. In-vessel releases that are not well-mixed in the containment and ex-vessel scenarios may result in flame acceleration and DDT.

Hydrogen combustion and detonation are detailed in Section 10.12.2.3. This section also includes the conditions and failures leading to potential for DDT.

10.10.5.12 Does the Operator Vent the Containment?

This top examines the availability of the operators to vent the containment to reduce the containment pressure. This top is valid for both the high pressure and low pressure CETs.

During severe accident progressions when PCS is unavailable to cool the containment atmosphere, the containment will begin to pressurize. To maintain containment integrity in these cases, the operator can vent the containment to reduce the containment pressure.

A positive response to this top implies that containment venting was successful and a controlled, vent release occurs. A negative response to this top implies that containment venting was not successful.

10.10.5.13 No Containment Failure from Over Pressurization Occurs?

If PCS is failed and the containment pressure cannot be vented, it is expected that the containment overpressure failure will occur in one of two timeframes. Containment failure within 24 hours is considered to be an intermediate containment failure (LIRF release category). If containment failure does not occur at 24 hours, then a late containment failure

will occur (LATE release category). This top is valid for both the high pressure and low pressure CETs.

10.10.5.14 No Base Mat Melt Through (BMMT) Failure in 24 Hours?

In the unlikely event of unquenched MCCI, there is a small probability of BMMT that occurs prior to 24 hours. This top is valid for both the high pressure and low pressure CETs.

A positive response to this question designates a late containment failure from BMMT. A negative response to this question designates an intermediate containment failure from BMMT.

10.10.6 Assumptions and Sources of Model Uncertainty

1. This model assumes that the time to reach an irreversible state for the post core damage operator action to recover water for PCS water cooling occurs when the containment atmosphere is steam inerted or at an elevated dry hydrogen concentration of 8 percent,, whichever occurs last.

2. This model considers two RV failure modes. These failure modes determine the spreading of the molten debris. The molten material will either remain in the reactor cavity or occupy the reactor cavity and the RCDT room. A 50 percent probability for each RV failure mode is assumed.

3. This model assumes that ADS Stage 1 actuation during the Level 1 and/or Level 2 accident progression does not impact the accident sequence; however, it is noted that one out of two ADS Stage 1 valves open would be sufficient to mitigate induced SGTR.

4. Hydrogen control by PARs is credited for well-mixed in-vessel hydrogen releases. Hydrogen control by the PARs is not credited for unmixed in-vessel releases and all ex-vessel releases. For ex-vessel scenarios, PARs are not credited for mitigating long-term non-condensable flammable gas generation associated with MCCI. The uncertainty in non-condensable gas generation during MCCI is too large to credit the effectiveness of the PARs for ex-vessel scenarios. Igniters are required to control flammable gas releases from MCCI.

5. This model assumes a 25 percent condensate bypassing the PXS gutters and the IRWST for all cases unless otherwise noted. The water that bypasses the gutters is directed to the containment sump. The bypass fraction is determined by engineering judgement of systems analysis as bounding conditions during plant operation.

6. This model assumes when the reactor vessel integrity is challenged by molten core debris and the RCS pressure is at or above the secondary side valves setpoint (i.e., at the pressuriser SV setpoint), an HPME occurs.

7. This model assumes that hydrogen igniter system success is defined as one successfully operating hydrogen igniter at each igniter location.

8. This model assumes that high pressure sequences without ADS depressurization and no induced SGTR (I-SGTR) phenomena (i.e., HPME sequences) cause RV failure and have successful spreading into the RCDT.

9. This model uses the secondary side valves top L2-SGS-SS-PA-PLA which considers eighty demands on each function of the MSSV. The SG PORVs are expected to open at

the lower pressure and modulate to control pressure. If the SG PORV sticks open, the automatic closure of the block valve is credited. If the SG PORV does not open, the MSSVs would open and have eighty cycles. The number of cycles is on the upper end of the estimates provided in NUREG-1570 (Reference 10.53). This estimate of MSSV demands is applicable to the AP1000 plant design. The SG design for the AP1000 plant and legacy plants are similar.

10. For CD events initiated by SGTR with successful ruptured SG isolation, ADS Stages 2-3 failures and ADS Stage 4 failures are conservatively binned as "large" containment bypasses.

11. The ISLOCA initiator %ISL-P04 progresses directly to CD and is also considered to be a large release. This ISLOCA pathway is limited to a 0.95 cm (3/8 inch) RCP heat exchanger tube.

12. The low pressure CET includes both LLOCA and MLOCA core damage events. Depressurization for these initiators is still required in the CET to support IVR, diffusion flame, and DDT.

13. The probabilities for reactor vessel failures and the corresponding containment failures are considered to be realistic estimates. The containment integrity may be challenged immediately by high energy phenomena that occur as a result of debris relocation to the reactor cavity.

14. Analysis has shown there is a potential for DDT within the IRWST if zero, one, or two ADS Stage 4 valves are open. The analysis also shows that there is a potential for DDT within the SG compartments if less than four ADS Stage 4 valves open. In cases where both DDT conditions could exist, the more conservative ADS Stage 4 success criteria are used.

15. This model assumes that low pressure sequences with no ADS depressurization is a LERF.

10.11 Uncertainty Analysis

The EPRI CAFTA-related code UNCERT was used to propagate the parametric uncertainty associated with basic event failure parameters. This was performed using the Level 1 at-power internal events PSA quantification results that include all cutsets above the 1E-14 truncation limit. The uncertainty analysis was performed using 1000 samples, the default random seed, and the Latin Hypercube sampling method. Table 10-65 provides the CDF and LRF results based on the uncertainty run.

10.12 Severe Accident Phenomena Treatment

10.12.1 Introduction

This section describes how the AP1000 NPP containment addresses challenges from severe accident phenomena, and how the challenges are evaluated in the PSA. In the PSA, the MAAP code (Reference 10.4) is used to evaluate severe accident scenarios. Severe accident phenomenological uncertainties are treated with Risk-Oriented Accident Analysis Methodology (ROAAM) (Reference 10.70) phenomenological evaluations, with AP1000 NPP specific decomposition event tree phenomenological evaluations, or with assumptions that certain low-frequency severe accident phenomena fail the containment. The objective of

these studies is to show, with a high degree of confidence, that the AP1000 NPP containment will accommodate the effects of severe accident phenomena that are expected to occur after the onset of core damage and afterward to establish a controlled, stable condition in which no further high energy challenges to containment integrity will occur. Such evaluations demonstrate the robustness of the containment design. The controlled, stable condition for the plant is defined as the plant condition, following core damage, in which containment conditions are controllable at or near desired values.

10.12.2 Treatment of Physical Processes

The following eight issues are identified in Reference 10.69 as being representative of the phenomenological issues pertaining to severe accident conditions:

1. Loss-of-coolant accident (LOCA)
2. Fuel-coolant interaction (steam explosion)
3. Hydrogen combustion and detonation
4. Melt attack on concrete structure or containment pressure boundary
5. High-pressure melt ejection
6. Core-concrete interaction (CCI)
7. Containment pressurization from decay heat
8. Elevated temperature (equipment survivability)

The challenge to the containment integrity from a LOCA blowdown is covered in the containment design basis and is not specifically addressed here. Treatment of physical processes affecting the remaining challenges is discussed in this chapter.

10.12.2.1 In-Vessel Retention of Molten Core Debris

In-vessel retention (IVR) of core debris by external reactor vessel cooling is a severe accident mitigation attribute of the AP1000 NPP design (Reference 10.75). With the reactor vessel intact and debris retained in the lower head, phenomena such as molten core-concrete interaction and ex-vessel steam explosion, which occur as a result of core debris relocation to the reactor cavity, are prevented.

The AP1000 NPP reactor vessel insulation and containment geometry promote in-vessel retention. Engineered design features of the AP1000 NPP containment flood the containment reactor cavity region during accidents and, thereby, submerge the reactor vessel in water.

Reference 10.75 presents an AP1000 NPP-specific evaluation to determine the likelihood that sufficient heat can be removed from the outside surface of the submerged reactor pressure vessel lower head to prevent reactor vessel failure and relocation of debris to containment. The methodology used to quantify the margin to vessel failure in DOE/ID-10460 (Reference 10.70) for the AP600 was adapted to the AP1000 NPP.

Design features of the AP1000 NPP promote the long term retention of core debris within the reactor vessel lower head as outlined in Reference 10.75. The two conditions that promote IVR are RCS depressurization and reactor vessel cavity flooding prior to the challenge to the vessel integrity.

Accounting for the uncertainties in thermal-hydraulic parameters, the heat fluxes to the vessel wall from the debris bed are calculated. Failure is defined as departure from nucleate boiling on the external surface of the reactor vessel. The results of the analyses show margin to failure for the reactor vessel if it is depressurized and externally cooled by water.

10.12.2.2 Fuel-Coolant Interaction (Steam Explosions)

A steam explosion may occur as a result of molten metal or oxide core debris mixing with water and interacting thermally. Steam explosions may be postulated to occur inside the reactor vessel when debris relocates from the core region into the lower plenum and in the reactor cavity if the vessel fails and debris is ejected from it into water in the reactor cavity.

10.12.2.2.1 In-Vessel Fuel-Coolant Interaction

In-vessel steam explosions were studied extensively in the AP600 analyses. A ROAAM analysis of the AP600 reactor vessel lower head integrity under in-vessel steam explosion loading is presented in DOE/ID-10541 (Reference 10.71). Typically, in-vessel steam explosion analyses focus on the α-mode containment failure, which is induced by the reactor vessel upper head failure. The ROAAM steam explosion analysis focused on failure of the lower head, because that vessel failure mode could impair the in-vessel retention capability of the reactor vessel. The ROAAM analysis concludes that lower-head vessel failure from in-vessel steam explosion is physically unreasonable with very large margin to failure.

Based on the in-vessel core relocation scenario for the AP1000 NPP, the in-vessel steam explosion ROAAM analysis results presented for the AP600 can be extended to the AP1000 NPP. The mass flow rate, superheat, and composition of debris in the relocation from the upper core region to the lower head are expected to be essentially the same as the AP600. The geometry of the lower head of the AP1000 NPP is the same as the AP600. Therefore, it is reasonable to extend the results of the AP600 in-vessel steam explosion ROAAM analysis to the AP1000 NPP.

The results of the in-vessel steam explosion ROAAM can also be extended to containment failure induced by in-vessel steam explosions (α-mode containment failure). The likelihood for vessel failure and subsequent containment failure due to in-vessel steam explosion is so small as to be negligible. This conclusion is in agreement with the conclusions of US Nuclear Regulatory Commission (US NRC) NUREG-1116 by the US NRC-sponsored Steam Explosion Review Group (Reference 10.72).

Therefore, in the PSA containment event tree quantification, α-mode containment failure and in-vessel steam explosion-induced lower head failure are considered to be negligible.

10.12.2.2.2 Ex-Vessel Fuel-Coolant Interaction

The first level of defence for ex-vessel steam explosion is the in-vessel retention of the molten core debris. If molten debris does not relocate from the vessel to the containment, there are no conditions for ex-vessel steam explosion.

An analysis of the structural response of the reactor cavity was performed for the AP600 in GW-GL-022 (Reference 10.73, Appendix B). The analysis assumed that the IRWST water was not drained into the reactor cavity and IVR fails. As in the in-vessel steam explosion analysis, the results of this AP600 ex-vessel steam explosion analysis are extended to the AP1000 NPP. The vessel failure modes for AP600 and AP1000 NPP are the same. The initial debris mass, superheat, and composition are assumed to be the same as the AP600. The reactor cavity geometry and water depth prior to vessel failure are the same as AP600. Therefore, the results of the AP600 ex-vessel steam explosion analysis are considered to be appropriate for the AP1000 NPP.

The PSA containment event tree quantification considers the potential for ex-vessel steam explosions that challenge containment integrity for cases with successful cavity flooding (high RCS pressure) and with cavity flooding failure (low RCS pressure).

10.12.2.3 Hydrogen Combustion and Detonation

A substantial mass of hydrogen may be released to the containment due to the oxidation of zirconium cladding in the reactor vessel. If IVR is not successful and molten core debris is relocated from the reactor coolant system, additional hydrogen will be released to the containment during molten core concrete interaction. Hydrogen combustion inside the containment may be postulated to threaten the containment integrity. Hydrogen plumes may burn as diffusion flames and create challenging thermal loading to the containment pressure boundary and equipment. Hydrogen-air-steam mixtures may burn as deflagrations that pressurize the containment or accelerate to detonations that will create challenging impulse loads to the containment structures.

The AP1000 NPP containment includes design features to mitigate uncontrolled hydrogen combustion challenges to the containment integrity. The VLSis comprised of PARsand hydrogen igniters that consume hydrogen and prevent challenging hydrogen-air-steam mixtures in the containment atmosphere. The hydrogen igniters are arranged in two independently powered trains. Each train is capable of controlling the containment hydrogen according to single failure criteria. Hydrogen monitors display the containment hydrogen concentration in the control room to allow the operators to observe the containment conditions while performing severe accident management. Passive containment cooling helps to mix the containment atmosphere by natural circulation to dilute the hydrogen concentration and allow it to burn as it is released from the RCS.

The severe accident hydrogen analyses conservatively neglect hydrogen depletion by the PARs and credit the operation of the igniters for controlling hydrogen during core damage scenarios. Successful operation of the igniters ensures hydrogen will burn as it is released preventing the containment atmosphere from reaching globally flammable concentrations and detonable conditions.

The AP1000 NPP provides defence-in-depth to address over-temperature containment failure due to diffusion flames that may be postulated from the ignition of a hydrogen plume by the igniters. The first level of defence is the stage four automatic depressurization system (ADS Stage 4) lines from the RCS, which prevent significant hydrogen releases to the IRWST and Passive Core Cooling System (PXS) compartments. ADS Stage 4 vents from the RCS hot legs to the loop compartments, which are shielded from the containment shell and have a constant source of oxygen from the natural circulation in the containment. Hydrogen can be burned continuously as it is released in the loop compartments without threatening the containment integrity. If ADS Stage 4 fails, the AP1000 NPP has provided design considerations in IRWST vents to mitigate diffusion flames by preventing hydrogen plumes from burning near the containment walls. Vents from the passive injection system compartments and chemical volume and control system compartment are located sufficiently away from the containment shell and penetrations in order to mitigate the threat from hydrogen diffusion flames.

If igniter operation is successful, and multiple ADS Stage 4 squib valves fail to open, the PSA containment event tree quantification evaluates the success of the IRWST vents to properly perform to mitigate potential for diffusion flames burning near the containment pressure boundary. If the IRWST vents fail to perform their function properly, containment shell overtemperature failure is assumed to occur.

In the event of igniter failure, the likelihood of containment failure due to deflagration and detonation in the containment is evaluated. The AP1000 NPP containment structure is capable of withstanding the peak pressurization from the deflagration of hydrogen generated by 100 percent cladding oxidation without exceeding ASME service Level C pressure limits. Therefore, the probability of containment failure due to deflagration is considered to be negligible. Containment integrity challenges from uncontrolled hydrogen combustion are primarily due to detonation.

Containment failure from a directly-initiated detonation wave is not considered to be a credible event for the AP1000 NPP containment. There are no ignition sources of sufficient energy to directly initiate a detonation in the AP1000 NPP containment. DDT is considered to be the only likely mechanism to produce a detonation in the AP1000 NPP containment.

In the event of igniter failure, the likelihood of DDT in the AP1000 NPP containment is evaluated locally in confined compartments during in-vessel hydrogen generation and release to the containment. DDT is evaluated globally after vessel failure and molten core concrete interaction ex-vessel hydrogen releases. For DDT to occur, the combination of the gas mixture sensitivity to detonation and the geometric configuration potential for flame acceleration must be conducive to DDT. The potential for flame acceleration and DDT in the AP1000 NPP containment is evaluated using the State-of-the-Art (SOAR) methodology in NEA/CSNI/R (2000)7 (Reference 10.76) to characterize the conditions leading to the potential for DDT.

In addition to igniter failure, the following are conditions and failures leading to potential for DDT:

- Condition 1
  - Elevated hydrogen releases into the IRWST due to ADS-4 failures
  - The water in the IRWST is sub-cooled to quench steam due to failure of PRHR cooling of the RCS
  - ADS Stages 1-3 success and spargers submerged during hydrogen and steam release to quench steam
- Condition 2
  - Dry core conditions, no in-vessel core re-flooding
  - Concentrated hydrogen release into one compartment due to ADS-4 failures
- Condition 3
  - Ex-vessel core debris does not spread or is not quenched following reactor vessel failure

The PSA containment event tree quantification evaluates these conditions and assumes DDT occurs and the containment fails in the event the unfavourable conditions are met.

10.12.2.4 High-Pressure Core Damage and High Pressure Melt Ejection

The AP1000 NPP incorporates design features that prevent high-pressure core melt. These features include the PRHR system and the ADS. These design features provide passive primary system heat removal and RCS depressurization to prevent high pressure core damage conditions. The consequences from postulated HPME are mitigated by the containment layout which provides a tortuous pathway from the reactor cavity to the upper compartment, and no direct pathway for the impingement of debris on the containment shell. Preventing debris from being dispersed at high pressure to the upper containment mitigates direct containment heating (DCH) challenges to the containment integrity. Preventing molten debris from impinging on the containment shell mitigates debris-induced failures of the containment pressure boundary.

In high-pressure core damage scenarios, the potential exists for creep-rupture-induced failures of the RCS piping at the hot-leg nozzles, the surge line, the steam generator tubes and, in the event of molten debris relocation to the lower plenum, in the reactor vessel lower head. Hot-leg nozzle or surge line failure prior to the failures of other components results in the rapid depressurization of the RCS. Failure of the steam generator tubes results in a potential containment bypass and a large release of fission products to the environment. Failure of the lower head of the reactor vessel results in the potential for HPME.

The PSA containment event tree quantification considers the effects of primary and secondary system pressures and temperature, as well as the aging of the steam generator tubes in assessing the likelihood and timing of induced failures of the RCS hot leg, surge line, steam generator tubes, and reactor vessel lower head.

10.12.2.5 Core Debris Coolability

In accident sequences where the reactor pressure vessel failure is not prevented, core debris may be discharged into the reactor cavity. The AP1000 NPP cavity design provides area for the core debris to spread into the reactor coolant drain tank room. Condensate water from the PCS returns to the reactor cavity, thereby providing a long-term supply of water to cool the surface of the core debris.

At vessel failure, it is very likely that the cavity will be filled with water from the RCS, CMTs, and accumulators to at least the 94.82 m (83 ft) elevation. There are significant uncertainties associated with debris spreading in a water-filled cavity. Given the reliability of the ADS, the likely vessel failure modes produce a low-pressure melt ejection (LPME) to the containment and, therefore, the debris will drain by gravity from the reactor vessel to the cavity. Debris spreading is mainly a function of the uncertain vessel failure mode. Global lower-head failure releasing molten debris at a high rate would enhance spreading, while a localized failure mode would release molten debris with less momentum, which would most likely cause the debris to pile up under the reactor vessel and limit the spreading.

The PSA containment event tree quantification considers a bifurcation of the debris spreading scenarios and the likelihood of debris failing to quench and basemat melt-through in the event that debris does and does not spread effectively.

10.12.2.6 Containment Pressurization from Decay Heat

The AP1000 NPP containment is cooled via the PCS. Evaporative water cooling of the containment shell provides long-term containment cooling and limits the containment pressure to less than the design pressure for all severe accident events except hydrogen combustion (which is addressed separately). Passive containment cooling water is provided to the external surface of the containment shell at the top of the containment via a redundant, diverse system of valves and lines, including a line that can be connected to an outside water source, such as a fire truck.

In the unlikely event that water cannot be supplied to the top of the containment shell for an extended period of time, air-only cooling by air flowing through the PCS annulus provides significant cooling to the containment. However, under nominal-to-conservative environmental conditions, containment integrity by air-cooling alone cannot be assured. In this case, containment failure is predicted to occur more than 24 hours after accident initiation.

A significant amount of time is available for operator action to vent the containment under the severe accident management guidance (SAMG). Containment venting mitigates uncontrolled releases of fission products from a failed containment. The AP1000 NPP can be vented under the SAMG from a number of containment penetrations, primarily via the RNS piping to the spent fuel pool.

On the PSA containment event tree, the availability of PCS water and the operator action to successfully vent the containment is considered. The evaluation considers the effects of molten core concrete interaction and non-condensable gas generation on the timing of venting and the effect on the fission product release magnitude.

10.12.2.7 Elevated Temperatures (Equipment Survivability)

Reference 10.74 states that equipment identified as being useful to mitigate the consequences of severe accidents must be designed to provide reasonable assurance that it will continue to operate in a severe accident environment for the length of time needed to accomplish its function. Also, US Regulation Title 10 of the Code of Federal Regulations (CFR) Part 50.44 requires Class-1 equipment to continue performing its function after being exposed to a containment environment created as a consequence of generating a quantity of hydrogen equivalent to 100-percent cladding oxidation. As the AP1000 NPP design uses thermal igniters to burn hydrogen in a controlled manner, it is necessary to demonstrate that the Class-1 equipment can continue to perform its function in the high-temperature environment created by the hydrogen burning.

The functions of the equipment in containment for which credit is taken in the AP1000 NPP PSA were reviewed to determine if the equipment is required to operate in a severe accident environment and beyond design basis limits.

10.12.2.8 Summary

The potential for and the consequences of severe accident phenomena are evaluated. The preventive and mitigative features of the AP1000 NPP addressing the severe accident phenomena are discussed. This information is applied to the containment event trees and used in the quantification of the large release frequency.

10.12.3 Analysis Method

Analyses of severe accident phenomena have been performed primarily using the MAAP4 code as well as fundamental phenomenological calculations using spreadsheets and hand calculations.

10.12.4 Severe Accident Analyses

10.12.4.1 Operator Actions and Human Reliability Analysis

MAAP4 analyses are performed to define operator action time window for recovery actions and manual actuations that could be performed in the severe accident containment analysis. These actions include:

- Recovery of containment isolation
- Recovery of ADS stages 1, 2 and 3
- Recovery of ADS stage 4
- Recovery of IRWST passive injection
- Recovery of sump passive recirculation/PXS gutter valve alignment
- Operator action to flood the containment for IVR
- Operator action to actuate the hydrogen igniters
- Recovery of PCS water cooling
- Operator action to vent the containment

10.12.4.2 Long-Term Core Cooling

Success criteria for the required sump gravity head as a function of time after shutdown are established using detailed thermal-hydraulic calculation methods, and the MAAP4 code is used to establish the sequence timing and water level transients for a matrix of scenario to develop ADS and PXS success criteria for long term passive core cooling.

10.12.4.3 Induced Steam Generator Tube Rupture Analysis

MAAP4 analyses are performed for high pressure core damage scenarios to establish temperature transients for the hot leg, steam generator tubes, and reactor vessel lower head. The timing of potential for creep rupture failures is investigated for a matrix of cases varying the secondary side pressure and reactor cavity flooding to determine likely RCS failure locations based on scenario conditions.

10.12.4.4 In-Vessel Retention of Molten Core Debris

MAAP4 analyses are performed to establish scenario timing and initial conditions for detailed IVR calculations. The analyses consist of a matrix of cases varying IEs, time of core cycle, IRWST drain time, and modelling parameters.

The fundamental IVR phenomenological calculations are based on test data and are performed using spreadsheets. The spreadsheet calculations allow the inclusion of reactor vessel internals and investigation of debris bed chemistry uncertainties that are not available in the MAAP4 code modelling.

10.12.4.5 Passive Containment Cooling Water Depletion

A matrix of MAAP4 analyses are performed to establish containment pressurization rates following the loss of PCS water at the depletion of the PCS water storage tank, the depletion of the PCS ancillary water storage tank, and total PCS water delivery failure. The analyses include the effect of the ambient air temperature on the containment pressure. The analyses evaluate the times that the containment pressure reaches design pressure limit, ASME service level C pressure, and the probability of containment failure at the equilibrium pressure.

10.12.4.6 Hydrogen Flame Acceleration and Deflagration to Detonation Transition

A matrix of MAAP4 analyses is performed to establish conditional failure that may lead to the potential for flame acceleration and DDT. The analyses vary the IE and combinations of ADS and PXS failures that impact the timing and addition rate of water to the core and hydrogen release locations from the RCS to the containment. Hydrogen generation from MCCI is modelled, and the challenge from DDT is quantified.

10.12.5 Insights and Conclusions

The analyses of the severe accident phenomena for the AP1000 NPP PSA highlight the following insights and conclusions:

- Preventing reactor vessel failure reduces the challenges to the containment integrity during a severe accident. The design of the AP1000 NPP reactor vessel, vessel insulation, and reactor cavity, and the ability to flood the cavity after a severe accident promote in-vessel retention of molten core debris. The RCS must be depressurized and the IRWST water drained into the reactor cavity (if it had not already spilled into the containment) to successfully promote IVR.

- Should a failure of the reactor vessel occur, the design of the reactor cavity and the recirculation of water condensed on the PCS shell promotes long-term water cooling of core debris that exits the vessel.

- Lower head vessel failure due to in-vessel steam explosions is physically unreasonable.

- The PRHR and ADS systems are design features that can be used to prevent and mitigate high-pressure core melt, induced steam generator tube failures, and direct containment heating in a severe accident. The reactor cavity is designed to limit the amount of debris from being expelled into the lower compartments and to prevent debris impingement on the containment shell.

- Loads due to the deflagration of hydrogen equivalent to 100 percent zirconium oxidation will not challenge containment integrity. Deflagration to detonation transition is unlikely because, in addition to failure of the hydrogen control system (igniters), it requires a number of identified specific conditions to occur. Conditions resulting in the potential for DDT to threaten containment integrity are modelled in the PSA. Containment over-temperature due to hydrogen combustion is mitigated by the design, and failures leading to potential for overheating are identified and modelled in the PSA.

- PCS water cooling ensures that containment pressure will remain below the ASME Service Level C pressure limit during severe accidents. Only in the event of failure of water supply could pressure exceed this limit; in such a case a long grace time (>24 hours) is available to realign alternative water sources, for which connections have been provided. The capability to vent the containment is provided but would only be used per SAMG in case of a total loss of PCS cooling including failure to align alternate water supplies.

- The equipment needed to mitigate the consequences of a severe accident is designed to provide reasonable assurance that it will continue to operate during an accident.

10.13 Level 3 Offsite Dose Evaluation

The Level 3 Analysis has not been updated since APP-GW-GL-022 (Reference 10.1).

The potential for a release of radioactive material to the environment and significant radiation dose to members of the public is very small. This is due to the very small CDF and LRF, but also to the containment design, which provides enhanced deposition of core materials that could be released in a severe accident, and the PCS minimises the energy available to expel such materials from the containment.

The Level 3 PSA for internal events at full power was carried out by multiplying the fission product release category (RC) frequencies by the appropriate RC mean doses. The doses calculated were the following:

- Effective dose equivalent (EDE) whole-body dose and acute red bone marrow dose at ground level at the site boundary (assumed 0.8 km (0.5 miles))

- Population collective whole-body dose out to 80.5 km (50 miles)

- Downwind centre-line ground level thyroid dose at the site boundary

The first of these was for comparison with the Westinghouse dose-risk goal of <0.25 Sv (0.025 rem) at 1.E-6/yr, consistent with the EPRI advanced light water reactor (ALWR) Utility Requirements Document (URD) (Reference 10.3).

Source terms for each of six RCs (intact containment (IC), BP, containment failure early (CFE), containment failure intermediate (CFI), containment failure late (CFL), and RC for containment isolation (CI) failure) and one sensitivity case (category IC without credit for deposition in the containment annulus, designated DIRECT) were defined to be used as inputs for this analysis. In order to estimate conservatively the ground level doses at the site boundary, it was assumed that the releases were at ground level. It was also assumed conservatively that 5 percent of the iodine released from the containment was in volatile form. Results were quantified based on both a 24-hour and 72-hour exposure.

Interpretation of these results in the context of the United Kingdom (UK) risk and dose targets is to be found below in Section 10.5.

Table 10-12 shows that for the RCs CFL, IC, and the DIRECT sensitivity study, the mean whole-body EDE at the site boundary in 24 hours is less than 0.06 Sv (0.006 rem). For all other RCs (BP, CI, CFE, and CFI) the mean dose at the site boundary in 24 hours is >0.25 Sv (0.025 rem). The sum of the probabilities of the RCs, including an IC excess leakage category, is approximately 2.4E-7 events/yr for at-power conditions. The results also show

that for the RCs CFL, IC, and the DIRECT sensitivity study, the acute red bone marrow dose at the site boundary in 24 hours is <0.01 Sv (0.001 rem). For all other RCs (BP, CI, CFE, and CFI), the mean dose at the site boundary in 24 hours is >0.25 Sv (0.025 rem). Again, the sum of the probabilities of the RCs including an IC excess leakage category is approximately 2.4E-7 events/yr for at-power conditions. Thus, the Westinghouse design goal is met that limits the frequency of exceeding the 0.25 Sv (0.025 rem) whole-body EDE for an individual at the site boundary 24 hours after core damage to 1.E-6 events/yr, without any emergency protective action.

10.14 Low Power and Shutdown PSA Assessment

The LPSD PSA has not been updated since APP-GW-GL-022 (Reference 10.1).

10.14.1.1 Contribution to Annual Core Damage Frequency

This section presents the results from the assessment for internal events during low power or shutdown states for the AP1000 plant, which was carried out based on the requirements of the EPRI ALWR URD (Reference 10.3). The assessment encompassed operation when the reactor is subcritical, or at power operations at up to 5 percent of rated power.

Events occurring during hot and cold shutdown conditions are grouped and referred to as non-drained events, and events during drain down of the RCS and when the plant is at mid-loop are referred to as drained events. The following results are from the updated PSA (Reference 10.2).

The estimated CDF for these drained and non-drained states is 1.03E-7/yr. The LRF is estimated to be 1.72E-8/yr. Reference 10.1 shows the dominant contributions to the CDF by basic events. The data is also tabulated in Table 10-3 and shown diagrammatically in Figure10-3.

The dominant contributor, at 76 percent of the CDF in LPSD states, is failure of the component cooling or service water systems during the RCS drained state. This state is during mid-loop/vessel flange operation, and lasts for about 120 hours, once in every 18-month refuelling cycle. The major contributions to risk due to loss of circulating water system (CWS) or SWS are the following failures:

- CCF of all ADS fourth stage squib valves to operate
- CCF of the squib valves in recirculation lines
- CCF of the IRWST squib valves in gravity feed lines
- CCF of the strainers in the IRWST
- CCF of the recirculation sump strainers

10.14.1.2 Peak Point-in-Time Risk

The current AP1000 shutdown PSA resolves the shutdown states into non-drained, drained and refuelling states, and accounts for time spent in these modes (and not at full power). This analysis is sufficient to determine that the risk from these modes is low and that the plant Category-A features provide adequate risk mitigation. However, it does not provide the information that would be used by the plant operating staff to identify the peak point-in-time risks during shutdown. A provisional set of plant operating states (POSs) has been identified for the purpose of estimating peak point-in-time risk (in terms of instantaneous CDF associated with each POS), and bounding values for the instantaneous CDF in these POSs have been estimated.

The peak point-in-time risk occurs during the period when the RCS loops are drained and the refuelling canal has not been flooded for refuelling. During this period the PRHR HX is not available, and if the RNS fails and cannot be recovered the only credited means of providing long-term core cooling is gravity injection from the IRWST through one of two lines.

The peak point-in-time risk corresponds to an instantaneous CDF of 8.3E-6/yr, and is estimated on the basis that no equipment is deliberately taken offline for maintenance. If the maximum equipment outage permitted by the technical specifications is implemented, the instantaneous CDF increases to 1.45E-4/yr, the increase being due almost entirely to the permitted outage of one of the two IRWST gravity injection lines. Instantaneous CDF is only used for the purpose of identifying peak risks. The instantaneous CDF values significantly overestimate the AP1000 plant shutdown risk because the plant would not operate continuously for a year in a shutdown drained condition with equipment in maintenance.

10.15 Internal Flooding Analysis

The Internal Flooding Analysis is summarized based on qualitative assessment, model development and design information input. The following tasks were performed using the guidance provided in the EPRI Guidelines for Performance of Internal Flooding Probabilistic Risk Assessment (Reference 10.54). Section 10.20.5 includes a summary of results for the Internal Flood model.

10.15.1 Plant Partitioning

Flood areas were chosen to include the partitioning of the plant into physically separate areas that were considered to be independent of the flooding effects from other areas.

10.15.1.1 Doors

Doors are a key element for plant partitioning and the propagation path development. The opening direction, along with the other characteristics of doors, is important information needed to support the identification of the propagation path of a flood event from its origin to the final accumulation point. Design documents and drawings were used for the identification and categorization of doors for the plant partitioning and propagation path development tasks.

10.15.1.2 Stairwells and Elevators

Stairwells are usually marked with a single room name across multiple elevations. In order to easily distinguish stairwells from different buildings, during the flood areas' naming convention process, a three-digit number was added (indicating building), followed by the stairwell name on drawings to designate stairwell flood areas. To allow for a more refined description of the pathways among levels, stairwells were split into multiple rooms.

Elevators are all marked as ELEV across multiple elevations. In order to easily distinguish elevators from different buildings, during the naming convention process for flood areas, a three-digit number was added (indicating building), followed by the elevator designator (EL) and a cardinal locator designator (N for North, S for South, W for West, and E for East) to differentiate the different elevators in the same building. Elevators were split into multiple rooms to allow for a more refined description of the pathways among levels.

10.15.1.3 Major Structures

The major plant structures identified and included in the internal flooding probabilistic safety assessment IF-PSA are listed below. This list was extracted from a typical site plan for the single unit AP1000 plant, along with whether the structures are included in the standard design.

- Containment and Shield Building (standard design)
- Turbine Building (standard design)
- Annex Building (standard design)
- Auxiliary Building (standard design)
- SWS Cooling Towers (standard design)
- Radwaste Building (standard design)
- Plant Entrance (site-specific design)
- Circulating Water Pump Intake Structure (site-specific design)
- Diesel Generator Building (standard design)
- CWS Cooling Tower (site-specific design)
- CWS Intake Canal (site-specific design)
- Fire Water & Clearwell Storage Tank (standard design)
- Fire Water Storage Tank (standard design)
- Transformer Area (site-specific design)
- Switchyard (site-specific design)
- Condensate Storage Tank (standard design)
- Diesel Generator Fuel Oil Storage Tanks (standard design)
- Demineralized Water Storage Tank (standard design)
- Boric Acid Storage Tank (standard design)
- Plant Gas System (PGS) Bulk Gas Storage Area (site-specific design)
- Turbine Building Laydown Area (site-specific design)
- Circulating Water Pipe (site-specific design)
- Waste Water Retention Basin (site-specific design)
- Passive Containment Cooling Ancillary Water Storage Tank (standard design)
- Diesel-driven Fire Pump & Enclosure (standard design)

10.15.2 Building Qualitative Screening and Identification of Flood Areas

A high-level screening was performed to remove from further evaluation those buildings and structures that did not contain potential flood sources and PSA-related components. Table 10-50 shows all the buildings that are screened out for further analysis.

10.15.2.1 Containment and Shield Buildings

The containment and Shield Building include the annulus structures. Containment is normally isolated during at-power operation and is not considered vulnerable to flood-specific failure modes since it is qualified for the harsh environment characteristic of post-LOCA, main steam line break (MSLB) or feedwater line break (FWLB) scenarios.

During normal operations, a primary function of the Shield Building is to provide shielding and protection for the containment vessel and the radioactive systems and components located in the Containment Building. The Shield Building does not contain flood susceptible PSA-related equipment. The Shield Building is of little relevance in the internal flooding analysis; although a review of the general arrangement drawings identified the potential for some areas in the Shield Building to be involved in the propagation path for flooding scenarios originated in the Auxiliary Building. The Shield Building is therefore retained in the internal flooding analysis as a potential source of propagation to other buildings or flood areas where PSA-related equipment may be impacted.

10.15.2.2 Turbine Building

The Turbine Building is a non-Class 1 structure which is subjected to flooding from a variety of potential sources including the Circulating Water, Service Water, Condensate/Feedwater, Component Cooling Water, Turbine Building Cooling Water, Demineralized Water, and Fire Protection Systems, as well as the de-aerator storage tank. It is concluded that the Turbine Building contains equipment modelled in the PSA which can be impacted by flood sources also located in this building. Therefore the Turbine Building is retained. Since the Turbine Building is divided into a number of very large open areas, it will not be addressed on a room-by-room basis.

10.15.2.3 Annex Building

The Annex Building is divided into two areas: radiological controlled areas and non-radiological controlled areas. The Annex Building contains equipment modelled in the PSA which can be impacted by flood sources also located in the Annex Building. The Annex Building is therefore retained in the analysis and is addressed on a room by room basis.

10.15.2.4 Auxiliary Building

The plant Auxiliary Building contains radiological controlled areas and non-radiological controlled areas which are physically separated by 0.61m and 0.91m (2 and 3 feet) structural walls and floor slabs. These structural barriers are designed to prevent flooding across the boundary between these areas by locating penetrations for piping and HVAC duct above maximum flood levels, or by sealing these penetrations. Three floors are above grade and two are located below grade. The Auxiliary Building is divided into radiological controlled areas and non-radiological controlled areas.

10.15.2.5 Radwaste Building

There is no PSA-related equipment located in any area of the Radwaste Building. There are flood scenarios that can be envisioned to propagate into other critical structures from the Radwaste Building. Therefore, the Radwaste Building is retained in the internal flooding analysis to evaluate scenarios in which water from applicable fluid sources propagate to other unscreened buildings.

10.15.2.6 Diesel Generator Building

The Diesel Generator Building is a non-Class 1 structure which contains equipment modelled in the PSA which can be impacted by flood sources also located in the building.

10.15.3 Identification of Flood Sources

Flood sources were assessed and screened out from further evaluation using the following considerations:

- The floor drain system was considered capable of handling the discharge from small bore diameter pipes < 5 cm (2"). Therefore, the small bore pipes were not considered as a flood source that would threaten PSA-related components by submergence.
- No PSA components would be failed by a release of the system inventory.
- No transient IE would result from flood-induced failures or component unavailability due to the isolation of the break.

10.15.3.1 Fluid System Screening

Each unscreened system was evaluated to determine whether it could produce a spray, flood, major flood or high-energy line break (HELB) event by reviewing the system's characteristics, including temperature, pressure, system inventory, and system capacity. Table 10-51 lists all the unscreened systems, and Table 10-52 shows the screened systems and the reasons why they are screened out of further analysis.

10.15.4 Component Location and Initial Flooding Fragility Assessment

While many components may be exposed to sprays and minor floods, not all components are susceptible to water damage and failure. An assessment of the potential susceptibility of all PSA-relevant SSCs to damage by spray, flood (submergence), and temperature was performed. Additionally, this analysis assumes that equipment in the vicinity of fluid sources, as well as high energy lines, is susceptible to submergence, spray, jet impingement, pipe whip, humidity, condensation, and temperature concerns. Failures such as jet impingement, pipe whip, humidity, condensation, and temperature concerns, are addressed on a case by case basis and are documented throughout the analysis. Additionally, equipment in the vicinity of the flood sources is conservatively failed in all cases unless specifically stated otherwise, and thereby inherently includes the identified failure mechanisms. The extent to which PSA-related components are susceptible was based on system/component design and installation information.

10.15.5 Propagation Path Development

The information on flood areas and on general arrangement drawings, room numbering drawings, and door numbering drawings is used to develop propagation paths to fully address the potential impact of each internal event flood scenario.

Propagation paths are dependent on physical characteristics of rooms and structures and are generally independent from the actual flood sources. For this reason, propagation paths are described on a flood area by flood area basis and all the sources identified in each flood area will share the same potential propagation path.

Generic considerations on door fragility are used as primary input to propagation path development. The main generic guidance is the EPRI guideline Appendix D (Reference 10.54).

According to the fire protection analysis results, openings through fire barriers for pipe, conduit, and cable trays are sealed or closed to provide a fire resistance. Therefore, electrical penetrations are considered sealed for the development of propagation pathways. The sealing of cable penetrations is considered a best practice within the industry, and propagation through these penetrations via failure of the sealant is considered non-preferential for internal flooding. However, piping penetrations are still assumed unsealed for conservatism.

A compilation of all flooding events at nuclear power plants world-wide, including the US plants, has been collected from a number of sources.

10.15.6 Flood Area Naming Convention

Flood scenarios were characterized for each of the sources within a flood area that were not screened out from further evaluation. A decision tree was used to identify the flood damage states for each flood area. The following naming convention was used to identify the flood scenarios and facilitate integration of the flood scenarios into the PSA model.

The naming convention for flood damage states and flood scenarios is as follows:

%FL – Prefix for all flood initiators

eeeeee – Flood Area Number (pertains to the five digit AP1000 plant room number with a 6th position available if needed. If the 6th position is not needed, it shall contain an 'X')

B – Building designator (see below)

S## – Decision tree flood damage state

PPP – Three-letter designator that represents the flood source (see below)

N – One-letter designator that represents the affected train of the flood source (i.e., A – Train A, B – Train B, Z – Train A&B, or N – non-train designator)

M – Flood source failure mode (i.e., S – Spray, F – Flood, X – Major Flood, M – Maintenance Activity, or H – HELB)

Flood scenarios will be represented using the above naming convention. The scenario naming convention is represented below:

Position	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T	U
	%	F	L	-	e	e	e	e	e	e	-	B	S	#	#	-	P	P	P	N	M

The designators used in this calculation note for the building and structures that required further evaluation are as follows:

T – Turbine Building
D – Diesel Generator Building
A – Auxiliary Building/Shield Building
X – Annex Building
R – Radwaste Building

Three letters are used to represent a flood source. The letters (i.e., PPP) and corresponding descriptions of flood sources (i.e., system) are shown in Table 10-53.

Using the above information, an example of the first flood scenario for the first flood area in the Auxiliary Building for a flood from the CCS (hypothetical) is: %FL-12101X-AS04CCSZF.

10.15.7 Diesel Generator Building Flood Scenario Characterization and Consequences

The Diesel Generator Building is a Class 2 structure which houses two standby diesel engine powered generators, the power conversion cycle equipment and the associated supporting equipment. These generators, separated by a three hour fire wall, provide backup power for plant operation in the event of the LOOP. There is no Class 1 equipment in the Diesel Generator Building. This building is located on a separate foundation at a distance from the Nuclear Island and other retained structures that will be further evaluated. The diesel generators are modelled in the PSA and are therefore PSA-related equipment. Review PSA indicated that no piping existed within the flood areas of this building for systems PSA. The diesels are cooled by using a closed loop cooling system cooled by the atmosphere. Any break or leakage from this would be insufficient to cause the failure of the opposite diesel generator due to the diesel generators being housed in independent compartments. Additionally, this same logic applies to any break of the Diesel Fuel Oil System. A break in any of these aforementioned systems would at most cause the loss of the one diesel generator. Loss of a single diesel generator would not cause a plant IE or an immediate plant shutdown, and the impact of such failure is already captured in the system model for the diesel generators. Therefore, the flood areas within the Diesel Generator Buildings are screened using the criteria of the ASME/ANS RA-Sa-2009 Standard SR IFSN-A15(c).

10.15.8 Annex Building Flood Scenario Characterization and Consequences

Most flood areas in the Annex Building do not contain any applicable flooding sources. Therefore, flood areas which lack any applicable flood sources will not be evaluated for scenario creation but will be retained to evaluate the impact of a flood from another flood area.

10.15.9 Auxiliary Building and Shield Building Flood Scenario Characterization and Consequences

From all the flood areas, most do not contain any applicable flooding sources. Flood areas that lack any applicable flood sources will not be evaluated for scenario creation but will be retained to evaluate the impact of a flood from another flood area (e.g., inter area propagation). 62 flood areas are retained in the Auxiliary Building.

Turbine Building Flood Scenario Characterization and Consequences

All 35 flood areas contain applicable flooding sources due to the fact that the Turbine Building is a large open area and exact location of piping cannot be easily identified.

10.15.10 Radwaste Building Flood Scenario Characterization and Consequences

The Radwaste Building is a non-Class 1, steel framed structure that houses low level waste processing and storage. The Radwaste Building includes facilities for segregated storage of various categories of waste prior to processing, for processing by mobile systems, and for storing processed waste in shipping and disposal containers. No Class 1 equipment is located in the Radwaste Building. Due to the lack of PSA-related equipment within this building, the insufficient inventory of the CCS to propagate to any building that contains PSA-related components, and due to the loss of the CCS system already being explicitly modelled, the Radwaste Building is screened out.

10.15.11 Determination of Scenario Frequencies

The flood area and pipe length information was used as input to the flooding IEFs. Flooding events were assumed to cause a direct failure of the ruptured system (except for spray events) and/or indirect failure of one or more PSA-related equipment (due to spray, submergence or steam) such that a reactor trip or plant shutdown is required. The reactor trip or plant shutdown may be a result of the system failure or the consequential failure of PSA-related equipment. This is significant for operating systems whose failure will cause a reactor trip. Depending on the location of a pressure boundary failure, certain systems may not cause a plant trip, and this was analysed on an individual basis.

There are twelve expansion joints located in the Turbine Building. Data from Reference 10.28 was examined and it was determined that the expansion joint failure rate data for CWS could be modified to produce failure rates more representative of this system. To do so, only failures from the service water systems were included. Once the applicable failures were identified, the ratio of these events to the total was used to adjust the given expansion joint failure rates (i.e., the fraction was multiplied by the failure rate).

10.16 Internal Fire Analysis

The Internal Fire Analysis is summarized based on the tasks performed using the guidance provided in NUREG/CR-6850 (Reference 10.55). Section 10.20.6 includes a summary of results for the Internal Fire model. The Fire PSA is dependent on the design information inputs, spatial information, and cable information which will evolve as the plant is constructed. Therefore, the internal fire analysis documented here is based on the best available information, assumptions and engineering judgement at the time of the analysis. The internal fire PSA also includes a limited set of refinements to demonstrate the overall process for the fire PSA which will also be further developed with future updates.

10.16.1 Plant Partitioning

The global plant analysis boundary (GPAB) was defined to include all areas of the plant associated with normal and emergency operation, support systems, and power production. The GPAB was then partitioned into fire compartments, which serve as the basic unit of analysis for the fire PSA. The general plan locations included in the internal fire analysis are: the annex building, auxiliary building (including the MCR), diesel generator building, radwaste building, turbine building, yard, and containment. The AP1000 fire compartments, their descriptions, fire frequency, and CDF are included in Table 10-54.

10.16.2 Component Selection

The component selection task identifies all initiating events, accident sequence models, and mitigating components to which a fire impact will be modelled in the fire analysis. The Internal Events analysis was reviewed for its applicability to the fire analysis. Additionally, events that were screened from the Internal Events analysis were re-evaluated for consideration in the fire analysis. The model was compared against the Fire Protection Analysis (Reference 10.56) to reconcile any differences in components, failure modes, high level success criteria, and system function differences. Single and multiple spurious events were reviewed for any modifications necessary for the fire analysis. Human actions, required instrumentation and high consequence components were all reviewed. The output of this task is a list of components that will be credited or screened in the fire PSA. Cable selection will be performed on those components credited in the fire PSA.

10.16.3 Cable Selection

Cable selection identified all cables associated with credited Fire PSA equipment and the routing/location of those cables.

The cable selection was performed by listing all cables linked to a Fire PSA piece of equipment that are directly linked or are in associated circuits. The cable selection criteria was developed to ensure that all cables that could affect the proper operation or cause the mal-operation of the Fire PSA equipment were identified and that these cables are properly related to the Fire PSA equipment whose functionality they could affect. To ensure all cables that could affect the operation of equipment are identified, the electrical or wiring diagrams were reviewed. The power, control, instrumentation, interlock, and equipment status indication cables related to the equipment were reviewed and documented. Electrical power requirements were reviewed during the Fire PSA cable selection task, and additional power supplies were identified and added to the Fire PSA equipment list as necessary.

The Fire PSA cable list provides a link between each cable and the associated Fire PSA component. The cable list also provides the information needed to identify the plant location (fire compartment and/or room) from the cable routing input.

10.16.4 Qualitative Screening

This task qualitatively screened fire compartments from further consideration if that fire compartment did not contain any credited Fire PSA equipment/cables or could not induce an automatic trip, a manual trip, or a mandate controlled shutdown prescribed by plant technical specifications. Three locations within the GPAB were qualitatively screened from the fire analysis: plant entrance, waste water retention basin and the simulator building.

10.16.5 Fire Risk Model

The fire PSA quantifies the fire risk model to calculate the fire-induced conditional core damage probability (CCDP) and Level 2 probabilities. The fire risk model integrated all model and data sources associated with each individual task. Model modifications were implemented to incorporate fire-induced initiating events, additional logic, equipment failures, and human failures.

10.16.6 Ignition Frequency

The AP1000 plant ignition source frequencies were developed based on apportioning generic fire frequencies developed from industry operating experience. The AP1000 plant Fire PSA used the updated generic ignition frequencies developed in NUREG-2169 (Reference 10.57). The fire scenario ignition frequency replaces the Internal Events initiating event frequencies during the fire PSA quantification. Fixed and transient ignition sources are reviewed and all fire compartments retained for quantitative analysis have a fire ignition frequency assigned.

10.16.7 Quantitative Screening

NUREG/CR-6850 (Reference 10.55) provides a framework and criteria for screening fire compartments from the fire analysis. The AP1000 plant fire analysis does not quantitatively screen any fire compartments. The CDF and LRF contributions of fire compartments meeting the quantitative screening criteria are retained in the fire PSA model.

10.16.8 Scoping Fire Modelling

This task identifies ignition sources that do not pose a threat to targets within a specific fire compartment. If that ignition source is a threat to a target, a severity factor is assigned which represents the probability that the target is damaged.

10.16.9 Detailed Circuit Failure Analysis

In the cable selection task, a generally conservative set of cables associated with each basic event is identified. The detailed circuit failure analysis is a refinement of the cable selection task. This task identified the specific cables that will induce the specific failures of concern for risk significant components.

10.16.10 Circuit Failure Likelihood Analysis

This task applied a conditional probability that a particular failure will occur given damage to a specific cable within a fire scenario.

10.16.11 Detailed Fire Modelling

In the detailed fire modelling task the single compartment analysis, main control room analysis, and multi-compartment analysis were performed. Single compartment analysis subdivides a fire compartment into a collection of fire scenarios, generally corresponding to individual ignition sources that are modelled to fail targets relatively local to the source. The MCR analysis assesses the risk associated with fires occurring inside the MCR including both abandonment and non-abandonment scenarios. Multi-compartment analysis assesses unsuppressed fire scenarios which grow to a size sufficient to generate a damaging hot gas layer and propagate to adjacent fire compartments.

The main control room scenarios, including abandonment and non-abandonment scenarios contribute less than 1 percent of the Fire CDF and Fire LRF. There are no locations in the plant which can result in the loss of control from the MCR. The abandonment and non-abandonment scenarios evenly contribute to the fire risk and are largely dependent on the ignition source whether abandonment may occur. If abandonment occurs, control is transferred to the remote shutdown room.

10.16.12 Fire Human Reliability Analysis

This task identified the HFEs to include in the Fire PSA, which included all HFEs from the internal events model required to mitigate fire-induced initiators and new HFEs developed specifically for fire. The Fire HRA was performed using NUREG-1921 (Reference 10.58) guidance. The fire HRA process accounted for fire impacts on credited cues, fire-generated conditions affecting the travel path to the action location, environmental conditions at the action location, and potentially increased stress due to the fire. HEPs were calculated based on a screening level approach which applied increased factors to the Internal Events HFEs. A process was developed to apply each relevant HFE to the fire cutsets and a dependency analysis was performed and applied to the model.

10.16.13 Fire Risk Quantification

This task quantified the fire-induced CDF and LRF for each fire scenario developed by the previous sections. The Fire PSA results, including significant fire risk contributors and fire risk insights, are identified and documented.

10.16.14 Fire Sensitivity Studies

This task performed sensitivity studies by varying the value of certain inputs to assess the impact on the model's output (CDF and LRF). Table 10-55 contains the results from various sensitivity studies on the internal fire results. The sensitivity studies were focused on the key sources of uncertainty of the model:

- Assumed cable routing,
    - Detailed cable routing information was not available for the site-specific systems. Not all fire scenarios linked to the assumed cable routing will be capable of failing these systems. The Fire PSA is moderately dependent on CDF and slightly dependent on LRF. The assumed routing for the offsite power supply system has the largest impact on the CDF reduction because the system is modelled to supply power to the start-up feedwater pumps to cool the steam generators.
- Severity factors,
    - Fires are unpredictable and assumptions are needed to model fire scenarios. The severity factor is the percentage of the ignition source expected to damage targets outside the source of origin. The Fire PSA is slightly dependent on the severity factor. This can be attributed to the scenarios being conservatively treated as full compartment burn or assigning very close distances between the ignition source and the nearest target.

- Detection time,
    - Manual fire detection is credited in the fire PSA for fire suppression. The detection time was reviewed to determine the uncertainty / sensitivity of the results to this input. The Fire PSA results are slightly dependent on the assumed detection time.
- Circuit failure likelihood probabilities,
    - The fire PSA incorporated conditional failure probabilities for various components. This sensitivity study demonstrates the importance of incorporating the circuit failure mode likelihood probabilities in the analysis for the Class-1 valves.
- Heat release rates,
    - The primary source of fire modelling uncertainty is the heat release rate, which directly affects the extent and timing of target damage. The Fire PSA utilised NUREG/CR-6850 (Reference 10.55) heat release rates which were higher for electrical cabinets than the latest industry guidance, which was released during the Fire PSA development. The Fire PSA electrical cabinets are currently conservative and have a moderate impact on the reported CDF and LRF.
- Automatic fire protection, and
    - Automatic detection is credited in the Fire PSA when ionization smoke detectors are present. Sprinkler systems (automatic suppression) are credited only when damaging hot gas layer temperatures are reached. The sensitivity demonstrates that crediting automatic detection and suppression has a moderate impact on CDF and a slight impact on LRF. Many scenarios are treated to damage all targets in the fire compartment and then propagate to adjacent compartments via the multi-compartment analysis. Automatic suppression is credited to mitigate hot gas layer formation and reduce the probability of fire propagating to adjacent fire compartments.
- Fire spread to multiple fire compartments.
    - The AP1000 plant fire PSA has a large number of small fire compartments modelled. The smaller fire compartments and conservative modelling of full compartment burn scenarios results in assumed multi-compartment propagation. Fires propagating to multiple fire compartments have a significant impact on the CDF and LRF. The impact is due to conservative assumptions, design reference point cable information, and the pre-operational state of the plant.

10.17 Winds, Floods, and Other External Hazards

10.17.1 Introduction

External hazards considered in the AP1000 NPP PSA are those hazards whose cause is external to all systems associated with normal and emergency operations situations. Some external hazards may not pose a significant threat of a severe accident. Some external hazards

are considered at the design stage and have a sufficiently low contribution to core damage frequency or plant risk.

Based on the list of external events requiring consideration from ASME/ANS-RA-Sa (Reference 10.61) and the preliminary qualitative screening guidelines provided in References 10.59, 10.60, and 10.62, the following list of external hazards were included for further consideration in the AP1000 NPP analysis. Note that Seismic Events and Internal Flooding are addressed separately in the AP1000 NPP PSA.

- High Winds
- Tornadoes
- External Flooding
- Transportation and Nearby Facility Accidents and Release of Chemicals from Onsite Storage
- Aircraft Impact
- External Fires
- Turbine Generated Missiles

These external hazards are addressed in this section.

Each potential site should re-evaluate the screening of each external hazard using site-specific information. Accordingly, if an external hazard cannot be screened out based on the criteria discussed in Section 10.17.2, the hazard may have to be modelled explicitly in the site-specific PSA.

Chapter 4 defines the site characteristics for which the AP1000 NPP is designed. It is very unlikely that sites with characteristics that fall within the AP1000 NPP site interface parameters defined in Chapter 4 will be unable to screen external hazards.

10.17.2 External Hazards Screening Analysis

Screening of external hazards that may impact the plant and contribute to risk can be accomplished using either qualitative or quantitative screening criteria outlined in ASME/ANS-RA-Sa (Reference 10.61). Any one of the following criteria provides an acceptable basis to qualitatively screen an external hazard:

- The event is of equal or lesser damage potential than the events for which the plant has been designed.
- The event has a significantly lower mean frequency of occurrence than another event, and the event could not result in worse consequences than those from the other event.
- The event cannot occur close enough to the plant to affect it.
- The event is included in the definition of another event.

- The event is slow in developing, and sufficient time is available to provide an adequate response.

External hazards which are not screened based on the qualitative criteria may be further assessed to determine if the following AP1000 NPP quantitative screening criteria can be satisfied:

- The current design-basis-hazard event cannot cause a core damage accident.
- The current design basis hazard event has a mean IEF of 1E-07 per year, and the mean value of the CCDP is assessed to be less than 1E-01.
- The CDF calculated using a bounding or demonstrably conservative analysis has a mean frequency less than 1E-08 per year.

The following equations can be used to determine if the hazard can be screened:

Equation 10-1

$$CDF = IEF * CCDP$$

Equation 10-2

$$IEF = CDF/CCDP$$

Where CDF is the annual core damage frequency, IEF is the annual IE frequency, and CCDP is the conditional core damage probability given the occurrence of the hazard.

Three CCDP cases were developed to assess risk associated with a particular external event based on the impact it may have on the plant. For example, high winds with speeds up to the AP1000 NPP operating basis may induce a LOOP, but are not expected to impact the availability of the Class 2 systems. High wind events with speeds that exceed the operating basis may induce a LOOP and also impact the Class 2 systems. Toxic chemical releases may impact the ability of the plant operators to respond to the event. The CCDPs for these scenarios as well as maximum site-specific IEFs that will support quantitative screening (i.e., would result in a CDF of 1E-08) were calculated. The results are presented in Table 10-58.

10.17.2.1 High Winds

As discussed in Chapter 4, the AP1000 NPP operating basis wind speed is 233.35 km/hr (145 mph). This value is assumed to be the maximum wind speed that will not challenge the non-Class 1 structures. The design basis wind speed for tornados is 482.80 km/hr (300 mph). This value is assumed to be the maximum wind speed that will not challenge the Class 1 structures. The structures protecting Category-A features of the AP1000 plant are designed for extreme winds and missiles associated with these winds. As long as the wind speed is less than these design basis wind speeds, the Category-A features of the AP1000 plant will be unaffected. In the unlikely event that the winds exceed the design values, then the integrity of the Class 1 structures may be compromised. The structures protecting non-Category-A safety functions of the AP1000 plant are designed according to Uniform Building Code or International Building Code and have some level of protection against seismic and high wind events. As long as the external event winds are less than the operating basis winds [233.35 km/hr (145 mph)], the non-Category-A features of the AP1000 plant will be unaffected. If the winds exceed the operating basis values, then the integrity of the non-Class 1 structures may be compromised.

High wind events that fall below the AP1000 NPP operating basis wind speed have the potential to induce a LOOP but would not impact any other SSCs. However, it is assumed that the site switchyard and surrounding grid are designed to withstand wind events up to the site-specific basic wind speed and that as long as the external winds are less than this value, the reliability of the switchyard and surrounding grid will be unaffected. The frequency of high wind events with speeds that exceed the site-specific basic wind speed but are below the AP1000 NPP operating basis wind speed of 233.35 km/hr (145 mph) should be determined, and the occurrence of a LOOP would be assumed. These events are not screened, but it is assumed that their frequency of occurrence is accounted for in the internal events PSA as a weather-induced LOOP.

High wind events that exceed the plant operating basis wind speed have the potential to induce a LOOP with a concurrent failure of non-Class 1 components which are not housed in Seismic Category 1 buildings.

The methodology for analysing plant risk due to high winds that exceed the AP1000 NPP operating basis wind speed is to perform a bounding or demonstrably conservative analysis to determine if the quantitative screening criterion can be met. For the AP1000 NPP, the quantitative screening criterion is that the total calculated CDF due to high winds has a mean frequency less than 1E-08 per year.

For a high wind event that exceeds the AP1000 NPP plant operating basis wind speed of 233.35 km/hr (145 mph) up to the design basis wind speed of 482.80 km/hr (300 mph), it can be conservatively assumed that the event results in a LOOP coincident with unavailability of the non-Class 1 systems. The CCDP for this scenario (CCDP Case 2) is 4.3E-06. Using Equation 10-2, the maximum IEF is determined to be 2.3E-03 per year.

Similarly, the maximum IEF for a high wind event resulting in the wind-induced unavailability of all non-Class 1 systems and all Class 1 systems (wind speed greater than 482.80 km/hr [300 mph]) can be estimated at 1E-08 per year, assuming a CCDP of 1.0. Due to the low frequency, high wind events above 482.80 km/hr (300 mph) can be screened from the total maximum IEF for high winds, and thus the total maximum IEF for high winds is determined to be 2.3E-03 per year.

The frequency of “straight line” high wind events can be determined based on information in historical weather datasets available at the US National Oceanic and Atmospheric Association (NOAA) National Climatic Data Centre website for a selected weather station surrounding the site. The annual exceedance frequency for a specific wind speed can be predicted using the Gumbel distribution which is a special case of the generalized extreme value distribution. This distribution is commonly used for predicting extreme value frequencies for parameters such as wind speed based on annual maximum observations.

High winds with wind speeds that exceed 233.35 km/hr (145 mph) are screened as a contributor to total plant risk if the total site-specific IEF is less than 2.3E-03 per year. This is a conservative result, and it is unlikely that sites selected based on the siting parameters in Chapter 4 would not be able to meet this criterion. However, sites that do not meet the screening criterion may need to perform more detailed analyses and include this hazard in the site-specific PSA.

High winds can also result due to hurricanes in coastal regions. Per the description of Table 10-60, Saffir-Simpson Scale (Hurricane), no hurricanes are expected to reach 482.80 km/hr (300 mph) winds and challenge the Class 1 systems; however, Category 3, Category 4, and Category 5 hurricane winds do exceed the operating basis of the AP1000 NPP. Additionally, the annual mean risk due to a Category 1, Category 2, and Category 3

hurricane-induced LOOP should be explicitly considered independent from the internal events PSA weather-induced LOOP due to the damage potential associated with the hurricanes. Site-specific IEFs for high winds associated with hurricanes and other causes should be determined based on information in historical weather datasets to determine if this hazard can be screened.

10.17.2.2 Tornados

Per the Operational Enhanced Fujita Scale for Tornados found on the Fujita Tornado Scale Intensity Wind Speed Relationship (Table 10-59), no tornados are expected to exceed the design basis wind speed of 482.80 km/hr (300 mph); however, EF3, EF4, and EF5 tornados do exceed the operating basis wind speed of the AP1000 NPP. Additionally, the annual mean risk due to an F0, F1, and F2 tornado-induced LOOP is explicitly considered independent from the internal events PSA weather-induced LOOP due to the damage potential associated with the tornado.

The methodology for analysing plant risk due to tornados is to perform a bounding or demonstrably conservative analysis to determine if the quantitative screening criterion can be met for the overall tornado hazard risk due to F0, F1, F2, F3, F4, and F5 tornados. For the AP1000 NPP, the quantitative screening criterion is that the total calculated CDF due to tornados has a mean frequency less than 1E-08 per year.

Using Equation 10-2, the maximum IEF for a F0, F1, and F2 tornado can be estimated at 2.6E-02 per year based on CCDP Case 1 (CCDP = 3.8E-07) for a tornado-induced LOOP.

Similarly, the maximum IEF for a F3, F4, and F5 tornado can be estimated at 2.3E-03 per year based on CCDP Case 2 (CCDP = 4.3E-06) for a tornado-induced LOOP coincident with unavailability of the non-Class 1 systems.

The total maximum IEF for tornado hazard is determined to be 2.8E-02 per year.

An analysis of tornado climatology in the United States is provided in US NRC NUREG/CR-4461 (Reference 10.64). The results include annual probabilities that wind speed exceeds a specified value given that a tornado strikes a structure. The expected annual strike probability for a structure the size of the AP1000 NPP ranges from approximately 1E-03 in the Central United States to approximately 1E-05 in the Eastern and Western United States. The methodology in US NRC NUREG/CR-4461 can be used to determine site-specific IEFs for tornados which are expected to fall within this range for most sites in the United States.

10.17.2.3 External Flooding

An external flooding analysis is performed to verify that any significant contribution to core damage frequency resulting from plant damage caused by storms, dam failure, and flash floods is considered. The analysis for external floods begins with an examination of the design basis for the plant, which is documented in PCSR Chapter 4. The AP1000 NPP is protected against floods up to the 100 m (100 feet) level. The 100 m (100 feet) level corresponds to the plant ground level. From this point, the ground is graded away from the structures. Thus, water will naturally flow away from the structures. Additionally, all seismic Category I SSCs are designed to withstand the effects of flooding. The seismic Category I SSCs below grade (below ground level) are protected against flooding by a waterproofing system. Unavailability of non-Class 1 SSCs that may potentially be impacted by external flooding events would not have a significant impact on total plant risk.

Sites with site characteristics that fall outside of the AP1000 NPP site interface parameters may be susceptible to external flooding that would exceed the 100 meter (100 feet) plant ground level are evaluated on a site-specific basis. Such sites may be vulnerable to external flooding due to hurricane surge water, dam failure, and flash floods.

The methodology for analysing plant risk due to external flooding is to perform a bounding or demonstrably conservative analysis to determine if the quantitative screening criterion can be met. For the AP1000 NPP, the quantitative screening criterion is that the total calculated CDF due to external flooding has a mean frequency less than 1E-08 per year.

For an external flooding event that exceeds the 100 meter (100 feet) level, it can be conservatively assumed that the event results in a LOOP coincident with unavailability of the non-Class 1 systems (CCDP Case 2). Using Equation 10-2 the maximum IEF for an external flooding event that exceeds the 100 meter (100 feet) level is determined to be 2.3E-03per year.

External flooding is screened for the site as a contributor to total plant risk if the site-specific IEF is less than this value. Information such as meteorological data for the site, historical flood height, and frequency data is used to determine the site-specific IEF. It is very unlikely that sites selected based on the siting parameters in Chapter 4 would not be able to meet this criterion. However, sites that do not initially meet the screening criterion could focus attention on areas, which due to their location and grading, may be susceptible to external flood damage. Site-specific information on such items as dikes, surface grading, locations of structures, and locations of equipment within the structures can be utilized to remove some of the conservatism in the initial evaluation. The resultant CCDP may be reduced and lead to meeting the quantitative screening criterion.

10.17.2.4 Transportation and Nearby Facility Accidents and Release of Chemicals from Onsite Storage

Transportation and nearby facility accidents and release of chemicals from onsite storage could result in an explosion, a flammable cloud or a toxic chemical release that could affect safe operation of the plant. A site-specific evaluation of potential accidents related to transportation routes and other facilities in the vicinity of the site is performed. The types of transportation routes to be considered include roads, railroads, and waterways. The types of facilities to be considered include industrial sites and military installations. Additionally, a review of chemicals stored onsite is performed. Many of the chemicals can be excluded from further consideration due to their properties (e.g., low volatility or low toxicity) or due to the relatively small quantities that are stored.

Sites within 8.05 kilometres (five miles) of transportation routes and industrial or military facilities need to consider potential accidents on roads, railroads, and waterways, and at nearby facilities. Evaluation of roads encompasses large truck traffic and other commercial carriers, and evaluation of waterways encompasses ship and barge traffic. The types of nearby facilities to be considered include industrial sites, other nuclear power plants at multi-unit sites, pipelines, and military installations. Hazardous materials that travel on nearby transportation routes or that are located at nearby facilities are identified and analysed based on volume and distance from the plant to verify they would not affect safe operation of the plant. Accidents on transportation routes or at nearby facilities have the potential to result in the release of toxic chemicals which may affect control room habitability, or explosions that could damage plant equipment.

A release of toxic materials into the atmosphere may compromise the safety of the plant operators, resulting in reduced operator reliability. The potential for this is determined based on site-specific evaluation of the types and volumes of material being transported or stored at nearby facilities. If the maximum calculated control room concentration subsequent to a postulated accident is less than the toxicity limit defined in US NRC Regulatory Guide 1.78 (Reference 10.65) for the material being analysed, then the hazard can be screened as a risk contributor.

The hazard could also be screened if it can be shown that the calculated CDF for such an event is less than 1E-08 per year. For sites where the toxicity limit is exceeded, the ability of operators to function may be impacted, but a toxic release would not directly lead to failure of plant equipment. The risk impact for this scenario can be calculated by assuming the occurrence of a general transient (reactor trip) with coincident failure of all operator actions included in the model. Failure of all PSA-credited operator actions obviates the need to evaluate specific toxic release events with respect to differences in the type and amount of material released and duration of the release. The CCDP for this scenario (CCDP Case 3) is 9.0E-07. Using Equation 10-2, the maximum total IEF for the hazard is determined to be 1.1E-02 per year. Transportation accidents, nearby facility accidents, and release of chemicals from onsite storage are screened separately for the site as a contributor to total plant risk if the total site-specific IEF for each hazard is less than this value. Sites that do not meet the screening criterion may need to perform more detailed analyses.

The above analysis is conservative as it does not take credit for the AP1000 NPP design feature which provides an additional level of defence against toxic airborne material. With advanced warning, the operators may actuate the passive control room habitability system. This system isolates the control room from normal HVAC and actuates a separate system supplied from compressed air containers. The compressed air slightly pressurizes the control room above atmospheric pressure, preventing the entrance of toxic material in the control room. This system is available for 72 hours, which is adequate time to withstand the event.

Explosions due to a transportation accident or release of chemicals from onsite storage, or at a nearby facility could result in an initiator as well as damage to mitigating equipment at the plant. Potential explosions to be considered include those that may occur coincident with the accident or subsequent to the accident due to a vapour cloud that may be generated as a result of the accident. The potential for an explosion is determined based on site-specific evaluation of the types and volumes of material being transported or stored onsite or at nearby facilities. For each postulated explosion, the safe equivalent distance beyond which the blast pressure would be less than 6.89kPa (1 psi), which is specified in US NRC Regulatory Guide 1.91 (Reference 10.66), is calculated. Evaluation of explosions due to a flammable vapour cloud would conservatively assume that the explosion occurs at the outer edge of the vapour cloud closest to the plant. If the distance between the point of the explosion and the plant is greater than the calculated safe equivalent distance, the hazard is screened. Sites that do not meet the screening criterion may need to perform more detailed analyses. These analyses should account for the location of the explosion relative to the plant and the potential impact on plant SSCs to calculate appropriate IEFs. Equation 10-1 and Equation 10-2 can then be used with IEFs and appropriate CCDPs to determine if the hazard can be screened on a quantitative basis using the AP1000 NPP screening criteria.

10.17.2.5 Aircraft Impact

Sites in the vicinity of airports and airways need to consider potential aircraft impacts. An aircraft impact would not inhibit the AP1000 NPP passive core cooling capability and would not impact containment integrity. However, aircraft impact could result in a LOOP or loss of some non-Class 1systems.

An evaluation of each nearby airport would account for the distance between the airport and the plant, and the total number of projected flight operations (take-offs and landings) to determine if the annual CDF for the airport is less than the AP1000 NPP criteria of 1E-08 per year.

An evaluation of airways is performed to determine the in-flight crash rate per kilometre for each type of aircraft using the airway, the number of flights of each type per year along the airway, and the airway width to determine the total annual frequency of an aircraft crashing into the site. The risk due to aircraft impacts is screened to determine if the total annual CDF for airplane crashes for the site is less than the AP1000 NPP criteria of 1E-08 per year.

US NRC Review Standard (RS)-002, Section 3.5.1.6 (Reference 10.68), provides a methodology for calculating the hazard frequency for airports and airways in the vicinity of the site. Sites where the total IEF for aircraft impact is greater than the 1E-07 per year screening criteria could conservatively assume that the impact results in a LOOP coincident with unavailability of the non-Class 1 systems. The CCDP for this scenario (CCDP Case 2) is 4.3E-06. Using Equation 10-2, the maximum total IEF for the hazard is determined to be 2.3E-03 per year. Aircraft impacts are screened as a contributor to total plant risk if the total site-specific IEF for this hazard is less than this value. Sites that do not meet the screening criterion may need to perform more detailed analyses.

10.17.2.6 External Fires

External fires in the vicinity of site could lead to high heat fluxes or smoke, and non-flammable gas or chemical-bearing clouds from the release of materials as a consequence. A site-specific evaluation of potential accidents that may result in forest fires, brush fires, and fires due to other sources is performed. Based on the postulated distance to the fire source, rate of spread, and duration, emission concentrations in the control room air intake would be calculated. These results are used to determine if the amount of toxic combustion products released poses a hazard to the control room operators. The heat flux and resultant temperature rise on plant structures due to an external fire should also be evaluated to determine if the Class-1 structures experience any thermal damage, based on the distance from the fire. If the analysis shows that the concentrations do not exceed toxicity limits, then external fires can be screened as a risk contributor. The hazard could also be screened if it can be shown that the calculated IEF for such an event is less than 1E-08 per year. For sites where the IEF screening criteria is not met and the toxicity limit is exceeded, the ability of operators to function may be impacted, but emissions from a fire would not directly lead to failure of plant equipment. The risk impact for this scenario can be calculated similar to how it was done for chemical releases as described in Section 10.17.2.4. This would be done by assuming the occurrence of a general transient (reactor trip) with coincident failure of all operator actions included in the model. The CCDP for this scenario (CCDP Case 3) is 9.0E-07. Using Equation 10-2, the maximum total IEF for the hazard is determined to be 1.1E-02 per year. External fires are screened for the site as a contributor to total plant risk if the total site-specific IEF for each hazard is less than this value. Sites that do not meet the screening criterion may need to perform more detailed analyses.

The above analysis is conservative as it does not take credit for the design of the AP1000 NPP control room HVAC design which includes smoke detectors. Any smoke detected from an onsite or offsite external fire would initiate isolation of the control room HVAC prior to toxicity limits being exceeded. With advanced warning, the operators may actuate the passive control room habitability system. This system isolates the control room from normal HVAC and actuates a separate system supplied from compressed air containers. The compressed air slightly pressurizes the control room above atmospheric pressure, preventing the entrance of toxic material in the control room. This system is available for 72 hours, which is adequate time to withstand the event.

10.17.2.7 Turbine Generated Missiles

PCSR Chapter 10, subsection 10.2.2, states that the AP1000 plant turbine-generator and associated piping, valves, and controls are located completely within the Turbine Building. There are no Class 1 systems or components located within the Turbine Building. An analysis was performed which concluded that the probability of destructive overspeed condition and missile generation, assuming the recommended inspection and test frequencies, is less than 1.00E-05 per year. In addition, orientation of the turbine generator is such that a high-energy missile would be directed at a 90 degree angle away from Class 1 structures, systems, or components. Failure of turbine-generator equipment does not preclude safe shutdown of the reactor. The turbine-generator components and instrumentation associated with turbine-generator overspeed protection are accessible under operating conditions.

US NRC Regulatory Guide 1.115 (Reference 10.67) provides a means to calculate the probability of failure of essential equipment because of turbine-generated missiles based on protection provided by turbine orientation. This probability is expressed as the product of the following three items:

- P1-the probability of turbine missile generation resulting in the ejection of turbine disk (or internal structure) fragments through the turbine casing
- P2-the probability of ejected missiles perforating intervening barriers and striking essential equipment
- P3-the probability of essential equipment that are struck failing to perform their Category-A functions

Mathematically, the probability of failure of essential equipment because of turbine missiles can be expressed as follows:

- $P4 = P1 \times P2 \times P3$

P4 is limited to less than 1.00E-07 per year, which US NRC Regulatory Guide 1.115 considers to be an acceptable risk rate for the loss of essential equipment from a single event. Considering P1, P2, and P3 in the placement of essential equipment, detailed strike and damage analyses have shown that separation of redundant equipment and special attention to turbine valve reliability have accomplished the objective of ensuring a low risk of damage from turbine missiles. As noted previously, there are no Class 1 systems or components located within the Turbine Building. Based on this, the AP1000 plant is considered to have a favourable turbine orientation and P2 x P3 can be credited to be 10^{-3} per Table 1 of US NRC Regulatory Guide 1.115. Combining this with the frequency of turbine missile generation frequency yields a value of P4 < 1.00E-08 per year. Although no Category-A functions could be impacted by this event, non-Category-A, defence-in-depth mitigating functions could be

adversely affected. Therefore, only the Class 1 systems are credited for this hazard. Using CCDP Case 2 for a LOOP coincident with failure of the non-Class 1 systems, the risk due to a turbine-generated missile can be conservatively estimated using Equation 10-1 as 4.32E-14 per year.

Based on these evaluations, the impact from a turbine-generated missile can be screened out from further considerations.

10.17.3 Conclusion

The risk due to external hazards is low for the AP1000 NPP design for sites that meet the siting parameters in PCSR Chapter 4. The AP1000 NPP design is shown to be highly robust against the external hazards discussed in this section. The design is resilient against high winds, external floods, and other external hazards that could potentially have an impact on the safe operation of the plant. Each potential site should re-evaluate the screening of each external hazard using site-specific information. Accordingly, if an external hazard cannot be screened out based on the criteria discussed in Section 10.17.2, the hazard may have to be modelled explicitly in the site-specific PSA.

The following conclusions and insights are derived from the AP1000 NPP external hazards assessment for events at power:

1. High winds were shown be of low risk to the AP1000 NPP design for sites that satisfy the siting parameters in PCSR Chapter 4. High wind events that exceed the plant operating basis wind speed of 233.35 km/hr (145 mph) have the potential to induce a LOOP with a concurrent failure of non-Class 1-related components; however, the frequency of such events is likely sufficiently low at most sites such that this hazard can be screened.

2. Tornados were shown to be of low risk to the AP1000 NPP design for sites that satisfy the siting parameters in PCSR Chapter 4. F0, F1, and F2 tornados have the potential to induce a LOOP, and F3, F4, and F5 tornados have the potential to induce a LOOP concurrent with the failure of non-Class 1components; however, the frequency of such events is likely sufficiently low at most sites such that this hazard can be screened.

3. The AP1000 NPP is designed to flooding levels described in PCSR Chapter 4. The site selection criterion provides that, for an accident that has potential consequences serious enough to affect the safety of the plant to the extent that US Regulation 10 CFR 50.34 guidelines are exceeded, the annual frequency of occurrence is significantly less than the maximum IEF required for quantitative screening as discussed in Section 10.17.2.3.

4. Transportation and nearby facilities accidents are likely able to be screened based on not being close enough to the plant to affect safe operation. Many of the chemicals that are stored onsite are likely able to be screened from further consideration due to their properties and/or the relatively small quantities that are stored.

5. An aircraft impact would not inhibit the AP1000 NPP passive core cooling capability and would not impact containment integrity. Aircraft impact could result in a LOOP or loss of some non-Class 1 systems; however, site selection criterion should demonstrate that the frequency of impact is sufficiently low and that this hazard can be screened.

6. External fires are likely able to be screened based on not being close enough to the plant to affect safe operation.

7. Turbine-generated missiles can be screened based on the bounding or demonstrably conservative analysis, which demonstrates a mean CDF less than 1E-08 per year.

A site-specific review of the generic PSA should be conducted to verify that the assumptions in the PSA bound the site-specific conditions for the applicant's site.

10.18 Seismic Margins Assessment (SMA)

The SMA has not been updated since APP-PRA-GSC-027 (Reference10.78).

A PSA-based seismic margin assessment (SMA) was performed for the AP1000 standard design and presented in Reference 10.1, Chapter 55.

The AP1000 design SMA was performed before the development of the American National Standards Institute/American Nuclear Society (ANSI/ANS) 58.21 (Reference 10.7) standard on external events PSA. Nevertheless, the adopted methodology is essentially consistent with the ANSI/ANS standard. Seismic-induced event trees were constructed, starting with structural or systems failures that could be postulated to occur as a result of a seismic event. The analysis considered all structures and components required to maintain the plant in a safe stable state (event tree top events). The maximum peak ground acceleration (pga) that gave at least 95 percent confidence of no more than 5 percent failure probability, i.e., representing high confidence of low probability of failure (HCLPF), was determined for the following:

- Each seismic event tree initiator
- Each seismic event tree core damage sequence
- The entire plant

To demonstrate margin over the design safe shutdown earthquake (SSE), a review-level earthquake was set at 1.67 times the SSE. This is consistent with the requirements of the US NRC (Reference 10.8). Since the AP1000 plant SSE is defined at 0.3g pga, the review-level earthquake for the AP1000 plant is set at 0.5g pga.

The following main assumptions are used in the development of the PSA-based seismic margins assessment model:

- The seismic event is assumed to occur while the plant is operating at full power.

- LOOP is assumed, since the ac power equipment is not seismic Category 1.

- No credit is taken for onsite emergency ac (diesel generators).

- No credit is taken for Class 2 systems.

The seismic IEs and event trees were established using a hierarchical approach to ensure that events presenting the greatest challenge to plant structures and systems were considered first.

All the structures or components postulated to initiate the accident sequences by their failure and needed to achieve safe shutdown following any such IE have been assessed. All the equipment and/or structures that are potentially driving the overall plant HCLPF are shown to

have an HCLPF value at or above 0.5g (and in most cases greater). Limiting components include the fuel and the pressuriser structure.

The min-max method is used on the IE HCLPF values to calculate the plant HCLPF values, which means that the maximum HCLPF value among the systems, structures, or components (SSCs) involved in a cut-set drive the cut-set HCLPF. The minimum, among all the relevant cut-sets, drives the HCLPF for the sequence, event tree, and overall plant. The AP1000 design PSA-based SMA confirmed that the plant-level HCLPF is 0.5g, thus, meeting the goal set by SECY-93-087 (Reference 10.8).

Multiple methods have been used to evaluate the HCLPF values for the SSCs assessed in the AP1000 design SMA. These include conservative deterministic failure margin methodology, probabilistic fragility analyses, other deterministic approaches, EPRI ALWR URD (Reference 10.3) recommended generic fragility data, design margin, code requirements, and test margins inherent to the seismic qualification testing.

Reference 10.7, Appendix D, describes a simple method to gain risk insights from the results of an SMA. Consideration of the seismic hazard curve allows a relation to be drawn between the established plant HCLPF value and a seismic return frequency. Reference 10.9, Figure 6, indicates that for a location with average UK seismicity, the return frequency of a seismic event of 0.5g is about 5E-6/yr. (Taking a high seismicity location could increase this by a factor of about 2.) Taking into account the definition of HCLPF, a further factor could be applied to allow for the actual probability of failure in the review earthquake being somewhat lower than 1, resulting in a possible estimate of between 1.E-7 and 1.E-6/yr, which is similar in magnitude to the CDF from internal events at power. More recent work by the British Geological Survey (Reference 10.10) indicates that the UK average seismic hazard curve (Reference 10.9) is about one order of magnitude too conservative. At this stage, this is taken only to add confidence to the above conclusions, since revised seismic assessment will be required at a later stage in the application process, and the seismic hazard curve for the specific location can then be applied.

The topic of seismic events is dealt with in more detail in Chapter 12.

10.19 Spent Fuel Pool Risk Assessment

The Spent Fuel Pool Risk Assessment has not been updated since UKP-GW-GL-743 (Reference 10.2) and is based on the APP-GW-GL-022 (Reference 10.1) internal events PSA.

Assessment of Spent Fuel Damage Frequency

A SFP PSA was conducted to estimate the AP1000 SFP fuel damage frequency (FDF) (Reference 10.2). The FDF of the AP1000 SFP was quantified to be 1.59E-10 occurrence per year using fault tree analysis, and includes the following events leading to potential fuel uncover/large radiation release:

- Loss of complete cooling during normal conditions (5.76E-12/yr.)
- Loss of complete cooling at refuelling only outage and at-power just after refuelling (1.55E-12/yr.)
- Loss of complete cooling at refuelling full core off-loads (8.19E-13/yr.)
- Loss of offsite power sequences leading to station blackout (2.69E-11/yr.)

  - Normal conditions
  - Refuelling only outage and at-power just after refuelling
  - Refuelling full core off-load

- Loss of component cooling/service water system (1.24E-10/yr.)

The main contributor to the failure of the AP1000 SFS is the loss of component cooling/service water system due to failure of the CCS or the SWS. The CCS provides cooling to both SFS HXs and the normal RNS HX. The RNS can provide backup cooling of the SFP. Note that the AP1000 design provides an alternate means of cooling the RNS HX using fire water.

Possible contribution to FDF from fuel transfer canal drain line rupture is not considered in this analysis. The level of water in the fuel transfer canal is closely monitored during fuel transfer operations. If a loss of water level is noted, fuel transfer is halted, and the one fuel rod assembly being moved is placed where impact of a loss of water level is minimised.

The CCF analysis uses the beta factor method, and follows the approach described in Section 29.3.1 of the UK AP1000 PSA report (Reference 10.1). The human error analysis uses the THERP method (Reference 10.6).

In the worst scenario of a seismic event (assuming water in the pool is initially drained to the level of the SFP cooling system connection simultaneous with a station blackout) immediately following a refuelling full core off-load, water in the pool could reach saturation in 1.4 hours. The time before reaching saturation during a seismic event at-power following a refuelling is at least 6.5 hours. The operator has enough time to align the different cooling and makeup sources if needed.

The EPRI guidance for fault tree modelling of SSIEs (Reference 10.11) has been used. The time-dependent failures that start the sequence of events that cause the IE are assigned a mission time of one year (for example, the loss of operating SFS train A during normal conditions). This ensures that the quantification results are expressed as a frequency instead of a probability. The time-dependent secondary failures in the sequence of events that cause the IE are assigned a mission time of 24 hours (for example, the loss of the standby SFS train B during normal conditions). A multiplier representing the fraction of time the system operates in a given configuration over a year is added at the top of each SSIE.

This quantification for FDF is determined by a PSA model that assumes that fuel damage occurs when makeup water cannot be provided. The AP1000 Abnormal Operating Procedures include mitigation actions for loss of SFP cooling that are credited in the current PSA analysis, including recovery of the failed SFP cooling function and water addition to the SFP using the fire water system to prevent fuel uncovery. These additional recoveries, quantified in the PSA, are quite possible due to the existence of alarms to alert the plant operating staff to the loss of SFP cooling, the existence of proceduralised actions to mitigate the loss of SFP cooling and SFP inventory loss, and the large amount of time between the alarm and the actual fuel uncovery. Thus, source term addition because of the fuel damage frequency could be overestimated by the quantified fuel damage frequency.

AP1000 SFP is located outside the reactor containment building, and fuel damage in the SFP is, therefore, considered to result in a release outside containment. The comparable LRF quantified in the “UK AP1000 PSA” is 1.95E-08 events per year (Reference 10.1). The AP1000 Level 3 PSA analysis was performed using the LRF results from the Level 1 and Level 2 PSA (Reference 10.1). The FDF value is 0.82 percent of the LRF value.

The fission product release for an SFP fuel damage event would be significantly different than the fission product release assumed for an at-power core damage event such as that analysed in the AP1000 Level 3 PSA. The differences and their effect on consequences can be characterised as follows:

- SFP fission product inventory would consist of long-lived radionuclides as opposed to the mix of short- and long-lived radionuclides for an at-power core damage event. When evacuation is considered in the Level 3 analysis, the offsite consequences of a large release are dominated by the shorter-lived radionuclides.

- The SFP fuel damage fission product inventory is primarily non-volatile species, some of which will deposit within the spent fuel building and not be released to atmosphere while others will deposit rapidly in areas within the controlled site area. Thus, the offsite consequences will be reduced compared to a large release from an at-power core damage event.

- The SFP fuel damage inventory will include multiple cores as opposed to a single core for a large release from an at-power event. This will result in the potential release of larger quantities of long-lived radionuclides compared to the large release from an at-power condition.

- The SFP fuel damage event may take place in an oxidizing environment as opposed to a reducing environment for an at-power core damage event. This can result in different radionuclide chemical species being formed. WASH-1400 analyses showed that a large release from a core damage accident in an oxidizing environment can have slightly greater health consequences compared to a large release from a core damage event in a reducing environment.

Due to the very low fuel damage frequency, the potential releases from spent fuel damage are below the UK numerical targets.

10.19.1 Assessment of Spent Fuel Pool Boiling Frequency

In addition to the FDF quantified for the SFP, an assessment of the AP1000 SFP boiling frequency has also been conducted for the UK AP1000 plant (Reference 10.12), which took into account the latest design changes relative to the systems that interact with the SFP. The boiling frequency of the AP1000 SFP was quantified to be 4.42E-04 occurrence per year using a similar fault tree analysis approach for the estimate of the FDF, and includes the following events:

- Loss of offsite power with plant trip and subsequent failure of both trains of the onsite standby diesel generators (with an estimated frequency of 7.69E-06/yr)

- Loss of both trains of SFS, plus the loss of both RNS trains

- Loss of both trains of CCS

- Loss of both trains of SWS

The SFP boiling frequency contribution from loss of offsite power is calculated by multiplying the frequency of loss of offsite power used in Reference 10.38 (3.59E-02/yr) by the probability of failing to recover offsite power in 8 hours, and by the probability of failure of the diesels to start and run for 24 hours.

An updated frequency for loss of the CCS /SWS (Reference 10.13) was used to estimate the SFP boiling frequency.

The SFP boiling contribution from pipe breaks is 2.77E-06/yr (Reference 10.12).

The loss of SFP cooling due to loss of the SFS and RNS trains documented in the FDF estimate (Reference 10.14) was modified to remove unnecessary conservatism and simplifications in the model of the defence-in-depth systems, and to reflect the AP1000 plant 50 Hz standard design as updated, including for example the capability to align the fire protection system to provide an alternative means of cooling for the RNS and SFS heat exchangers in case of loss of both CCS/SWS trains. The SFP boiling contribution from the loss of SFS and RNS

The modification also corrected some errors in the FDF model, and used reliability data from NUREG/CR-6928 (Reference 10.15).

10.20 PSA Results and Insights

10.20.1 Introduction

This section summarizes the use of the AP1000 NPP PSA in the design process, PSA results and insights, plant features important to reducing risk, and PSA input to the general design assessment process.

The AP1000 NPP is expected to achieve a higher standard of severe accident safety performance than current operating plants, because of the adoption of simple passive Class 1 SSCs and because both prevention and mitigation of severe accidents have been addressed during the design stage, taking advantage of PSA insights, PSA success criteria analysis, severe accident research, and severe accident analysis. Since PSA considerations have been integrated into the AP1000 NPP design process from the beginning, many of the traditional PSA insights relating to current operating plants are not at issue for the AP1000 NPP. The Level 1, Level 2, and Level 3 results show that addressing PSA issues in the design process leads to a low level of risk. The PSA results indicate that the AP1000 NPP design meets the higher expectations and goals for new generation passive PWRs.

The CDF and LRF for at-power internal events (excluding seismic, fire, and flood events) are 1.7E-07 events per reactor-year and 1.7E-08 events per reactor-year, respectively. These frequencies are at least two orders of magnitude less than a typical pressurized water reactor plant currently in operation. This reduction in risk is due to many plant design features, with the dominant reduction coming from highly reliable and redundant passive Class 1 systems that impact both at-power and shutdown risks. These passive systems are much less dependent on operator action and support systems than plant systems in current operating plants.

The CDF and LRF for at-power internal flood events are 4.4E-09 events per reactor-year and 1.2E-09 events per reactor-year, respectively. These frequencies are also at least two orders of magnitude less than a typical pressurized water reactor plant currently in operation. This reduction in risk is due to consideration of potential flood sources and propagation paths during the design of the AP1000 NPP structures that contain Class 1 equipment as well as the use of simple passive SSCs that are less dependent on support systems than systems in current operating plants.

The CDF and LRF for at-power internal fire events are 6.7E-07 events per reactor-year and 5.6E-08 events per reactor-year, respectively. This includes contribution from all credible

fire sources and unscreened fire compartments within the fire PSA global plant analysis boundary.

As discussed in Section 10.16, the external events evaluation concludes that there are no external hazards with an initiation frequency high enough to require further quantification.

The PSA based Seismic Margin Assessment (Section 10.18) provides results in terms of acceleration to show the plant is sufficiently robust for seismic events.

A synopsis of the insights gained from the PSA about the AP1000 NPP design includes:

- The AP1000 NPP design benefits from the high level of redundancy and diversity of the passive Class 1 systems. The passive systems have been shown to be reliable; their designs are simple so that a limited number of components are required to function.

- The AP1000 NPP is less dependent on non-Class 1 systems than current plants or advanced light water reactor evolutionary plants.

- The non-Class 1 support systems (ac power, component cooling water, service water, and instrument air) have a limited role in the plant risk profile because the passive Class 1 systems do not require cooling water or ac power.

- The AP1000 NPP is less dependent on human actions than current plants or advanced light water reactor evolutionary plants. Even when no credit is taken for operator actions, the AP1000 NPP meets the United States Nuclear Regulatory Commission (US NRC) safety goal, whereas current plants may not.

- Single system or component failures are not overly important due to the redundancy and diversity of Class 1 systems in the design. For example, the following lines of defence are available for reactor coolant system (RCS) makeup:

  – CVS

  – CMTs

  – Partial automatic depressurization system in combination with normal residual heat removal

  – Full automatic depressurization system with accumulators and in-containment refuelling water storage tank

  – Full automatic depressurization system with core makeup tanks and in-containment refuelling water storage tank

- Typical current PSA dominant IEs are significantly less important for the AP1000 NPP. For example, the RCP seal LOCA event has been eliminated as a core damage initiator since AP1000 NPP uses sealless reactor coolant pumps. Another example is the LOOP event. The station blackout and loss of offsite power event is a minor contributor compared to legacy plants to AP1000 NPP since the passive Class 1 systems do not require the support of ac power.

- Passive Class 1 systems are available in all shutdown modes. Planned maintenance of passive features is only performed during shutdown modes when that feature is not risk important. In addition, planned maintenance of non-Class 1 defence-in-depth features used during shutdown is performed at power when these systems are less risk important.

- The potential for containment isolation and containment bypass is lessened by having fewer penetrations to allow fission product release. In addition, normally open and risk important penetrations are fail-closed, thus eliminating the dependence on C&I and batteries for these penetrations.

- The reactor vessel lower head has no vessel penetrations, thus eliminating penetration failure as a potential vessel failure mode. Preventing the relocation of molten core debris to the containment eliminates the occurrence of several severe accident phenomena, such as ex-vessel fuel-coolant interactions and core-concrete interaction, which may threaten the containment integrity. Therefore, AP1000 NPP, through the prevention of core debris relocation to the containment, significantly reduces the likelihood of containment failure.

- The potential for the spreading of fires and floods to Class 1 equipment is reduced by the AP1000 NPP layout.

10.20.2 Use of PSA in the Design Process

The AP1000 NPP design has evolved over a period of years, including the work done for the AP600 design. PSA techniques have been used since the beginning in an iterative process to optimize the AP600/AP1000 NPP with respect to public safety. Each of these iterations has included:

- Development/refinement of the PSA model
- Use of the model to identify weaknesses
- Quantification of PSA benefits of alternate designs and operational strategies
- Adoption of selected design and operational improvements.

The scope and detail of the PSA model has increased from the early studies as the plant design has matured. This iterative design process has resulted in a number of design and operational improvements.

10.20.3 Core Damage Frequency from Internal Initiating Events at Power

Internal IEs are transient and accident initiators that are caused by plant system, component, or operator failures. External IEs, which include internal fire and flooding events and events at shutdown, are discussed in other subsections.

The AP1000 NPP mean plant core damage frequency for internal IEs at power is calculated to be 1.7E-07 events per year. Forty-four separate IEs were defined to accurately represent the AP1000 NPP design. Of these IEs 22 are loss-of-coolant accidents and 22 are transients. Initiating events unique to the AP1000 NPP design have been defined and evaluated, including direct vessel injection line breaks, core makeup tank line breaks, and passive residual heat removal heat exchanger (HX) tube ruptures and line breaks, and spurious actuation of core makeup tanks, passive residual heat removal, depressurizing valves, and IRWST injection and circulation. The resulting core damage frequency is very small; a value of 1.7E-07 means that only one core damage event is expected in 5.8 million plant-years of

operation. This core damage frequency value is two orders of magnitude (i.e., 100 times) smaller than corresponding values typically calculated for current pressurized water reactors.

The contribution of IEs to the total plant core damage frequency is summarized in Table 10-61. Figure 10-3 illustrates the relative contributions to core damage frequency from the various at-power IEs.

The top five IEs contribute 70 percent of the total at-power plant core damage frequency. The remaining IEs contribute a total of approximately 30 percent to the core damage frequency from internal events. The dominant IEs are:

- Small Loss-of-Coolant Accident
- Reactor Vessel Rupture
- Spurious IRWST Recirculation
- Loss of Offsite Power
- Steam generator tube rupture

Within this group of events, each of the first three contributes 8 percent or more to the total core damage frequency. These three events account for approximately 58 percent of the total core damage frequency. The next five events each contribute less than 4 percent to the total core damage frequency and account for an additional 15 percent to the total core damage frequency.

The results show a very low core damage frequency dominated by primarily rare events (IEs that are not expected to occur during the lifetime of a plant). This indicates that the AP1000 NPP design is robust with respect to its ability to withstand challenges from more frequent events (e.g., transients) and that adequate protection against the more severe events is provided through the defence-in-depth features.

The CDF uncertainty results show an approximately normal distribution when displayed on a log scale. This indicates that the overall uncertainty associated with CDF can be represented by a lognormal distribution. The range between the 5th and 95th percentiles indicates an error factor of approximately 3 for a lognormal distribution.

10.20.3.1 Dominant Core Damage Sequences

The dominant sequences which contribute approximately 90 percent of the total are given in Table 10-62.

The top five dominant accident sequences make up nearly 50 percent of the core damage frequency. These sequences are:

1. Sequence SLOCA-008 is the most dominant contributor to CDF at 13.4 percent. This sequence is a small LOCA followed by successful reactor trip, secondary side pressure relief, actuation of PRHR, and CMT injection. ADS Stages 2-3 are successful; however, ADS Stage 4 fails which prevents gravity injection from the IRWST. Core damage occurs due to failure of injection via the RNS.

2. The second dominant sequence is SPRECIRC-37 which contributes 9.5 percent to the total CDF. This sequence represents a spurious PXS recirculation actuation followed by failure of the operator to isolate the recirculation pathway, success of reactor trip, and successful secondary side pressure relief. MFW and SFW fail which prevents successful secondary side heat removal. PRHR decay heat removal and passive and active injection

are not credited due to the reduced IRWST level. With failure of both passive and active decay heat removal the sequence goes to core damage.

3. The third most dominant sequence is SLOCA-002 and contributes 8.8 percent to the total CDF. A small LOCA occurs followed by successful reactor trip, secondary side pressure relief, and actuation of PRHR and CMT injection. ADS Stages 2-3 and ADS Stage 4 are successful, as is gravity injection from the IRWST. Core damage occurs due to failure of recirculation via the containment sump.

4. Sequence SLOCA-005 is the fourth most dominant sequence and contributes 8.0 percent to the total CDF. This sequence represents a small LOCA followed by successful reactor trip, secondary side pressure relief, and actuation of PRHR and CMT injection. ADS Stages 2-3 and ADS Stage 4 are successful, but, gravity injection from the IRWST and RNS injection from the IRWST fail.

5. Sequence SLOCA-022 is the fifth most dominant sequence and contributes 6.8 percent to the total CDF. This sequence represents a small LOCA followed by successful reactor trip, secondary side pressure relief, and actuation of PRHR. CMT injection fails. ADS Stages 2-3 are successful, but ADS Stage 4 fails. Core damage occurs due to subsequent failure of injection via the RNS.

10.20.3.2 Sensitivity Analyses Summary for At-Power Core Damage

Importance and sensitivity analyses were performed on the core damage model for internal IEs at power.

The analyses were chosen to address the following issues:

- Importance of individual basic events and their effect on plant core damage frequency
- Importance of Class 1 and non-Class 1 systems in maintaining a low plant core damage frequency
- Effect of human reliabilities as a group on plant core damage frequency

The sensitivity analyses results show that:

- The common cause failure basic events, particularly those associated with Class 1 systems, are important individually, and also as a group for plant core damage frequency. This is expected for a plant with highly redundant Class 1 systems, for which individual component random failure contributions are of reduced significance.
- A sensitivity analysis is made for the unavailability of all non-Class-1 systems. The plant CDF obtained is 1.4E-04. This sensitivity analysis shows that the passive Class-1 and non – Class-1 systems are needed to support the current low level of core damage frequency for internal events.
- The most important systems by risk achievement worth (RAW) and risk reduction worth (RRW) are the PMS, RCS, PXS, and PCS. The only non-Class 1 systems identified by the importance measures were RNS and ECS.

- If no credit is taken for operator actions, the plant core damage frequency is 1.8E-05 events per year. This compares well with core damage frequencies for existing plants where credit is taken for operator actions.

- If the squib valve component failure probability is increased by a factor of 10, the resulting plant core damage frequency is 7.33E-07 events per year. This sensitivity case included recalculating squib valve CCF equations based on the increased component failure probability.

10.20.4 Large Release Frequency for Internal Initiating Events at Power

The results of the Level 2 (containment response) analysis for the internal IEs PSA at power demonstrate that the AP1000 NPP containment design is robust in its ability to prevent releases following a severe accident and that the risk to the public due to severe accidents for AP1000 NPP is very low. The LRF of the AP1000 NPP can be divided into two types of failures: 1) initially failed containment, in which the integrity of the containment is either failed due to the IE or never achieved from the beginning of the accident; and 2) containment failure induced by high-energy severe accident phenomena. The total of these failures is the overall large release frequency. LRF is composed of three release categories: 1) LERF, 2) large intermediate release frequency (LIRF), and 3) large venting release frequency (LVRF). The LERF category includes releases to the environment which are greater than nominal containment leakage and occur during core relocation. The LIRF category includes releases to the environment which are greater than nominal containment leakage and occur after core relocation, but within 24 hours of core damage. The LVRF category includes releases to the environment from a containment vent which are greater than nominal containment leakage. The total of these frequencies is the overall LRF.

The overall LRF for AP1000 NPP is 1.7E-08 events per year. This is approximately 10 percent of the core damage frequency for internal IEs at power. The ability of the containment to prevent releases (i.e., the containment effectiveness) is approximately 90 percent.

The LRF uncertainty results show an approximately normal distribution when displayed on a log scale. The range between the 5th and 95th percentiles indicates a lognormal error factor of approximately 10 for the LRF release category.

10.20.4.1 Plant Damage State Importance

Each of the PDSs was evaluated and the top state by frequency was a high pressure scenario with ADS Stages 1-3 actuation and failure of IRWST injection (H2I) with 30 percent of core damage. Second and third highest by frequency PDS were high pressure scenarios with failure of ADS Stages 1-4 actuation (HN) or partial automatic depressurization system with failure of passive and active (normal residual heat removal systems) IRWST injection (H1I). The “H” designators indicate the RCS pressure at the initiation of the event is considered high. The top three by frequency PDS contribute over 70 percent of core damage.

10.20.4.2 Dominant Contributors to Large Release Frequency Sequences

The LRF is dominated by the LERF-BYPASS category with 32 percent of the LRF. The second dominant LRF is LERF-EV2 with 26 percent. The dominant component failures by RAW are primarily due to common cause failure of PMS components which prevent automatic actuation of the Class 1 systems. The most significant operator error by RAW is the failure to recognize the need to actuate PRHR.

The dominant IE in the LERF is SLOCA which contributes approximately 29 percent. The next most dominant contributor is a SGTR which contributes approximately 28 percent to the total LERF.

10.20.5 Results of Internal Flooding Assessment

The AP1000 NPP design philosophy of minimizing the number of potential flooding sources along with the physical separation of redundant Class 1 components and systems from each other and from non-Class 1 components, minimizes the consequences of internal flooding. The core damage frequencies from flooding events at power are not an appreciable contributor to the overall AP1000 NPP core damage frequency. The CDF and LRF for at-power internal flood events are 4.4E-09 events per reactor-year and 1.2E-09 events per reactor-year, respectively.

10.20.6 Results of Internal Fire Assessment

The AP1000 NPP design philosophy of separation of Class 1 circuits and equipment along with physical separation of redundant Class 1 components and systems from each other and from non-Class 1 components minimizes the consequences of internal fires. The CDF and LRF for at-power internal fire events are 6.7E-07 events per reactor-year and 5.6E-08 events per reactor-year, respectively. This includes contribution from all credible fire sources and unscreened fire compartments within the fire PSA global plant analysis boundary. The fire-induced CDF is driven by the fire failing DAS combined with independent failure of the automatic and manual PMS. If only the automatic PMS signal fails, the manual operator actions to respond to this loss of automatic signal fail. This loss of redundant signaling capability fails many sequences required to mitigate core damage such as PRHR, CMT injection, steam generator cooling, and depressurization. LRF results are driven by fire-induced loss of the VLS hydrogen igniters, as well as fire-induced failures to isolate containment. Figure 10-1 shows the Internal Fire CDF by building or location. Figure 10-2 shows the Internal Fire LRF by building or location. The top fire compartments contributing to CDF are discussed in Table 10-56. The top fire compartments contributing to LRF are discussed in Table 10-57.

The results from the Fire PSA led to evaluations in the ALARP assessment centred on cable routing, separation of hydrogen igniter power supplies, ADS valve cable design, and fire protection system detection and suppression. The at-power Fire PSA results demonstrate that the CDF and LRF are below the Basic Safety Level (BSL) and Basic Safety Objective (BSO) Target 8, and therefore a graded approach is appropriate to demonstrate ALARP considerations for the at-power Fire PSA (refer to Section 10.23). Therefore, it is recognised that although ALARP is not directly required for the Fire PSA, it was performed to show how potential enhancements with small plant impacts were considered.

10.21 Review of Uncertainties

The PSA results are subject to some uncertainty, arising from various limitations in the way they were derived. This section reviews those limitations, and shows that the resulting uncertainty does not affect the conclusions drawn in this report from the results.

Limitations that could affect the PSA results are considered under the following categories:

- Limitations in scope
- Limitations in methodology
- Uncertainty in the validity of assumptions

- Uncertainties in reliability data
- Uncertainties in CCF data
- Uncertainties in Level 2/Level 3 source terms
- Uncertainties in the underpinning deterministic analysis

10.21.1 Limitations in Scope

10.21.1.1 Non-reactor Faults

The PSA does not (by definition) consider sources of radiation outside the reactor. However, the risks and dose-frequencies from accidents involving such sources are assessed separately in Chapter 9 of this PCSR and added to the corresponding figures for reactor accidents to allow a further comparison with the UK numerical targets to be made.

10.21.1.2 Seismic

As noted in Section 10.4.10 above, so far, only an SMA has been done, and not a Seismic PSA.

10.21.1.3 External Hazards

When a complete treatment of external hazards is included in the PSA, it is inevitable that the CDF and the LRF will increase, since they will then take into account additional IEs. The main reason for expecting that this increase will be small is that the design of the AP1000 is exceptionally robust against loss of external provisions. Excepting seismic events (which are treated separately), in general, the main threat from external hazards comes from their potential to disable either the external grid (and at the same time increase the chance of failure of the diesel generators) or the service water/component cooling water ultimate heat sink. The risk importance of the diesel generators and the component cooling/service water systems is very low because the passive Class-1 systems require neither ac power nor cooling to heat exchangers or to pumps. Furthermore, those passive systems are housed within the reactor containment and as such, have the best possible protection from external influences. In addition, the passive Class-1 systems are fail safe (requiring no electrical power or C&I) for non-LOCA faults.

The consequences of this robustness are already demonstrated in the PSA, as can be seen in Figure 10-2. Although the PSA assumes IE frequencies of greater than 1E-1/yr for both LOOP and loss of service water/component cooling, the contribution to CDF from each of these events is less than 1E-9/yr. It is inconceivable that external initiators having the same net effect could have frequencies of comparable magnitude, and their contribution to CDF will, therefore, be much less.

10.21.1.4 Human Factors Scope Limitations

Since the PSA model was developed, the human factors (HF) aspects of the AP1000 design safety case have been significantly revised, and this revision is continuing. As a consequence of the revisions, limited HEPs used in the PSA have been substantiated by human factors (refer to Chapter 13).

10.21.2 Limitations in Methodology

10.21.2.1 Methodology for Level 3 Dosimetry

The calculation of doses in the Level 3 treatment of the PSA was performed using a methodology which does not comply with current UK guidelines (Reference 10.1) in the following two significant ways:

- Dose coefficients are based on ICRP30, rather than on ICRP72, as required by Reference 10.1.

- No account is taken of doses from groundshine and ingestion, which must be considered according to Reference 10.1.

From a detailed comparison of representative calculations performed according to the two different approaches, it is estimated that an upper bound to the dose "as it would be calculated following the UK guidelines" is obtained by multiplying the dose as calculated in the PSA by a factor of six. This is explained in more detail above in Section 10.5, where the adjustment is made for the purpose of comparison with the ONR numerical targets.

10.21.3 Uncertainty in Level 2/Level 3 Source Terms

The source terms and Level 3 analysis have not been updated and, therefore, do not reflect the updated Plant Damage States of the Level 2 internal events model.

The Level 2 PSA identified six containment end states, or RCs. For each RC, a single combination of PDS and CET path was selected for the calculation of a source term. A single source term was calculated for each RC.

For the RCs "intact containment" and "bypassed containment", it was relatively straightforward to identify a single PDS/CET path whose resulting best estimate source term would be bounding in terms of overall dose, even though it was not separately bounding in terms of quantity of each isotope released (Reference 10.5).

For the four RCs that involved containment failure, there were large numbers of PDS/CET paths that were similar in terms of the parameters affecting the best estimate source term development. To identify from all of these the one best estimate source term that was bounding in terms of dose would have required a large number of complicated deterministic calculations, each followed by a dose calculation. This was considered to be impractical, but more importantly, it was also considered to be unnecessary because the variation in source term between PDS/CET paths was believed to be small compared with the uncertainty in the finally calculated source term due to the inherent uncertainty in the calculation process, i.e., in the analysis of fission product transport from fuel to environment. In other words, the variations in best estimate source term are far overshadowed by the change in source term for fission product modelling uncertainties. The procedure adopted, therefore, was to select a single representative PDS/CET path for each RC, and then to perform a detailed sensitivity analysis to determine the effect on the calculated source term of varying the important modelling options and assumptions in the fission product transport analysis (Reference 10.5). The set of options and assumptions that gave the largest source term was then used to perform the definitive source term calculation.

As a consequence of following this procedure for the four failed containment RCs, there is high confidence that the source terms finally assigned to the end states bound any real release

because of the use of conservative modelling assumptions throughout the fission product transport analysis. This remains true, even though it is also likely that there are other PDS/CET paths which would have given slightly greater calculated source terms with the same set of modelling assumptions (and would, therefore, be even more bounding). In other words, numerical manipulations of the source term to obtain an absolute worst case, bounding source term considering all uncertainties would provide no further insights related to design or operational changes. Therefore, the existing analyses are adequate to demonstrate that the risks are ALARP.

10.22 Planned Update to the Reactor PSA

The next planned update to the AP1000 plant PSA will be to support site licensing of the AP1000 plant in the UK. The PSA will be updated to reflect a DRP that includes site specific design and address UK site licensing requirements to work towards the UK Technical Assessment Guides (TAGs).

Key items for future consideration include the following:

1. There is an uncertainty concerning the piping response to a spurious actuation of one or more ADS Stage 4 valves at-power. The piping is not designed for valve actuation at full RCS pressure. To construct the event tree, assumptions were made regarding the consequences of spurious actuation.

2. For the spurious IRWST actuation IE, there is an uncertainty of the plant consequences that result if the check valve(s) upstream of the spuriously opened IRWST squib valve(s) have an internal failure. The check valve failure would result in a LOCA into the IRWST. This condition has not been evaluated and is taken to core damage if two or more sets of valves (IRWST squib and its check valve) fail. The failure of one IRWST valve and its check valve is treated as a DVI LOCA.

3. Common cause of all PMS and PLS software are modelled. There is currently no accepted methodology for modelling and quantifying software reliability. It is not known whether the scope and level of detail of these failures is appropriate or whether all possible failures have been accounted for.

10.23 Conclusions

As the PSA continues to evolve and move toward a site-specific PSA, the safety assessment principles (SAPs, Reference 10.77) are also reviewed and assessed. Not all SAPs that use probabilistic methods are documented, but a subset to summarize the PSA results are documented here. PSA methods are used throughout the design process to support and compliment deterministic methods as documented with other safety cases. As the PSA develops into a site-specific PSA, the SAPs will continue to be used to enhance the PSA.

SAP	Description	PSA Comments
FA.10	*"Suitable and sufficient PSA should be performed as part of the fault analysis and design development and analysis."*	PSA is used as an integral part of the design and analysis. The scope and depth of the PSA at this stage of the design is documented throughout Chapter 10. A comprehensive PSA has been developed but will continue to evolve as the design develops and moves toward site-licensing.
FA.11	*"PSA should reflect the current design and operation of the facility or site."*	At this point in the design, a site-specific PSA has not been evaluated. However, the overall goal of the generic design PSA to influence the design and support the overall risk assessment of the plant has been achieved.
FA.12	*"PSA should cover all significant sources of radioactivity, all permitted operating states and all relevant initiating faults."*	The scope of the PSA will continue to evolve as site-licensing approaches. Some areas in Chapter 10 have not been updated for the generic design assessment.
FA.13	*"The PSA model should provide an adequate representation of the facility and/or site."*	The PSA is a comprehensive model and analysis that assesses the design and generic site.
FA.14	*"PSA should be used to inform the design process and help ensure the safe operation of the site and its facilities."*	The PSA has been used in ALARP activities and has been used to understand the overall risk of the plant to support design decisions.
FA.15	*"Fault states, scenarios and sequences beyond the design basis that have the potential to lead to a severe accident should be analysed."*	The severe accident analysis (SAA) uses a systematic approach to analysis beyond design basis states and scenarios.
FA.16	*"Severe accident analysis should be used in the consideration of further risk-reducing measures."*	SAA has been used in the overall design process as part of ALARP assessments and design investigations.
FA.25	*"The severe accident analysis should be performed in a manner complementary to the DBA and PSA, so that each type of analysis informs the others in a mutually consistent manner within the facility's safety case."*	The SAA has and will continue to be used as part of the PSA which will continue to assess against the fault study's conclusions.

The essence of demonstrating that risks have been reduced ALARP is to show that the costs of improving safety any further would be grossly disproportionate to the effort of implementing improvements compared to the current design. From Reference 10.77, paragraph 698, "It is ONR's policy that a new facility or activity should at least meet the BSLs. However, even if the BSLs are met, the risks may not be ALARP; in such cases the designer/dutyholder must reduce the risks further. Deciding when the level of risk is ALARP needs to be justified by the designer/dutyholder on a case-by-case basis, applying the legal test of gross disproportion. A graded approach should be used so that the higher the risk (or hazard), the greater the degree of disproportion applied, and the more robust the argument needed to justify not implementing additional safety measures."

Additionally, paragraph 710, states "The BSOs also recognise that there is a level beyond which further consideration of the safety case would not be a reasonable use of ONR

resources, compared with the benefit of applying these resources to areas of higher risk. Inspectors therefore need not seek further improvements from the designer/dutyholder but can confine themselves to assessing the validity of the arguments presented."

The CDF and LRF values for the at-power PSA results (Internal Events, Internal Flooding, and Internal Fire) which assess the total per reactor year core damage or large early releases are summarized below:

	CDF	LRF
At-Power Internal Events	1.7E-07	1.7E-08
At-Power Internal Flooding	4.4E-09	1.2E-09
At-Power Internal Fire	6.7E-07	5.6E-08
Total At-Power PSA (sum of listed contributors)	**8.4E-07**	**7.4E-08**

Target 8 is the target for the total predicted frequencies of accidents on an individual facility per annum which would give doses to a person off the site. These targets were compared to the CDF and LRF values for the at-power PSA results (Internal Events, Internal Flooding, and Internal Fire).

BSL Target 8 1E-04 pa

BSO Target 8 1E-06 pa

Target 9 is the target for the total risk of 100 or more fatalities, either immediate or eventual, from accidents at the site resulting in exposure to ionising radiation. This parameter will be highly site specific and cannot be calculated precisely in a generic assessment. Nevertheless, a simplified assessment can be made that assumes that all large releases (i.e., with the containment not intact) will result in more than 100 fatalities, either immediate or eventual, and no other events will result in that number of fatalities. In this case, these targets were compared to the total LRF value for the at-power PSA results (Internal Events, Internal Flooding, and Internal Fire).

BSL Target 9 1E-05 pa

BSO Target 9 1E-07 pa

The AP1000 at-power PSA risk demonstrates margin to the Target 8 and Target 9 BSO as shown above. Since it is anticipated that the AP1000 plant at-power PSA will continue to meet the BSO, there is little need to further reduce the AP1000 at-power PSA risk.

Table 10-4. LLOCA Event Tree Description

Top Event	Top Event Description
ACC	The accumulators are designed to deliver a large volume of borated water to the reactor vessel (RV) at a high flowrate in the event of an LLOCA. The success of this top event (ACC-1) requires one out of two accumulators to inject into the direct vessel injection (DVI) line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads to core damage because the core reflood does not occur in time.
CMT	The success of this top event (CMT-2-PA-DA) requires two out of two core makeup tanks (CMTs) to inject. Each CMT must inject through one out of two parallel valves on the discharge piping, and at least one must provide a CMT actuation signal to ADS. Failure of this top event leads directly to core damage because there is insufficient water inventory for the core and insufficient time for operator action.
IRWST	The success of this top event (IRWST-1-PA) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event leads directly to core damage because there is insufficient water inventory for the core and insufficient time for operator action.
ADS4	For the most likely LLOCA sequences, the ADS Stage 4 valves are not required for successful IRWST gravity injection because the size of the LOCA sufficiently reduces the RCS pressure. However, there are conditions for which ADS relief is required. Once the break in the RCS is covered by the rising water level in containment, an open ADS Stage 4 valve is required to ensure there is adequate flow out of the RCS for proper core cooling. In addition, if containment isolation fails, an ADS Stage 4 valve is required to ensure that the RCS pressure is low enough for IRWST injection and recirculation. The success criteria for this top event (ADS4-2L-PA) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. If ADS4 fails, the sequence goes to core damage because there is insufficient RCS venting for the passive recirculation function.
RECIRC	This top event is associated with containment sump recirculation on a Protection and Safety Monitoring System (PMS) signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-5. MLOCA Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and Diverse Actuation System (DAS) reactor trip signals and operator action HEPO-RT using E-0. Void formation is not sufficient to shut down the reactor core. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
CMT	Due to timing considerations, credit is not taken for operator action to actuate the CMTs. The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping and a CMT actuation signal to ADS. The CMTs will be actuated automatically either through the PMS or DAS. If this top event fails, then accumulator injection is required to provide water to the RCS.
ACC	For MLOCAs, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure path of top event CMT.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event can lead to a non-core damage state if top event ADS4 is successful.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of top event ADS4 leads directly to core damage on the failure paths of ADS23 because there is insufficient RCS depressurization for IRWST or RNS injection. On success paths of ADS23, failure of ADS4 does not lead directly to core damage because there is sufficient RCS depressurization to allow RNS injection to be successful.

Table 10-5. MLOCA Event Tree Description (cont.)

Top Event	Top Event Description
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS ADS Stage 4 actuation signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS with operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the cask loading pit (CLP), then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-6. SLOCA Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Void formation is not sufficient to shut down the reactor core. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
SS FAULT	Because the SLOCA, especially on the small end of the break size range, can be a slow depressurization of the RCS, the initial part of the event is similar to a transient with a safeguards actuation signal (S signal). After reactor trip the secondary side relief valves will likely be challenged. The success for this top event (SGS-SS-PA-PLA) is defined as one out of two power-operated relief valves (PORVs) opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or main steam safety valve (MSSV) may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to secondary side failure event tree LOCA-SSFAULT.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX-L) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT using E-0. The success of this top event (CMT-1-PX-DX) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four reactor coolant pumps (RCPs) to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.

Table 10-6. SLOCA Event Tree Description (cont.)

Top Event	Top Event Description
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. There are three branch names and two sets of success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2, ADS23-3-PX-DM-C1). The success criteria for ADS23-2-PX-DM-C1 and ADS23-2-PM-DM-C2 are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the top CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure paths because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. The success criteria for ADS23-3-PX-DM-C1 are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. If top events PRHR and CMT are successful and ADS23 fails, core damage can be prevented by successful operation of ADS4 and IRWST or RNS injection.
ACC	For SLOCAs, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS4 does not lead directly to core damage if sufficient RCS depressurization has occurred to enable RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS ADS Stage 4 actuation signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.

Table 10-6. SLOCA Event Tree Description (cont.)

Top Event	Top Event Description
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS with operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the cask loading pit (CLP), then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-7. LEAK Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. An RCS Leak initiator not mitigated by CVS requires a reactor trip. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
SS FAULT	Because the RCS leak is a slow depressurization of the RCS, the initial part of the event is similar to a transient with an S signal. After reactor trip the secondary side relief valves will likely be challenged. The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to secondary side failure event tree LOCA-SSFAULT.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX-L) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT using E-0. The success of this top event (CMT-1-PX-DX-BD) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.

Table 10-7. LEAK Event Tree Description (cont.)

Top Event	Top Event Description
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. There are different success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2, ADS23-3-PX-DM-C1). For ADS23-2-PX-DM-C1 and ADS23-2-PM-DM-C2, success is two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the top CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure paths because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. For ADS23-3-PX-DM-C1, success is three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. If top events PRHR and CMT are successful and ADS23 fails, core damage can be prevented by successful operation of ADS4 and IRWST or RNS injection.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS4 does not lead directly to core damage if sufficient RCS depressurization has occurred to enable RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS ADS Stage 4 actuation signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.

Table 10-7. LEAK Event Tree Description (cont.)

Top Event	Top Event Description
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS with operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the cask loading pit (CLP), then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-8. SPADS13 Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Void formation is not sufficient to shut down the reactor core. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
CMT	Similar to the MLOCA event, credit is not taken for operator action to actuate the CMTs due to timing considerations. The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. The spurious opening of some number of ADS Stages 1-3 valves initiates this event. The success criteria require two out of four ADS Stages 2 and 3 valves (similar to what is required for the traditional MLOCA) in addition to the valve(s) that opened causing the IE. If all of the ADS Stages 1-3 valves spuriously open, then there is no failure of this top event. The success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST in addition to the valve(s) that opened causing the IE. ADS23-2-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated.

Table 10-8. SPADS13 Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS4 leads directly to core damage on the failure paths of ADS23 because there is insufficient RCS depressurization for IRWST or RNS injection. On success paths of ADS23, failure of ADS4 does not lead directly to core damage because there is sufficient RCS depressurization to allow RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS with operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the cask loading pit (CLP), then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-9. SPADS4 Event Tree Description

Top Event	Top Event Description
# ADS4 VALVES	This branch in the event tree separates the tree into different events based on the number of ADS Stage 4 valves that spuriously open. The top branch (SPADS4-2-IE) models either two ADS Stage 4 valves in the same compartment or all four ADS Stage 4 valves spuriously opening which results in an LLOCA. The top branch does not require a reactor trip because the LLOCA event has sufficient void formation in the core to shut down the reactor. The bottom branch (SPADS4-1-IE) models one ADS Stage 4 valve spuriously opening which results in an MLOCA event.
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. For an MLOCA, void formation is not sufficient to shut down the reactor core, a reactor trip is required. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
CMT	There are two sets of success criteria for this top event. For the top portion of the event tree, the success of this top event (CMT-2-PA-DA) requires two out of two CMTs to inject. Each CMT must inject through one out of two parallel valves on the discharge piping and at least one provides a CMT actuation signal to ADS. Failure of this top event leads directly to core damage because there is insufficient water inventory for the core and insufficient time for operator action. For the bottom portion of the event tree, the success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. For this case, the CMTs will be actuated automatically either through the PMS or DAS. Similar to the MLOCA event, credit is not taken for operator action to actuate the CMTs due to timing considerations. If this top event fails, then accumulator injection is required to provide water to the RCS.
ACC	For LLOCAs, the accumulators provide the initial reflooding of the core. The CMTs alone do not have sufficient volume to mitigate an LLOCA. For MLOCAs, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because there is insufficient makeup to the core.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event can lead to a non-core damage state if top event ADS4 is successful.

Table 10-9. SPADS4 Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-1-PA-S4, ADS4-1-PX-DM-S4-C1, ADS4-1-PM-DM-S4-C2) depend on the number of ADS Stage 4 valves that spuriously open. If two valves spuriously open, then the success criteria are one out of two ADS Stage 4 valves on the other loop actuating and providing a signal for IRWST gravity injection and recirculation (ADS4-1-PA-S4). If all four valves spuriously open, then only the signals for IRWST gravity injection and recirculation are required (ADS4-1-PA-S4). If one valve spuriously opens, then the success criteria are one out of two ADS Stage 4 valves on the other loop actuating and providing a signal for IRWST gravity injection and recirculation (ADS4-1-PX-DM-S4-C1, ADS4-1-PM-DM-S4-C2). ADS4-1-PX-DM-S4-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-1-PM-DM-S4-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. In the top portion of the event tree, failure of ADS4 leads directly to core damage because there is insufficient RCS venting for the passive recirculation function or the signal to open the IRWST valves fails. In the bottom portion of the event tree failure of ADS4 does not lead directly to core damage if ADS23 is successful because there is sufficient RCS depressurization to allow RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. There are two sets of success criteria for this top event (IRWST-1-PA, IRWST-1-PX-DM). For both sets, the success of this top event requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. No credit is taken for operator action for IRWST-1-PA because it is part of an LLOCA event. IRWST-1-PX-DM is modelled for an MLOCA event and credit for operator action is taken. In the bottom portion of the event tree, failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS with operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the cask loading pit (CLP), then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-10. SPIRWST Event Tree Description

Top Event	Top Event Description
# IRWST VALVES	This branch identifies the number of IRWST squib valves that spuriously open. The top branch (SPIRWST-2-IE) represents two or more IRWST squib valves spuriously opening. The bottom branch (SPIRWST-1-IE) represents one IRWST squib valve spuriously opening.
PXS CKV	This top event determines whether the check valve(s) upstream of the spuriously opened IRWST squib valve(s) remains intact and closed. In the top part of the event tree, success for this top event (IRWST-4-CKV) is four out of four check valves remain intact and closed. This bounds the cases of two or three valves spuriously opening. Success of this top event is transferred to the SLOCA event tree because the check valves are leaking RCS inventory into the IRWST through the 1/8” diameter hole in each check valve. Failure of this top event goes to core damage because of the uncertainty in the consequences that result from a larger LOCA into the IRWST, and because of failure of the piping upstream of the check valves, which is not designed for RCS pressure. In the bottom part of the event tree, success for this top event (IRWST-1-CKV) is one out of one IRWST check valve remains intact and closed. Success of this top event is transferred to the LEAK event tree because only one check valve is leaking into the IRWST. Failure of this top event is transferred to the DVILB event tree because the plant response is expected to be similar to failing a DVI line.

Table 10-11. CMTLB Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Void formation is not sufficient to shut down the reactor core. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT using E-0. For this event, one CMT is unavailable due to the pipe break. Similar to the MLOCA event, credit is not taken for operator action to actuate the CMTs due to timing considerations. The success of this top event (CMT-1-PA-DA) requires one out of one CMT (without the broken pipe) to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure path of top event CMT. If ACC fails, then there is no RCS makeup available prior to depressurization for IRWST injection and core damage occurs.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. There are two sets of success criteria for ADS23 (ADS23-3-PX-DM-C1, ADS23-2-PM-DM-C2). The success criteria for ADS23-3-PX-DM-C1 are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. For ADS23-2-PM-DM-C2 the success criteria are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-3-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event leads directly to core damage because RCS depressurization and IRWST or RNS injection does not occur quickly enough to prevent core damage.

Table 10-11. CMTLB Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS Stage 4 does not lead directly to core damage because there is sufficient RCS depressurization to allow RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because the RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-12. DVILB Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Void formation is not sufficient to shut down the reactor core. Like the MLOCA, this initiator requires a reactor trip. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to reactor trip failure event tree LOCA-NOTRIP.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT using E-0. The success of this top event (CMT-1-PA-DA) requires one out of one CMT (on the non-faulted DVI line) to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of one accumulator (on the non-faulted DVI line) to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure path of top event CMT. If ACC fails, then there is no RCS makeup available prior to depressurization for IRWST injection and core damage occurs.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. There are two sets of success criteria for ADS23 (ADS23-3-PX-DM-C1, ADS23-2-PM-DM-C2). The success criteria for ADS23-3-PX-DM-C1 are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. For ADS23-2-PM-DM-C2, the success criteria are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-3-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. To cover a range of DVI line break sizes, top event ADS23 success for RCS depressurization is required to successfully actuate ADS4. Therefore, failure of this top event leads directly to core damage.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-3-PX-DM-C1, ADS4-3-PM-DM-C2) are three out of four ADS Stage 4 valves actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-3-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-3-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS4 leads directly to core damage because there is insufficient RCS depressurization for IRWST injection.

Table 10-12. DVILB Event Tree Description (cont.)

Top Event	Top Event Description
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of two gravity injection line squib valves (on the non-faulted DVI line) to actuate and provide IRWST injection into the RV. Failure of this top event leads directly to core damage because RNS is unavailable for this event.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-13. PRHRLB Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Because this event covers a range of break sizes, it is modelled that void formation is not sufficient to shut down the reactor core; therefore, reactor trip is required. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in core damage because an ATWS event requires decay heat removal and the PRHR heat exchanger function fails due to the line break.
CMT	The success of this top event (CMT-2-PA-DA) requires two out of two CMTs to inject, four out of four RCPs to trip, and a CMT actuation signal to ADS. Each CMT must inject through one out of two parallel valves on the discharge piping. Failure of this top event leads directly to core damage because there is insufficient water inventory for the core and insufficient time for operator action.
ADS23	The success criteria for ADS23 (ADS23-3-PA) are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. Failure of this top event leads directly to core damage because depressurization and IRWST injection does not occur in time to prevent core damage.
ACC	To cover a range of break sizes, it is modelled that the CMTs alone do not have sufficient volume to mitigate the loss of RCS inventory. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure.
ADS4	The success criteria for this top event (ADS4-2L-PA) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. Failure of ADS4 leads directly to core damage because there is insufficient RCS depressurization for IRWST injection.
IRWST	The success of this top event (IRWST-1-PA) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event leads directly to core damage because no credit is taken for the operator to establish injection through the RNS.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. Operator action is included for this top event because switching from IRWST injection to recirculation will occur after more than 2 hours. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-14. SGTR Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to a reactor trip failure event tree.
SS FAULT	The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose, or one turbine bypass valve recloses. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in core damage if top event CMT also fails because the plant conditions are beyond those modelled in the success criteria analyses.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT using E-0. The success of this top event (CMT-1-PX-DX, CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. CMT-1-PX-DX is used on the success path of top event SS FAULT because there is sufficient time for operator action to initiate the CMTs. If CMT-1-PX-DX fails, then an accumulator is required on the RCS depressurization paths to provide RCS inventory makeup to prevent core damage. CMT-1-PA-DA is used on the failure path of top event SS FAULT because the path is treated like the secondary side break event trees and requires automatic actuation of the CMTs. Failure of CMT-1-PA-DA leads to core damage because a CMT is required to operate for secondary side break conditions.
PRHR	This top event is associated with PRHR actuation on a PMS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DM) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long-term cooling. Failure of this top event requires SFW or RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.

Table 10-14. SGTR Event Tree Description (cont.)

Top Event	Top Event Description
SFW	This top event is associated with SFW actuation on a PLS signal or operator action HEPO-SFWS using E-0, operator action HEPO-SFWCD using ES-0.4 to perform the plant cooldown with SFW, and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLX-C-SGTR) requires one out of two SFW pumps providing flow through the SFCV to the intact SG removing decay heat from the RCS and the operator action to control the cooldown. In addition, one out of two blowdown isolation valves close on the intact steam generator, and one SG PORV must operate to dump the steam from the intact SG. This top event also includes the refill of the CST. Failure of this top event requires RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
I&I	This top event is associated with operator action HEPO-SGI using E-3 to isolate the faulted SG. The success of this top event (SGI-1-PLM) requires the ruptured SG to be isolated by the closure of the valves listed in E-3 including CVS isolation to the ruptured SG. In addition, the MFW line to the ruptured SG must be isolated (this occurs on the S signal). SG cooldown using SFW is not credited if this top event fails because SFW may be isolated on a High SG level signal. If this top event fails, core damage can be prevented by successful SG overfill protection and PRHR operation, or by RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation.
OFILL	This top event is associated with the PMS automatic protection features to prevent SG overfill and operator action HEPO-OFILL using E-3. The success of this top event (SGI-1-PX) requires the termination of CVS, and SFW flow to both SGs. In addition, the MFW line to the ruptured SG must be isolated (this occurs on the S signal). If this top event fails, RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation is needed to prevent core damage.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1-SGTR or HEPO-ADS-C2-SGTR using E-3. The success criteria for ADS23 (ADS23-2-PX-DM-C1-SGTR, ADS23-2-PM-DM-C2-SGTR) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. The event tree branch names include a "–SGTR" because the associated operator action for the SGTR event is based on E-3. ADS23-2-PX-DM-C1-SGTR is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2-SGTR is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event leads to core damage.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only when top event CMT has failed.

Table 10-14. SGTR Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of ADS4 leads directly to core damage.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of top event IRWST does not directly lead to core damage because sufficient RCS depressurization occurs and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long-term cooling is not established.

Table 10-15. ISL-CVS Event Tree Description

Top Event	Top Event Description
ISO	This top event is associated with a PMS signal to isolate CVS and operator action HEPO-CVSISO using ECA-1.1 or HEPO-CVSISO-Z using E-0. This top event is for the isolation of the RCS leak outside containment. On a PMS Low-1 pressuriser water level signal valves CVS-PL-V001, -002, and -003 close to prevent uncovering of the pressuriser heater elements. The success of this top event (CVSISO-PX-CIE) varies based on the specific CVS ISLOCA event. The system fault tree logic addresses the appropriate success criteria for the specific ISLOCA event. Failure of this top event leads to core damage because RCS inventory is continually lost outside containment.
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using in E-0. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to the ATWS-LMFW event tree.
SS FAULT	Because the ISLOCA, especially on the small end of the break size range, can be a slow depressurization of the RCS, the initial part of the event is similar to a transient with an S signal. After reactor trip and isolation of the leak, the secondary side relief valves will likely be challenged. The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose, or one turbine bypass valve recloses. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to steam line break (SLB) upstream of the main steam isolation valves (MSIVs) event tree SLBU.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires Startup Feedwater (SFW) or RCS depressurization and IRWST or RNS injection to prevent core damage.

Table 10-15. ISL-CVS Event Tree Description (cont.)

Top Event	Top Event Description
SFW	This top event is associated with SFW actuation on a Plant Control System (PLS) signal or operator action HEPO-SFWS following E-0 or HEPO-SFWM following FR-H.1, and operator action for refilling the condensate storage tank (CST) following the CST alarm response procedure. The success of this top event (SFW-1-PLX-C) for decay heat removal requires one out of two SFW pumps providing flow through one out of two startup feedwater control valves (SFCVs) to one out of two steam generators (SGs), and one out of two blowdown isolation valves close on the SG loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT-GT using FR-H.1. The success of this top event (CMT-1-PX-DX-GT) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-GT using FR-H.1. There are different success criteria for ADS23 (ADS23-3-PX-DM-GT, ADS23-2-PM-DM-GT). The success criteria for ADS23-3-PX-DM-GT are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. ADS23-3-PX-DM-GT is used on the CMT success path because both automatic and manual actuations via the PMS are possible. The success criteria for ADS23-2-PM-DM-GT are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PM-DM-GT is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event leads directly to core damage because decay heat removal has been lost and the RCS pressure is not low enough to successfully use the ADS Stage 4 valves.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.

Table 10-15. ISL-CVS Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because automatic actuation via the PMS is not available. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1 (note that E-1 would be entered from FR-H., or E-0). The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-16. GTRAN-WS Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Note that a spurious S signal will also cause a reactor trip in the PMS. Reactor trip (RT-PX-DX-LOCA) is successful when the control rods are inserted into the core and reactivity control is achieved. RT-PX-DM-LOCA is used because the IE is a spurious S signal. Failure of this top event results in a transfer to the ATWS-LMFW event tree.
SS FAULT	The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose, or one turbine bypass valve recloses. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to SLB upstream of the MSIVs event tree SLBU.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires SFW or RCS depressurization and IRWST or RNS injection to prevent core damage.
SFW	This top event is associated with SFW actuation on a PLS signal or operator action HEPO-SFWS following E-0 or HEPO-SFWM following FR-H.1, and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLX-C) for decay heat removal requires one out of two SFW pumps providing flow through one out of two SFCVs to one out of two SGs and one out of two blowdown isolation valves close on the SG loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.

Table 10-16. GTRAN-WS Event Tree Description (cont.)

Top Event	Top Event Description
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT-GT using FR-H.1. The success of this top event (CMT-1-PX-DX-GT) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. No credit is taken for CMT actuation on the S signal that initiated the event. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-GT using FR-H.1. There are different success criteria for ADS23 (ADS23-2-PM-DM-GT, ADS23-3-PX-DM-GT). For ADS23-2-PM-DM-GT, success is two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PM-DM-GT is used on the CMT failure paths because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. For ADS23-3-PX-DM-GT, success is three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. Failure of this top event leads directly to core damage because RCS depressurization and IRWST or RNS injection does not occur quickly enough to prevent core damage.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.

Table 10-16. GTRAN-WS Event Tree Description (cont.)

Top Event	Top Event Description
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-17. GTRAN Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Reactor trip (RT-PX-DX) is successful when the control rods are inserted into the core and reactivity control is achieved. Failure of this top event results in a transfer to the ATWS event tree.
SS FAULT	The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose, or one turbine bypass valve recloses. Credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to SLB upstream of the MSIVs event tree SLBU.
MFW	This top event is associated with MFW cooling using the PLS or operator action HEPO-MFW using ES 0.1. The loss of MFW IE, and support system IEs that result in the loss of MFW, fail this top event and are addressed in the system fault tree logic and the logic for the quantification model. The success of this top (MFW-1-PLX) event is one booster/MFW pump supplying water through two out of two SFCVs (one per loop) to two out of two SGs and one turbine bypass valve dumping steam to the condenser. Failure of this top event requires decay heat removal from the SFW system, the PRHR system, or RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
SFW	This top event is associated with SFW actuation on a PLS signal or operator action HEPO-SFWX using ES-0.1 and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLX) for decay heat removal requires one out of two SFW pumps providing flow through two out of two SFCVs (one per loop) to two out of two SGs, and one out of two blowdown isolation valves close on each loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires operation of the PRHR system or RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS or operator action HEPO-PRHR-GT using ES-0.1. The success of this top event (PRHR-PX-DX-GT) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.

Table 10-17. GTRAN Event Tree Description (cont.)

Top Event	Top Event Description
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT-GT using FR-H.1. The success of this top event (CMT-1-PX-DX-GT) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-GT using FR-H.1. There are different success criteria for ADS23 (ADS23-2-PM-DM-GT, ADS23-3-PX-DM-GT). For ADS23-2-PM-DM-GT, success is two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PM-DM-GT is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. For ADS23-3-PX-DM-GT, success is three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. Failure of this top event leads directly to core damage because RCS depressurization and IRWST or RNS injection does not occur quickly enough to prevent core damage.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E 1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.

Table 10-17. GTRAN Event Tree Description (cont.)

Top Event	Top Event Description
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-18. LOOP Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	For the LOOP event, power is lost to the control rod drive mechanisms and the rods fall into the core. If the rods fail to insert, then there is a mechanical binding issue and no operator action is modelled. Reactor trip (RT-LP) is successful when the control rods are inserted into the core and reactivity control is achieved. For RT-LP, a trip signal is not required because power is lost to the control rods. Failure of this top event results in a transfer to the ATWS-LMFW event tree.
NO SBO	This top event is associated with starting the standby DGs on a PLS signal or operator action HEPO-SDG using AOP-323. The success of this top event (SBO-1-PLX) is the starting and running of one out of two of the standby DGs. Failure of this top event results in SBO conditions (no onsite or offsite ac power).
SS FAULT	The success for this top event (SGS-SS-PA-PLA) is defined as one out of two safety valves (the two with the lowest set pressure) opening and relieving steam. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than MSSV may open after a reactor trip, the success for the valves reclosing is two out of two MSSVs reclose. Failure of this top event, the required valves failing to open or failing to reclose, results in a transfer to SLB upstream of the MSIVs event tree SLBU.
SFW	This top event is associated with SFW actuation by a PLS signal or operator action HEPO-SFWX using ES-0.1and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLX) for decay heat removal requires one out of two SFW pumps providing flow through two out of two SFCVs (one per loop) to two out of two SGs, and one out of two blowdown isolation valves close on each loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires the PRHR system or RCS depressurization via the ADS valves and IRWST or RNS injection/recirculation to prevent core damage.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR-GT using ES-0.1. The success of this top event (PRHR-PX-DX-LP, PRHR-SB) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. PRHR-PX-DX-LP is used when the diesel generators are successful. PRHR-SB is used for SBO conditions. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.

Table 10-18. LOOP Event Tree Description (cont.)

Top Event	Top Event Description
DISABLE TIMER	This top event (22HRTIMER) is associated with the operator action HEPO-22HRTIMER for SBO conditions to turn off the retentive timer that would actuate ADS at approximately 22 hours into the SBO event using AOP-323. ADS actuation is not required if PRHR is successful so the success path of this top event transfers to long term cooling event tree LTCP. Failure of this top event means that the 22 hour timer sends an actuation signal to ADS Stages 1-4. ADS actuation requires that top events CMT (or ACC), IRWST, and RECIRC be addressed.
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.
CMT	This top event is associated with CMT actuation on PMS or DAS signal or operator action HEPO-CMT-GT using FR-H.1. The success of this top event (CMT-1-PX-DX-LOOP, CMT-1-SB) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, and a CMT actuation signal to ADS. CMT-1-PX-DX-LOOP is used when the DGs are successful. CMT-1-SB is used for the SBO portion of the tree. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-GT using FR-H-1. There are different success criteria for ADS23 (ADS23-2-PM-DM-GT, ADS23-3-PX-DM-GT, ADS23-3-PX, ADS23-2-PM). For ADS23-2-PM-DM-GT and ADS23-2-PM, success is two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. They are both used on the CMT failure paths because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. ADS23-2-PM is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. For ADS23-3-PX-DM-GT and ADS23-3-PX, success is three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. ADS23-3-PX-DM-GT and ADS23-3-PX are used on the CMT success paths because both automatic and manual actuations via the PMS are possible. ADS23-3-PX is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. Failure of this top event leads directly to core damage because RCS depressurization and IRWST or RNS injection does not occur quickly enough to prevent core damage.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.

Table 10-18. LOOP Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2, ADS4-2L-PX-C1, ADS4-2L-PM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-C1 and ADS4-2L-PM-C2 are used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. ADS4-2L-PX-DM-C1 and ADS4-2L-PX-C1 are used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 and ADS4-2L-PM-C2 are used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. ADS4 is only modelled on the success paths of ADS23; therefore, except for SBO conditions, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves. For SBO conditions, both top events ADS23 and ADS4 must be successful to prevent core damage.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM, IRWST-1-PX) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. IRWST-1-PX is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. Except for SBO conditions, failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS. For SBO conditions, the RNS system does not have power, therefore, the IRWST is the only source for injection after the ADS valves are actuated and its failure leads to core damage.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM, RRWST-1-PX) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. RRWST-1-PX is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. RRWST-1-PX-DM is used for top event ADS4 success paths because automatic opening of the recirculation valves will occur in the PMS on a Low-3 level signal from the IRWST and an ADS Stage 4 actuation signal. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-19. SLBD Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	A large steam line break is a rapid transient that requires a quick reactor trip. To bind this event, no credit is taken for the operator to manually trip the reactor. Reactor trip (RT-PA-DA) is successful when the control rods are inserted into the core and reactivity control is achieved. Note that for this transient, additional boration is needed to counter the effects of a steam line break cooldown. The boration is addressed in top events CMT and CVS. Failure of this top event results in core damage if SG isolation fails because the plant conditions are beyond those considered in the ATWS success criteria analyses.
ISO	The success of this top event (SGI-2-PA) is closure of one out of one MSIV on each loop, one MFW isolation valve, control valve, or check valve on each loop, and one out of two SG blowdown isolation valves on each loop. In addition, the SG PORV or block valve on both SGs must close to keep the SGs intact. On the reactor trip success path, successful isolation changes the transient to a loss of feedwater type transient and transfers to transient without MFW event tree SLBD-GTRAN. On the reactor trip failure path, successful isolation transfers to the ATWS-LMFW event tree because the break has been isolated and the event is similar to one of the ATWS events. Also on the reactor trip failure path, isolation failure results in core damage because the plant conditions are beyond those considered in the ATWS success criteria analyses.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.
CMT	The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then core damage can be prevented if PRHR and CVS injection are successful.
CVS	The need for this top event is based on the steam line break IE and mitigating the reactivity effects of the cooldown with boration from the CVS pump. If the CMTs fail to inject, boration can be provided by the CVS pumps taking suction from the BAST. The success of this top event (CVS-1-PLA) requires one out of two CVS pumps injecting from the BAST into the RCS. If this top event fails, the reactivity control is not adequate and the path goes to core damage.
PZR SV	The pressuriser safety valves are modelled to address the RCS pressure increase due to the return to power from a large steam line break cooldown. They also address a potential RCS pressure increase that may occur for the feedwater line break event. Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.

Table 10-19. SLBD Event Tree Description (cont.)

Top Event	Top Event Description
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success paths because both automatic and manual actuations via the PMS are possible. Because this event tree covers both steam line and the feedwater line breaks, failure of this top event leads directly to core damage because decay heat removal has been lost.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1 (note that E-1 would be entered from FR-H.1 or E-0). The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on IRWST Low-3 level and operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-20. SLBU Event Tree Description

Top Event	Top Event Description
REACTOR TRIP	A large steam line break is a rapid transient that requires a quick reactor trip. To bind this event, no credit is taken for the operator to manually trip the reactor. Reactor trip (RT-PA-DA) is successful when the control rods are inserted into the core and reactivity control is achieved. Note that for this transient, additional boration is needed to counter the effects of a steam line break cooldown. The boration is addressed in top events CMT and CVS. Failure of this top event results in core damage because the plant conditions are beyond those considered in the ATWS success criteria analyses.
ISO	The success of this top event (SGI-1-PA) is closure of one out of two MSIVs and, on the faulted SG, closure of the MFW isolation valve or the main feedwater control valve (MFCV), the SFW control or isolation valve, and one out of two SG blowdown isolation valves. In addition, the SG PORV or block valve on the intact SG must close to keep the SG intact. The sequences on the failure path of this top event are tracked because these represent two SGs blowing down inside containment.
PRHR	This top event is associated with the PRHR heat exchanger actuation on a PMS or DAS signal and operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.
CMT	The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then core damage can be prevented if PRHR and CVS injection are successful.
CVS	The need for this top event is based on the steam line break IE and mitigating the reactivity effects of the cooldown with boration from the CVS pump. If the CMTs fail to inject, boration can be provided by the CVS pumps taking suction from the boric acid storage tank (BAST). The success of this top event (CVS-1-PLA) requires one out of two CVS pumps injecting from the BAST into the RCS. If this top event fails, the reactivity control is not adequate and the path goes to core damage.
PZR SV	The pressuriser safety valves are modelled to address the RCS pressure increase due to the return to power from a large steam line break cooldown. They also address a potential RCS pressure increase that may occur for the feedwater line break event. Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.

Table 10-20. SLBU Event Tree Description (cont.)

Top Event	Top Event Description
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success paths because both automatic and manual actuations via the PMS are possible. Because this event tree covers both steam line and the feedwater line breaks, failure of this top event leads directly to core damage because decay heat removal has been lost.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1 (note that E-1 would be entered from FR-H.1 or E-2). The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-21. SPRECIRC Event Tree Description

Top Event	Top Event Description
IRWST RECIRC ISO	This top event (RRWSTISO-4-PLM) is associated with the operator action HEPO-RRWSTISO to isolate the recirculation paths after spurious opening of the recirculation squib valves by closing valves PXS-PL-V117A&B and PXS-PL-121A&B using alarm response procedure PXS-401.
REACTOR TRIP	This top event is associated with PMS and DAS reactor trip signals and operator action HEPO-RT using E-0. Reactor trip (RT-PX-DX) is successful when the control rods are inserted into the core and reactivity control is achieved. If IRWST isolation is successful then failure of this top event is transferred to the ATWS event tree. If IRWST isolation fails, then failure of this top event is conservatively assigned core damage.
SS FAULT	The success for this top event (SGS-SS-PA-PLA) is defined as one out of two PORVs opening, or one out of two safety valves (the two with the lowest set pressure) opening and relieving steam, or one turbine bypass valve dumping steam to the condenser. In addition, turbine trip (steam flow stopped to both the high pressure and low pressure turbines) must be successful. Because more than one PORV or MSSV may open after a reactor trip, the success for the valves reclosing is one PORV or block valve on each steam line reclose and two out of two MSSVs reclose, or one turbine bypass valve recloses. Credit is not taken for the operator to close the PORV block valve. If IRWST isolation is successful then failure of this top event is transferred to the SLBU event tree. If IRWST isolation fails, then failure of this top event is conservatively assigned core damage.
MFW	This top event is associated with MFW cooling using the PLS or operator action HEPO-MFW using ES-0.1. The success of this top (MFW-1-PLX) event is one booster/MFW pump supplying water through two out of two SFCVs (one per loop) to two out of two SGs and one turbine bypass valve dumping steam to the condenser. Failure of this top event requires SFW or RCS depressurization and IRWST or RNS injection to prevent core damage.
SFW	This top event is associated with SFW actuation on a PLS signal or operator action HEPO-SFWX using ES-0.1 and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLX) for decay heat removal requires one out of two SFW pumps providing flow through two out of two SFCVs (one per loop) to two out of two SGs, and one out of two blowdown isolation valves close on each loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. If the IRWST is not isolated, failure of this top event leads to core damage because the IRWST has lost its inventory and is not available for passive injection.
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event leads to event tree logic based on the MLOCA event tree.

Table 10-21. SPRECIRC Event Tree Description (cont.)

Top Event	Top Event Description
CMT	The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then accumulator injection is required to provide water to the RCS prior to injection from the IRWST.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure paths of top event CMT.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 or HEPO-ADS-C2 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1, ADS23-2-PM-DM-C2) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. ADS23-2-PM-DM-C2 is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. Failure of this top event can lead to a non-core damage state if top event ADS4 is successful.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-3-PX-DM-C1, ADS4-3-PM-DM-C2) are three out of four ADS Stage 4 valves actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-3-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-3-PM-DM-C2 is used when top event CMT fails because there is no automatic PMS actuation and the operator action is based on RCS hot leg level. Failure of top event ADS4 leads directly to core damage on the failure paths of ADS23 because there is insufficient RCS depressurization for IRWST or RNS injection. On success paths of ADS23, failure of ADS4 does not lead directly to core damage because there is sufficient RCS depressurization to allow RNS injection to be successful.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS ADS Stage 4 actuation signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.

Table 10-21. SPRECIRC Event Tree Description (cont.)

Top Event	Top Event Description
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-22. ATWS-LMFW Event Tree Description

Top Event	Top Event Description
TURBINE TRIP	The success for this top event (MSS-TT-PA-DA) is the isolation of steam flow to the high and low pressure turbines by the closure of the appropriate combination of turbine control, stop, reheat stop, and intercept valves. Failure of this top event goes directly to core damage because the ATWS success criteria require turbine trip to aid in the negative reactivity feedback to the reactor to limit the RCS pressure increase.
SS FAULT	The success for this top event (SGS-SS-PA-PLA-ATWS) is defined as the six lowest set pressure MSSVs open and reclose, or two SG PORVs open and reclose and five of the six lowest set pressure MSSVs open and reclose. Credit is not taken for the steam dump to the condenser and credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in core damage because the plant conditions are beyond what are considered in the success criteria analyses.
SFW	This top event is associated with SFW actuation by a PLS signal and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLA-ATWS) for decay heat removal requires one out of two SFW pumps providing flow through two out of two SFCVs (one per loop) to two out of two SGs, and one out of two blowdown isolation valves close on each loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires operation of the PRHR, a CMT, and the pressuriser safety valves.
PRHR	The success of this top event (PRHR-PA-DA-ATWS) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event leads to core damage because core cooling cannot be established in time to prevent RCS over pressurization.
PZR SV (OPEN)	Success of this top event (PZRSV-2-ATWS) is the opening of two out of two pressuriser safety valves. Failure of this top event results in core damage because RCS pressure relief is required to keep the pressure below 220.63 Bar (3200 psig).
PZR SV (CLOSE)	Success of this top event (PZRSV-2C-ATWS) is the closing of two out of two pressuriser safety valves. Failure of this top event transfers to the LOCA-NO TRIP event tree.
CMT	The success of this top event (CMT-1-PA-DA-ATWS) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping and four out of four RCPs to trip. If this top event fails, then core damage results due to insufficient reactivity control and subsequent RCS over pressurization.
NO SBO	This top event is associated with starting the standby DGs on a PLS signal or operator action HEPO-SDG using AOP-323. The success of this top event (SBO-1-PLX) is the starting and running of one out of two of the standby DGs. Failure of this top event results in SBO conditions (no onsite or offsite ac power).

Table 10-22. ATWS-LMFW Event Tree Description (cont.)

Top Event	Top Event Description
DISABLE TIMER	This top event (22HRTIMER) is associated with the operator action HEPO-22HRTIMER for SBO conditions to turn off the retentive timer that would actuate ADS at approximately 22 hours into the SBO event using AOP-323. ADS actuation is not required if PRHR is successful so the success path of this top event transfers to long term cooling event tree LTC. Failure of this top event means that the 22 hour timer sends an actuation signal to ADS Stages 1-4. ADS actuation requires that top events IRWST and RECIRC be addressed. Note that at this point in the event tree, top event CMT has already been addressed and this branch occurs on the success path of CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-C1 is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. ADS4-2L-PX-C1 is used because top event CMT is successful so both automatic and manual actuations via the PMS are possible. Failure of ADS4 leads directly to core damage because RNS injection and recirculation is not possible due to the SBO conditions.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event leads directly to core damage because the RNS system does not have power due to the SBO conditions and the IRWST is the only source for injection after the ADS valves are actuated.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-23. ATWS Event Tree Description

Top Event	Top Event Description
TURBINE TRIP	The success for this top event (MSS-TT-PA-DA) is the isolation of steam flow to the high and low pressure turbines by the closure of the appropriate combination of turbine control, stop, reheat stop, and intercept valves. Failure of this top event goes directly to core damage because the ATWS success criteria require turbine trip to aid in the negative reactivity feedback to the reactor to limit the RCS pressure increase.
SS FAULT	The success for this top event (SGS-SS-PA-PLA-ATWS) is defined as the six lowest set pressure MSSVs open and reclose, or two SG PORVs open and reclose and five of the six lowest set pressure MSSVs open and reclose. Credit is not taken for the steam dump to the condenser and credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in core damage because the plant conditions are beyond what are considered in the success criteria analyses.
MFW	The success of this top (MFW-1-PLA-ATWS) event is one booster/ MFW pump supplying water through the SFCV to two out of two SGs and one turbine bypass valve dumping steam to the condenser. Failure of this top event requires decay heat removal from the SFW system or the PRHR system to prevent core damage.
SFW	This top event is associated with SFW actuation on a PLS signal, and operator action for refilling the CST following the CST alarm response procedure. The success of this top event (SFW-1-PLA-ATWS) for decay heat removal requires one out of two SFW pumps providing flow through two out of two SFCVs (one per loop) to two out of two SGs, and one out of two blowdown isolation valves close on each loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event requires operation of the PRHR, a CMT, and the pressuriser safety valves.
PRHR	The success of this top event (PRHR-PA-DA-ATWS) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event leads to core damage because core cooling cannot be established in time to prevent RCS over pressurization.
PZR SV (OPEN)	Success of this top event (PZRSV-2-ATWS) is the opening of two out of two pressuriser safety valves. Failure of this top event results in core damage because RCS pressure relief is required to keep the pressure below 22063 kPa (3200 psig).
PZR SV (CLOSE)	Success of this top event (PZRSV-2C-ATWS) is the closing of two out of two pressuriser safety valves. Failure of this top event transfers to the LOCA-NO TRIP event tree.
CMT	The success of this top event (CMT-1-PA-DA-ATWS) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping and four out of four RCPs to trip. If this top event fails, then core damage results due to insufficient reactivity control and subsequent RCS over pressurization.

Table 10-23. ATWS Event Tree Description (cont.)

Top Event	Top Event Description
NO SBO	This top event is associated with starting the standby DGs on a PLS signal or operator action HEPO-SDG using AOP-323. The success of this top event (SBO-1-PLX) is the starting and running of one out of two of the standby DGs. Failure of this top event results in SBO conditions (no onsite or offsite ac power).
DISABLE TIMER	This top event (22HRTIMER) is associated with the operator action HEPO-22HRTIMER for SBO conditions to turn off the retentive timer that would actuate ADS at approximately 22 hours into the SBO event using AOP-323. ADS actuation is not required if PRHR is successful so the success path of this top event transfers to long term cooling event tree LTC. Failure of this top event means that the 22 hour timer sends an actuation signal to ADS Stages 1-4. ADS actuation requires that top events IRWST and RECIRC be addressed. Note that at this point in the event tree top event CMT has already been addressed, and this branch occurs on the success path of CMT.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-C1 is used for SBO conditions because the DAS battery is only designed for 2 hours so DAS actuation is not modelled. ADS4-2L-PX-C1 is used because top event CMT is successful so both automatic and manual actuations via the PMS are possible. Failure of ADS4 leads directly to core damage because RNS injection and recirculation is not possible due to the SBO conditions.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event leads directly to core damage because the RNS system does not have power due to the SBO conditions and the IRWST is the only source for injection after the ADS valves are actuated.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-24. LOCA-NOTRIP Event Tree Description

Top Event	Top Event Description
TURBINE TRIP	To be consistent with the ATWS event tree model this top event is included in the event tree. The success for this top event (MSS-TT-PA-DA) is the isolation of steam flow to the high and low pressure turbines by the closure of the appropriate combination of turbine control, stop, reheat stop, and intercept valves. Failure of this top event goes directly to core damage because the ATWS success criteria require turbine trip to aid in the negative reactivity feedback to the reactor to limit the RCS pressure increase.
SS FAULT	To be consistent with the ATWS event tree model, this top event is included in the event tree. The success for this top event (SGS-SS-PA-PLA-ATWS) is defined as the six lowest set pressure MSSVs open and reclose, or two SG PORVs open and reclose and five of the six lowest set pressure MSSVs open and reclose. Credit is not taken for the steam dump to the condenser and credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in core damage because the plant conditions are beyond what are considered in the success criteria analyses.
PRHR	The success of this top event (PRHR-PA-DA-L) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event leads to core damage because the plant conditions are beyond what are considered in the success criteria analyses.
PZR SV (OPEN)	Success of this top event (PZRSV-2-ATWS) is the opening of two out of two pressuriser safety valves. Failure of this top event results in core damage. This approach is taken to be consistent with the success paths in the ATWS event trees and because the plant conditions are beyond what are considered in the success criteria analyses.
CMT	The success of this top event (CMT-1-PA-DA-ATWS) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping and four out of four RCPs to trip. Failure of this top event leads to core damage because there is insufficient makeup to the RCS and insufficient reactivity control.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-C1 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-2-PX-DM-C1) are two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. Failure of this top event leads to core damage because insufficient RCS depressurization occurs to permit IRWST injection.

Table 10-24. LOCA-NOTRIP Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-S4-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-S4-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. Failure of this top event does not lead directly to core damage because this top event is addressed on the success path of top events PRHR and ADS23; therefore, there is sufficient RCS depressurization for RNS injection.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not lead directly to core damage because this top event is addressed on the success path of top events PRHR, ADS23, and ADS4; therefore, there is sufficient RCS depressurization and time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-25. LOCA-SSFAULT Event Tree Description

Top Event	Top Event Description
CMT	The success of this top event (CMT-1-PA-DA) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. Failure of this top event leads to core damage because there is insufficient makeup to the RCS and insufficient reactivity control for the cooldown aspect of this event.
ADS23	This top event is associated with ADS Stages 1-3 actuation on PMS signal or operator action HEPO-ADS-C1 using E-1 or the Foldout Page for E-1. The success criteria for ADS23 (ADS23-3-PX-DM-C1) are three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-3-PX-DM-C1 is used on the CMT success path because both automatic and manual actuations via the PMS are possible. Failure of this top event leads to core damage because insufficient RCS depressurization occurs to permit IRWST injection.
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 using E-1 or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. ADS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. Failure of top event ADS4 does not lead directly to core damage because there is sufficient RCS depressurization for RNS injection.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1. The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not lead directly to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of this top event leads directly to core damage because top event RNS is addressed when IRWST injection is not available.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-26. SGTR-NOTRIP Event Tree Description

Top Event	Top Event Description
TURBINE TRIP	To be consistent with the ATWS event tree model, this top event is included in the event tree. The success for this top event (MSS-TT-PA-DA) is the isolation of steam flow to the high and low pressure turbines by the closure of the appropriate combination of turbine control, stop, reheat stop, and intercept valves. Failure of this top event goes directly to core damage because the ATWS success criteria require turbine trip to aid in the negative reactivity feedback to the reactor to limit the RCS pressure increase.
SS FAULT	To be consistent with the ATWS event tree model, this top event is included in the event tree. The success for this top event (SGS-SS-PA-PLA-ATWS) is defined as the six lowest set pressure MSSVs open and reclose, or two SG PORVs open and reclose and five of the six lowest set pressure MSSVs open and reclose. Credit is not taken for the steam dump to the condenser and credit is not taken for the operator to close the PORV block valve. Failure of this top event, the required valves failing to open or failing to reclose, results in core damage because the plant conditions are beyond what are considered in the success criteria analyses.
CMT	The success of this top event (CMT-1-PA-DA-ATWS) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping and four out of four RCPs to trip. If this top event fails, then the result is core damage because the CMT is needed for reactivity control due to the failure of reactor trip.
PRHR	The success of this top event (PRHR-PA-DA) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long-term cooling. Failure of this top event leads to core damage.
OFILL	The success of this top event (SGI-1-PA-SGTR) requires the termination of CVS, and SFW flow to both SGs. In addition, the MFW line to the ruptured SG must be isolated (this occurs on the S signal). The failure of this event leads to core damage because the plant conditions are beyond what are considered in the success criteria analyses.
PZR SV (OPEN)	Success of this top event (PZRSV-2-ATWS) is the opening of two out of two pressuriser safety valves. Failure of this top event results in core damage based on the success criteria results for the ATWS event.
PZR SV (CLOSE)	Success of this top event (PZRSV-2C-ATWS) is the closing of two out of two pressuriser safety valves. Failure of this top event results in core damage because the plant conditions are beyond those considered in the ATWS success criteria analyses.

Table 10-27. SLBD-GTRAN Event Tree Description

Top Event	Top Event Description
PRHR	This top event is associated with the PRHR heat exchanger actuation on PMS or DAS signal or operator action HEPO-PRHR using E-0. The success of this top event (PRHR-PX-DX) requires one out of two of the PRHR heat exchanger control valves to open and establish flow through the PRHR heat exchanger. In addition, one out of two IRWST gutter isolation valves must close to return condensate to the IRWST to sustain long term cooling. Failure of this top event requires RCS depressurization and IRWST or RNS injection to prevent core damage.
PZR SV	Success of this top event (PZRSV-2) is the opening of one out of two pressuriser safety valves and the closing of two out of two pressuriser safety valves. Failure of this top event results in a transfer to the MLOCA event tree.
CMT	This top event is associated with CMT actuation on a PMS or DAS signal or operator action HEPO-CMT-GT using FR-H.1. The success of this top event (CMT-1-PX-DX-GT) requires one out of two CMTs to inject through one out of two parallel valves on the discharge piping, four out of four RCPs to trip, and a CMT actuation signal to ADS. If this top event fails, then core damage can be prevented if top events ADS23 and ACC are successful.
ADS23	This top event is associated with ADS Stages 1-3 actuation on a PMS signal or operator action HEPO-ADS-GT using FR-H-1. There are different success criteria for ADS23 (ADS23-2-PM-DM-GT, ADS23-3-PX-DM-GT). For ADS23-2-PM-DM-GT, success is two out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. ADS23-2-PM-DM-GT is used on the CMT failure path because automatic actuation via the PMS will not occur because either the signal fails or the CMT valves fail and the CMT Low level input to actuate ADS will not be generated. For ADS23-3-PX-DM-GT, success is three out of four ADS Stages 2 and 3 valves open and discharge into the IRWST. This is used when top event PRHR fails and top event CMT is successful to achieve the necessary RCS depressurization prior to ADS Stage 4 actuation. Failure of this top event leads directly to core damage because RCS depressurization and IRWST or RNS injection does not occur quickly enough to prevent core damage.
ACC	For this event, the accumulators provide a source of water when the CMTs fail, prior to injection from the IRWST, to maintain water in the core. The success of this top event (ACC-1) requires one out of two accumulators to inject into the DVI line, when the RCS pressure is below the accumulator pressure. Failure of this top event leads directly to core damage because it is addressed only on the failure path of top event CMT.

Table 10-27. SLBD-GTRAN Event Tree Description (cont.)

Top Event	Top Event Description
ADS4	This top event is associated with ADS Stage 4 actuation on a PMS signal or operator action HEPO-ADS4-C1 or HEPO-ADS4-C2 using E-1or the Foldout Page for E-1. The success criteria for this top event (ADS4-2L-PX-DM-C1, ADS4-2L-PM-DM-C2) are one out of two ADS Stage 4 valves on each loop (two out of four total) actuating and providing a signal for IRWST gravity injection and recirculation. DS4-2L-PX-DM-C1 is used when top event CMT is successful because both automatic and manual actuations via the PMS are possible. ADS4-2L-PM-DM-C2 is used if top event CMT fails because automatic actuation via the PMS is not available. ADS4 is only modelled on the success paths of ADS23; therefore, failure of ADS4 does not lead directly to core damage because RNS injection and recirculation is possible due to the depressurization of the RCS by the ADS Stages 2 and 3 valves.
IRWST	This top event is associated with IRWST gravity injection actuation on a PMS signal or operator action HEPO-INJ using E-1 (note that E-1 would be entered from FR-H.1). The success of this top event (IRWST-1-PX-DM) requires one out of four gravity injection line squib valves to actuate and provide IRWST injection into the RV via the DVI lines. Failure of this top event does not directly lead to core damage because ADS Stage 4 has successfully depressurized the RCS and there is sufficient time for the operator to establish injection through the RNS.
RNS	This top event is associated with using the RNS to provide low pressure injection to the RCS and operator action HEPO-RNSINJ and HEPO-RNSIRWST using ES-1.3. Success for this top event (RNS-1-PLM-L) includes successful operator action and the equipment functioning to align and start one out of two RNS pumps to take suction from the CLP, then to realign the RNS pump to take suction from the IRWST to maintain flow into the RV through one out of two DVI lines. Failure of both IRWST and RNS injection results in loss of all low pressure injection to cool the reactor and to mitigate the loss of RCS inventory through the ADS valves.
RECIRC	This top event is associated with containment sump recirculation on a PMS signal or operator action HEPO-RECIRC using E-1. The success of this top event (RRWST-1-PX-DM) requires one out of four containment sump recirculation line squib valves to actuate and provide flow into the RV via the DVI lines or to the suction line to the RNS. Failure of this top event leads to core damage because long term cooling is not established.

Table 10-28. LTC and LTCP Event Tree Description

Top Event	Top Event Description
NO SBO	This top event is associated with starting the standby DGs on a PLS signal or operator action HEPO-SDG using AOP-323 if ac power is lost. This top event is used to check if SBO conditions exist. The success of this top event (SBO-1-PLX) is the starting and running of one out of two of the standby DGs. Failure of this top event results in SBO conditions (no onsite or offsite ac power). ForSBO conditions, the containment isolation valves will close either from the loss of power or from the subsequent loss of instrument air and top event CI is not addressed.
CI	This top event is associated with Containment Isolation (CI) actuation on a PMS or DAS signal or operator action HEPO-CNT using E-0. The Containment System (CNS) Isolation System provides the Category -A function of containment isolation for containment boundary integrity and provides a barrier against the release of fission products to the atmosphere. The success criteria for CI (CI-PX-DX) are the closure of one isolation valve on each of the lines listed in E-0 and closure of applicable containment hatches and doors. Failure of this top event does not lead directly to core damage as long as Passive Containment Cooling System (PCS) is successful.
PCS	This top event is associated with PCS actuation on a PMS or DAS signal or operator action HEPO-PCS using FR-Z.1. The success criteria for PCS (PCS-1-PX-DX, PCS-1-PM-DX, PCS-1-SB) are flow from one out of three flow paths to the distribution bucket, or makeup water provided to the distribution bucket from the PCS recirculation pumps, for 72 hours. Failure of this top event results in core damage, except as indicated below.
SFW	This top event is associated with SFW actuation on a PLS signal or operator action HEPO-SFWS following E-0 or HEPO-SFWM following FR-H.1, and operator action for refilling the CST. This top event is modelled in transfer tree LTCP to recover core cooling via SFW if PCS fails. This is a long term recovery. The success of this top event (SFW-1-PLX-C) for decay heat removal requires one out of two SFW pumps providing flow through one out of two SFCVs to one out of two SGs, and one out of two blowdown isolation valves close on the SG loop. One SG PORV or one MSSV must operate to dump the steam from the SG. In addition, the CST must be refilled. Failure of this top event leads to core damage because it is the recovery of failed PCS and long term core cooling.

Notes:

1. This system is not a support system but used as a transfer to a system.
2. ECS is a dependency for PXS as it is used for the RCP breakers for CMT injection. The ac power modelled in the PSA is for control power to the RCP breakers to open.
3. It is noted that PRHR and CMT are fail safe. The accumulator sub-system of PXS does not require any support systems for actuation. Only ADS and IRWST require dc power for support.
4. Main AC power system provides motive power to PCS-PL-V001C and the PCS pumps and is therefore modelled in the PCS, but not required for successful PCS. PCS-PL-V001C serves the same purpose as normally closed, fail open air operated valves, PCS-PL-V001A/B.

Note:

1. ECS is a dependency for PXS as it is used for the RCP breakers for CMT injection.
2. PMS is modelled as a support to PLS in the PSA model to show the interface in the linked model for the PMS-PLS interface.
3. Non-Class 1 dc and UPS power supply system is noted as a dependency for PMS Category-A functions. The sequence of events (SOE) subsystem of PMS is the only subsystem that requires the non-class 1 and UPS power supply system. A specific isolation barrier in the PMS-PLS interface is powered through the SOE subsystem and therefore is modelled in this unique case for PMS.

HEPO-22HRTIMER						OPERATOR FAILS TO DISABLE 22 HR TIMER
HEPO-ADS4-C1						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGE 4 ON LOW CMT LEVEL
HEPO-ADS4-C2						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGE 4 ON LOW HL LEVEL
HEPO-ADS-C1						OPERATOR FAILS TO DEPRESSURIZE RCS WITH THE ADS STAGES 1 – 3 ON CMT LEVEL
HEPO-ADS-C1-SGTR						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON CMT LEVEL DURING A SGTR
HEPO-ADS-C2						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOW HL LEVEL
HEPO-ADS-C2-SGTR						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOW HL LEVEL DURING A SGTR
HEPO-ADS-GT						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOSS OF HEAT SINK CUE
HEPO-ANC-DG						OPERATOR FAILS TO START ANCILLARY DG AND LOAD PCS RECIRCULATION PUMPS
HEPO-CCSFAN						OPERATOR FAILS TO LOAD THE CCS AHU FANS ONTO THE SDG FOLLOWING A LOOP
HEPO-CMT						OPERATOR FAILS TO MANUALLY START CMT INJECTION

Table 10-32. Post-Initiator Operator Action Time Windows (cont.)

BE ID	T(sw)[1]	T(d)[2]	T(1/2)[3]	T(M)[4]	T(rec)[5]	Description
HEPO-CMT-GT						OPERATOR FAILS TO MANUALLY START CMT INJECTION DURING A LOSS OF HEAT SINK EVENT
HEPO-CNT						OPERATOR FAILS TO MANUALLY ISOLATE CONTAINMENT
HEPO-CST						OPERATOR FAILS TO REFILL THE CST
HEPO-CSTFILL						OPERATOR FAILS TO REFILL THE CST WITH FIRE TRUCK
HEPO-CVSISO						OPERATOR FAILS TO MANUALLY ISOLATE CVS DURING AN ISLOCA EVENT
HEPO-CVSISO-Z						OPERATOR FAILS TO MANUALLY ISOLATE CVS ZINC INJECTION LINE DURING AN ISLOCA EVENT
HEPO-INJ						OPERATOR FAILS TO ACTUATE IRWST INJECTION
HEPO-L2-ADS13						OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 VALVES ON LOSS OF CORE COOLING CUE
HEPO-L2-CAVFLD						OPERATOR FAILS TO FLOOD RV CAVITY FOR IVR ON LOSS OF CORE COOLING CUE
HEPO-L2-CNT						OPERATOR FAILS TO MANUALLY ISOLATE CONTAINMENT
HEPO-L2-H2I						OPERATOR FAILS TO MANUALLY ACTUATE HYDROGEN IGNITERS

Table 10-32. Post-Initiator Operator Action Time Windows (cont.)

BE ID	T(sw)[1]	T(d)[2]	T(1/2)[3]	T(M)[4]	T(rec)[5]	Description
HEPO-L2-IRWST						OPERATOR FAILS TO ACTUATE IRWST INJECTION ON LOSS OF CORE COOLING CUE
HEPO-L2-PCS						OPERATOR FAILS TO ACTUATE PCS
HEPO-L2-PXSGUT						OPERATOR FAILS TO CLOSE IRWST GUTTER DRAIN VALVES ON LOSS OF CORE COOLING CUE
HEPO-L2-RECIRC						OPERATOR FAILS TO MANUALLY OPEN THE PXS RECIRCULATION VALVES ON LOSS OF CORE COOLING CUE
HEPO-MFW						OPERATOR FAILS TO ALIGN MFW AFTER A REACTOR TRIP
HEPO-OFILL						OPERATOR FAILS TO ISOLATE RUPTURED SG (ON HIGH-3 NR SG LEVEL – PMS BACK-UP)
HEPO-PCS						OPERATOR FAILS TO ACTUATE PCS
HEPO-PCSDIST						OPERATOR FAILS TO SUPPLY WATER DIRECTLY TO THE PCS DISTRIBUTION BUCKET
HEPO-PRHR						OPERATOR FAILS TO ACTUATE PRHR DURING AN EVENT W/ S SIGNAL
HEPO-PRHR-GT						OPERATOR FAILS TO ACTUATE PRHR DURING AN EVENT W/O S SIGNAL
HEPO-RECIRC						OPERATOR FAILS TO MANUALLY OPEN THE PXS RECIRCULATION VALVES
HEPO-RNSINJ						OPERATOR FAILS TO ALIGN RNS FOR INJECTION

Table 10-32. Post-Initiator Operator Action Time Windows (cont.)

BE ID	T(sw)[1]	T(d)[2]	T(1/2)[3]	T(M)[4]	T(rec)[5]	Description
HEPO-RNSIRWST						OPERATOR FAILS TO ALIGN THE IRWST FOR RNS INJECTION
HEPO-RRWSTISO						OPERATOR FAILS TO ISOLATE IRWST RECIRC FOLLOWING SPURIOUS RECIRC ACTUATION
HEPO-RT						OPERATOR FAILS TO MANUALLY TRIP THE REACTOR
HEPO-RWS						OPERATOR FAILS TO START STANDBY RIVER WATER PUMP
HEPO-SDG						OPERATOR FAILS TO MANUALLY START THE DIESEL GENERATOR
HEPO-SFWCD						OPERATOR FAILS TO MANUALLY CONTROL THE PORV SETPOINT FOR COOLDOWN DURING SGTR
HEPO-SFWS						OPERATOR FAILS TO MANUALLY START SFW PUMP DURING AN S SIGNAL EVENT
HEPO-SFWX						OPERATOR FAILS TO MANUALLY START SFW PUMP
HEPO-SGI						OPERATOR FAILS TO ISOLATE RUPTURED SG
HEPO-SWSFAN						OPERATOR FAILS TO START STANDBY SWS COOLING TOWER FAN

Notes:

1. T(sw) = total time available (minutes)
2. T(d) = time until cue is received (minutes)
3. T(1/2) = time to diagnose the cue (minutes)
4. T(M) = time to perform the action following diagnosis of cue (minutes)
5. T(rec) = time available for recovery (T(sw) – (T(d) + T(1/2) + T(M))) (minutes)

Table 10-33. Post-Initiator Quantification Summary

Event ID	Description	Total HEP	Error Factor
HEPO-22HRTIMER	OPERATOR FAILS TO DISABLE 22 HR TIMER		
HEPO-ADS4-C1	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGE 4 ON LOW CMT LEVEL		
HEPO-ADS4-C2	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGE 4 ON LOW HL LEVEL		
HEPO-ADS-C1	OPERATOR FAILS TO DEPRESSURIZE RCS WITH THE ADS STAGES 1 – 3 ON CMT LEVEL		
HEPO-ADS-C1-SGTR	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON CMT LEVEL DURING A SGTR		
HEPO-ADS-C2	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOW HL LEVEL		
HEPO-ADS-C2-SGTR	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOW HL LEVEL DURING A SGTR		
HEPO-ADS-GT	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 ON LOSS OF HEAT SINK CUE		
HEPO-ANC-DG	OPERATOR FAILS TO START ANCILLARY DG AND LOAD PCS RECIRCULATION PUMPS		
HEPO-CCSFAN	OPERATOR FAILS TO LOAD THE CCS AHU FANS ONTO THE SDG FOLLOWING A LOOP		
HEPO-CMT	OPERATOR FAILS TO MANUALLY START CMT INJECTION		
HEPO-CMT-GT	OPERATOR FAILS TO MANUALLY START CMT INJECTION DURING A LOSS OF HEAT SINK EVENT		
HEPO-CNT	OPERATOR FAILS TO MANUALLY ISOLATE CONTAINMENT		
HEPO-COG-CONT	OPERATOR FAILS TO DIAGNOSE HIGH CONTAINMENT PRESSURE		

Table 10-33. Post-Initiator Quantification Summary (cont.)

Event ID	Description	Total HEP	Error Factor
HEPO-COG-CORECOOLING	OPERATOR FAILS TO DIAGNOSE INADEQUATE CORE COOLING		
HEPO-COG-HEATSINK	OPERATOR FAILS TO DIAGNOSE A LOSS OF HEAT SINK EVENT		
HEPO-COG-LOOP	OPERATOR FAILS TO DIAGNOSE A LOSS OF OFFSITE POWER EVENT		
HEPO-COG-SGTR	OPERATOR FAILS TO DIAGNOSE A SGTR EVENT		
HEPO-CST	OPERATOR FAILS TO REFILL THE CST		
HEPO-CSTFILL	OPERATOR FAILS TO REFILL THE CST WITH FIRE TRUCK		
HEPO-CVSISO	OPERATOR FAILS TO MANUALLY ISOLATE CVS DURING A ISLOCA EVENT		
HEPO-CVSISO-Z	OPERATOR FAILS TO MANUALLY ISOLATE CVS ZINC INJECTION LINE DURING A ISLOCA EVENT		
HEPO-INJ	OPERATOR FAILS TO ACTUATE IRWST INJECTION		
HEPO-L2-ADS13	OPERATOR FAILS TO DEPRESSURIZE THE RCS WITH THE ADS STAGES 1 – 3 VALVES ON LOSS OF CORE COOLING CUE		
HEPO-L2-CAVFLD	OPERATOR FAILS TO FLOOD RV CAVITY FOR IVR ON LOSS OF CORE COOLING CUE		
HEPO-L2-CNT	OPERATOR FAILS TO MANUALLY ISOLATE CONTAINMENT		
HEPO-L2-H2I	OPERATOR FAILS TO MANUALLY ACTUATE HYDROGEN IGNITERS		
HEPO-L2-IRWST	OPERATOR FAILS TO ACTUATE IRWST INJECTION ON LOSS OF CORE COOLING CUE		
HEPO-L2-PCS	OPERATOR FAILS TO ACTUATE PCS		
HEPO-L2-PXSGUT	OPERATOR FAILS TO CLOSE IRWST GUTTER DRAIN VALVES ON LOSS OF CORE COOLING CUE		
HEPO-L2-RECIRC	OPERATOR FAILS TO MANUALLY OPEN THE PXS RECIRCULATION VALVES ON LOSS OF CORE COOLING CUE

$PMS-RNC-FOP-B			CCF FAILURE PMS RNC FAIL TO OPERATE, BETA FACTOR
$PMS-RST-FOP-B			CCF FAILURE PMS RST FAIL TO OPERATE, BETA FACTOR
$PMS-RUV-FOP-B			CCF FAILURE PMS RUV FAIL TO OPERATE, BETA FACTOR
$PMS-SRD-FOP-B			CCF FAILURE PMS SRD FAIL TO OPERATE, BETA FACTOR
$PMS-SRN-FOP-B			CCF FAILURE PMS SRN FAIL TO OPERATE, BETA FACTOR
$PMS-STU-FOP-B			CCF FAILURE PMS STU FAIL TO OPERATE, BETA FACTOR

Table 10-45. Unique C&I Common Cause Variables

Type Code	Description	Value	α	β	Variance
$GEN-SOF-FOP-MM	Software Common Cause Failure (PMS and PLS)				
$GEN-SOF-FOP-IE	Software Common Cause Failure Results in Spurious IE (PMS)				
$GEN-HWY-FOP-LM	Common Cause Failure of Ovation Data Network (PLS)				

Table 10-46. Loss of Long Term Cooling Common Cause Variables

Type Code	Description	Value	Variance
PXS-SSC-LLI	Loss of Long Term Core Cooling – LLOCA		
PXS-SSC-MLI	Loss of Long Term Core Cooling – MLOCA		
PXS-SSC-SLI	Loss of Long Term Core Cooling – SLOCA		
PXS-SSC-TRN	Loss of Long Term Core Cooling – Transient		

Table 10-47. PDS Naming Convention

RCS Pressure/Condition	Hydrogen Generation	Water Availability
H (high)	N (no ADS actuation)	F (reflood failure)
L (low)	1 (ADS sparging into IRWST)	I (injection failure)
A (ATWS)	2 (ADS sparging into IRWST and discharging into containment)	R (recirculation failure)
BL (large bypass)	C (ADS discharge into containment)	
BS (small bypass)		

Table 10-48. High Pressure Recovery Event Tree Definitions

Associated PDSs	Recovery Event Tree	Recoveries Applied
H1 H1F	HP-1	ADS Stage 4 IRWST Recirculation
H1I	HP-H1I	ADS Stage 4 IRWST Recirculation
H1R	HP-H1R	ADS Stage 4 Recirculation
H2I	HP-H2I	IRWST Recirculation
H2R HCR	HP-H2CR	Recirculation
HCI	HP-HCI	IRWST Recirculation
HNI(1)	HP-HNI	ADS Stages 2-3 ADS Stage 4
AN ANF HN HNF	HP-N	ADS Stages 2-3 ADS Stage 4 IRWST Recirculation

Note:

1. This PDS has no recovery of IRWST because the initiator is spurious IRWST. In this instance, the IRWST is not recoverable.

Table 10-49. Low Pressure Recovery Event Tree Definitions

Associated PDSs	Recovery Event Tree	Recoveries Applied
L1I	LP-LI1	ADS Stage 4 IRWST Recirculation
L1R	LP-L1R	ADS Stage 4 Recirculation
L2I	LP-L2I	IRWST Recirculation
L2R	LP-L2R	Recirculation
LC LCF LCI	LP-LC	ADS Stages 2-3 IRWST Recirculation
LCR	LP-LCR	ADS Stages 2-3 Recirculation
LN LNF LNI	LP-N	ADS Stages 2-3 ADS Stage 4 IRWST Recirculation

Table 10-50. List of Screened Out Buildings from the Internal Flooding Analysis

Building	Reason
SWS Cooling Towers	These towers are isolated structures in an open area
Plant Entrance	The entrance is an isolated structure in an open area which is not expected to host critical equipment and flood sources
Circulating Water Pump Intake Structure	Any flood scenario that can occur is only expected to impact CWS given the fact that the Circulating Water Pump Intake Structure is a completely separate structure
CWS Cooling Tower	This tower is a completely separate structure; any flood scenario is only expected to impact the Circulating Water System and no other equipment is affected
CWS Intake Canal	Any flood scenario that can occur is only expected to impact CWS given the fact that the Circulating Water Pump Intake Structure is a completely separated structure. No other equipment is affected
Fire Water & Clearwell Storage Tank	It is a carbon steel tank located in an open area at the north end of the Turbine Building and is only analysed as a potential flood source
Fire Water Storage Tank	It is a carbon steel tank located in an open area at the northwest end of the Turbine Building and is only analysed as a potential flood source
Transformer Area	It is an isolated structure in an open area immediately adjacent to and north of the Turbine Building which is not expected to host flood sources
Switchyard	It is an isolated structure in an open area which is not expected to host flood sources
Condensate Storage Tank	This structure is only considered in the analysis as a potential flood source
Diesel Generator Fuel Oil Storage Tanks	This structure is located in the yard area and has mitigative features to prevent the outflow of oil to the outside, it can be screened out from the analysis
Demineralized Water Storage Tank	This structure is only considered in the analysis as a potential flood source
Boric Acid Storage Tank	This tank is a free-standing stainless steel cylindrical design, located adjacent to the Annex Building and to the Demineralized Water Storage Tank in an open area This structure is only considered in the analysis as a potential flood source
PGS Bulk Gas Storage Area	This structure is situated in the yard areas and is screened from the internal flooding

Table 10-50. List of Screened Out Buildings from the Internal Flooding Analysis (cont.)

Building	Reason
Turbine Building Laydown Area	This structure is outside the Turbine Building boundary. There is neither vulnerable equipment nor flood sources located in this open structure and it is screened from the internal flooding
Circulating Water Pipe	This Circulating Water piping inside the Turbine Building is only considered in the analysis as a potential flood source
Waste Water Retention Basin	This structure is only considered in the analysis as a potential flood source
Passive Containment Cooling Ancillary Water Storage Tank	This cylindrical steel tank is located at ground level in an open area at the west side of the Auxiliary Building. This structure is only considered in the analysis as a potential flood source
Diesel-driven Fire Pump & Enclosure	The diesel pump enclosure is located in the yard and, therefore, it is screened out from the internal flooding analysis

Table 10-51. List of Fluid Systems Included in the Internal Flooding Analysis

System	Description	Spray	Flood	Major Flood	HELB
Auxiliary Steam Supply	A line break in the steam portion of the ASS is expected to result in a steam release in the Turbine Building, which can impact other PSA equipment and induce administrative shutdown				X
Steam Generator Blowdown	Loss of BDS due to a pipe break would not result in a direct plant shutdown, and indirect flood or major flood concerns are not likely due to the limited capacity of the system	X			
Component Cooling Water	A line break in the CCS system has the potential for inducing a plant shutdown	X	X	X	
Condensate	A line break in the CDS system has the potential for inducing a plant shutdown	X	X	X	
Chemical and Volume Control	A break of the CVS piping system will likely cause a reactor trip since CVS is directly connected to the RCS; however, the flowrate is small enough to screen out a major flooding risk	X	X		X
Circulating Water	Circulating Water piping located inside the Turbine Building cannot be screened out. A pressure boundary failure of this piping would have a significant impact on other PSA equipment located inside the Turbine Building.	X	X	X	
Demineralized Water Treatment	The influent to the DTS for treatment is pumped from the RWS which operates at ambient temperature and pressure. Thus, the HELB risk of the DTS is not a concern. The major flood risk is not considered due to the maximum flowrate being low and, therefore, only the flood and the spray risk should be evaluated.	X	X		
Demineralized Water Transfer	Given the tank's size and flowrate, flood and spray risks are a concern. The tank temperature is monitored; therefore, the DWS does not pose a HELB threat. From the information contained in Table 3-1 of the system SSD, the major flood is not considered credible.	X	X		
Fire Protection	HELB is not considered as a credible risk for the FPS, as its operating temperature is below the cutoff criteria.	X	X	X	
Main and Startup Feedwater	A loss of MFW will cause a reactor trip and degrade the mitigating capability. Due to the FWS header design pressure and temperature the HELB is a risk to be evaluated for FWS.	X	X	X	X

Table 10-51. List of Fluid Systems Included in the Internal Flooding Analysis (cont.)

System	Description	Spray	Flood	Major Flood	HELB
Gland Seal	A loss of GSS is likely to cause a reactor trip due to degraded turbine performance	X	X		X
Heater Drain	The HDS does not perform or support any Category-A function, any other licensing-related function or any defence-in-depth function; however, HDS major equipment is located in Turbine Building where plant trip and mitigative equipment are located	X	X	X	X
Hydrogen Seal Oil	Given the location of HSS equipment and piping in the Turbine Building, it will only affect the turbine generator, and it has a limited inventory in comparison to the large area present in the Turbine Building. The risk of oil spray needs to be evaluated.	X			
Main Steam	The MSS does not perform any Category-A functions or mitigative functions. However a loss of MSS will cause a reactor trip	X	X	X	X
Main Turbine	The MTS performs energy conversion and steam flow control, and a loss of MTS will cause a reactor trip.	X	X	X	X
Primary Sampling	Since sampling activities are not performed continuously and only with manual operation of isolation valves, limited spray effects can be envisioned as a result of line/component leakage during sampling procedures. HELB is considered as a risk due to the number of other HELB defined systems that the PSS interfaces with to provide samples for analysis. The flood and major flood risk is not included due to the limited size of the piping that exists within this system.	X			X
Potable Water	Flood, major flood and HELB risks are not a concern due to the operating flow, temperature, and pressure. The PWS system will only be evaluated in risk significant flood areas were the spray impact on the equipment would lead to a plant IE.	X			
Spent Fuel Pool Cooling	Based on its pressure, temperature, and flowrate parameters, the SFS is retained for spray, flood, and major flood risk evaluation. The HELB risk is screened out.	X	X	X	
Steam Generator	A loss of SGS will cause a reactor trip and degrade accident mitigation.	X	X	X	X

Table 10-51. List of Fluid Systems Included in the Internal Flooding Analysis (cont.)

System	Description	Spray	Flood	Major Flood	HELB
Service Water	SWS does not perform or support any Category-A function or any other licensing-related functions. However, the SWS supplies cooling water for the CCS heat exchangers to support the defence-in-depth functions of the CCS. Loss of SWS will cause a reactor trip and degrade mitigating capability.	X	X	X	
Turbine Building Closed Cooling Water	The TCS does not perform or support any Category-A function or any other licensing-related functions. However, the TCS does support normal power generation and non-Class 1 mitigation system. A loss of TCS will cause a reactor trip and degrade mitigative functions.	X	X	X	
Central Chilled Water	The VWS provides cooling, directly and indirectly, to MCR and various Turbine Building rooms. A loss of VWS will not directly cause a reactor trip. However, with a potential temperature increase in MCR, Class 1 equipment rooms and Turbine Building electrical equipment rooms, a manual shutdown is likely for prolonged loss of VWS.	X	X	X	
Hot Water Heating	VYS supplies heated water to selected non-Class 1 AHUs. The loss of VYS will not cause a reactor trip or degrade mitigating functions.	X	X		
Liquid Radwaste	The WLS flood and major flood risks are screened out based on the maximum flowrate of the system.	X			

Table 10-52. List of Screened Out Fluid Systems From the Internal Flooding Analysis

System	Reason
Compressed and Instrument Air	The CAS only includes air filled lines (CAS SSD). Any condensate liquid from the CAS is expected to be of limited capacity and is not considered a credible flood or spray source.
Condenser Tube Cleaning	The CES is not considered as a fluid system, as its function consists in injecting cleaning balls into the condenser tubes, and by itself the system does not contain its own inventory
Turbine Island Chemical Feed	The CFS is not considered risk due to the lines being sufficiently small, the relative low flowrate of the system, and the small system inventory for each chemical used.
Condenser Air Removal	The CMS is not considered a risk due to the limited water inventory and the system is at a low pressure and temperature
Containment	The CNS is screened out from the analysis due to the fact that any fluid system covered within this system is already explicitly considered
Condensate Polishing	The CPS is screened out from the internal flooding analysis as it is not used above 33% plant power level nor does it support any Category-A function, any licensing-related functions or any defence-in-depth function
Standby Diesel and Auxiliary Boiler Fuel Oil	The system components are to be located outdoors in the yard area and inside the Diesel Generator Building of the plant facility which is located on a separate foundation at a distance from the Nuclear Island structures
Storm Drain	DRS is a passive system which is not normally intended to contain fluid inventory
Generator Hydrogen and CO_2	Since the operating fluids of HCS are hydrogen and carbon dioxide, there is no risk of flood, spray or HELB effects in this system
Main Turbine and Generator Lube Oil	According to Section 1.4.1 of the EPRI guidelines any pressure boundary failure is excluded and should be addressed in an internal fire PSA
Passive Containment Cooling	The PCCWST is normally isolated from its makeup sources, precluding any flooding as PCS piping located in the Auxiliary Building does not normally contain water
Plant Gas	This is not a fluid system that could cause a plant trip through one of the common modes of internal flooding failure
Passive Core Cooling	There is no flooding risk from a PXS pressure boundary break in the unscreened flood areas, and the system can be screened out from the internal flooding analyses
Gravity and Roof Drain Collection	The RDS is a passive system, not normally intended to contain fluid inventory
Normal Residual Heat Removal	The RNS is a normal standby non-Class 1 system. A pressure boundary failure will not cause a system actuation.

Table 10-52. List of Screened Out Fluid Systems From the Internal Flooding Analysis (cont.)

System	Reason
Raw Water	There is no RWS piping inside any building of the plant
Sanitary Drainage	Flood, major flood, and HELB risks are not a concern due to the operating flow, temperature, and pressure. The SDS spray risk is screened out based on the fact spray effects can affect no more than one system.
Secondary Sampling	The SSS does not perform or support any Category-A function, any other licensing-related functions or any defence-in-depth function. The SSS has a limited system inventory.
Turbine Island Vents, Drains and Relief	As TDS is used for venting, drainage, and high energy fluid relieving when needed, it is not considered to normally have water inventory in its piping.
Containment Leak Rate Test	The VUS performs containment isolation as a Category-A function. Containment isolation valves and the portion of piping that maintains the integrity of the containment pressure boundary are discussed in individual systems.
Gaseous Radwaste	The WGS operates with a gaseous fluid, so there is no flood risk to be concerned with.
Radioactive Waste Drain	WRS is not considered to normally have water inventory in its piping, and, therefore, it can be screened out as a potential flood source from the internal flooding analysis.
Solid Radwaste	The WSS in general does not handle fluid.
Waste Water	WWS performs drainage functions and is not considered to have normally water inventory in its piping.
Yard Fire Water	Based on the intended function of the system, yard fire control, the system equipment and piping are located outside areas where reactor trip or mitigating equipment is housed.

Table 10-53. Internal Flood Source List

PPP	System Description
ASS	Auxiliary Steam Supply System
BDS	Steam Generator Blowdown System
CCS	Component Cooling Water System
CDS	Condensate System
CVS	Chemical and Volume Control System
CWS	Circulating Water System
DTS	Demineralized Water Treatment System
DWS	Demineralized Water Transfer and Storage System
FPS	Fire Protection System
FWS	Main and Startup Feedwater System
GSS	Gland Seal System
HDS	Heater Drain System
MSS	Main Steam System
MTS	Main Turbine System
PSS	Primary Sampling System
PWS	Potable Water System
SFS	Spent Fuel Pool Cooling System
SGS	Steam Generator System
SWS	Service Water System
TCS	Turbine Building Closed Cooling Water System
VWS	Central Chilled Water System
VYS	Hot Water Heating System
WLS	Liquid Radwaste System

Table 10-55. Internal Fire Sensitivity Studies

Case	CDF	ΔCDF (%)	LRF	ΔLRF (%)
Assumed routing equipment set to "screened"	5.46E-07	-19.4	[ ]	-2.9
All Severity Factors set to 1.0	7.46E-07	10.2	[ ]	8.2
Manual Detection Time = 5 minutes	6.52E-07	-3.7	[ ]	-3.2
Manual Detection Time = 25 minutes	6.77E-07	0.0	[ ]	0.0
All conditional failure probabilities removed and their corresponding basic event set instead to 1.0	1.17E-06	72.8	[ ]	43.8
HRRs updated per NUREG-2178 methodology(1)	6.02E-07	11.1	[ ]	10.4
Removing credit for automatic detection and suppression	8.27E-07	22.2	[ ]	5.9
Screening all Multi-Compartment Analysis scenarios	4.13E-07	-39.0	[ ]	-26.1

Note:
(1) The benefit of applying the two NUREG-2178 heat release rates is suppressed by the fact that many ignition sources go to full compartment burn or detailed sources have very small assumed distances to the nearest target.

Table 10-56: Review of Top Fire Compartments for CDF

Fire Compartment	Fire Compartment Description	CDF	% Contribution to CDF	Description of Risk Contributors
1232AF12312	Division C RCP Switchgear Room	1.96E-07	28.91%	The fire risk is primarily driven by a High Energy Arcing Fault (HEAF) or an electrical fire starting in one of the RCP switchgear cabinets. This fire compartment has many cable trays routed through it and the switchgear fire may ignite these trays, causing the temperature in the fire compartment to exceed the damaging hot gas layer temperature of 330°C. Multi-compartment effects therefore have to be taken into consideration. The risk for these multi-compartment scenarios are driven by common cause failure of automatic and manual PMS signals, combined with the fire failing DAS. If common cause failure of PMS only affects the automatic PMS signal, operators have a relatively high failure probability to manually take action to maintain cooling. These actions include failing to depressurize the RCS, failing to start CMT injection, and failure to actuate PRHR.
1254AF12554	Auxiliary Building Security Room	7.56E-08	11.17%	The fire risk is primarily driven by transient fires and two fixed ignition sources in the fire compartment. A fire in this fire compartment causes a spurious DAS signal that operators fail to prevent, which initiates spurious IRWST recirculation. Operators then fail to isolate the recirculation line. ZRS power supports are assumed to be failed for this fire compartment given the uncertainties in cable routing. Loss of ZRS fails startup feedwater cooling to both steam generators and plant-specific power failures fail makeup water, resulting in loss of main feedwater pump capability to cool the steam generators. Failure to isolate the recirculation line is assumed to fail PRHR decay heat removal and IRWST injection (both passive and active) due to draining of the IRWST tank.

Table 10-56: Review of Top Fire Compartments for CDF (cont.)

Fire Compartment	Fire Compartment Description	CDF	% Contribution to CDF	Description of Risk Contributors
2030AF20300	Turbine Building Elevation 100’	4.61E-08	6.80%	The fire risk is driven by the assumption that the fire damages all targets in the fire compartment. The consequence of a fire in this fire compartment is low but there are hundreds of ignition sources present and the increased frequency increases the risk. Components important to risk in this area include the condenser steam dump valves (can induce steam line break downstream of the MSIVs) and cables linked to the station transformers (can induce a loss of offsite power).
0000AF01	Yard	3.45E-08	5.09%	The fire risk is driven by loss of offsite power sequences caused by fire-induced failure of the station transformers. This area is modeled such that all fire scenarios are assumed to damage all targets in the fire compartment. The consequence of a fire in this fire compartment is low but there are hundreds of ignition sources present and the increased frequency increases the risk. ZRS power supports are assumed to be routed through this fire compartment, which fails startup feedwater from cooling both steam generators. Cables linked to ZRS components can be revisited once the routing has matured.

Table 10-56: Review of Top Fire Compartments for CDF (cont.)

Fire Compartment	Fire Compartment Description	CDF	% Contribution to CDF	Description of Risk Contributors
1201AF06	MSIV Room	3.09E-08	4.57%	The fire risk is driven by transient and oil fires, both of which are assumed to damage all targets in the fire compartment. Transient fires are typically refined based on routing of high value cables; however, given the pre-operational state of the plant, transients should be refined after the cable routing information has matured for this location. Oil scenarios have a very high degree of uncertainty with how the pool will spread and this fuel often produces very high heat release rates due to the large area available for combustion. Given the uncertainty with oil spill behavior, it is common industry practice to fail all targets in a fire compartment for oil fires. Components important to risk in this area include steam line valves whose failure can induce a steam line break upstream of the MSIVs and the air-handling units for the Train B CVS makeup pump train. These fire-induced failures, combined with independent failure of CMT injection, leads to core damage.
2050AF20500-Partial	Turbine Building 141’	2.56E-08	3.79%	Fire compartment 2050AF20500 is elevation 141’ 3” in the turbine building. This floor of the turbine building contains cables linked to the station transformers in one corner of the compartment. Ignition sources that are sufficiently far from these transformer cables are mapped to the fire compartment 2050AF20500 – Partial, which excludes these cables from failing. The consequence of a fire in this fire compartment is low but there are over a hundred ignition sources present and the increased frequency increases the risk. The dominant cutset for this fire compartment is spurious opening of the condenser steam dump valves coincident with the independent failure of the reactor control rods to insert and the turbine failing to trip due to failures in PMS and DAS.

Table 10-56: Review of Top Fire Compartments for CDF (cont.)

Fire Compartment	Fire Compartment Description	CDF	% Contribution to CDF	Description of Risk Contributors
1240AF01	Non-Class 1E Penetration Room	2.53E-08	3.74%	The fire risk is driven by the assumption the fire damages all targets in the fire compartment. Cables/components important to risk in this area include power supplies for DAS. The top cutsets for this fire compartment consist of fire-induced loss of DAS, common cause failure of PMS, and operators failing to respond following automatic failure of PMS.
2151AF21580	South Bay Elevation 135'-3" General Area	2.10E-08	3.11%	The fire risk is driven by the assumption the fire damages all targets in the fire compartment. Transient fires are typically refined based on routing of high value cables; however, given the pre-operational state of the plant, transients should be refined after the cable routing information is more mature for this location. This fire compartment is not as risk-significant as fires propagating from this location and damaging surrounding fire compartments.

Table 10-57: Review of Top Fire Compartments for LRF

Fire Compartment	Fire Compartment Description	LRF	% Contribution to LRF	Description of Risk Contributors
1232AF12312	Division C RCP Switchgear Room	1.01E-08	18.04%	Following the failures leading to core damage identified in Table 10-56, LRF is driven by failure to isolate VFS penetrations when the VFS purge and supply lines are open and the PMS and DAS isolation signals fail.
2030AF20300	Turbine Building Elevation 100’	7.76E-09	13.86%	Following the failures leading to core damage identified in Table 10-56, LRF is driven by fire-induced failure of the power systems supporting the VLS Hydrogen igniters. Independent failure of the diesel generators combined with a fire-induced loss of offsite power fails ac power to the buses that support the dc battery chargers. Loss of the station transformers also fails the diverse ac power source for the Hydrogen igniters.
1240AF01	Non-Class 1E Penetration Room	7.64E-09	13.66%	Following the failures leading to core damage identified in Table 10-56, LRF is driven by fire-induced failure of the VLS Hydrogen igniters.
0000AF01	Yard	3.55E-09	6.35%	Following the failures leading to core damage identified in Table 10-56, LRF is driven by failure of the PCS to provide flow to the containment shell. Primary PCS fails when the automatic PMS and DAS signals independently fail and operators fail to diagnose high containment pressure and manually actuate PMS and DAS. Alternate PCS alignments also fail due to the operator error to diagnose high containment pressure.
4031AF40310	Annex Building Battery Room 2	3.40E-09	6.08%	The fire risk is primarily driven by the assumption the fire damages all targets in the fire compartment and propagates to multi-compartment scenarios. Important mitigating equipment/cables contained in this compartment are the electrical buses powering the DAS signal to close IRWST gutter valves, and the power supply for PLS signalling to support SFW.

Table 10-57: Review of Top Fire Compartments for LRF (cont.)

Fire Compartment	Fire Compartment Description	LRF	% Contribution to LRF	Description of Risk Contributors
2040AF20400	Turbine Building Elevation 121'6" General Floor Area	2.31E-09	4.13%	The fire risk is primarily driven by the assumption the fire damages all targets in the fire compartment. The consequence of a fire in this fire compartment is low but there are hundreds of potential ignition sources present. The increase fire ignition frequency increases the fire risk. Components important to risk in this area include the site transformers, which can induce a loss of offsite power, loss of power to Hydrogen igniters and loss of power to the buses supporting DAS. Independent failure of the diesel generator combined with common cause failure of PMS challenges the signalling capability to actuate essential Class-1 systems.
4031AF40308	Annex Building Battery Room 1	2.28E-09	4.08%	The fire risk is primarily driven by the assumption the fire damages all targets in the fire compartment and propagates to multi-compartment scenarios. Important mitigating equipment/cables contained in this compartment are the Train B SFW pump, and the bus supporting the electrical support to the Train A SFW pump.
4032AF01	Annex Building Radiologically Controlled Area Entry/Exit	2.10E-09	3.75%	The fire risk is primarily driven by the assumption the fire damages all targets in the fire compartment. Core damage is driven by cable failures of the DAS power supply combined with common cause failure of PMS. LRF is driven by cable failures of the diverse power supplies to the Hydrogen igniters, with the EDS transformer failing ac power and the battery charger failing to recharge the batteries to provide dc power.

Table 10-57: Review of Top Fire Compartments for LRF (cont.)

Fire Compartment	Fire Compartment Description	LRF	% Contribution to LRF	Description of Risk Contributors
4031AF40303	Annex Building – Turbine Building Corridor	1.93E-09	3.45%	The fire risk is primarily driven by the assumption the fire damages all targets in the fire compartment. Transient fires are typically refined based on routing of high risk value cables; however, given the pre-operational state of the plant, transients should be refined after the cable routing is more mature for this location. Components important to risk in this area include the redundant and diverse power supplies for the Hydrogen igniters and for DAS control.
1100AF11300B	Containment Floor (North half)	1.66E-09	2.98%	The fire risk is driven by a transient fire scenario. The fire occurs in an area that induces a PMS signal that induces spurious recirculation of the IRWST. Additionally the fire fails the Train B IRWST isolation path from actuating. Independent failure of the SFW control valves cause a loss of cooling to the steam generators and results in core damage. LRF is driven by fire-induced failure of the VLS Hydrogen igniters.

Table 10-58. External Hazards Screening Scenarios

Case	Description	CCDP	Max. IEF
1	Hazard-induced LOOP	3.8E-07	2.6E-02
2	Hazard-induced LOOP coincident with unavailability of the non-Class 1 systems	4.3E-06	2.3E-03
3	Hazard-induced reactor trip (general transient with main feedwater) and failure of all operator actions	9.0E-07	1.1E-02

Table 10-59. Fujita Tornado F Scale Intensity Wind Speed Relationships (From Table 2-1 of Reference 10.64)

Intensity	Description	Original Fujita Scale [Fastest 0.40 km (Quarter Mile), km/hr (mph)]	Fujita Scale [3-Second Gust, km/hr (mph)]	Operational Enhanced Fujita Scale [3-Second Gust, km/hr (mph)
F0	Light Damage	64.37 – 115.87 (40-72)	72.42 – 125.53 (45-78)	104.61 – 136.79 (65-85)
F1	Moderate Damage	117.48 – 180.25 (73-112)	127.14 – 188.29 (79-1170	138.40 – 177.03 (86-110)
F2	Considerable Damage	181.86 – 252.76 (113-157)	189.90 – 259.10 (118-161)	178.64 – 217.26 (111-135)
F3	Severe Damage	254.28 – 331.52 (158-206)	260.71 – 336.35 (162-209)	218.87 – 265.54 (136 – 165)
F4	Devastating Damage	333.13 – 418.43 (207-260)	337.96 – 420.04 (210-261)	267.15 – 321.87 (166-200)
F5	Incredible Damage	420-04 – 511.77 (261-318)	421.65 – 510.16 (262-317)	> 321.87 (>200)

Table 10-60. Description of Saffir-Simpson Scale (Hurricanes) (Reference 10.63)

Category Number	Wind Speed	Category Description
1	119.09 – 152.89 km/hr (74-95 mph)	Storm surge generally 1.22-1.52 m (4-5 ft) above normal. No real damage to building structures. Damage primarily to unanchored mobile homes, shrubbery, and trees. Some damage to poorly constructed signs. Also, some coastal road flooding and minor pier damage.
2	154.50-177.03 km/hr (96-110 mph)	Storm surge generally 1.83 – 2.44 m (6-8 ft) above normal. Some roofing material, door, and window damage of buildings. Considerable damage to shrubbery and trees with some trees blown down. Considerable damage to mobile homes, poorly constructed signs, and piers. Coastal and low-lying escape routes flood 2-4 hours before arrival of the hurricane centre. Small craft in unprotected anchorages break moorings.
3	178.64 – 209.21 km/hr (111-130 mph)	Storm surge generally 2.74-3.66 m (9-12 ft) above normal. Some structural damage to small residences and utility buildings with a minor amount of curtain wall failures. Damage to shrubbery and trees with foliage blown off trees and large trees blown down. Mobile homes and poorly constructed signs are destroyed. Low-lying escape routes are cut by rising water 3-5 hours before arrival of the centre of the hurricane. Flooding near the coast destroys smaller structures with larger structures damaged by battering from floating debris. Terrain continuously lower than 1.52 m (5 ft) above mean sea level may be flooded inland 12.87 km (8 miles) or more. Evacuation of low-lying residences with several blocks of the shoreline may be required.
4	210.82 – 249.45 km/hr (131-155 mph)	Storm surge generally 3.96- 5.49 m (13-18 ft) above normal. More extensive curtain wall failures with some complete roof structure failures on small residences. Shrubs, trees, and all signs are blown down. Complete destruction of mobile homes. Extensive damage to doors and windows. Low-lying escape routes may be cut by rising water 3-5 hours before arrival of the centre of the hurricane. Major damage to lower floors of structures near the shore. Terrain lower than 3.05 m (10 ft) above sea level may be flooded requiring massive evacuation of residential areas as far inland as 9.66 km (6 miles).
5	>249.45 km/hr (>155 mph)	Storm surge generally greater than 5.49 m (18 ft) above normal. Complete roof failure on many residences and industrial buildings. Some complete building failures with small utility buildings blown over or away. All shrubs, trees, and signs blown down. Complete destruction of mobile homes. Severe and extensive window and door damage. Low-lying escape routes are cut by rising water 3-5 hours before arrival of the centre of the hurricane. Major damage to lower floors of all structures located less than 4.57 m (15 ft) above sea level and within 457.20 m (500 yards) of the shoreline. Massive evacuation of residential areas on low ground within 8.05 – 16.09 km (5-10 miles) of the shoreline may be required.

APPENDIX 10A
THE USE OF PROBABILISTIC SAFETY ASSESSMENT AND SEVERE ACCIDENT ANALYSIS TO INFORM THE AP1000 DESIGN

10A.1 Introduction

The information presented in this appendix represents historical information on the use of the PSA to inform the AP1000 plant design.

Westinghouse Electric Company has developed the AP1000 design to have a comparable electric power production capability to existing nuclear power stations, but with a level of risk more than an order of magnitude lower than the best reactors currently operating. Current nuclear power stations have achieved an acceptable level of risk by evolving ever-increasing complexity with respect to their engineered safety features, but this complexity is subject to the law of diminishing returns. If taken too far in developing a new design, very low levels of risk might be achievable but at a price so high that it would be uneconomical to build the nuclear power station.

Westinghouse has taken an alternative approach in designing the AP1000; it has reduced complexity by making the engineered safety features passive rather than active to the maximum degree feasible, thereby achieving a very high level of safety and a simplified design. The basic design, based on AP600 design, uses the concepts of inherent safety, fault tolerance, passive safety and defence in depth to produce a design whose risks are significantly lower than earlier designs.

This basic design was subsequently enhanced by using PSA to identify worthwhile improvements, that is, reasonably practicable improvements that would decrease the overall risk from the plant.

This process has two components: a systematic review of the dominant or major cut-sets for CDF and LRF to determine design changes that would have a significant contribution to risk reduction; and using the conclusions of the SAMDA process to identify further risk-reducing measures by evaluating the potential for modifications that might provide significant and practical improvements to the radiological risk profile of the design.

10A.2 Use of Probabilistic Safety Assessment to Inform the Design

10A.2.1 Background

The AP1000 designers chose to use the PSA as a tool to investigate various detailed design solutions and operational strategies to optimise safety. The PSA provides insights on what is contributing to the risk, and it enables potential design improvements to be explored quantitatively. Addressing PSA issues at the design process leads to a low level of risk and results in an ALARP design.

10A.2.2 Design Improvements Introduced as a Result of the AP600 Design Probabilistic Safety Assessment

Design improvements were incorporated in the AP600 design based on the results of the AP600 PSA.

The most significant design changes prompted by the AP600 design PSA are as follows:

- ADS Stages 1, 2, and 3 in-service test frequency was been changed to occur every refuelling. This change had a positive impact on the spurious ADS actuation frequency.

- In the first three stages of the ADS, both series MOVs are closed during normal operation instead of one closed/one open. This reduces the frequency of spurious actuation of the ADS.

- The ADS Stage 4 valves were originally motor operated like the ADS Stage 1/2/3 valves. This led to a low reliability of ADS. The ADS Stage 4 valves were changed to gas piston gate valves, and later changed to squib valves to gain even more reliability.

- The number and size of the fourth-stage ADS valves has been increased. In the event of a SLOCA, this modification provides a redundant and diverse path for depressurisation in case of a CCF of the MOVs in the first three stages of the ADS.

- The DAS is provided to automatically actuate selected systems such as the PRHR, the CMT, the PCS, reactor trip, and containment isolation. In addition, the system provides alarms and information to the MCR for manual actuation of these systems.

- Diversity is provided in the DAS by using components that are diverse from the microprocessor-based components used in the PMS and the PLS. This reduces the importance of potential CCFs (both hardware and software) of microprocessor-based components of the PMS and the PLS that process information and provide for actuation of accident mitigation systems.

- The diversified functions are selected on the basis of PSA insights to reduce the CDF and to reduce the conditional probability of large-release frequency given core damage.

- Manual actuation of the RNS can be accomplished from the MCR. The RNS provides diverse means of coolant injection in case of failure of the check valves of the IRWST. An emergency operating procedure requires aligning the RNS when the ADS is actuated.

- Two parallel paths, each containing a squib valve and a check valve in series, are used for gravity injection from the IRWST. This improves the IRWST reliability for the case of single valve failure during an SI line break event or for the case of a CCF of the two check valves in other events requiring full reactor depressurisation.

- The check valves in the CMT injection lines are designed so that they remain in the open position during the plant normal operation. This design eliminates opening failures and CCFs with the accumulator check valves.

- The ADS is automatically actuated during a transient event with loss of both secondary side heat removal and PRHR capability. This is accomplished by the provision to automatically actuate the CMTs on low SG level and high hot leg temperature signals. CMT injection subsequently causes actuation of the ADS. This improvement reduces the importance of the operator actions.

- Automatic opening of the MOV of the IRWST injection line occurs on a low hot leg water level signal. These valves are closed during shutdown conditions, such as

mid-loop and vessel-flange operation when the RCS is at atmospheric pressure. This also reduces the importance of operator action on these events.

- Alarms are provided in the MCR to inform the operator of mis-positioned isolation valves (IVs) of the PXSs that have remote manual control capability. This reduces the probability of valve mis-positioning.

- Protection system logic is adopted to preclude the SG from overfilling during an SGTR event. This reduces the need for full reactor depressurisation and reduces the frequency of core damage for SGTR events with BP.

- The capability to manually actuate the draining of IRWST water into the reactor cavity is provided. This is incorporated to address a core damage event in which the injection of IRWST water to the RV fails. This drained water cools the core debris inside the RV, removing the heat through the RV wall and avoiding failure of the RV.

10A.2.3 Review of Defence-in-Depth Systems

The International Atomic Energy Agency (IAEA) recognises a number of levels of defence in depth:

- Level 1 – Duty systems
- Level 2 – Systems that are deployed to control abnormal operation and detect failures
- Level 3 – Robust safety measures

These levels correspond to the AP1000 Class 3, Class 2 and Class 1 SSCs, respectively. In the case of the AP1000 design, nuclear safety is less dependent on the Class 3 and Class 2 (Levels 1 and 2) systems then conventional PWRs because of the presence of Class 1 systems. These are robust because they do not require support systems such as ac power, component cooling water and service water.

Nevertheless, sensitivity studies have been performed with the AP1000 risk model to evaluate the significance on risk of the Class 3 and Class 2 (IAEA Level 1 and Level 2) safety measures, to identify those SSCs that are important in providing defence in depth. The following systems have been identified as providing significant additional defence in depth:

- DAS, Class 2 dc and Uninterruptable Power Supply System (EDS)
- Offsite power, main ac power, and onsite standby power systems
- RNS
- CCS
- SWS

Once identified, appropriate functional requirements were incorporated into their design and into the arrangements covering their operation, maintenance and testing, so as to provide reasonable assurance that these SSCs would be operable during the anticipated events. For most of the SSCs involved, a substantial operating history is available, which defines the significant failure modes and their likely causes. The identification and prioritisation of the various possible failure modes for each SSC lead to design improvements for failure prevention or mitigation.

The AP1000 Operating Rules (Reference 10A.1, Section 4) provide control on the availability of some of these SSCs, and on their surveillance and testing frequencies, thereby

providing confidence that the reliability values assumed for them in the PSA will be maintained during plant operations.

These SSCs are also included in the design reliability assurance programme (D-RAP) (Reference 10A.2, Section 17.4) whose purpose is to make sure that the important reliability assumptions made as part of the PSA remain valid throughout plant life (see Section 5.9.3 of this PCSR). The PSA input includes specific values for the reliability of the various SSCs in the plant that provide the defence-in-depth capability.

10A.2.4 AP1000 Design Enhancements Implemented Based on PSA Insights

This section summarises the main design enhancements that are incorporated into the AP1000 plant due to PSA insights and results.

Insights from the AP1000-specific PSA and supporting risk analyses for external and shutdown events, including importance analyses and cut-set screening were used continuously throughout the development of the AP1000 design. The PSA dominant cut-sets and sequences were reviewed to identify the major risk contributors and if feasible risk-reducing alternatives were identified (analysis, procedural, design, and technical specification) and implemented. The total plant risk has been lowered to a point that it has become very difficult to find further cost-effective plant improvements. This design improvement process has been an intimate and natural part of the design and risk evaluation process. This process has resulted in the following plant design modifications:

- Changed the normal position of the two containment motor-operated recirculation valves (in series with squib valves) from closed to open.

  The normal position of the two MOV lines in the two sump recirculation lines have been changed from normally closed to normally open to improve the reliability of opening these paths. These two paths support containment recirculation for core cooling and IRWST draining for IVR. This change reduced the CDF and LRF contribution from the failure modes to open the MOVs.

- Changed IRWST drain procedure so it occurs earlier for IVR support

  Credit is taken for operator action to drain the IRWST into the sump to preserve RV integrity following core melt. The procedure for this severe accident response has been modified so that the operator action associated with IRWST draining is moved to the beginning of the procedure to allow more time for operator success and also to fill the cavity as soon as possible. This improves the probability of success of the operator action.

- Improved IVR heat transfer

  In going from AP600 to AP1000, the heat loads during IVR are increased due to the larger core power level which reduced the margins in the heat removal capability through the RV head during IVR. To compensate for the increase in core power, the critical heat flux (CHF) limit on the outside of the RV has been increased by a reactor vessel insulation design that provides an improved design of the baffle around the lower head to enhance the heat removal.

- Improved IRWST vents

  The larger core in the AP1000 can generate more hydrogen in a severe accident. In the AP1000 hydrogen analysis for Level 2, it was observed that the standing hydrogen diffusion flames at the IRWST vents resulted in a larger thermal loads to the containment steel shell, potentially leading to containment wall failure. The design of the vents has been changed to minimise this potential concern; during a severe accident, the IRWST vents located well away from the containment wall will open and the IRWST vents located next to the containment wall will not open.

- Added third PCS drain valve

  Due to the reduced containment surface area per MW of core power in the AP1000 core, natural air circulation without a PCS water drain may not always be sufficient for long-term (>1 day) containment heat removal in AP1000. For AP600, it was always sufficient for an indefinite time. To reduce the uncertainty in whether air cooling is sufficient to provide adequate long-term containment heat removal, a third path was added to the PCS drain lines to increase PCS reliability. The IV used in the third path is an MOV, which is diverse from the AOVs used in the other two lines. This provides considerable improvement in the PCS water drain reliability.

- Improved reliability of containment recirculation

  An examination of the AP1000 plant CDF cut-sets revealed that the CCF of 4/4 recirculation line squib valves was a dominant contributor to CDF and LRF. This failure mode was reduced by adopting diverse squib valves; two of the IRWST injection paths use high-pressure squib valves, and two use low-pressure (LP) squib valves. The design change reduces the CCF failure contribution of the recirculation squib valves to CDF and LRF. The two types of squib valves are sufficiently different and belong to different CCF groups. The increase in the group size of the high-pressure squib valves from four to six (including the four from the IRWST injection lines) does not add an appreciable contribution to the plant CDF.

10A.3 Conclusions

APPENDIX 10A describes how the basic design of AP600 and, subsequently, AP1000 were reviewed using insights from the PSA and severe accident analysis to identify reasonably practicable design changes that would significantly reduce the risk from the plant.

The risks from AP1000 were already lower than comparable plants of an earlier generation. As a result of these reviews, a number of design improvements have been implemented that reduce the risk further, to levels that can be seen to be ALARP.

WLS	Liquid Radwaste System
WRS	Radioactive Waste Drain System
WSS	Solid Radwaste System
WWS	Waste Water System
ZOS	On-site Standby Power System

11 INTERNAL HAZARDS

11.1 Introduction

This chapter identifies and assesses the consequences and demonstrates the tolerance of the AP1000 design to a systematically defined set of internally generated safety hazards. Internal Hazards are defined as natural or man-made hazards that originate within the controlled site and its processes as potentially influencing Category A or supporting Category B safety functions. In addition, this chapter considers appropriate consequential hazards arising from the combined influences of both internal and relevant external hazards. External hazards are further addressed in Chapter 12.

The information within this chapter is developed from the fundamental premise of identifying and addressing key safety claims of the AP1000 design. The overarching high level safety claim addressing internal hazard challenges within the AP1000 design basis is summarised as:

Claim IH-0: An internal hazard within the design basis does not prevent delivery of the Category A safety functions and supporting post 72-hour Category B safety functions necessary to respond to the postulated event.

Within the basis for this claim, operation of the AP1000 plant is tolerant to faults as the passive design significantly improves the response of the plant with appreciably reduced risk to the public, workforce, and environment. As a consequence of this design, and as consistent with the high level safety claim, AP1000 operations do not result in:

- Loss of control of core reactivity;
- Loss of control of removal of heat from the core;
- Uncontrolled exposure of plant personnel or the public to radiation, and;
- Uncontrolled dispersion of radioactivity.

The overarching high level nuclear safety claim is supported by more detailed specific claims and Sub-Claims as appropriate to the individual hazards. These claims or Sub-Claims are presented within the following sections of the Chapter as well as identification and discussion of evidentiary substantiation.

Each of these claims or subclaims falls under the general classifications of:

- Prevention of the internal hazard fault. Where claims of this nature are made, minimisation and elimination of hazards so far as is reasonably practicable from the AP1000 design have been used in the prevention of hazard initiation.

- Protection from the internal hazard fault. Where claims of this nature are made, protective measures have been incorporated into the design to safeguard the delivery of Category A safety functions from the effects of an internal hazard.

- Mitigation of the internal hazard fault. Where claims of this nature are made, mitigation of the resulting faulted conditions occurs through crediting the SSC design, selection of materials, limiting inventories, or use of redundant divisions of Class 1 SSCs.

There are a number of important conservative attributes which have been applied universally to all internal hazards assessments within the AP1000 safety case. These attributes are used to

define both the fundamental assessment approach and to establish the degree of safety margin relative to a realistic assessment of the internal hazards fault. In brief, these conservatisms are represented as:

- All internal hazards assessments within the AP1000 safety case are performed from a deterministic perspective. Hazards have not been excluded from consideration based on their hazard curve frequency of exceedance as below once in ten million years per Safety Assessment Principle EHA.19. This attribute conservatively addressed the explicit occurrence of an internal hazard faults without filtering the lower probability faults, thus creating a broader base of initiating events in assessing the internal hazard. In addition to the deterministic assessment, internal hazards have also been assessed from a realistic probabilistically perspective within the AP1000 PRA as discussed within chapter 10, "Reactor Faults Probabilistic Safety Assessment and Severe Accident Analysis".

- Each of the internal hazards assessments focus on the use of unmitigated consequences as a basis for the analyses acceptance. In this manner, use of conservative assumptions as applicable to these consequences is used consistently throughout the internal hazards assessments in determining an acceptable result.

- Operator actions have been minimized in so far as possible as mitigation responses in all internal hazard assessments. In the few areas where such actions are required, cross cutting inputs and reviews from the Human Factors area (Chapter 13), including consideration of human errors, have been used to assess viability of the action and suitability of the time required.

- Analysis of internal hazard faults assume the event occurs simultaneously with the facility's most adverse permitted operating state.

- Single failure has been applied throughout the internal hazards assessments.

Further fundamental safety elements relevant to the AP1000 design and as included within the internal hazards evaluations are identified in Section 1.5, "Key Safety Attributes", including identification of passive safety systems and use of separation, segregation, redundancy, and diversity provided by the design to minimise the effects of internal and external hazards and human errors.

The internal hazards applicable to the AP1000 plant have been derived from a process of assessment and review of the internal hazards lists from the International Atomic Energy Agency (IAEA), Health and Safety Executive (HSE), a plant safety case, and in-house Westinghouse work. This process has been systematic and robust. It has produced a comprehensive list of internal hazards (Reference 11.1) against which the AP1000 plant can be assessed.

Through this structured technical review, the following list of internal hazards has been determined applicable for assessment against the overarching safety claim, supporting claims and Sub-Claims:

- Section 11.2 Internal Fires
- Section 11.3 Internal Flooding
- Section 11.4 Pressure Part Failure
- Section 11.5 Internal Explosion

- Section 11.6 Internal Missiles
- Section 11.7 Releases of Toxic, Corrosive, and Flammable Material
- Section 11.8 Dropped Loads
- Section 11.9 Biological Agents
- Section 11.10 Onsite Transport Accidents
- Section 11.11 Electromagnetic Interference

Further, the combinations of hazards, including relevant externally generated hazards, have also been assessed within the overall internal hazards scope. In doing so, Section 11.12, Combination of Hazards, is also presented.

Internal hazards may initiate internal reactor faults or other non-reactor faults (for example in the fuel and waste handling routes); together these are termed 'internally initiated faults'. The fault identification and analysis of these faults is presented in Chapter 9. This analysis has shown that there are no faults that are unique to internal hazards.

Assessments of the internal hazards relative to the AP1000 design conclude that appropriate safety measures are in place and that there is no reasoned potential for common-cause failure of a claimed safety measure due to internal hazards.

Satisfaction of the claims and Sub-Claims identified throughout this chapter demonstrates that the generic design has incorporated adequate and sufficient defences to ensure the AP1000 design is robustly secured from vulnerabilities associated with internal hazards.

11.1.1 AP1000 Site, Buildings and Plant Description

The relevant AP1000 site and buildings applicable to the internal hazards assessments in this chapter are composed of the five principal buildings of the AP1000 plant:

- Nuclear Island, comprising the Containment/Shield building and Auxiliary Building;
- Turbine building;
- Annex building;
- Diesel Generator building; and
- Radwaste building.

These structures, as well as pertinent information and technical characteristics of the AP1000 design and SSCs may be found in Chapter 6. Detailed information pertinent to assessment of individual internal hazards or combinations of hazards may be found in the relevant section.

11.1.2 AP1000 Approach to Safety

Passive safety systems are the principal means of providing Category A safety functions, i.e., any function that plays a primary role in ensuring nuclear safety (see Chapter 5). These passive SSCs alone are designed to mitigate Design Basis Accidents (DBAs) and meet safety goals for the initial 72 hours following an initiating event; this capability is demonstrated in Chapter 9. The Class 1 SSCs are the principal means of delivering the Category A safety functions.

In so far as internal hazards are concerned, the safety case demonstrates that an internal hazard within the design basis cannot initiate a fault and also prevent delivery of the safety functions that mitigate the fault. Failure of the safety system as a result of an internal hazard, where the hazard does not also initiate a reactor fault, would simply require the reactor to be manually shut down using the duty systems. Should the initiating hazard event cause failure of the duty systems but not the safety systems, then the safety systems will respond to the fault as intended and as described in Chapter 9.

Systems containing Class 1 SSCs that function to mitigate DBAs have component redundancy to satisfy the single failure criterion, such that their Category A safety functions will be performed, even in the unlikely event of the most limiting single failure occurring coincident with the postulated DBA. Additionally, all Class 1 safe shutdown SSCs are located within the Nuclear Island (NI) and, therefore, for hazards originating outside the NI, it only needs to be demonstrated that the outer structures of the NI provide sufficient protection to prevent propagation of the hazard to areas within the NI.

Within the Containment, the segregation of Class 1 SSCs is considered. For each hazard that can arise in the Containment, it is shown that safe shutdown capacity is maintained.

Since the passive Class 1 SSCs used for DBA mitigation are not used in normal operation and on their own can mitigate DBAs, the safety case can be made by demonstrating protection of Class 1 SSCs from internal hazards such that they can still deliver their safety function as shown in Table 8A-2.

11.1.2.1 Safety Functions

Presentation of the categorisation and classification methodology, in addition to a discussion of the Category A, B and C safety functions and SSC Classifications 1, 2, and 3 may be found in Chapter 5, Section 2. Further discussion on categorization and classification may be found in Chapter 15 and in References 11.26 and 11.59. SSCs that are claimed to mitigate hazard faults are listed in Table 8A-2.

11.1.2.2 Additional Defence in Depth

The AP1000 provides multiple levels of defence for most faults, especially the more frequent faults. As shown in Chapter 8, Table 8A-2, frequent faults have two diverse sets of systems that provide mitigation. For example, a typical intact circuit frequent fault, the primary reactor heat removal system is by use of the Class 1 PRHR heat exchanger. The diverse backup is a passive feed and bleed capability that uses Class 1 ADS, Accumulators, IRWST injection and Containment recirculation.

In addition, to these credited Class 1 SSCs, the AP1000 plant has another level of defence for more frequent faults that provides improved investment protection. These Class 2 defence in depth (DiD) systems use active components, such as pumps, with power from onsite AC power supplies. Redundancy for more likely failures is provided to improve system and response reliability. Examples of these systems include the SFW, RNS, SFS, CCS and SWS. These Class 2 DiD systems are not credited in the AP1000 deterministic safety case and, as a result, are not further assessed for internal hazards.

11.2 Internal Fire

11.2.1 Introduction

In demonstrating that a postulated fire within the design basis does not prevent delivery of the Category A safety functions, an assessment within each area of the AP1000 plant as based on a set of criteria and assumptions is undertaken in light of both international and national guidance (References 11.4, 11.21, 11.22, 11.23, and 11.24). The detailed analysis which underpins this assessment is presented in full in Table 11.2-2. This fire analysis follows the guidance of Branch Technical Position (BTP) CMEB 9.5-1 (Reference 11.22) to evaluate the consequence of fires within the plant, document the capabilities of the passive and active fire protection features and evaluate the impact of fire on the delivery of Category A safety functions. The analysis was an integral part of the process of selecting passive fire protection methods, ventilation and smoke control, fire detection, alarm and suppression systems, and provides a design basis for the FPS. Chapter 8, Table 8A-2, lists the Class 1 SSCs claimed to mitigate design basis fires.

11.2.2 Internal Fire Claims, Arguments and Evidence

11.2.2.1 Claims Overview

This section presents the claims, arguments and underlying evidence made in relation to internal fire hazards with the potential to impact safe shutdown.

11.2.2.2 High Level Claim

An internal fire could cause a transient from normal operation of the reactor power plant with the potential to result in a hazard on or off site being realised. In response to such a transient, it may be necessary to shut down the reactor and return it to a safe state. Depending on the exact nature of the transient, there are a number of courses of action to take to shut the reactor down. Ensuring the availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be shut down and maintained in a safe state, and is the basis of the following high level claim.

Claim IH-1.0 **Postulated fire events within the design basis do not prevent the delivery of the Category A safety functions and the supporting post-72 hour Category B safety functions necessary to respond to postulated events.**

Within the design of the AP1000 plant, this has been achieved by:

- Minimising the fire hazard so far as reasonably practicable;
- Protecting redundant divisions of Class 1 SSC by segregation with the use of fire barriers where practicable;
- Protecting redundant divisions of Class 1 SSC by separation within the Containment ;
- The use of fail-safe equipment.

11.2.2.3 Prevention Claims

For the purposes of the design basis fire assessment, an internal fire is assumed to occur wherever combustible material is present; no claim is made on the absence of an ignition source. Therefore, the fire safety case does not utilise specific prevention claims to minimise the potential for postulated fire events.

Although it is not possible to preclude the possibility of a fire where combustible material is present, it is possible to minimise the severity of the fire by minimising the quantity and type of combustible material present.

Claim IH-1.1: **The internal fire hazard has been minimised so far as is reasonably practicable**

11.2.2.4 Protection Claims

Whilst it is not possible to protect the SSC present in the fire compartment, fire compartmentalisation has been used to protect redundant SSC.

Claim IH-1.2: **Class 1 SSCs will be protected from the direct or indirect effects of a fire by isolating the source of the fire**

Sub-Claim IH-1.2.1: **A postulated fire outside containment will not propagate beyond the fire area of inception; therefore, redundant Class 1 SSCs will not be disabled by a postulated fire event.**

Sub-Claim IH-1.2.2: **A postulated fire within containment will not propagate to the extent that it damages redundant safe shutdown components.**

Sub-Claim IH-1.2.3: **Penetrations through barriers do not degrade the fire withstand capability of the barrier itself.**

11.2.2.5 Mitigation Claims

The AP1000 fire safety case does not utilise mitigation claims by use of SSCs or operator actions.

11.2.2.6 Arguments and Evidence

Prevention Arguments and Evidence

Claim IH-1.1: The internal fire hazard has been minimised so far as is reasonably practicable

In the AP1000 design, the potential for a fire to affect Class 1 SSCs that are not located in the zone of the fire has been reduced by minimising the quantities, controlling the use, and providing appropriate storage of combustible materials. Significant quantities of combustible or flammable materials are not stored in the NI, and areas with high fire loads are segregated from areas containing Class 1 SSCs by appropriately classed fire barriers. Within the AP1000 design, the fire hazard has therefore been minimised by:

- Selecting materials for construction which are non-combustible, fire-retardant and fire resistant wherever possible (see Chapter 6);
- Minimising the fire loading;
- Segregating significant fire loads from areas containing Class 1 SSCs (i.e., the Nuclear Island).

11.2.2.7 Protection Arguments and Evidence

Claim IH-1.2: Redundant divisions of SSC will be protected from the direct or indirect effects of a fire by isolating the source of the fire

The AP1000 design utilises two principles to inhibit the spread of fire during a design basis event:

- In areas outside Containment, the plant is segregated into fire compartments, composed of one or more rooms within a plant area, separated by suitably rated fire barriers. The fire barriers are capable of withstanding a total burn of all combustible material within the fire area;
- Within the Containment, fire spread is prevented by providing adequate separation of equipment by distance or height (particularly for redundant Class 1 SSCs), and by the use of passive fire-protection features to partially segregate redundant SSCs.

Sub-Claim IH-1.2.1: A postulated fire outside containment will not propagate beyond the fire area of inception; therefore, except for the main control room, redundant Class 1 SSCs will not be disabled by a postulated fire event

Argument: The barriers which physically segregate fire areas are capable of withstanding, without failure, the complete burnout of all combustible material within the fire area

Based on a review of the layout of Class 1 SSC delivering Category A safe shutdown safety functions, the AP1000 NI has been sub-divided into a series of fire areas. To prevent the spread of fires, each fire area is enclosed by fire-resistant barriers which provide passive fire protection of the Class 1 SSCs located in other fire areas.Fire compartmentalisation is used extensively throughout AP1000 plant. The fire compartments are detailed in Table 11.2-1.

The Hazard Barrier Matrix (Reference 11.9) identifies the walls, floors, and ceilings forming the fire barriers in the NI, which together make up the fire compartments. The fire barriers separating safe shutdown equipment are constructed to withstand the complete combustion of the fire load within the fire compartment (full-room burnout) as determined in Reference 11.8, thereby preventing the fire from propagating across to, or otherwise causing direct or indirect damage to, materials or items on the sides of the fire barrier that are not directly exposed to the fire. This prevents the effects of a fire in one fire area from damaging redundant SSCs located in adjacent fire areas. Although, in the majority of cases, the walls, floors and ceilings of individual rooms are able to are to withstand the complete combustion of fire load within the room, no claim is made on the fire resistance rating of these internal walls, floors and ceilings.Substantiation (Reference 11.69) that the fire barriers are able to withstand the complete combustion of fire loading within the fire area has been undertaken, using the methodology described in EN 1991-1-2 (Reference 11.43), to confirm, by way of quantitative uncertainty analysis, that the fire loading is less than the claimed withstand of the fire barriers in all cases.

The effects of realistic fires have also been considered (Reference 11.69) and a comparison was made to the standard fire test time/temperature curve, as described in ASTM E119. The review concludes that, with the exception of an oil fire, the maximum hot gas layer temperatures are significantly below the ASTM E119 curve. Although the oil fire does initially exceed the ASTM E119 curve, suche a fire within the NI would self-extinguish due to a lack of combustible material before the peak temperature of the ASTM E119 curve is reached. Furthermore, the ASTM E119 curve is characterised by the ramp up rate of the furnace used for the test, rather than the properties of the test material and the initial exceedance is therefore not considered to be significant in terms of the barrier's ability to withstand the fire.

The sensitivity of the AP1000 plant to localised fires has been assessed (Reference 11.69). Although a number of instances were identified where adjacent fire areas contain redundant divisions of Class 1 SSC, the fire load in the adjacent rooms was determined to pose an insignificant challenge to the integrity of the fire barrier.

The fire barriers protecting Class 1 SSCs are themselves Class 1 structures and are rated for load-bearing capacity, integrity, and insulation as appropriate. A review (Reference 11.10) of the fire resistance rating for NI reinforced concrete (RC) structures demonstrates that the AP1000 design meets or exceeds the requirements of BS EN 1992-1-2 (Reference 11.11). For the composite steel-concrete (SC) walls, floors and ceilings, detailed heat transfer analysis (Reference 11.12) has been performed which demonstrates that their structural integrity is maintained following a three hour standard fire.

Detailed analysis of the fire segregation and separation approaches adopted in the AP1000 design has been undertaken. This demonstrates that the consequences of credible fires are shown to be acceptable.

Sub-Claim IH-1.2.2: A postulated fire within Containment will not propagate to the extent that it damages redundant safe shutdown components

It is assumed that, wherever combustible material is present, an internal fire may. Within containment, the only requirement is that the fire does not subsequently spread sufficient to damage the claimed redundant Class 1SSC.

For the effects of a fire to be communicated to adjacent fire zones, absent the cross-boundary influences of cabling to be examined on a site specific basis, the source fire needs to initiate a fire in the adjacent fire zone. As the in-Containment combustible loadings are low (in most

cases, integral to SSC designs) and the influence of non-combustible structural walls largely prohibit a direct interface between fire zones except for areas of personnel access, no credible locations for such a fire being transmitted between fire zones have been identified. However, for the purposes of assessing fire spread, it is noted that damaging effects of fire spread may be realised through flame impingement, via thermal radiation or due to exposure to smoke. These potential mechanisms are discussed below. It is noted that the mechanisms of flame impingement and thermal radiation require a direct line of sight between the source flame and the target combustible material.

If the combustible material in the adjacent fire zone is sufficiently close to the source flame, and in a suitable configuration, it may be possible for the fire to spread by flame impingement. Where this is not the case, fire spread may occur through radiative heat transfer. In order to ignite a target comprising combustible material by thermal radiation, it is necessary to raise the temperature of the target to at least its flash point[1]; otherwise it is necessary to raise its temperature to the auto-ignition temperature. It is recognised that the functionality of Class 1 SSC may be lost at a temperature below the auto-ignition temperature. However, the sensitivity of the design to this depends upon detailed analysis and final plant layout which will not be confirmed until detailed design. Should it be required, Class 1 SSC will be qualified to operate in elevated temperatures or protected by insulation.

Although smoke could damage Class 1 SSC, particularly sensitive electronic equipment, the vast majority of combustible material within containment is associated with the cable insulation and jacketing material. The cable insulation and jacketing materials have been selected to meet the fire and flame requirements of IEEE 1202 (Reference 11.37) or IEEE 383 (Reference 11.38) and as such are low smoke. Smoke is therefore not expected to be a significant hazard following a fire within Containment.

Argument: The physical segregation by partition between fire zones precludes surface ignition of combustible material

For surface ignition of combustible materials to occur, it is necessary for:

- A flame to impinge on the target; and,
- The thermal flux received to be greater than the target's critical flux or the target's temperature to be raised above its auto-ignition temperature.

Where present, the majority of fire zones in Containment are separated by a combination of non-combustible walls and ceilings/floors as well as spaces devoid of combustible material with recognition that there are some locations where cable trays cross zone boundaries; see the discussion below.

Flames spread by entraining sufficient air to burn the evolved volatiles; however, the exact behaviour of flames depends on a number of factors, many of which are the subject of detailed design (e.g. proximity of combustible material to the surrounding structures). The

[1] The flash point is the temperature at which flammable vapours are released in sufficient quantities to generate a flammable atmosphere. The combustible material will only continue to burn if either the flux imparted on the combustible material remains present or combustion of the flammable vapour/air mix imparts sufficient energy to maintain the process.

walls and ceilings/floors between fire zones will act to completely or partially confine the flame, and thus prevent fire spreading to combustible material located in adjacent fire zones.

The walls/floors which make up the rooms within the Containment are SC structures formed as pre-fabricated modules. As part of the demonstration of the structural integrity of the CA20 module for example, analysis has been undertaken (Reference 11.12) to determine the point at which the walls would fail. The theoretical fire necessary to compromise the CA20 module is significantly more onerous and requires significantly more combustible loading than that present in any of the individual Fire Zones (Reference 11.8). As such, it is not considered credible that an internal fire could degrade the structural partitions to the extent that they are no longer able to perform as required to separate combustible material between fire zones. In addition, the division B & D cabling is routed from the electrical penetration room (11306) to Fire Zone 1100 AF 11500 in a fully enclosed steel-composite chase, which will be tested in accordance with the requirements of BS EN 13501-3 (Reference 11.139) to confirm that the insulation provides a 3 hour resistance to a standard fire.

In areas where the flame is not confined (i.e. not touching a boundary wall/floor/ceiling), the horizontal spread will not be significantly different to the actual size of the combustible material itself. While flames can lean when exposed to air movement, the Containment is an enclosed structure and this phenomena is not considered to be a significant factor.

It is recognised that cables and cable trays may pass between fire zones and, as such, it is possible for fires to spread along cable insulation. In general, fire zones contain cabling associated with either Divisions A and C or B and D, and therefore a fire in one fire zone will not affect all 4 Divisions of Class 1 SSC. However, there are limited fire zones where all four divisions of PMS cabling may by routed together. In these instances, redundancy is provided by an alternative SSC. Management and design specifics of cable routing are the subjects of site specific licensing as per findings AF AP1000 IH 02 through IH 04 (Reference 11.137). In addressing these Assessment Findings, the exact routing of cables and the potential for cabling to detrimentally affect the internal fire safety case will be determined. At such time, assessments are expected which confirm this argument. Where required, design changes may be considered such as cabling routing to minimise the potential for fire spread or specifications of fire wrapped / stopped cable designs used to preclude the propagation of fire or cable trays fitted with fire blocking along the exposed cable route.

Hence, absent the detailed assessment of cable routing as the mechanism for flame spread, the physical segregation by partition between fire zones precludes surface ignition of combustible material in an adjoining fire zone.

Argument: **The separation distance between the heat source(s) and target combustible materials are sufficiently large, and the duration of the fires sufficiently short, that insufficient energy would be imparted to raise their temperature to the flash point; necessary for piloted ignition.**

An evaluation of combustible material (Reference 11.8) has identified that trash, paper, volatiles, lubricating oil and cable insulation may be present variously within Containment. Some of the identified combustible materials (trash, paper and volatiles) would be transient and subject to site specific management arrangements. It is likely that these arrangements would restrict their presence within Containment to plant modes 5 & 6 only (at a time when Containment is occupied), therefore in plant modes 1 to 4 the combustible inventory will be less than that quoted.

In the absence of direct flame impingement, where the target combustible material is a liquid (e.g. lube oil), the bulk temperature of material must be raised to the flash point for piloted ignition to occur, or the temperature increased to the auto-ignition temperature for spontaneous combustion. For solid combustibles (paper, trash & cable insulation), volatiles will only be released once the surface of the material starts to decompose.

Heat transfer between a heat source and the target is possible through a combination of conduction, convection and radiation. Where the heat source and the target are not connected, heat transfer by conduction is not possible. While convection will contribute to heat transfer, the greater proportion of heat received by the target will be through thermal radiation, provided the heat source and target are not physically obscured by a medium which absorbs the thermal radiation. The amount of heat transferred to the target by radiation will depend on the:

- Emissive power of the heat source;
- Spatial relationship of the heat source to the target (view or configuration factor);
- Length of time the source continues to emit radiation.

Flame temperatures in room fires generally have zones of 900 °C but wide spatial variations may be seen and the maximum value which is regularly found is approximately 1200 °C (see Chapter 10 of Reference 11.138). At this temperature, the emissive power at the surface of the flame would be approximately 290 $kW.m^{-2}$; the emissive power is proportional to the 4th power of flame temperature and would therefore be significantly less at lower temperatures.

The radiative energy transferred between the flame source and the combustible target will depend on the geometry and orientation of the two surfaces (Reference 11.138), as well as the presence of any intermediate barriers (either full or partial). Generally speaking, thermal radiation intensity follows an inverse square law with distance, so the greater the separation distance between the source and the target, the less radiative energy will be transferred to the target.

While the geometry of the source could be approximated based on the physical constraints of a fire zone, the geometry of the target and its relationship to the source (both in terms of distance and angle) would not be fully known until detailed design.

The source will continue to emit radiation until all combustible material has been consumed. By reducing the quantity of combustible material present within each fire zone, the duration for which radiation is emitted is also minimised. Based on the fire protection analysis (Reference 11.8), the majority of fire zones within Containment have an equivalent fire duration of less than 10 minutes, with a maximum duration of 24 minutes[2].

Given this, the potential for a fire to propagate from one fire zone to another by means of heat transfer is likely to be minimal due to the short duration for which the effects of a fire in one

[2] It is recognised that the equivalent fire durations have been determined using the methodology described in the NFPA handbook, and that in some respects this may not be conservative. However a comparison (Reference 11.69) using the method described in EN 1991-1-2 (Reference 11.43) has been performed for Fire Areas outside of containment, which shows that for rooms containing just cable insulation the Eurocode derives a fire duration which is approximately 50% longer.

fire zone will exist and the extent to which those effects will have diminished before they are transmitted to the target combustible material in an adjacent fire zone.

Sub-Claim IH-1.2.3: Penetrations through barriers do not degrade the fire withstanding capability of the barrier itself.

Argument: Penetrations through fire barriers are fire-stopped to the same qualifications as the barrier through which they pass.

The number of penetrations (e.g. cabling, ventilation, pipework and doorways) through fire barriers (see Reference 11.9) have been minimised so far as is reasonably practicable. Where possible, penetrations through Class 1 barriers adjoining rooms containing redundant divisions of Class 1 SSC have been avoided.

The penetration seal schedule (Reference 11.13) provides details of all penetrations passing through walls and floors. In accordance with the AP1000 fire protection design criteria and guidelines (Reference 11.64):

- Penetrations through fire barriers will be qualified in accordance with Reference 11.15 to meet the requirements of BS EN 1366 Part 3 (Reference 11.16);
- The number of openings and penetrations in exterior fire barrier walls of safety-related buildings will be minimised.

In order to minimise the number of openings, the AP600 architectural design criteria[3] (Reference 11.140) stipulates that, where possible, multiple commodities should be grouped into a single opening to minimise the number of barrier penetration. Furthermore, the AP1000 plant design criteria (Reference 11.141) set out the requirements to develop a design that:

- Uses the minimum number of SSCs
- Requires the minimum amount of instrumentation, control functions and control loops.

In satisfying these design criteria, the AP1000 plant has minimised the number, and combined size of penetrations through barriers, including fire barriers.

In addition to penetrations, the AP1000 HVAC system passes through fire barriers. As such the HVAC system incorporates fire, smoke and combination fire/smoke dampers to prevent the propagation of fire and/or smoke to adjacent fire areas (Note: the containment shield building is a single fire compartment and ventilation dampers do not restrict the movement of air). Based on a review of ventilation dampers (Reference 11.17), all Class 1 barriers are fitted with redundant combination fire/smoke dampers. The combination fire/ smoke dampers, and associated ductwork up to the fire barrier, will be tested in accordance with BS EN 13501-3 (Reference 11.139) to demonstrate that they have a fire rating at least equivalent to the barrier through which they pass (e.g. 3 hours). The dampers will comply with the relevant parts of BS ISO 10294 (Reference 11.18), and shall be tested in accordance with the requirements of BS EN 1366-Part 2 (Reference 11.19).

[3] The AP600 is the predecessor to the AP1000 and as such the design philosophy was carrier forwards into the AP1000.

Fire doors are fitted with self-closing mechanisms to ensure that they return to the closed position when not in use. The fire doors themselves, including surround, will be qualified in accordance with BS 476: Part 24 (Reference 11.20) to provide the same fire resistance as the barrier through which they pass. In all but the following five instances, a fire would have to pass through two fire doors in order to affect redundant Class 1 SSC in a given fire area. In these five instances, the fire doors are fitted with Portal Access Controllers which monitor the door. In the event that the door is opened, and remains open for a prolonged period[4], an alarm is generated in the MCR. The Portal Access Controllers and associated alarms are Class 2 on the basis that they support the Category A safety function which is principally delivered by the fire barriers and doors. The following doors are fitted with Portal Access Controllers:

- APP-12303-AD-D01;
- APP-12304-AD-D01;
- APP-12305-AD-D01;
- APP-12423-AD-D01;
- APP-12422-AD-D01.

11.2.3 Internal Fire Safety Case Summary

11.2.3.1 Introduction and Overview

The safety design approach adopted for internal fire consists of a range of complementary design features. These are applied as appropriate to individual items of equipment or systems to prevent a fire from occurring, contain a fire to its area of origin or prevent it from propagating to protect Class 1 SSC from the effects of fire. Suitable and sufficient design features and measures are identified such that a postulated fire within the design basis, does not prevent delivery of the Category A safety functions. An assessment within each area of the AP1000 plant based on a set of criteria and assumptions is undertaken in light of both international and national guidance (References 11.4, 11.21, 11.22, 11.23, and 11.24) and the detailed analysis which underpins this assessment is presented in full in Table 11.2-2.

11.2.3.2 Applicable Codes and Standards

The internal fire hazard analysis has been undertaken in accordance with NFPA guidance (Reference 11.33), to determine the fire loading and equivalent fire duration of those combustible materials present within the plant. A comparative review has been undertaken (Reference 11.69) in accordance with BS EN 1991-1-2 (Reference 11.43), which is considered relevant good practice, the results of which form the basis of the safety assessment.

The Equivalence/Maturity Study of U.S. Codes and Standards (Reference 11.25), identifies applicable codes and standards. It also provides a clear and auditable demonstration that all

[4] The prolonged period is set by the utility, although it is intended that the 'grace period' corresponds to the length of time required for an operator to traverse the boundary of the room.

codes and standards to support the design substantiation of UK Class 1 and 2 SSCs have been identified.

To evaluate the AP1000 design's codes and standards against the UK expectations, the codes and standards applicable to the AP1000 design have been organised by the relative safety significance of the SSCs to which they have been applied. To support this organisation, the UK Safety Categorisation and Classification Methodology (Reference 11.26) describes the process for categorisation of safety functions and classification of SSCs, which indicate the significance of an SSC to deliver the relevant safety function.

Fire Barriers

The fire resistance rating of claimed fire barriers constructed from reinforced concrete have been determined in accordance with ACI 216.1 (Reference 11.45). A comparison (Reference 11.10) to BS EN 1992-1-2 (Eurocode 2) (Reference 11.11) has been undertaken to confirm that the fire resistance rating of claimed fire barriers remains valid when compared to UK codes and standards.

For SC structures, there are no codes and standards against which comparison can be made. Instead, detailed heat transfer analysis has been performed (Reference 11.12) to demonstrate the suitability of these structures when exposed to a 3 hour fire.

The UK AP1000 plant fire barriers are designed in accordance with BSI and IAEA guidance (References 11.4 and 11.23).

Fire Compartment Penetrations

Fire dampers and doors penetrating fire barriers are also fire rated for integrity and will comply with the relevant parts of the appropriate standards (References 11.44 and 11.46). UKP-GW-AF-001, "AP1000 Fire Protection Dampers – UK Compliance Report" (Reference 11.17) demonstrates that the AP1000 design conforms to appropriate BS EN codes and standards.

All penetrations within barriers will be fire stopped in accordance with relevant and appropriate BS EN standards such as BS9999 (Reference 11.4) and relevant industrial standards as described in the Association of Specialist Fire Protection (ASFP) Grey and Red Books (References 11.48 and 11.49).

Provision of Redundant Systems

The detailed fire assessment included as part of this report identifies the Category A, Class 1 components used for safe shutdown and the safety functions that they deliver (Tables 11.2-2 and 11.2-3). Where there is the potential for the Class 1 safe shutdown SSCs to be compromised by fire, redundant Class 1 safety equipment has been identified such that all Category A safety functions continue to be supported. This redundancy has been incorporated into the design taking into account the following:

- IAEA-NS-G-1.7 "Protection against Internal Fires and Explosions in the Design of Nuclear Power Plants" (Reference 11.23).
- IAEA NS-R-1, "Safety of Nuclear Power Plants: Design" (Reference 11.21).
- BTP CMEB 9.5-1, "Guidelines for Fire Protection for Nuclear Power Plants" (Reference 11.22).

- NFPA 804, "Standard for Fire Protection for Advanced Light Water Reactor (ALWR) Electric Generating Plants," 2010 (Reference 11.33).

Automatic Fire Protection System

The design philosophy for the FPS is in accordance with the guidance provided in IAEA-NS-G-1.7 (Reference 11.23) and as a minimum the FPS system is designed in accordance with the appropriate standards, such as BS 5839-1 (Reference 11.54), to provide comprehensive coverage and appropriate protection for the fire hazards identified. No safety case claim is made on the FPS.

11.2.3.3 Redundancy, Segregation, and Separation

Redundancy

In the event of a fire within any fire compartment forming part of the AP1000 plant (fire area within the Auxiliary Building and fire zone within the Containment), it is pessimistically assumed that all SSCs fail within that area. In general, this might result in the safety function(s) supported by the equipment within that fire compartment no longer being delivered and/or spurious actuations that may have a negative impact on plant safety. Therefore, in order that no safety functionality is lost, the AP1000 plant is designed such that:

- No single SSC failure can result in the failure to deliver the Category A safety functions.
- No spurious activation can cause erroneous actions that may have a negative impact on plant safety.

These two areas of design are discussed in the following subsections.

Provision of Redundant Systems

The detailed fire assessment (Reference 11.73) identifies the Class 1 safe shutdown SSCs and the safety functions that they deliver (Tables 11.2-2 and 11.2-3). Where there is the potential for the Class 1 safe shutdown components to be compromised by fire, redundant Class 1 safety equipment have been identified such that all Category A safety functions continue to be supported.

The availability of redundant equipment during a design basis fire is ensured either through use of SSCs that are qualified to withstand the effects of the fire hazard or by the controlling the spread of fire hazards through segregation and separation (e.g. by Class 1 fire barriers). These approaches ensure that no other redundant train of equipment is susceptible to the same fire.

Defence in Depth

The internal hazards nuclear fire assessment has taken no credit for the Class 2 systems that provide defence in depth for Category A safety functions, The assessment pessimistically assumes that all Class 2 systems providing Category A safety functions are unavailable, and therefore, the assessment identifies redundant Class 1 equipment in order to fulfil the safety function.

However, in practice, duty systems and Class 2 defence in depth systems are used to control abnormal conditions, should they be available, to reduce the demand on the high integrity Class 1 systems.

Prevention of Spurious Actuations of Equipment

An assessment of multiple/simultaneous spurious actuations or signals resulting from the fire leading to electrical power supply failure faults and spurious component actuations was undertaken in the AP1000 Fire Induced Multiple Spurious Actuation Report (Reference 11.56), in which components were assumed to be energised or de-energised by one or more circuit faults.

The assessment concludes that either spurious actuations do not occur, or the consequences are such that they do not prevent delivery of the Category A safety function and the Category B support functions. Principal spurious actuations are discussed below.

High-Low Pressure Interfaces

High-low pressure interfaces between the RCS and interfacing systems, such as the RNS, typically contain two redundant and independent motor-operated valves in series. On a typical PWR plant, these two valves and their control and power cables may be subject to a single fire and therefore warrant specific identification; this is considered below for the AP1000 design. Potential high-low pressure system interfaces of particular interest are discussed below. Additional discussion is contained in UKP-GW-GLR-111, "UK AP1000 Internal Hazards Topic Report – Fire Protection" (Reference 11.73).

- RCS Valve Actuation:

  Nuclear Regulatory Commission (NRC) Generic Letter 81-12 (Reference 11.57) specifically addresses the reactor coolant/residual heat removal system interface on PWRs. For the AP1000 design, the RCS to RNS interface is similar to the typical PWR configuration. However, the RNS is not a Class 1 system and is not required for safe shutdown. To preclude the spurious opening of the interface valves as a result of a fire, the power to the valves is locked out during power operations. Thus, spurious actuation of the RCS to RNS interface valves does not occur and the safe shutdown capability is not affected. In addition, the RCS to RNS interface contains a third isolation valve whose power is locked out during power operations and which is segregated from the first two valves. Finally, the RNS design pressure has been upgraded so that RCS pressure would not rupture the RNS if the two systems were connected inadvertently or as the result of a spurious valve actuation.

- ADS Valve Actuation:

  The ADS valves are not considered to be high-low pressure interface valves when postulating spurious actuations following a fire. The concern is that the spurious opening of two or more isolation valves forming the boundary between the RCS and a low pressure system could lead to damage to the low pressure system and a loss of coolant outside the Containment. Since the ADS valve actuation cannot damage a low pressure system, and since the system is entirely within Containment, the ADS valves do not represent a high-low pressure interface.

  Spurious actuation of the ADS stage 4 squib valves, as a result of fire, is prevented by the use of a squib valve controller circuit controlled by the AP1000 PMS which requires multiple simultaneous hot shorts for actuation. In the event of a fire affecting one of the PMS interface cabinets the operator is able to remove the power from that electrical division, although failure to do so does not lead to spurious actuations in other PMS interface cabinets.

ADS stages 1, 2, and 3 consist of parallel paths, each path having two motor-operated valves in series. Spurious actuation of stages 1, 2, or 3 is prevented by the use of physical separation of control circuits for the two series valves and provisions for operator action to remove power from the affected fire zone. No fire was identified which could spread to both sets of ADS stage 1, 2 and 3 valves or both sets of the ADS stage 4 squib and block valves. In addition the ADS 4 squib valve initiation charge and propellant have been shown to not initiate due to a localised fire (Reference 11.147).

- RCS Reactor Vessel Head Vent Valve Actuation:

  The reactor vessel head vent valves are connected to the reactor vessel head and discharge to the IRWST. The head vent valves are not required to operate following a fire. There are four head vent valves arranged in two flow paths with two series valves in each path. The head vent valves are fail-closed dc powered solenoid valves, and each valve is powered by a separate, Class 1 power supply. In the unlikely event that a spurious signal was to open a head vent valve, the flow path is blocked by the closed series head vent valve.

  The head vent valves are controlled from switches mounted on the primary and secondary dedicated safety panels in the control room. Each safety panel contains a switch for controlling each head vent valve.

- Other Spurious Actuations

  Principal spurious actuations not involving high-low pressure interfaces are discussed below.

  – PXS PRHR HX Valve Actuation:

    One normally open valve is provided to isolate the inlet line to the PRHR HX. To preclude the spurious closing of the inlet valve as a result of a fire, the power to the valve is locked out during power operations. Therefore, spurious closing of the passive core cooling PRHR HX inlet valve does not occur and the safe shutdown capability is not affected.

    Two normally closed air operated globe valves, in parallel, are provided to isolate the outlet line from the PRHR HX. Spurious actuation of either of these valves could result in reactivity insertion (see Chapter 8). However, the Class 1 SSC required to achieve a safe shutdown are not affected by the same fire, and therefore the safe shutdown capability is not affected (see Table 11.2-2).

  – PCS Valve Actuation:

    Two valves in series isolate each of the three discharge flow paths from the PCS storage tank. For the purposes of system reliability, one valve in each flow path is normally open and the other is normally closed.

    Spurious actuation of one of these valves is assumed to occur where a fire affects its electrical circuitry. Such a fire can occur in the MCR, an electrical equipment fire area, in the PCS valve room, or in fire areas or fire zones through which the applicable electrical cables are routed.

    Spurious actuation of one of these valves causes a PCS flow path to be disabled or inadvertently opened, depending on which valve is affected. If a normally closed

valve spuriously opens, PCS water delivery from that flow path will be initiated which does not adversely affect the capability to achieve and maintain safe shutdown. If one of the normally open valves were spuriously closed to prevent PCS water delivery through that flow path when called upon during the safe shutdown process, the redundant PCS water delivery flow paths would be sufficient to achieve and maintain safe shutdown.

Segregation

Within the AP1000 design, redundant divisions of Class 1 SSC are segregated from one another such that a fire cannot result in the loss of all divisions.

The AP1000 design utilises two principles to inhibit the spread of fire during a design basis event:

- In areas outside of Containment, the plant is segregated into fire areas composed of one or more rooms. Fire areas are segregated from one another by credited fire barriers, capable of withstand the complete burn of all combustible material present within the given fire area.

- Due to limitations on equipment positioning and routing, and the requirements of the PCS to maintain the free movement of gases and liquids, the Containment represents just one fire area. The Containment is instead divided into fire zones determined by a zone of influence. The potential for fire to spread from one fire zone to another is minimised by maximising the separation, horizontal distance or height (particularly for redundant trains of safety systems), and by the use of partial structural barriers to separate redundant divisions of Class 1 SSC, so far as is reasonably practicable.

An assessment of the adequacy of the segregation and separation design philosophy for AP1000 design forms part of the detailed assessment of individual fire areas presented within the topic report (Reference 11.73).

The location and fire resistance rating of the fire barriers is identified in the Hazard Barrier Matrix (Reference 11.9). Of note regarding these barriers:

- The walls, floors, and ceilings of fire compartments in the NI are surrounded by fire-resistant barriers. The fire barriers are constructed to withstand the complete combustion of the fire load within the enclosure (full-room burnout), thereby preventing the fire from propagating across to, or otherwise causing direct or indirect damage to, materials or items on the sides of the fire barrier that are not exposed to the fire. This prevents the effects of a fire in one compartment from damaging redundant SSCs located in adjacent fire compartments.

- Primary fire area barriers protecting Class 1 SSCs are themselves Class 1 structures and are rated for load bearing capacity, integrity, and insulation. Other fire barriers are fire rated for integrity and insulation only. In all other fire areas, the fire resistance of fire barriers is specified based on the fire load and the calculated fire severity of the fire area.

- With the exception of stairwells and elevator shafts, which are rated for 2 hours, all fire areas within the NI are all 3-hour fire compartments, except for the MCR room, where the ceiling is only credited as a fire barrier in one direction; instead, which provides adequate 3 hour fire barrier protection against for the MCR from a fire originating in the room above. These barriers are Class 1 SSCs. This is discussed in detail in the relevant

part of the non-radiologically controlled Auxiliary Building assessment within this report and assessed as adequate. Although there are no Class 1 SSCs located outside of the NI, many of the fire areas in these other buildings also form fire –resistant compartments, but these are not nuclear Class 1 barriers.

- In instances where fire severity is estimated to be greater than three hours (such as locations with a significant oil inventory), 3-hour barriers are specified, and additional active fire protection systems are installed so that the barrier are not compromised. Such barriers occur within the turbine, annex, and DG buildings, and do not occur within the NI. A fuel oil pool fire in these areas does not threaten the Category A safety function, even in the event that the active fire protection systems fail to operate (Reference 11.69). The adequacy of the fire barriers to withstand full-room burn out is presented as part of the AP1000 design assessment discussed in the topic report (Reference 11.73).

- Penetrations in fire compartment barriers including ventilation ductwork, cables and pipework, are minimised in barriers separating redundant divisions of Class 1 SSC, and fire stopped to the same fire resistance as the barrier they penetrate to reduce the potential for the spread of fire. Additionally, where vent ductwork passes between fire areas containing redundant divisions of Class 1 SSC, dual redundant combination fire/smoke dampers are provided in accordance with the requirements of the single failure criterion (Reference 11.17).

Separation

Where the segregation of fire areas by a fire-rated full enclosure is not practicable for functional reasons, Class 1 SSCs are separated by distance (horizontal and vertical) to the maximum extent practicable.

Within the Containment, the segregation and separation of Class 1 safety systems is considered. For each postulated fire hazard that can arise in the Containment, it is shown that design basis events cannot affect more than one train of redundant Class 1 SSC and that these SSC remain unaffected and are therefore available to deliver the required Category A safety function to safely shut down the reactor. There are a few specific instances where all Divisions of Class 1 SSC could be affected, however the assessment has shown that alternative means of delivering the Category A safety functions remain unaffected (Reference 11.73).

Inside the Containment, fire compartmentalisation cannot be provided because of the need to maintain the free exchange of gases and liquids for purposes such as passive Containment cooling. Instead, the Containment is a single fire area encompassing the entire building and is a 3 hour fire compartment. Within this fire area, fire zones are identified that establish each zone of influence; i.e., the extent to which a fire originating within any given location can spread and cause damage to equipment. Fire resistant barriers are incorporated where practicable to minimise fire spread beyond the fire zone via radiated and conducted heat. Detailed analysis of each arrangement is discussed in the topic report (Reference 11.73), which demonstrates that the consequences of fires are shown to be acceptable.

11.2.4 Internal Fire Assessment Approach

11.2.4.1 Identification of Fire Sources

The fire protection analysis presented in the topic report (Reference 11.73) details, on a fire area by fire area basis, the type and quantity of combustible material inherent in the AP1000

design. In accordance with relevant international guidance (Reference 11.23), a single fire is assumed to occur at any one time wherever there is combustible material present (i.e., no credit is taken for the apparent absence of ignition sources).

Assumptions

The fire-related assumptions used in the assessment of the design are of three types:

- Design basis fire assumptions.
- Design assessment assumptions.
- Initiating event and fault progression assumptions.

Design Basis Fire Assumptions

- Only a single, independent fire is assumed to occur in any plant location.

- An independent fire is not assumed to occur simultaneously with the most severe natural phenomena, e.g., tornadoes, flooding or earthquakes or during other internal initiating events such as Loss of Coolant Accidents (LOCA) or loss of off-site power. Combined hazard evaluations are presented in Section 11.12.

- The fire is assumed to occur under worst case normal plant conditions for the initiating fire which may include such states as loss of a redundant train for maintenance purposes or under early shutdown conditions when the systems are pressurised.

- Fire spread to adjacent fire areas is only discounted where adequate fire resistant barriers (and their penetrations) appropriate to the fire hazard are provided.

- Fire spread to adjacent fire zones within Containment is only discounted where adequate fire separation and or passive fire protection features are provided.

- A design basis fire is a credible initiating event for other internal hazards such as internal explosions, internal floods or loss of off-site power (the combined consequential effects of which are discussed in Section 11.12).

- Consequential fires, generated as a result of other internal initiating events, such as explosions are discussed in Section 11.12.

Design Assessment Assumptions

- Only Class 1 SSCs are assumed to be available to deliver Category A functions with no benefit claimed for available duty systems unaffected by the fire.

- A concurrent single active component failure (independent of the fire) is considered within the design assessment.

- FPS is available to detect fire and extinguish fires but no credit is taken for active systems to control or extinguish fire (no safety case claim made).

Initiating Event Assumptions

- Only a single, independent fire is assumed to occur in any plant location whether or not the area contains in situ combustible materials or any credible ignition sources are present.

- The fire leads to full room burn out damaging all equipment immediately within the fire area (or fire zone within Containment) even where normal operation of equipment (e.g., fire suppression systems) or movement of valves within the fire area would mitigate potential consequences.

- Re-entry into the affected fire area for repairs and operator actions is not considered when assessing consequences of plant safety.

- Where 3 hour fire resistant (integrity and insulation) passive fire protection features are used to protect electrical cables or ducts that only pass through the affected fire area, these are not included in the consequence assessment.

- Inside Containment, only SSCs beyond the zone of influence of the fire are assumed to be unaffected by smoke.

11.2.4.2 Fire Assessment

Each fire compartment has been assessed to determine:

- The potential for fire, and the fire severity, based on the fire loading.
- The segregation or separation between redundant divisions of Class 1
- Adequacy of redundant Class 1 SSCs required in delivering the Category A function.
- Ventilation system design to minimise fire spread.

This assessment is undertaken in the light of both international and national guidance as discussed above, reported in full in the topic report (Reference 11.73), and is achieved through the following:

- Deterministic assessment of fire within each individual fire compartment for each of the plant areas:

  – Containment.
  – Shield building.
  – Non-Radiologically Controlled Area of the Auxiliary Building.
  – Radiologically Controlled Area of the Auxiliary Building.
  – Turbine building.
  – Annex building.
  – Diesel Generator building.

- Identification of the combustible load within each fire area and, where appropriate, analysis of concentrated fire loads and the locations of these in relation to Class 1 SSCs within that area. For fire in areas containing radioactive materials, the capability to minimise and control a potential release of radioactivity is specifically addressed.

- Identification of Class 1 SSCs located within the fire area.

- Identification of the provision of segregation of Class 1 SSCs by fire compartmentalisation, other passive fire protection features or the separation by distance within each fire area (or fire zone within Containment) so as to demonstrate that a fire cannot spread to more than one train of Class 1 SSCs.

- Assessment of the provision of redundancy in the event of the postulated fire, demonstrating that alternative means of providing the Category A safety functions is maintained during and after this event so far as is reasonably practicable. This analysis also seeks to demonstrate that no design basis fire can result in the failure of multiple redundant trains of safety equipment. The potential for consequential loss as a result of fire spread is also considered.

Because of the roles the ventilation plays in preventing fire spread and maintaining plant habitability, control of fire and smoke spread via the ventilation system is specifically assessed to demonstrate that no design basis fire can result in the failure of multiple redundant trains of safety equipment.

The potential for a postulated fire to impact upon the plant control room areas is assessed due to the importance of these areas in ensuring the safety of plant operators and controlling the plant during design basis and beyond design basis faults.

11.2.4.3 Interface with Other Internal Hazards

The internal fire hazards assessment (Reference 11.73) considers, on a deterministic basis, a single fire event and the consequential impact on SSC in the affected plant areas.

The consideration of credible combinations of internal fire with other postulated internal hazards likely to occur independently of fire is considered in Reference 11.75. This reference provides a coherent approach across all internal hazard types (e.g., fire, explosion, missiles, dropped loads, pressure part failure). This is discussed in Section 11.12.

Combinations of independent internal and external hazards are considered to be Beyond Design Basis events and as such have not been explicitly considered in this section. However, compliance with relevant equipment and structural design codes ensure that combinations of internal hazards with the relevant abnormal operating occurrences (including environmental hazards) are addressed.

11.2.4.4 Conclusions

The assessment of internal fire hazards for the AP1000 plant has been completed and documented in the internal hazards fire protection internal hazards topic report (Reference 11.73) and the hazard schedule (see Tables 11.2-2 and 11.2-3). The assessment was an integral part of the process of selecting fire protection barriers, equipment and systems and provides a design basis for the FPS. The internal fire assessment demonstrates that a postulated fire does not prevent delivery of the Category A safety functions.

11.2.5 Internal Fire Analysis and Assessment

11.2.5.1 Introduction

This section presents a summary of the results of the fire hazard analysis of the AP1000 design.

11.2.5.2 Identification of Fires

A fire protection analysis (Reference 11.58) has been prepared detailing, on a room by room basis, the type and quantity of combustible material present as part of the AP1000 design. In accordance with relevant international guidance (Reference 11.23), a single fire is assumed to occur at any one time wherever there is combustible material present (i.e., no credit is taken for the apparent absence of ignition sources). The fire areas or zones are detailed in Table 11.2-1

11.2.5.3 Assessment of Fires

The fire protection analysis (Reference 11.58) provides a detailed assessment of fire hazards.

Outside of the Containment building, the AP1000 plant is broken down into a series of fire areas as defined in the Hazard Barrier Matrix (Reference 11.9). A fire is not considered to propagate beyond the confines of the fire area in which it initiates, based on the substantiation of fire barriers (References 11.10, 11.12, and 11.69). Inside the Containment Building, it is not possible to provide complete segregation of fire zones owing to the need to maintain the free exchange of gases for purposes such as passive containment cooling. Instead, the fire zones are separated by distance or passive structures which will limit the zone of influence of the fire to the fire zone in which it initiates.

The basis of the fire hazard analysis is that all SSC within a fire area (or fire zone within the Containment Building) are damaged sufficient to inhibit further operation.

11.2.5.4 Hazard Schedule

The internal fire hazard schedule (see Tables 11.2-2 and 11.2-3) has been prepared based on the fire hazard analysis.

The internal fire hazard schedule presents, for each fire area (or fire zone), the:

- SSCs affected by the fire along with the Category A safety function at risk
- Potential unmitigated consequences should the plant be unable to effect safe shutdown
- Details of any protected redundancy
- Fault conditions (see Chapter 8) for which the fire has been identified as a potential initiator.

The schedule is presented in tabular form providing a concise and comprehensive summary of the postulated fires, their significance and how the AP1000 plant is designed to cope with the hazard.

11.2.5.5 Discussion of Results

A detailed fire hazard analysis has been undertaken. The analysis details, by fire compartment, those Class 1 SSC which would be affected and the adequacy of redundant SSC to deliver Category A Safety Functions in support of safe shutdown. The following sections present a summary of the analysis.

11.2.5.5.1 Containment/Shield Building

The Shield Building, part of the NI, is a Class 1, 3-hour credited fire barrier which separates it from the Auxiliary Building. Within the Shield Building is the steel containment which is the containment vessel. The structure and the construction of both of these are discussed in detail in Chapter 16.

For fire segregation purposes the Containment and Shield Building comprises one fire area (designated 1000 AF 01) and includes the spaces inside Containment as well as the valve room for the PCS, the middle annulus, the upper annulus, and the operating deck staging area outside Containment.

The Containment/Shield Building comprises a series of fire zones separated from one another using a combination of distance and physical structures, which inhibit fire propagation. Many of the fire zones (e.g., each of the SG rooms) form significant physical barriers from other fire zones for much of their height. However, complete segregation cannot be achieved inside Containment given the need to maintain the free exchange of gases for purposes such as passive Containment cooling.

Within the detailed fire hazard analysis (Reference 11.73), it is assumed that a fire within a fire compartment affects all equipment within it (including the Class 1 SSCs) and the impact to delivery of the Category A safety functions is assessed. A review of in Containment fires has been undertaken (Reference 11.14), which identified the following eight instances where redundant divisions of Class 1 SSC are located in adjacent fire zones:

- The core exit thermocouples located in 1100 AF 11500 are redundant to the excore detectors in 1100 AF 11105.
- Divisions A and C of the Hot Leg 1 & 2 flow instrumentation are located in 1100 AF 11204 with the redundant Divisions B & D located in 1100 AF 11301 and 1100 AF 11302 respectively.
- Divisions A and C of the IRWST level instrumentation are located in 1100 AF 11300B with the redundant Divisions B & D located in 1100 AF 11300A.
- Divisions A and C of the Steam Generator 2 wide range level instrumentation are located in 1100 AF 11300B with the redundant Divisions B & D located in 1100 AF 11300A.
- Divisions A and C of the pressuriser pressure and level instrumentation are located in 1100 AF 11300B with the redundant Divisions B and D located in 1100 AF 11500.
- The reference leg temperature instrumentation located in 1100 AF 11300B and the Reactor Coolant System (RCS) temperature instrumentation located in 1100 AF 11301 and 1100 AF 11302 are redundant.
- Division A of Automatic Depressurisation System (ADS) valve stages 1, 2 and 3 are located at 1100 AF 11303A with the redundant Division B ADS valve stages 1, 2 and 3 located in 1100 AF 11303B.
- Divisions A and C of the IDS electrical cable penetrations are located in 1100 AF 11300B with the redundant Divisions B and D located in 1100 AF 11500.

The analysis concludes that, in all eight instances, the separation between the adjacent fire zones minimises the potential for fire to spread to the extent that redundant divisions of Class 1 SSC are affected by a single fire. Given this, the Category A safety functions necessary for achieving a safe shutdown can be delivered following a design basis fire within Containment.

In addition to the potential impact on the delivery of Category A safety functions, fire has been identified as an initiator to a number of faults (see Table 11.2-2). In all instances, the fire zone in which the fault is potentially initiated is separate from the fire zone containing the Class 1 SSC necessary to safeguard against the unmitigated consequences of the fault (see Chapter 8).

11.2.5.5.2 Auxiliary Building – Non-Radiologically Controlled Areas

The non-radiological area of the Auxiliary Building comprises the portion of the NI to the north of the Containment. The building houses SSCs associated with the auxiliary functions that do not directly involve radioactive material but have been designed to meet their nuclear safety functions.

For fire segregation purposes, the Auxiliary Building is segregated into a series of fire areas each of which is enclosed by a 3 hour fire barrier(s). The fire barriers are designed to inhibit the propagation of fire from one fire area to another. Ventilation ductwork which passes through a Class 1 barrier separating redundant divisions of Class 1 SSC are fitted with dual redundant combination fire/smoke dampers. These damper arrangements ensure that the ventilation penetration is not a potential source of single failure leading to the loss of redundant divisions of Class 1 SSC.

In the detailed fire hazard analysis (Reference 11.73) it is assumed that a fire within a given fire area affects all equipment within it (including the Class 1 SSCs) and the potential impact to the delivery of the Category A safety functions is assessed. Given the physical segregation, and the redundancy provided, the Category A safety functions can be delivered following a fire.

11.2.5.5.3 Auxiliary Building – Radiologically Controlled Areas

The radiologically controlled part of the Auxiliary Building, located to the south side of the Containment, is designed to handle and store nuclear fuel outside of Containment as well as holding the intermediate level radioactive waste, in the form of filters and spent ion exchange resin, and containing elements of the liquid and gaseous radwaste systems.

In the detailed fire hazard analysis (Reference 11.73) it is assumed that a fire within a given fire area affects all equipment within it (including the Class 1 SSCs) and the impact on delivering the Category A safety functions is assessed. Given the physical segregation, and the redundancy provided, the Category A safety functions can be delivered following a fire.

The radiologically controlled areas of the Auxiliary Building contain radioactive material which may be exposed to the effects of an internal fire hazard, and therefore there is the potential to release radioactive material. From the fire hazards analysis, it is concluded that, for there to be a release of radiological material, the fire would have to breach vessels/ pipework, which is considered to be unlikely. A release of radiological material from the radiologically controlled areas of the Auxiliary Building is therefore considered unlikely.

Additionally, the ventilation fire or combination fire/smoke dampers on the exhaust ductwork are located externally to the wall. This arrangement minimises the maintenance burden and potential radiological risk to the workers.

Therefore a fire initiating in an individual fire area within the radiologically controlled area of the Auxiliary Building will not prevent delivery of the Category A safety functions required to effect and maintain safe shutdown or present a significant direct radiological hazard.

11.2.5.5.4 Areas outside the Nuclear Island

There are no Class 1 SSCs located in buildings outside of the NI. The fire hazard analysis shows that a fire initiating in a fire area outside of the NI will have no impact on Class 1 SSC. Therefore a fire initiating in an individual fire area outside of the NI will not prevent delivery of any Category A safety functions required to effect and maintain safe shutdown.

11.2.6 Sensitivity of Results and Cliff Edge Effects

The fire hazard analysis assumes that a single fire will occur wherever combustible material is present. That is to say that no account is taken for the probability of whether or not a fire will occur. The results are therefore not sensitive to event frequency.

Further, the analysis assumes that all SSC present in the affected fire compartment are unable to perform their Category A safety functions but that the fire will not propagate between fire compartments due to the respective segregation and separation. The following sensitivity considers the potential for a fire to propagate between fire compartments and the significance of this.

Within the Containment/Shield Building, it is not possible to provide discrete fire areas separated by fire barriers owing to the need to maintain the free exchange of gases and liquids for purposes such as passive Containment cooling. Given that the Containment/Shield Building houses the reactor vessel and associated primary circuit, it is inevitable that all divisions of Class 1 SSC providing some Category A safety functions are present in some locations and therefore potentially at risk of fire damage. It is not considered reasonably practicable to further reduce the risk of a fire propagating between the fire zones. On this basis, a sensitivity analysis within the Containment has not been carried out as it is considered to offer no benefit.

Propagation of Fire between Fire Areas

The fire load in each Fire Area has been calculated (Reference 11.8) based on the estimated quantity and type of combustible material present in similar plant areas for commercial nuclear power plants and these values adjusted to account for the design of the AP1000 plant. In addition, an amount of ‘transient material’ has been allowed for during outage and refuelling operations.

The fire load assumes that the combustible material is evenly spread over the floor area of the Fire Area/Zone. Where a Fire Area comprises more than one Fire Zone, the severity of fire from the combustible material within one Fire Zone may be higher than the average contribution to the whole Fire Area. The fire loading and duration for each individual fire zone has been calculated as well to ensure that fire zones with higher loads than that averaged over the entire fire area does not exceed the fire resistant rating of the fire area barriers. The potential of these ‘hot spots’ to challenge the integrity of the fire barrier, potentially resulting in propagation of the fire to adjacent Fire Areas has been further evaluated (Reference 11.69) and described in the section below.

Equivalent Fire Load Methodology

The correlation of fire loading and fire severity are used to determine equivalent fire durations as described in the Fire Analysis Combustible Loading and Fire Severity calculation (Reference 11.8). Those durations are compared to the ASTM E119 curve to justify that the fire barrier rating for the compartment provides adequate protection for the calculated combustible fire loading/duration.

A complementary analysis of equivalent fire duration has been performed (Reference 11.69) in accordance with the methodology described in the European structural fire protection standard EN 1991-1-2 (Reference 11.43). While this complementary technique has derived longer equivalent fire durations, than those determined using the methodology described in the NFPA Fire Protection Handbook, in all instances, within the NI, the equivalent fire duration remains within the prescribed fire duration rating of the Class 1 fire barriers.

A quantitative uncertainty analysis has also been performed (Reference 11.69) which indicated that there is a very high probability (99.7%) that the barriers will confine the fire to the fire area of inception.

Consideration of Realistic Fires

The adequacy of the fire barriers is based on a comparison of the equivalent fire duration, calculated in accordance with EN 1991-1-2 (Reference 11.43), against the fire rating of the exposed wall/ floor/ ceiling (Reference 11.9). The equivalent fire duration assumes that the time/temperature profile of the fire follows the curve given in ASTM E119 against which the barrier's performance is tested. However, 'realistic fires' may lead to localised conditions that for a period could exceed the predictions which support the ASTM E119 curve.

In order to demonstrate that the use of equivalent fire durations is conservative and bounding, a number of realistic fires have also been modelled (Reference 11.69). The results of this review are summarised below:

- With the exception of the oil, the hot gas layer temperature following a fire in RNS pump room 'A' (room 12162) would be significantly lower than the ASTM E119 curve. Although the oil fire initially exceeds the curve, the fire would self-extinguish due to a lack of combustible material and, as such, quickly returns below the curve. The hot gas layer temperature in the room would return to ambient after approximately 37 minutes, which is less than the 45 minute equivalent fire duration for fire area 1200 AF 01.

- The hot gas layer temperature in the Division C I&C penetration room (room 12313) would reach a peak of approximately 200 °C after 18 minutes before returning to ambient temperature after approximately 25 minutes. The equivalent fire duration for fire area 1202 AF 03 is 85 minutes.

- The hot gas layer temperature in the lower pressuriser compartment (room 12303) reaches a peak of 250 °C around the actual fire, with temperatures of 100 °C to 200 °C in the area above the pressuriser. The open ceiling of this compartment allows the hot gases to escape into the larger containment space without significantly increasing the temperature in the affected fire zone.

In addition, an assessment of the structural integrity of the SC structures (Reference 11.12) has been performed to determine the required fire hazard necessary to cause structural collapse. The assessment concluded that the required fire hazard would be significantly in excess of the combustible loading, irrespective of the location of the combustible material

relative to the structural element (i.e. the wall was exposed to the adiabatic flame temperature).

Therefore, the use of equivalent fire durations in assessing the adequacy of the fire barriers is shown to be conservative and bounding.

Heat Transfer Analysis – Nuclear Island Fire Barriers

Heat transfer calculations were performed for the module fire barriers (Reference 11.12). Thermal gradients (temperatures through the barrier) were developed for a three hour fire load on the barriers, even though the actual combustible loading are substantially less than three hour fire loading in all cases in the nuclear island. The analysis shows that even with a three hour fire assumed the thermal gradient only increases the wall temperature to a point halfway through the wall thickness with no effects on the unexposed side of the wall. Margin is demonstrated in both the wall thickness along with the estimated combustible loading used in the analysis.

11.2.7 Combined Hazards Discussion

The fire hazard analysis considers on a deterministic basis, a single fire in each of the fire areas/zones and the consequential spread of that fire to adjacent fire areas.

The consideration of credible combinations of fire with other internal hazards, either consequentially or due to a common cause, is discussed in Section 11.12.

However, compliance with relevant equipment and structural design codes as expressed in Chapter 5 ensure that combinations of internal hazards discussed in Section 11.12 with the relevant abnormal operating occurrences (including environmental hazards per References 11.60 and 11.61) are addressed.

11.2.8 ALARP Assessment and Discussion

Deterministic analysis of postulated, design basis, internal fire events shows that all Class 1 SSCs will continue to provide their Category A safety functions following the worst case postulated internal fire, even in the presence of an unrelated single failure elsewhere in the plant design. In the unlikely event that the Class 1 SSCs fail for some unrelated reason, the Category A safety function would be maintained by other, additional and redundant, Class 2 SSCs. SSC design classification and categorisations are discussed in Chapter 5 and References 11.26 and 11.59.

Further Mitigation Measures

In addition, other measures have been taken within the AP1000 design that, although not claimed in the deterministic analysis, will further reduce the consequences of postulated internal fires such as the provision of active fire suppression systems in some areas.

The AP1000 fire safety design has been achieved by:

- Minimising combustible loads and ensuring that no significant concentrations exist that could cause failure of Class 1 SSCs.

- Ensuring that a fire is prevented from spreading between redundant trains of equipment utilising appropriate combinations of physical separation, partial fire resistant barriers and fire barriers, including Class 1 nuclear fire barriers.

- Providing sufficient redundancy in the design such that if one train of protection fails as a result of fire, coincidental with an unrelated single active failure elsewhere, the safety functions continue to be provided by the equipment that remains unaffected.

- Providing a ventilation system that minimises the spread of fire between fire compartments and the damage to electrical systems from smoke.

- Ensuring a suitable and adequate early warning system of fire and the provision of fire-fighting equipment to extinguish fires.

- Maintaining the habitability of control room areas.

While combustible loads have been minimised the use of combustible materials in the AP1000 design cannot practically be avoided. In particular, for cable insulation organic compounds provide the best combination of flexibility, electrical insulation and resistance against ageing. Oils are also required for most rotating and sliding machinery in order for them to operate effectively. The arguments presented in the above subsections, together with the Hazard Schedule (Table 11.2-2) indicate how the combustible materials are distributed within the plant, and demonstrates that the design intent is met.

High concentrations of combustible material (typically oil tanks) are required to ensure the safe and reliable operation of items of machinery such as diesel generators, which are required for operations. The volume stored within the buildings is limited to minimum 'day' amounts and is within robust and reliable systems to minimise leaks. In mitigation these areas are adequately segregated from areas containing Class 1 SSCs by fire barriers and distance and are further protected by reliable active automatic suppression systems. This meets the design intent of containing fires involving large quantities of combustible material and relevant good practice.

The prevention of fire spread between redundant trains of SSCs using segregation by compartmentalisation within Containment is not possible because of the requirements of the Passive Containment Cooling System. However, of those walls and floors present most are either of substantial concrete construction or proprietary passive fire protection systems and provide some protection (insulation and integrity) from the effects of fire. However, the principal fire safety design philosophy for the protection of Class 1 SSCs within Containment has been achieved by separating redundant trains of Class 1 SSCs by distance, with some use of passive fire protection measures to segregate electrical supplies of different divisions. This approach has been shown to provide adequate protection.

Additional Features to Detect and Mitigate Internal Fire

No claim is made on the firefighting system within the AP1000 design. Instead, these systems and the fire detection and alarm system are provided to minimise the consequences of fire and to limit fire spread. In addition, the firefighting systems are used to protect Class 2 and 3 equipment; keeping the Class 2 and 3 systems operational minimises the demand placed on Class 1 systems.

Firefighting Systems

The FPS provides defence in depth functions and comprises automatic fire detection, an alarm system, and firefighting equipment, and meets the requirements of IAEA NS-R-1 (Reference 11.21) to:

- Detect fires early;

- Extinguish fires quickly;
- Minimise fire spread;

As a result, the damage to SSCs and the spread of radiological contamination is minimised. In order to achieve this, the AP1000 plant FPS is designed to perform the following functions:

- Detect and locate fires and provide the operator with an indication of the location.
- Provide the capability to extinguish fires in any plant area, protect site personnel, limit fire damage, and enhance safe shutdown capabilities.
- Supply fire suppression water at a flow rate and pressure sufficient to satisfy the demand of any automatic sprinkler system, plus adequate capacity for fire hoses, for a minimum of 2 hours.
- Maintain 100 percent of fire-pump design capacity, assuming failure of the largest fire pump or the loss of offsite power.
- Following a safe shutdown earthquake, provide water to hose stations for manual firefighting in areas outside of Containment containing Class 1 SSCs.
- Satisfy the requirements of the PCS as an alternate source of water to wet the Containment dome or to refill the PCCWST after a Loss-of-Coolant accident, if the FPS is available, as discussed in detail in Chapter 6.
- Provide an alternate supply of cooling water to the RNS or SFS HX for decay heat removal after a loss of normal CCS function, as discussed in detail in Chapter 6.
- Provide additional Containment spray capability for severe accident management, if available.

The FPS piping and instrumentation drawings covering the FPS are shown in Reference 11.71. The fire protection provision for each room within the plant containing automatic fire suppression systems is discussed in detail within the topic report (Reference 11.73), summarised below, and where appropriate, assessed as to its suitability to control the identified fire hazards. Although not relied upon in the deterministic assessment, the consequences of failures are also discussed. The system comprises the following:

- Automatic fire detection and alarm system;
- Manual firefighting equipment, i.e., portable fire extinguishers and hose stations;
- Automatic fire suppression systems, i.e., fixed firefighting systems such as sprinklers in specific locations outside Containment.

The fixed firefighting system has seismic design requirements applied to portions of the standpipe system located in areas containing equipment required for safe shutdown following a safe shutdown earthquake so that water is available to manual hose stations. However, there are no identified operator actions required to protect Category A safety functions via use of the manual hose stations. The standpipe system serving areas containing equipment required for safe shutdown following a safe shutdown earthquake is designed and supported so that it remains functional. In addition, the Containment isolation valves and associated penetration piping for the FPS are Class 1 and C-I.

Automatic Fire Detection System

The design philosophy for the automatic fire alarm and detection system is in accordance with the guidance provided in IAEA NS G 1.7 (Reference 11.23), and as a minimum, the defence in depth system provided throughout the AP1000 plant is designed in accordance with the appropriate standards (such as BS 5839 1:2002 (Reference 11.54) to provide comprehensive coverage and appropriate protection for the fire hazards identified.

Exact locations and types of detectors will be reviewed as part of the site-specific licensing process to take account of relevant good practice and operating conditions to ensure that factors such as obstructions to gas flow, crane movements, and concealed spaces have been considered. The installation of the system will be in accordance with BS 5839-1 (Reference 11.54) and manufacturers' recommendations. The installer will be approved according to LPS 1014 (Reference 11.55) or the equivalent.

Additional Means of Providing Safety Functions

Since the Category A safety functions can be maintained despite internal fires, the safety of the plant is ensured. As such, it is judged that there would be no benefit in providing additional means of delivering the Category A safety functions, or enhancing the existing SSCs. On this basis, the risk of internal fire on the ability of the AP1000 plant to deliver the Category A safety functions required to safely shutdown the reactor has been shown to be broadly acceptable and ALARP.

11.3 Internal Flooding

11.3.1 Introduction

The AP1000 Internal Flooding Hazard Analysis is performed in order to assess the bounding effects to Structures, Systems and Components (SSCs) resulting from an internal flood within the AP1000 plant. The AP1000 plant has been designed such that flooding events within the design basis will not compromise the ability of the plant to safely shutdown. The Category A safety functions required for safe shutdown following flooding and the supporting post 72 hour Category B safety functions are shown to be maintained through a combination of claims made on compartment barriers and the segregation of Class 1 SSCs.

Flooding within the AP1000 plant which has the potential to damage SSCs required to deliver Category A safety functions or supporting Category B safety functions is addressed in more detail within the Flooding Topic Report (Reference 11.76). Detailed flooding assessments have been carried out for the AP1000 design. The demonstration of the plant response to internal flooding has been performed on a deterministic basis making the following conservative assumptions:

- Gross failure (e.g., circumferential double ended guillotine fracture) of pipework and vessels (except those qualified as Highest Safety Significance [HSS]);
- Total release of system inventory; for systems with an inexhaustible supply the release is assumed to continue for at least 7 hours before isolation is effected;
- Flood heights based on effective room volume where components are present (except where the flood height does not exceed the bottom of the vessels/components);

- No credit taken for mitigation of flood height by building drains which cannot readily be inspected along their full length;

- Failure will occur during the most restrictive plant operating state.

The overall scope of the analysis considers sources of flooding within the Nuclear Island (NI), those in adjacent buildings and those originating in the yard area, for potential impact on Class 1 SSC delivering Category A safe shutdown safety functions. Although flooding will ensue following a pressure part failure[5], the mechanical effects of pressure part failure (e.g., pipe whip, jet impingement) on Class 1 SSC are not considered in this section and are instead addressed separately in Section 11.4 and Reference 11.77.

The internal flooding assessment concludes that Category A safety functions can continue to be delivered by Class 1 passive SSCs following a design basis flood through a combination of claims made on structural barriers, equipment qualification, passive flood relief systems and, where necessary, minimal operator actions to isolate inexhaustible sources of flooding following identification by a level sensor (i.e., no claim has been made on the prevention or limitation of fault occurrence).

11.3.2 Internal Flooding Claims, Arguments and Evidence

11.3.2.1 Claims Overview

This section presents the claims, arguments and underlying evidence made in relation to internal flooding hazards with the potential to impact safe shutdown.

11.3.2.2 High Level Claim

Internal flooding could cause a transient from normal operation of the reactor power plant with the potential to result in a hazard on or off site being realised. In response to such a transient, it may be necessary to shut down the reactor and return it to a safe state. Depending on the exact nature of the transient, there are a number of courses of action available to safely and reliably shut the reactor down. Availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim.

Claim IH-2.0: **Postulated internal flooding events within the design basis will not prevent the delivery of the Category A safety functions by Class 1 SSCs and supporting post 72 hour Category B safety functions necessary to respond to the postulated event.**

This has been achieved by:

- Protecting delivery of Category A safety functions by Class 1 SSCs with structural barriers (i.e., walls, ceilings, floors) to prevent flood propagation;

- Protecting Class 1 SSC through appropriate qualification for the environment (e.g., submergence);

5. Within the PCSR, the term pressure part failure has been used interchangeably with the term Pipe Rupture Hazard to better reflect the hazard assessed within the Flooding Topic Report.

- Protecting Class 1 SSC by positioning above the maximum flood height;
- Protection through segregating Class 1 SSC delivering Category A safety functions from flooding sources, when physical barriers cannot be provided;
- Minimising the severity of flooding by limiting the number of sources of flooding and their volumes.
- Providing engineered discharge routes to alleviate the effects of flooding.
- The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.3.2.3 Prevention Claims

Flooding is deterministically assumed to occur as a result of gross failure of pipework, vessels and components handling fluid, except those justified by the Structural Integrity Classification as HSS. There are therefore no specific claims made on the prevention of internal flooding hazards.

11.3.2.4 Protection Claims

Protective measures have been incorporated into the design to protect the delivery of Category A safety functions from the effects of flooding. These claims are based on protecting Class 1 SSC from being exposed to a flooded environment or, as required, ensuring that Class 1 SSC can continue to operate in a flooded environment. The following protective claims and Sub-Claims are therefore made in support of the overall high level claim:

Claim IH-2.1: **Class 1 SSCs required for delivery of Category A Safety Functions are protected from sources of internal flooding by civil/structural barriers**

Sub-Claim IH-2.1.1: **PXS Room A and PXS Room B will not flood concurrently**

Sub-Claim IH-2.1.2: **Flooding in the non-RCA Auxiliary Building mechanical areas will not spread to the electrical areas of the Auxiliary Building**

Claim IH-2.2: **Where Class 1 SSCs are not qualified to operate in a submerged state, sources of flooding will be isolated prior to exposing Class 1 SSC to a flooded environment**

Claim IH-2.3: **Where required, Class 1 SSC will be capable of delivering the Category A safety function when submerged**

11.3.2.5 Mitigation Claims

The extent to which flooding impacts Class 1 SSC has been minimised by limiting the maximum flood height in rooms/areas by reducing the available inventory of the leaking system and through the use of passive measures.

Claim IH-2.4: **The available inventory of flood sources has been minimised so far as is reasonably practicable.**

Claim IH-2.5: **Flooding will be alleviated by passive flood relief measures.**

Sub-Claim IH-2.5.1: **Flood heights in Division A, B, C & D I&C Rooms, 12301, 12302, 12304 & 12305, will not exceed 0.076 m**

Sub-Claim IH-2.5.2: **Flood height in the Valve/Pipe Penetration Room, 12306, will not exceed 0.533 m**

Sub-Claim IH-2.5.3: **Flood height in Middle Annulus, 12341, will not exceed 2.36 m**

Sub-Claim IH-2.5.4: **Flood heights in the Main Steam Isolation Rooms, 12404 and 12406, will not exceed 0.91 m**

Sub-Claim IH-2.5.5: **Flood heights in the Truck Bay/Filter Storage Area and RNS HXs Rooms, 12371, 12372 and 12362, will not exceed 1.22 m**

Sub-Claim IH-2.5.6: **Flood heights in the VBS MCR/A&C Equipment Room, 12501, will not exceed 0.152 m**

Sub-Claim IH-2.5.7: **Internal doors, will not retain the full volume of fluid within the affected room**[6]

11.3.2.6 Arguments and Evidence

Prevention Arguments and Evidence

There are no specific claims made on the prevention of flooding. Flooding is assumed to occur as a result of gross failure of pipes, vessels and components containing fluids.

Claim IH-2.1: **SSCs required for delivery of Category A Safety Functions are protected from sources of internal flooding by civil/structural barriers**

Passive structural barriers are used to limit the spread of internal flooding throughout the NI and as such the extent to which Class 1 SSC are exposed to a flooded environment. The application of the design criteria for protection from flooding ensures that:

- Structural barriers are identified to limit the extent of flooding;
- Maximum flood levels, and therefore loading, on the structural barriers are derived.

6. It is recognised that watertight doors are present in the design; however these are present to limit the loss of water from the spent fuel pools and not to protect against a flooding event.

The Hazard Barrier Matrix (Reference 11.9) identifies those walls, floors and doors which are required to prevent the propagation of flooding to adjacent areas of the nuclear island. The identified barriers have been designed to withstand the loading associated with the maximum flood-up height (Reference 11.76), as determined by the relevant Pipe Rupture Hazards Analysis (PRHA), present on either side of the barrier. The principal flood areas segregated by flood retaining barriers are the:

- Steel Containment
- Containment Shield Building
- Radiologically controlled area (RCA) of the Auxiliary Building
- Non-Radiologically controlled area (non-RCA) of the Auxiliary Building

The Auxiliary Building is sub-divided into the RCA and non-RCA, separated from one another by 0.61 m (2 ft) and 0.91 m (3 ft) thick walls and floors (References 11.9 and 11.78).

The number of penetrations in the flood retaining barriers have been minimised below the maximum flood height, or will be sealed to eliminate flow paths (Reference 11.76).

Sub-Claim IH-2.1.1: PXS Room A and PXS Room B will not flood concurrently

Partitions between rooms or areas below the 100 m (100'-00") level, rising to different elevations, require the affected room to flood completely before the next lowest room/area becomes affected. Based on the bounding flood source (in terms of volume) within Containment, it is not possible to flood both PXS room A and PXS room B from a single event.

In order to maintain the free exchange of air, and therefore cooling, the Containment has a largely open internal structure with no full height walls. Furthermore, for certain design basis events (e.g., Loss of Coolant Accident), as well as refuelling purposes, it is necessary to flood portions of the Containment in order to ensure that the fuel remains submerged.

Below the maintenance floor, 100 m (100'-0") elevation, the Containment is divided into four compartments: PXS room A; PXS room B; CVS room; General Containment (including the vertical access tunnel, Steam Generator A and B areas and the refuelling cavity), which are separated by partition walls. During a design basis accident, it is necessary to prevent premature flooding of the PXS compartment and the CVS compartment. The drain line from each of these compartments to the sump has two check valves in series. These check valves prevent reverse flow through the drain lines which could cause premature cross flooding. These check valves (back flow preventers) are included in the design and are UK Category A and Class 1. Extending above the maintenance floor, each of the compartments (PXS room A, PXS room B and CVS room) has an elevated curb around the perimeter (Reference 11.76). The curbs prevent water from passing into the enclosed compartment until the flood level in the general Containment proceeds beyond the height of the curb. The curb elevations are as follows:

- PXS room A: 103.1 m (110.17 ft)
- PXS room B: 103.07 m (110.08 ft)
- CVS room: 103.05 m (110 ft)

- Refuelling Cavity: 102.8 m (109.28 ft)[7]

The PRHA of Containment (Reference 11.77) concludes that:

- The bounding source in the general Containment would be wholly retained without over-spilling the curbs into the CVS room, PXS room A or PXS room B;
- The bounding source in the CVS room, assuming ADS actuation, would flood the general Containment and CVS rooms with some over-spill into PXS room B;
- The bounding source in PXS room B, assuming ADS actuation, would flood the general Containment space and PXS room B with some over-spill into the CVS room;
- The bounding source in PXS room A, assuming ADS actuation, would flood the general Containment space and PXS room A with some over-spill into the CVS room.

On this basis, there is no scenario where both the PXS room A and PXS room B become submerged concurrently. Note that this Sub-Claim applies to the initial post fault flood. In longer term plant recovery scenarios, it is assumed that all of the Containment rooms that do not flood initially do eventually flood due to leakage.

Sub-Claim IH-2.1.2: Flooding in the non-RCA Auxiliary Building mechanical areas will not spread to the electrical areas

Within the non-RCA side of the Auxiliary Building, rooms containing electrical equipment are segregated from those containing mechanical equipment. The rooms containing mechanical equipment are:

- 12306: Valve/piping penetration room;
- 12404: Lower Main Steam Isolation Valve (MSIV) compartment B;
- 12405: Lower VBS B&D Equipment room;
- 12406: Lower MSIV compartment A.

The Hazard Barrier Matrix (Reference 11.9) identifies those walls, floors and ceilings which are required to prevent the propagation of flooding to adjacent rooms within the non-RCA side of the Auxiliary Building. The identified barriers have been designed to withstand the loading associated with the maximum flood-up height (Reference 11.76), as determined by the relevant PRHA, present on either side of the barrier. Penetrations in the flood retaining barriers have been minimised below the maximum flood height, or will be sealed to eliminate flow paths (Reference 11.76).

Claim IH-2.2: Where Class 1 SSCs are not qualified to operate in a submerged state, sources of flooding will be isolated prior to exposing Class 1 SSC to a flooded environment

7. This is the elevation of the refuelling canal connecting line, and the elevation above which the refuelling cavity will flood.

Differential pressure level sensors located in the Auxiliary Building RCA and Auxiliary Building non-RCA will alert operators, via the PMS, to flooding in the respective areas and the need to effect isolation of the affected system.

There are two redundant differential pressure level sensors (WLS-LT-400A and WLS-LT-400B) within the Auxiliary Building RCA sump room (12154), located at 0.30 m (1 ft.) above the 89.8 m (66'-6") level. These differential pressure level sensors are provided to ensure that all sources of flooding can be isolated prior to the 95.58 m (85'-6") criteria flood-up level being exceeded; the criteria flood-up level is the point at which Class 1 SSC would become submerged and therefore cease to function. Each differential pressure level sensor has two set-points. Exceeding each set-point annunciates an alarm in the MCR via the PMS, these sensors will be designed to meet UK Category A and Class 1 criteria.

The bounding flooding event in the Auxiliary Building RCA to be a HELB of the CVS in room 12255 leading to cascade failure of CCS, FPS and Central Chilled Water System (VWS) pipework present in the vicinity.

Similarly, there are two redundant differential pressure level sensors (WWS-LT-030 and WWS-LT-031) within rooms 12104 and 12105. Both sensors are located at 0.1 m (4 inches) above the 89.8 m (66'-6") level. The differential pressure sensors are provided to ensure that all sources of flooding can be isolated prior to the level reaching 0.19 m (7.5 inches) above the basemat, at which point the bottom of the batteries in rooms 12101, 12102, 12104 and 12105 would come into contact with the liquid. These sensors will be designed to meet UK Category A, Class 1.

The bounding flooding event in the Auxiliary Building non-RCA is a MELB of the Potable Water System (PWS) line in room 12111. It should be noted that flood water contacting the bottom of the batteries does not render the batteries inoperable but potentially reduces their capacity depending upon the temperature of the fluid. The rooms must flood up to the top of the terminals to short out the batteries, which is another 0.60 m (23.5 inches), providing additional margin to the total loss of battery function.

The only sources of flooding with the potential to trigger the differential pressure sensors originate from the FPS and the PWS, however the FPS has insufficient inventory to exceed the criteria flood height. The operators will therefore be required to isolate the PWS only.

Claim IH-2.3: Where required, Class 1 SSC will be capable of delivering the Category A safety function when submerged

Class 1 SSCs credited to operate when located below the maximum flood height will be qualified for operation in a submerged environment.

Environmental qualification tests and methods are detailed in Reference 11.61 based on the guidelines provided in IEEE 323-1974 (Reference 11.124) and IEEE 344-1987 (Reference 11.79), and include:

- Type testing: Testing of equipment in the environment, normal and abnormal, under which it will be required to perform its function;
- Analysis: Review of relevant data for similar components;
- On-going qualification: Maintenance and surveillance of in service equipment.
- Equipment qualification program documentation consists principally of:

- Methodology for Qualifying Safety-Related Electrical and Mechanical Equipment (Reference 11.60): Over-arching document detailing the strategy for equipment qualification.

- Equipment Qualification Data Packages: Details the qualification program objectives, methods performance specification and qualification plan for each SSC subject to qualification.

- Equipment Qualification Test Reports: Details of the specific methods used during qualification and the results of the process.

The criterion for equipment qualification depends upon the environment, during normal and abnormal conditions, under which the SSC is required to operate. The AP1000 plant has been broken down into 11 environmental zones and a number of associated sub-zones. The normal and abnormal environmental conditions for equipment qualification in each zone/sub-zone have been established (Reference 11.61).

11.3.2.7 Mitigation Arguments and Evidence

Claim IH-2.4: The available inventory of flood sources has been minimised so far as is reasonably practicable

The principal areas comprising the NI (Containment/Shield Building; Auxiliary Building RCA; Auxiliary Building non-RCA, which itself is sub-divided into mechanical and electrical compartments) are separated by structural partitions (see Chapter 6) such that flooding in one area will be retained without affecting another area. So far as is reasonably practicable the pipework comprising each of the systems has been routed to minimise the number of rooms through which they pass. Furthermore, where practicable, significant accumulations of water have been located outside of the Nuclear Island.

Within the Auxiliary Building non-RCA side, the FPS draws water from the PCCWST via a standpipe during all plant modes. The standpipe has been elevated such that the maximum flood height on level 1 of the Auxiliary Building RCA is limited to 19 cm (7.5 inches).

Within Containment, the FPS is isolated during plant modes 1-4 and only available during plant modes 5 & 6. The FPS cannot therefore contribute an additional source of flooding within Containment, except when the reactor is already shut down.

Claim IH-2.5: Flooding will be alleviated by passive flood relief measures

Where it is not possible to either limit the maximum flood height in a room or area, or to qualify the SSC for operation in a submerged environment, it is necessary to credit passive flood relief design attributes such that the flood height does not affect Class 1 SSC. Situations where this may be the case include flooding sources where:

- Isolation cannot be provided for operational reliability reasons;
- Isolation cannot be effected sufficiently quickly.

Sub-Claim IH-2.5.1: Flood heights in Division A, B, C & D I&C Rooms, 12301, 12302, 12304 & 12305, will not exceed 0.076 m

The bounding pipe rupture in 12300 is a MELB of FPS, which would result in water being discharged into the room. There exist five drains (WWS-D212 through WWS-216) in room

12300 which feed into a common header; these drains are UK Category A, Class 1.. The drain discharges, from 12300, to the Auxiliary Building north sump.

The MELB of FPS discharge into the Auxiliary Building sump; accumulation of FPS water on level 1 is insufficient to challenge Class 1 SSC present on this level.

Sub-Claim IH-2.5.2: Flood height in the Valve/Pipe Penetration Room, 12306, will not exceed 0.533 m

The bounding pipe rupture in 12306 is a MELB of FPS. There exists two floor drains (WWS-D104 and WWS-D235) in room 12306, both drains feed into a common header; these drains are UK Category A, Class 1. The drain discharges into the Turbine Building sump. The sump tanks each have sufficient capacity to accommodate the total discharge from the FPS. Should the sump tanks become full; as a defence-in-depth measure, four sump pumps will automatically discharge to the oil separator tank located outside of the Turbine Building.

Sub-Claim IH-2.5.3: Flood height in Middle Annulus, 12341, will not exceed 2.36 m

The bounding flood height in 12341 is a result of a MELB of FPS in room 12351. Four floor drains are present in room 12351 (WRS-D313 to WRS-D316 and seven floor drains in room 12341 (WRS-D318, D319, D321, D324, D328, D330 and D333). These drains will be designed as UK Category A, Class 1.. The four drains from 12351 feed into a common header. The seven drains from 12341 feed into a separate common header. Floor drains present in 12341 and 12351 will discharge into the Auxiliary Building south sump.

The drain discharges to the Auxiliary Building south sump in 12154. The sump has a limited capacity and once full would overflow throughout the 89.79 m (66'-6") level; this overflow is bounded by a cascade failure in 12255 initiated by failure of the CVS which is shown to have no impact on Class 1 SSC.

Sub-Claim IH-2.5.4: Flood heights in the Main Steam Isolation Rooms, 12404 and 12406, will not exceed 0.91 m

Pressure relief panels (12404-AY-P01 and 12406-AY-P01, UK Category A and Class 1), located at floor level in each of 12404 and 12406, provide an engineered discharge route into the Turbine Building 1st Bay. In accordance with the design specification (Reference 11.80) the pressure relief panel will actuate when a pressure head acts on the panels' surface.

The bounding pipe rupture in the MSIV compartments is a gross failure (full guillotine break of 0.508 m [20 in] diameter pipe) of the SGS main feedwater pipe upstream of the check valve. The analysis demonstrates that the flood heights in 12404 and 12406 are below the criteria flood height.

Sub-Claim IH-2.5.5: Flood heights in the Truck Bay/Filter Storage Area and RNS HXs Rooms, 12371, 12372 and 12362, will not exceed 1.22 m

Pressure relief door located within 12362-AD-D02 door, UK Category A and Class 1, located on the floor level of room 12362, provides and engineered discharge route into the lower levels of the RCA side of the Auxiliary Building. In accordance with DCP (APP-GW-GW-4568) which is part of the Design Reference Point (Reference 11.3) the pressure relief device will actuate when a pressure head acts on the panel surface equivalent to 0.61 m (2 feet).

The bounding pipe rupture in the Truck Bay/Filter Storage Area is a gross failure of the FPS pipe. The analysis demonstrates that the flood heights ini 12371, 12372 and 12362 are below the criteria flood height.

Sub-Claim IH-2.5.6: Flood heights in the VBS MCR/A&C Equipment Room, 12501, will not exceed 0.152 m

The flow orifice plate (DWS-PY-R002) limits the DWS supply flow rate to less than the Room 12501 floor drains (WWS-D251, D229 and D230) capacity to ensure flood waters are directed out the Auxiliary Building and into the Turbine Building floor sump. These UK Category A and Class 2 components will be designed in accordance with the design specification,

The bounding pipe rupture in the VBS MCR/A&C Equipment Room is a gross failure of the DWS pipe. The analysis demonstrates that the flood height in Room 12501 is below the criteria flood height.

Sub-Claim IH-2.5.7: Internal doors will provide a means of discharge from the flood affected room

Divisional barriers separating rooms will allow a flow of water to pass into the adjacent room(s).

A range of divisional barriers (e.g., wire mesh door, safety chain & standard door) are utilised throughout the AP1000 plant. Wire mesh doors and safety chains offer little or no resistance to flows out of the room and are not considered explicitly. Standard doors are fitted with a 1.6 cm (5/8") door gap at the bottom of the door. The door gap allows liquid to pass to adjacent compartments; the rate at which liquid passes through the door gap depends upon the pressure head generated by liquid in the flooded compartment.

11.3.3 Internal Flooding Safety Case Summary

11.3.3.1 Introduction and Overview

The safety design approach adopted for internal flooding hazards consists of a range of complementary approaches. These are applied as appropriate to reduce the potential disruption to the passive safe shutdown Class 1 SSC. Flooding events within the design basis do not prevent the delivery of the Category A safety functions necessary to respond to a postulated event. Preservation of required safety functions ensures alignment with fault studies (see Chapter 8) and structural integrity analysis (see Chapter 20).

Flooding is assumed to occur as a result of an initiating event leading to the gross failure of piping or equipment, except that which is justified by the Structural Integrity Classification (Reference 11.72) as HSS (see Chapter 20). Passive protective measures have been incorporated into the design to protect SSCs that deliver Category A safety functions from the effects of internal flooding. The consequences of flooding hazards are contained through the use of passive barriers to limit the impact to and loss of a safety function and by the qualification of SSC to operate in a flood affected environment.

In summary, the safety case approaches adopted are as follows:

- Protection of SSC, whose availability is required to deliver Category A safety function, from the effects of flooding;

- Qualification of SSC in a submerged environment;
- Provision of redundant SSC, capable of delivering the Category A safety function, in segregated locations which cannot be affected by a single flood hazard.

The AP1000 design employs a mixture of the approaches stated above to form levels of defence in depth which, together, reduce the risk of internal flooding to a level which is As Low As Reasonably Practical (ALARP).

11.3.3.2 Applicable Codes and Standards

The PRHAs have been undertaken in accordance with the following codes and standards, as specified by the pipe rupture protection design criteria (Reference 11.81):

- ACI 349-01, 'Code Requirements for the Design, Fabrication and Erection of Steel Safety-Related Structures for Nuclear Facilities';
- ANS-58.2, 'Design Basis for Protection of Light Water Nuclear Power Plants against the Effects of Postulated Pipe Rupture';
- ASME Boiler and Pressure Vessel Code, Section III, 'Rules for Construction of Nuclear Power Plants';
- ASME B31.1, 'Power Piping';
- ASME Boiler and Pressure Vessel Code, Section XI, 'Rules for Inservice Inspection of Nuclear Power Plant Components'.

In addition, the PRHAs of internal flooding have been undertaken in accordance with the following codes and standards, as specified by the design criteria for protection from flooding (Reference 11.78):

- ANSI/ANS-56.10, 'Subcompartment Pressure and Temperature Transient Analysis in Light Water Reactors';
- ANSI/ANS-56.11, 'Design Criteria for Protection against the Effects of Compartment Flooding in Light Water Reactor Plants';
- ANS-58.2, 'Design Basis for Protection of Light Water Nuclear Power Plants against the Effects of Postulated Pipe Rupture';
- ANSI/ANS-58.8, 'Time Response Criteria for Safety-Related Operator Actions'.

The AP1000 Equivalence/Maturity Study of US Codes and Standards (Reference 11.25) determines, based on their importance to safety, the applicability, adequacy and sufficiency of those standards when compared with relevant UK and international good practice. It also provides a clear and auditable demonstration that all codes and standards to support the design substantiation of UK safety related or safety significant SSCs have been identified.

To evaluate the AP1000 design codes and standards against the UK expectations, the codes and standards have been organised by the relative safety significance of the SSCs to which they have been applied. The safety significance has been determined in accordance with the

AP1000 UK Safety Categorisation and Classification Methodology (Reference 11.26), which describes the process for categorisation of safety functions and classification of SSCs.

11.3.3.3 Redundancy and Segregation

The design of the AP1000 plant incorporates redundant Class 1 SSCs, each of which is capable of delivering the Category A safety function. Where there is the potential for Class 1 SSCs to be compromised by flooding, the redundant Class 1 SSC delivering the Category A safety function have been identified. The provision of redundancy takes into account the following:

- IAEA-NS-G-1.11 "Protection against Internal Hazards other than Fires and Explosions in the Design of Nuclear Power Plants" (Reference 11.82).
- IAEA NS-R-1, "Safety of Nuclear Power Plants: Design" (Reference 11.21).
- APP-GW-J1R-008, April 2002, "Safety Criteria for the AP1000 Instrumentation and Control Systems" (Reference 11.51).
- APP-GW-J1R-004, April 2002, "AP1000 Instrumentation and Control Defence in Depth and Diversity Report" (Reference 11.52).
- NS-TAST-GD-011 Technical Assessment Guide, "The Single Failure Criterion" (Reference 11.83).

Within the Containment/Shield Building, redundant divisions of Class 1 SSC have been separated, so far as is reasonably practicable, by distance. While the Containment/Shield Building is a largely open space to maintain the free movement of gases, some compartments have been segregated by walls and floors. Curbs around the top of each compartment determine the sequence in which each one floods.

Outside the Containment/Shield Building, the Auxiliary Building comprises RCA and non RCA, which are physically segregated from one another by walls, floors and ceilings. Adjoining buildings are also physically segregated from the Auxiliary Building by walls, floors and ceilings. Access to either the RCA or non-RCA portions of the Auxiliary Building is from the adjoining buildings, which are themselves sub-divided into RCA and non-RCA sections (as appropriate) by walls, floors and ceilings. A flooding hazard which initiates on the RCA side cannot therefore propagate to the non-RCA side of the NI, and vice-versa.

11.3.3.4 Internal Flooding Assessment Approach

The internal flooding assessment has been carried out in accordance with the pipe rupture protection design criteria (Reference 11.81) and the design criteria for protection from flooding (Reference 11.78), with the following exceptions:

- Systems which during normal operation may be considered high energy, regardless of duration, will be assessed for HELBs.
- One inch, and below, Nominal Pipe Size (NPS) piping will be considered for the effects of flooding;
- Seismically-supported piping is not exempt from postulated MELBs.

- For areas or rooms where drains are available as a discharge flow path, flood levels are evaluated based on a range of drain blockages.

For each system where an initiating event leading to equipment failure could result in flooding of the surrounding room/area, the flooding hazard analyses have determined:

- The maximum inventory of the affected system;
- The path, and therefore affected areas, of flooding;
- The maximum flood height in affected rooms/areas.

The output of the flooding hazard analyses has been compared against the location of Class 1 SSC to determine those which could be affected by flooding in order to demonstrate that Category A and supporting post-72 hour Category B safety functions will continue to be delivered.

11.3.3.5 Interface with Other Internal Hazards

The AP1000 has been evaluated for internal hazards to confirm that SSCs delivering Category A functions will perform as required for the identified internal hazards listed in Section 11.1.

It is recognised that internal flooding may occur, due to a common initiator, coincidentally with other internal hazards or selected external hazards. In such instances, the combined effects of both hazards constitute the full extent of the internal hazard.

An assessment of the consequences of combined hazards has been completed and documented in Section 11.12 based on the combined hazards analysis (Reference 11.75). Section 11.12 demonstrates that for credible combinations of flooding with other potential internal hazards, the Category A and/or supporting Category B safety functions can continue to be delivered, as consistent with the individual internal hazard assessments.

11.3.3.6 Conclusions

Sufficient evidence has been shown throughout this section that the risk of loss of Class 1 SSCs as a result of internal flooding is low and controlled. Internal flooding has been shown to not prevent the delivery of the Category A safety functions and the post 72-hour Category B safety functions. This is due to the combination of inherent design features, routine and non-routine early detection regimes, and the application of routine and non-routine remediation actions, respectively preventing, detecting and controlling the risk to the AP1000 plant from such flooding.

11.3.4 Internal Flooding Analysis and Assessment

11.3.4.1 Introduction

The internal flooding assessments have been prepared according to the following general assumptions:

- With the exception of SSC qualified as HSS, any pipe, vessel or component could fail;
- Any PIE will result in the most limiting equipment failure (e.g., gross failure of the pipe, vessel or component);

- The entire system inventory will be released following failure; for systems with an inexhaustible supply, the release will continue for a further reasonable human response time before isolation is effected with a total of 7 hours as the maximum allowable operator response time following the alarm;

- Secondary effects may be induced following the PIE;

- Dynamic effects of a HELB induced pipe whip resulting in cascade failure of piping with a smaller diameter (regardless of wall thickness) and piping of an equal or greater diameter (with the same or smaller wall thickness);

- Only passive flood mitigation features are credited; active features are assumed failed except where the system is appropriately classified and qualified for the fault induced environment;

- Floor drains are assumed to be blocked, except where the drain may lead to flooding in downstream rooms;

- The PIE will occur during the most limiting plant state (e.g., full power operation);

- A single active component failure is assumed to pre-exist prior to the PIE, or a single active failure occurs post fault, but not both;

- Penetrations through fire barriers (see internal fire assessment in Section 11.2) are leak tight. Flood levels are used to create design pressure loading conditions and/or specification requirements;

- The volume occupied by equipment in a room is accounted for in determining the flood height.

This internal flooding safety case does not consider the effects of:

- Seismically induced internal flooding, where such an event is assumed to result in multiple system failures from non-seismically qualified SSC (see Section 11.12);

- Internal flooding on civil structural integrity (see Chapter 16).

11.3.4.2 Internal Flooding Sources

The piping rupture protection design criterion establishes the guidelines for determining the location and configuration of pipe ruptures in accordance with Section 11.4. Such pipework falls into one of the two following categories:

- High-energy piping: systems or portions of systems in which the maximum normal operating temperature exceeds 93 °C (200 °F) or the maximum normal operating pressure exceeds 2.0 MPa (275 psig).

- Moderate-energy piping: systems or portions of systems pressurised above atmospheric pressure during normal plant conditions that are not classified as high energy.

Due to the potential of pipe whip resultant from a HELB, cascading ruptures may occur in pipework present in the vicinity except where the high energy line is fitted with pipe whip restraints. Systems subject to cascade rupture will add additional fluid inventory to that of the

HELB. In accordance with the design criteria for protection from flooding (Reference 11.78), such cascade ruptures will initiate as follows:

- Gross failure of pipework with a smaller nominal pipe diameter, regardless of pipe wall thickness;
- Through Wall Crack (TWC) of pipework with an equal or larger nominal pipe diameter with an equal or thinner wall thickness;
- No failure in pipework with an equal or larger nominal pipe diameter with a thicker wall thickness.

All pipe ruptures, except those cascade ruptures leading to a TWC as defined above, are taken to be a gross failure of the pipe.

Based on the approach outlined in subsection 11.3.3.4, internal flooding sources have been identified as applicable to the various PRHA calculations. A brief summary is presented in the following discussion:

Containment Building

The Containment is a sealed environment designed to contain the primary circuit in the event of a LOCA, along with any radioactive discharges. The only systems with the potential to flood the Containment are therefore those which are wholly contained within or pass through the Containment structure.

The PRHA evaluation of flooding in Containment (Reference 11.76) identifies the SGS, RCS, PXS, RNS, SFS, CCS, VWS, DWS and CVS systems as potential flood sources during plant modes 1-4. During plant modes 5 & 6, the reactor is in a shutdown state and the impact of flooding to safe shutdown is bounded. Table 11.3.2 details in which rooms each of the various systems are present.

The DWS and FPS are both normally isolated from the Containment by locked closed manual valves. These valves are only opened during shutdown and maintenance activities and therefore the DWS and FPS are not considered to comprise flood sources during normal operation; the coincident failure to isolate these systems and a pipework failure/spurious operation of the FPS is considered to be beyond the design basis.

The WLS pumps liquid effluent from the Containment sump to storage tanks in the Auxiliary Building. It is not possible to siphon effluent from these tanks and therefore the WLS is not considered to be a potential flood source in Containment.

Auxiliary Building

The following sections provide a brief description of each of the systems present within the Auxiliary Building. Table 11.3.1 details in which rooms each of the various systems are present. Details of tank volumes and refill capability are presented in (Reference 11.76).

CCS – Component Cooling Water System

The CCS includes three system tanks, two 20.4 m3 (5400 US gallon) CCS surge tanks and the 82 litre (21.6 US gallon) CCS chemical addition tank. In addition to this, the CCS system has a total volume of 160 m3 (42,406 US gallons), giving a total system inventory of 182.6 m3 (48228.6 US gallons).

During normal operation, parts of the CCS will operate at temperatures in excess of 79.4 °C (175 °F) Makeup to the CCS is provided by the DWS from the Demineralised Waster Storage Tank (DWST), which is itself made-up by the Demineralised Water Treatment System (DTS).

CVS – Chemical and Volume Control System

The CVS comprises the Boric Acid Storage Tank (BAST), Boric Acid Batching Tank (BABT) and associated pipework. The maximum capacities of the BAST and BABT are 300 m3 (79,315 US gallons) and 3.03 m3 (800 US gallons) respectively.

In general terms, there are three sections of the CVS makeup lines which have different flow rates. The three sections are:

1. Upstream of the Makeup Pump (CVS-MP-01A/B);
2. Between the Makeup Pump (CVS-MP-01A/B) and the Cavitating Venturi (N01);
3. Downstream of the Cavitating Venturi (N01).

In section 1, the flow rate is driven by the static head of pressure from the BAST. In section 2, the flow rate would be limited by the run out flow from one of the CVS makeup pumps. Section 2 is wholly contained within room 12255. In section 3, the flow rate is limited by the cavitating Venturi.

Makeup to the CVS is provided from the DWST, which is itself made-up by the DTS (see Chapter 6), at a rate of 1.1E-02 m3 s-1 (175 gpm).

Section 1 of the CVS is Moderate Energy, while sections 2 and 3 are High Energy.

DWS – Demineralised Water Transfer and Storage System

The DWST has a maximum capacity of 477 m3 (126,000 US gallons). Demineralised water is distributed throughout the DWS by two motor driven pumps each of which has a run out flow rate of 2.52E-02 m3 s-1 (400 gpm) giving a maximum system flow of 5.05E-02 m3 s-1 (800 gpm).

Within the Annex Building, the DWS pipework incorporates an orifice plate (DWS-PY-R002, UK Category A, Class 2) to limit flow within the DWS in room 12501 to no greater than 1.89E-02 m3 s-1 (300 gpm). The flow rate is therefore less than the capacity of the floor drain within the room, and as such it is not possible for there to be significant accumulations arising from a pipe rupture in the DWS.

Makeup to the DWS is provided by the DTS direct to the DWST on low level in the DWST. The DTS pumps have a maximum flow rate of 2.3E-02 m3 s-1 (360 gpm), and feed from an unlimited source.

FPS – Fire Protection System

The FPS is present in both the Auxiliary Building RCA and non-RCA, as well as elsewhere outside of the nuclear island. The FPS is also present within Containment; however, it is isolated external to Containment during plant modes 1-4.

The FPS has a 30.5 cm (12 inch) diameter distribution header, feeding a network of branch lines the smallest of which has a 1.27 cm (0.5 inch) diameter. The system is designed as a

loop such that gross failure of any pipe comprising the FPS would see a flow from both ends of the rupture location.

The FPS is served by two 1910 m3 (504,000 US gallon) yard tanks operating in duty and standby modes. A make-up source, provided by the Raw Water System (RWS), supplies both FPS yard tanks independently. The 15.24 cm (6 inch) lines provide an 8 hour refill of each yard tank. Each 15.24 cm (6 inch) line is fitted with a butterfly valve which is normally locked closed, isolating the main refill line. A smaller, 5.08 cm (2 inch), line provides automatic makeup to either yard tank. The automatic makeup lines are fitted with motor operated valves and an orifice plate to limit the automatic makeup flow to no more than 3.16E-03 m3 s-1 (50 gpm).

The FPS has a normal operating pressure of 1.27 MPa to 1.34 MPa (185 psig to 195 psig), which is maintained by a jockey pump. Should the system pressure drop below 1.24 MPa (180 psig), an electric pump will begin to supply flow at 1.26E-01 m3 s-1 (2000 gpm). If, as for a pipe rupture, the system pressure continues to drop, a diesel pump will also begin to supply flow at an additional 1.26E-01 m3 s-1 (2000 gpm). The affected room(s) will therefore flood at a combined flow, from both the electric and diesel pumps, of 2.52E-01 m3 s-1 (4000 gpm) until the duty tank is depleted or system isolation is affected.

During all plant modes, the Auxiliary Building non-RCA portion of the FPS is isolated from the two yard tanks by a normally closed and locked valve and is instead gravity fed, via a standpipe, in the PCCWST. The elevation of the standpipe is such that the maximum system inventory is limited to 99 m3 (3500 ft3).

As well as being a source of flooding following a pipe rupture, the FPS may be actuated in rooms where there are sprinklers and a pipe ruptures in a system with a temperature which exceeds 79.4 °C (175 °F), contributing an additional 2.27E-02 m3 s-1 (360 gpm) of water. Such systems are only present in the Auxiliary Building RCA and therefore the FPS will not contribute to flooding in the Auxiliary Building non-RCA (note: systems satisfying this criteria are also present within Containment, however the FPS is isolated within Containment during plant modes 1-4.

PCS – Passive Containment Cooling System

The PCCWST has a capacity of at least 2,864 m3 (756,700 US gallons). When full, each of the flow paths from the PCCWST delivers a flow rate of 3.0E-02 m3 s-1 (469 gpm) to the outside of the Containment structure.

The Passive Containment Cooling Auxiliary Water Storage Tank (PCCAWST) has a capacity of at least 2,952 m3 (780,000 US gallons). Two recirculation pumps each provide 6.3E-03 m3 s-1 (100 gpm) of makeup water from the PCCAWST to the PCCWST.

Gross failure of the pipework on one of the three flow paths would result in an unrestricted, gravity fed, flow from the PCCWST into the upper annulus. During normal operation of the PCS, water discharged from the PCCWST would flow, via two floor drains to the building exterior where it is removed by storm drains. In order to prevent the upper annulus becoming flooded, the floor drains are claimed in support of the internal flooding hazard analysis.

During all plant modes, the PCCWST provides the supply of water for the FPS within the non-RCA side of the Auxiliary Building. The elevation of the standpipe within the PCCWST is such that the supply of water is limited to 99 m3 (3500 ft3). PCS pipework within the non-RCA of the Auxiliary Building is restricted to that supplying the FPS.

PWS – Potable Water System

The PWS is an unlimited water supply distributed throughout the Auxiliary Building. The PWS incorporates regulating valves to reduce system pressure as appropriate. The design flow rate for the PWS is 1.1E-02 m3 s-1 (172 gpm); however, adherence to international plumbing code in both the RCA and the Non-RCA will restrict the flooding flow rate to 2.8E-03 m3 s-1 (44 gpm) as PWS lines are limited to 0.55 MPa (80 psig), equating to 0.03 m (1 inch) diameter piping.

RNS – Normal Residual Heat Removal System

The RNS is essentially a closed loop system with a limited volume which removes heat from the core and RCS and provides RCS low temperature over-pressure protection at reduced RCS pressure and temperature conditions after shutdown. The RNS also provides a means for cooling the IRWST during normal plant operation.

SFS – Spent Fuel Pool Cooling System

The Spent Fuel Pool (SFP) (including Cask Loading Pit (CLP), Cask Washdown Pit (CWP), spent fuel storage pit and Fuel Transfer Canal) has a surface area of 141 m2 (1516 ft2). The volume of liquid which could be released is 254 m3 (67,131 US gallons). For the same reduction in height of the refuelling cavity, the volume of liquid discharged would be 241 m3 (63,677 US gallons). The combined volume is therefore 495 m3 (130,808 US gallons).

If the pipe rupture is in the discharge side of the SFS pump, the release would be limited by the pump runout flow rate. If the rupture occurs in the suction side, the release rate would be limited by the gravity feed through the piping. For a pressure head of 13.5 m (44.36 ft) through a 0.2 m (8 inch) NPS pipe, the flow rate would be 5.29E-01 m3 s-1 (8384.6 gpm). Makeup to the SFP is from the DWST and DTS at 6.31E-03 m3 s-1 (100 gpm).

A second scenario exists where the SFS piping is aligned to the IRWST. A drop in the IRWST level by 4% will automatically isolate all valves. The IRWST has a design capacity of 2140 m3 (75,626 ft3), the maximum leak is therefore 85.7 m3 (3025 ft3). In this scenario, the flow rate would be limited by the gravity feed through the pipe at 5.5E-01 m3 s-1 (8684.9 gpm).

VWS – Central Chilled Water System

The VWS comprises a 0.07 m3 (18.3 US gallon) chemical feed tank, 1.2 m3 (318 US gallon) expansion tank and the volume of the connecting pipework at 60 m3 (15,813 US gallons), giving a total system inventory of 61.1 m3 (16,149 US gallons). The flow rate within the system is 0.5 m3 s-1 (7947 gpm).

Automatic makeup to the VWS is from the DWS on low-low level within the expansion tank. The makeup flow from the DWS is 3.1E-04 m3 s-1 (5 gpm), which is considered to be negligible for the purpose of the internal flooding analysis.

VYS – Hot Water Heating System

The Hot Water Heating System (VYS) comprises a 3.2 m3 (855 US gallon) surge tank and an 82 litre (21.6 US gallon) chemical addition tank. During normal power operations , hot water is circulated throughout the VYS by a single pump rated to a total flow of 5.0E-02 m3 s-1 (788 gpm). During operation, the VYS operates at temperatures in excess of 79.4 °C (175 °F).

A low level within the VYS surge tank will initiate a makeup flow, of 1.58E-03 m3 s-1 (25 gpm), from the DWS, which is considered to be negligible for the purpose of the internal flooding analysis.

WLS – Liquid Radwaste System

The WLS comprises the following tanks:

- Reactor Coolant Drain Tank – 3.4 m3 (900 US gallons)
- Containment Sump – 0.4 m3 (99 US gallons);
- Effluent Holdup Tanks (2) – 106 m3 (28,000 US gallons) each;
- Waste Holdup Tanks (2) – 56.8 m3 (15,000 US gallons) each;
- Monitor Tanks (3) – 56.8 m3 (15,000 US gallons) each;
- Chemical Waste Tank – 33.7 m3 (8,900 US gallons).

The total system inventory for the WLS is therefore 533 m3 (140,899 US gallons). The maximum flow rate of the WLS is 7.19E-03 m3 s-1 (114 gpm).

Makeup to the WLS is provided from the DWST, which is itself made-up by the DTS at a rate of 4.73E-03 m3 s-1 (75 gpm).

WSS – Solid Radwaste System

The WSS comprises two resin basin tanks, each of which has a capacity of 8.6 m3 (2,274 US gallons). The WSS can also be aligned with the SFS, which has a total system inventory of 495 m3 (130,808 US gallons), at a maximum flow rate of 4.73E-03 m3 s-1 (75 gpm).

Makeup flow to the WSS is provided from the DWST, which is itself made-up by the DTS, at a rate of 4.73E-03 m3 s-1 (75 gpm).

11.3.4.3 Flood Paths

Flooding is expected to propagate both horizontally throughout the level on which the pipe rupture occurs as well as vertically between levels. While it is typical for flooding to proceed to lower levels, it is also possible for flooding to affect higher levels through back flow processes when all available space on the lower level(s) has become flooded. In accordance with the guidance provided in ANS/ANSI 56.11 (Reference 11.85), flood propagation from the room of inception considers the following paths:

- Door gaps;
- Pipe chases which are not sealed;
- Stairwells/elevator sumps;
- Radioactive Waste Drain System (WRS) and Waste Water System (WWS) drains;
- Penetrations (e.g., cable tray or piping) which are not sealed;
- Floor gratings, weirs and unsealed ladder and hatch openings.

Various door types are present throughout the NI and connected buildings. Depending on which type of door separates two rooms, dictates the flow between the rooms. The door types and their influence on flow are as follows:

- Physical barriers which obstruct flow between adjacent divisions (e.g., standard door, steel door). Where present, the flow to an adjacent compartment is assumed to be through a door gap present at the base of the door.

- Adjacent rooms or compartments which are not segregated by physical barriers (e.g., safety rope, wire mesh doors). Flow to an adjacent compartment is assumed to be unobstructed and would proceed as a flow through a contracted rectangular weir.

- The watertight doors in rooms 12166 and 12167 are assumed to be conservatively closed in which increases the water heights in adjacent areas for flooding originating outside these rooms.

Stairwells and elevators provide an opportunity for flooding to proceed vertically between different levels. Although the room itself may flood, stairwells and elevators are treated as conduits through which flooding propagates to other areas of the plant.

The drains provide a means for flood mitigation within affected rooms, but in doing so communicate the flood to downstream rooms (typically only the rate at which the downstream room is flooded will be affected, with the flood height largely unchanged). In accordance with the guidance provided in section 5.2.2 of ANS 56.11-1988 (Reference 11.85), the efficacy of flood mitigation by the drains is subject to the following conditions:

- Drains in rooms subject to a HELB are assumed to be 100% clogged by debris;

- Drains in rooms subject to a MELB are assumed to be 25% clogged by debris;

- Drains in rooms other than that in which the pipe rupture occurred are assumed to be 25% clogged;

- A 10.16 cm (4 inch) drain can extract up to 1.58E-02 m3 s-1 (250 gpm) (Reference 11.76). Where multiple drains combine into a single 10.16 cm (4 inch) header, the combined rate of extraction from all drains is limited to 1.58E-02 m3 s-1 (250 gpm).

- A 15.24 cm (6 inch) drain can extract up to 1.97E-02 m3 s-1 (312 gpm) (Reference 11.76). Where multiple drains combine into a single 15.24 cm (6 inch) header, the combined rate of extraction from all drains is limited to 1.97E-02 m3 s-1 (312 gpm).

Broadly speaking, the Containment area comprises of four areas separated from one another by walls and floors such that flooding in one area would not propagate to another area unless the height of the flood exceeds the height of the separating wall. The four areas are:

- CVS room (11209);
- PXS room B (11207 and 11208);
- PXS room A (11206);
- General Containment Area (including refuelling cavity).

Curbs around the PXS and CVS rooms ensure that, during postulated flooding scenarios, the refuelling cavity is flooded from the Containment sump before flood water overflows into the PXS or CVS rooms. The curbs for each area are designed such that the CVS room will flood prior to both PXS rooms, and that PXS room B will flood prior to PXS room A. This arrangement is shown diagrammatically in Reference 11.76.

The RCA and non-RCA portions of the Auxiliary Building are separated from one another by thick concrete walls and floors (Reference 11.76). Flooding within the RCA will therefore not propagate to the non-RCA and vice-versa.

The connections, for flood propagation, between the rooms/areas which together constitute the Auxiliary Building RCA and non-RCA are shown in Figures 10-2 to 10-11 in Reference 11.76. The rooms which may be affected by flooding are shown in Figures 10-12 to 10-23 in Reference 11.76. Where the flood height in a room/area reaches the full height of the room, flooding progresses upwards via stairwells or migrates through drains and pipe chases, etc.

The ground elevation of the Turbine Building, Annex Building and Radwaste Building are all graded such that significant flooding would flow away from the nuclear island. However, doorways between the nuclear island and each of these buildings provide potential pathways through which flooding could migrate.

11.3.4.4 Hazard Schedule

The internal flooding hazard schedule (see Table 11.3-3) has been prepared based on the results of the PRHA. In accordance with relevant international guidance (Reference 11.82), the flooding hazard analysis has considered single pipework failures, secondary effects and cascade events in determining the bounding case. The flooding hazard analysis has been prepared on the basis that:

- Flooding will not propagate from one flood area to another; i.e., a flood in Containment may not find its way to the RCA or non-RCA areas;
- All SSC below the maximum flood height for that room will be lost, except where the SSC is qualified for a submerged environment;
- The unmitigated flood height comprises exhaustible sources and 7 hour of inexhaustible supply; significant flooding would not go undetected for longer than 7 hours without operator intervention.

The internal flooding hazard schedule presents, for each room (or group of rooms), the:

- The Fault ID (listed in Chapter 8) associated with the listed flooding event;
- Divisions of each SSC affected[8] by the flood;

8. Only those SSC located below the maximum flood height, which are not qualified for operation in a submerged environment, are reported in the hazard schedule. All SSC not reported in the hazard schedule, but otherwise present in the room, are assumed to be unaffected by flooding and therefore capable of delivering their Category A safety function as required.

- Category A safety function at risk;
- Unmitigated consequences should the plant be unable to effect safe shutdown;
- Redundant SSC available to deliver the Category A safety function, which have not been exposed to the same internal hazard.

The hazard schedule is presented in tabular form providing a concise and comprehensive summary of the postulated flood events, their significance and how the AP1000 plant is designed to cope with the hazard.

11.3.4.5 Discussion of Results

The PRHA have shown the flood heights as a result of pipe rupture in each of the rooms comprising the NI (Reference 11.76).

The analysis has produced the bounding flood height, and the associated bounding flood height. The bounding flood heights have been compared against the elevation of SSC to determine the Class 1 SSC which may become submerged. The results of this analysis are summarised in the following subsections.

Containment Building

The Containment is, in order to maintain the free movement of gases, an open space. The majority of rooms are separated by open grate structures which would not inhibit the movement of fluid; however, the CVS room (11209), PXS valve room B (11207/11208) and PXS valve room A (11206) have substantial concrete partitions/curbs rising to the 103.05 m (110.00 ft), 103.7 m (110.08 ft) and 103.1 m (110.17 ft) levels respectively. Flooding in the general Containment space would therefore only impact the CVS room, PXS valve room B and subsequently PXS valve room A once the partition/curb height has been exceeded (Reference 11.76). The rupture/failure of the RCS or PXS pipework represents the worst case bounding flooding event due to the impacts to floodup levels, environmental conditions, submergence pressure, submergence temperature conditions, containment pressure and external containment cooling environment. Similarly, pipework failure in one of these compartments would initially result in the affected compartment flooding, before cascading into separate compartments. The VWS pipework break coupled with ADS actuation will provide higher flood levels however the related environmental impacts are significantly lower.

During refuelling operations, the refuelling cavity is flooded and, as such, the SSC present in these areas are qualified to operate in a submerged environment.

The CVS room doesn't contain any Class 1 SSCs. PXS valve room A and PXS valve room B contain redundant divisions of the PXS IRWST injection isolation valves. It is not postulated that both PXS valve room A and PXS valve room B flood from a single design basis event, therefore the redundant division remains available to deliver the Category A safety function of coolant make-up following a LOCA.

That PXS room A and PXS room B do not both become flooded from a single design basis internal flooding event is a result of the curb height elevations ensuring preferential flooding of non-sensitive areas of the Containment and the back flow preventers between each of these rooms and the general Containment space.

Auxiliary Building – Radiologically Controlled Area

The Auxiliary Building RCA is physically segregated from the non-RCA by 2 ft (0.61 m) thick (at least) concrete walls and floors. The only systems with the potential to flood the Auxiliary Building RCA are therefore those which originate in or pass through the Auxiliary Building RCA.

In the majority of rooms from 94.7 m (82'-6") level upwards, a rupture of the FPS produces the bounding case flood height for that specific room; given that the FPS is the subject of cascade failure following rupture of the CVS in room 12255, the flood height in communicated rooms is bounded by the HELB of the CVS in room 12255. In all instances, the bounding flood height for the affected room is below the level at which Class 1 SSC would be affected.

The analysis of internal flooding within the RCA has identified the bounding flood source to be a failure of the high energy CVS line in room 12255. This fault is assumed to result in the cascade failure of all other piping systems in the room, namely the CCS, FPS and VWS.

There are no Class 1 SSCs located on Level 1 of the Auxiliary Building RCA; however, Class 1 SSCs would become submerged once flooding progresses to level 2.

At the onset of flooding in the RCA, two redundant Class 1 differential pressure sensors located in the Auxiliary Building RCA sump, located on level 1, will alert operators present in the MCR via the PMS. On receipt of the alarm, operators are required to identify and isolate the sources of flooding. There are several hours to effect isolation of the systems prior to Class 1 SSC becoming submerged.

Auxiliary Building – Non-Radiologically Controlled Area

The Auxiliary Building non-RCA is physically segregated from the RCA by 2 ft (0.61 m) thick (at least) concrete walls and floors. The only systems with the potential to flood the Auxiliary Building non-RCA are therefore those which originate in or pass through the Auxiliary Building non-RCA. The non-RCA is further segregated into electrical and mechanical areas, which are physically segregated from one another by concrete walls and floors such that flooding in the mechanical areas cannot propagate into the electrical areas and vice-versa.

Within the mechanical area, the bounding flood is presented by a failure of the SGS in rooms 12404 or 12406 which is a high energy line. The flood height is limited by pressure relief panels, in each of the rooms, the function of which is to discharge flooding to the Turbine Building 1st bay.

The flood relief panels and floor drains protect Class 1 SSC from the effects of flooding by ensuring that the maximum flood heights in these rooms remains below the elevation at which they would become submerged.

Within the electrical area, all sources of flooding would eventually migrate to level 1 where the batteries are located. With the exception of the PWS, all flood sources are exhaustible and the inventory of individual systems is insufficient to submerge the battery banks which are the lowest elevated Class 1 SSC. The PWS is inexhaustible and would eventually submerge the batteries.

Two differential pressure sensors, located in 12104 and 12105, will alert operators in the MCR of the presence of flooding in this area. The alarm, actuated via the PMS, will prompt

an operator to effect isolation of the PWS (or other flood source) before the level reaches the base of the batteries.

A failure of the PWS located in the operator break room within 12401, will initially flood rooms 12400 and 12401 before spreading, via stairwell S05 to the remote shutdown room, 12303. The door between 12400 and 12411 is watertight. The analysis of flooding in this area (Reference 11.76) shows that it is not credible that flooding progresses to the extent that Class 1 SSC becomes submerged.

Areas Outside the Nuclear Island

Areas outside of the Nuclear Island do not contain any Class 1 SSC and therefore flooding of these areas cannot directly result in a loss of Category A safety functions. However, it is possible that flooding originating in these areas, including that originating from yard tanks, could migrate to the Auxiliary Building. Detailed discussions of the flooding origination and consequences are provided in Reference 11.76. The following subsections consider the implications of flooding in the buildings directly abutting the Nuclear Island (radwaste, annex and turbine) for impact on the Nuclear Island.

Turbine Building

The Turbine Building 1st bay communicates with rooms 12306, 12405, 12504, 12505 and 12506 in the Auxiliary Building non-RCA. The flooring within the Turbine Building 1st bay, at elevations other than the 100 m (100'-0") level, comprises grating with a largely open structure; flooding originating in the Turbine Building 1st bay will flow down to the 100 m (100'-0") level without significant accumulation at higher elevations. Flooding of the Turbine Building 1st bay could therefore only migrate into room 12306.

The MSS is a HE line, failure of which could cause a cascade rupture of the BDS; CCS; CDS; CFS; DWS; FPS; FWS; LOS; MSS; PWS; SSS; SWS; TCS; TDS; TOS; VWS and the VYS. The maximum flood height in the Turbine Building 1st bay is conservatively assumed to exist in room 12306, however this flood height is bounded by a MELB of the SGS. All other communicated areas of the Auxiliary Building non-RCA become wetted only and as such pose no hazard to Class 1 SSC.

Annex Building

There are no sources of flooding present in the Annex Building which are not also present in the Auxiliary Building. Given that there are additional discharge routes, away from the Auxiliary Building, for flooding initiated in the Annex Building, the flood heights as a result of pipe failure are bounded by those which originate in the Auxiliary Building.

Radwaste Building

There are no sources of flooding present in the Radwaste Building which are not also present in the Auxiliary Building. Given that there are additional discharge routes, away from the Auxiliary Building, for flooding initiated in the Radwaste Building, the flood heights as a result of pipe failure are bounded by those which originate in the Auxiliary Building.

11.3.5 Sensitivity of Results and Cliff Edge Effects

The three bounding flooding cases determined for the Containment, RCA portion of Auxiliary Building and the Non-RCA side of the Auxiliary Building demonstrate that the Category A and post-72 hour Category B safety functions can be delivered. Each of the flood

bounding cases are based on large volumes and will require several hours to reach their full flood up heights but these flood heights are not that sensitive not are there any cliff edge effects.

Containment

The Containment flooding is based on all the available flooding volumes possible within the Containment vessel. Flood levels have been reviewed and applicable weirs have been designed and installed to preferentially flood key compartments and not flood others. There is as significant margin and appropriate passive overflow mechanisms to ensure flooding of the PXS-A and PXS-B, is prevented or minimized. The redundancy of trains and barriers between compartments also ensures the boundary flooding event can be accommodated while still delivering the required Category A safety functions to place the plant in a safe shutdown mode.

RCA Side of Auxiliary Building

The PRHA calculations have shown that the cascading break in room 12255 delivers the enveloping flooding condition and still allows the Category A safety functions to occur as necessary. This flooding event occurs over a long duration with sufficient time for operators to react to the event and to isolate the failed pipework before challenging the Containment isolation valves. The flooding event assumes the conservative flood volumes and assumes the water volume spreads over a large portion of the RCA side of the Auxiliary Building undetected. The safety grade sensors identify the break event only after 12 inches of water which provides early indication of this flooding event. There are no cliff edge effects since the time durations are well understood flood volumes are also limited.

Non-RCA Side of Auxiliary Building

The enveloping event on the non-RCA side is related to the possible flooding of the 4 divisions of the Class 1 batteries at the basemat elevation. The worst case enveloping event is the break of the PWS with unlimited water volume. The installation of the Class 1 sensors provides early warning to the MCR operators of the possible flooding event. These sensors provide warnings at the 0.1 m (4 inches) level prior to water making contract with the bottom of the batteries at 0.19 m (7.5 inches). The low flooding rate provides adequate time for operators to isolate the flood sources which are within one floor of the MCR. In addition, the batteries can still deliver the safety function once the bottom of the batteries are contact by water which may reduce their capability, but the flood level can rise another 0.60 m (23.5 inches) before batteries become shorted out. Therefore based on the early warning to the MCR, low flooding rate and extra margin to shorting out batteries eliminates any cliff edge effects. Furthermore, AP1000 can mitigate the consequences of shorting out batteries using self-actuating Class 1 SSCs or by the use of Class 2 SSCs.

11.3.6 Combined Hazards Discussion

The PRHA calculations (Reference 11.77) consider, on a deterministic basis, a single flooding event[9] and the consequential impact on SSC in the affected plant areas.

9. A single flooding event could be a HELB, MELB or cascade failure following HELB.

The consideration of credible combinations of flooding with other postulated internal hazards likely to occur independently of flooding is discussed in Section 11.12. Reference 11.75 provides a coherent approach across all internal hazard types (e.g., fire, explosion, missiles, dropped loads, pressure part failure).

Combinations of independent internal and external hazards (e.g., internal flooding and extreme low ambient air temperatures) are considered to be Beyond Design Basis events and as such have not been explicitly considered in this section. However, compliance with relevant equipment and structural design codes ensure that combinations of internal hazards with the relevant abnormal operating occurrences (including environmental hazards) are addressed.

11.3.7 ALARP Assessment and Discussion

Deterministic analysis of postulated, design basis, internal flooding events shows that the Category A safety functions will be available to provide a safe shutdown following the worst case postulated internal flood.

The AP1000 plant, by its very nature, makes extensive use of water and water based systems to operate normally. It is therefore not possible to remove the hazard of internal flooding from the design of the plant. However, the use of structural barriers has made it possible to protect sensitive areas of the plant from significant sources of liquid, primarily the non-RCA side of the Auxiliary Building.

Where it has not been possible to remove or isolate sources of flooding, Class 1 SSC have been located above the maximum flood height or qualified for operation in a submerged environment. In order to ensure that the maximum flood height does not exceed that of the Class 1 SSC, passive discharge routes have been incorporated into the design (e.g., door gaps, floor drains & flood relief panels).

Further Mitigation Measures

The analysis supporting this assessment of internal flooding has, wherever possible, made claims on passive features to mitigate the effects of flooding. These features include flood relief panels, door gaps and internal floor drains; for the majority of pipe ruptures, the maximum flood level takes no credit of floor drains and the flood height would therefore be considerably lower than that which is presented.

Sump pumps are located in all areas of the Nuclear Island. In the event that a pipe ruptures, as fluid percolates down, the sump pumps would automatically start to displace the liquid as it builds up.

The majority of systems which present a source of flooding require a minimum inventory in order to function correctly. Should the water level drop in the delay/storage tanks as a result of a leak, a number of process level alarms would alert operators in the MCR to the event and corrective action would be taken in significantly shorter times than those credited. For a number of systems, the hazard potential presented by a loss of fluid is such that the reactor would trip, initiating a safe shutdown, long before the hazard to Class 1 SSC was realised.

Additional Means of Providing Safety Functions

The primary Class 1 SSC used to mitigate internal flooding identified in Chapter 8 self-actuate on loss of Class 1 dc power or on loss of the instrument air pressure. This reduces the vulnerability to flooding.

Furthermore, the AP1000 design provides several additional levels of defence that are separate and diverse from the primary Class 1 SSC. As shown in Chapter 8 for frequent faults such as loss of main feedwater, there are separate and diverse Class 1 SSCs that can provide the necessary safety functions. These SSCs provide a passive feed and bleed capability using ADS, Accumulators, IRWST injection and Containment recirculation.

Another level of defence is provided by active Class 2 SSC. These SSCs are separate and diverse from the Class 1 SSC, and are powered by the standby DGs when off-site electrical power and house power are not available. Note that these Class 2 features are not claimed / credited in the deterministic UK safety case.

The active Class 2 SSC includes the following:

- Make-up of borated water to the RCS using the CVS
- Heat removal from the SGs using SG Power Operated Relief Valves and the SGs using start-up feedwater pumps
- Heat removal from the RCS (at reduced pressure) using the RNS
- Supporting functions include:
    - CCS and SWS
    - AC power from the Standby DGs
    - VWS air cooled chillers
    - HVAC by the VBS
    - I&C by the PLS

Internal floods within the NI are anticipated to occur at frequencies <1E-3 per year as shown in Chapter 8 and as a result are classified as infrequent faults. As such, diverse mitigation is not required in the UK. Even so, there are self-actuation and diverse Class 1 passive features of the AP1000 design in providing additional mitigation capability.

Nonetheless, the design of these active, Class 2 SSC has taken into account the potential effects of internal floods in accordance with the American Light Water Reactor Utility Requirements Document (Reference 11.87).

As such, measures have been taken to protect the above listed equipment from postulated internal floods:

- Separating Class 2 equipment from possible flood sources, where practicable.
- Locating equipment above the postulated flood height.
- Separating the redundant of Class 2 equipment

Furthermore, failure of the Class 2 equipment, whether due to an inherent fault or an internal flood, will not prevent the Class 1 SSC from fulfilling their Category A safety functions.

On the basis of the above discussion, and given that Category A safety functions can be maintained in the event of internal flooding, it is judged that there would be minimal safety benefit from introducing additional measures to protect or mitigate the effects of flooding; the risk from internal flooding hazards is therefore considered to be broadly acceptable and

ALARP.

The assessment concludes that Category A safety functions can continue to be delivered following a design basis flood through a combination of claims made on structural barriers, equipment qualification, passive flood relief systems and, where necessary, minimal operator actions to isolate inexhaustible sources of flooding following identification by a level sensor.

11.4 Pressure Part Failure

11.4.1 Introduction

The AP1000 plant Pressure Part Failure assessment (Reference 11.77) has been performed to determine the effects to Class 1 SSC, delivering Category A safety functions and the supporting post-72 hour Category B safety functions necessary to achieve and maintain a safe shutdown plant, resulting from the failure of pressure retaining fluid systems.

The assessment has been based on the deterministic assumption of gross failure of applicable fluid systems. The exception to this is those systems with a structural integrity classification of Highest Safety Significance (HSS) (see Chapter 20). The following conservative assumptions have formed the basis of the assessment of PPF:

- All fluid systems without an Incredibility of Failure (IoF) claim are candidates for gross failure.
- Gross failures are instantaneous circumferential break events.
- Longitudinal breaks are also considered as a function of pipe size and failure location.
- Calculation of the maximum thrust load for pipe whips and jet impingement.
- No operator action will be taken to control or mitigate a failure.
- All SSCs within the zone of influence (ZOI) of a postulated pressure part failure are unavailable, unless the SSCs are designed for the associated loads.
- All SSCs designed for the resulting environmental conditions following a pressure part failure are available.
- A single active failure is present in the plant response to a pressure part failure event.

The assessment concludes that SSCs delivering Category A and supporting post 72-hour Category B are protected from the effects of pressure part failure through a combination of claims made on the location of failures, the protection of SSCs by means of restraints, shield, and barriers, and the engineering qualification of SSCs for post-failure environmental conditions.

11.4.2 Pressure Part Failure Claims, Arguments and Evidence

This section presents the claims, arguments and underlying evidence made in relation to pressure part failure hazards with the potential to inhibit safe shutdown of the reactor plant.

11.4.2.1 Claims Overview

This section presents the claims, arguments and underlying evidence made in relation to pressure part failure hazards with the potential to inhibit safe shutdown of the reactor plant

11.4.2.2 High Level Claim

A pressure part failure event could cause a transient from normal full power operation of the reactor power plant with the potential to result in a hazard on or off site being realised. In response to such a transient, it may be necessary to shut down the reactor and return it to a safe state. Depending on the exact nature of the transient, there are a number of courses of action to shut the reactor down. Ensuring the availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be shut down, and is the basis of the following high level claim:

Claim IH-3.0: **Postulated pressure part failure events within the Design Basis do not prevent the delivery of the Category A safety functions and the supporting post-72 hour Category B safety functions necessary to respond to the postulated event.**

Within the design of the AP1000 plant, this has been achieved by:

- No claim is made on the prevention of gross failure of systems and components without an incredibility of failure (IoF) argument
- Protecting redundant divisions of Class 1 structures, systems, and component (SSCs) by separation using barriers or physical distance
- Protecting redundant divisions of Class 1 SSCs by restricting the hazard impact through use of restraints, shields, or physical separation
- The use of passively-designed fail-safe equipment
- Where required, SSCs required to implement Category A safety functions are designed for failure conditions
- The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.4.2.3 Prevention Claims

The AP1000 plant pressure part failure safety case utilises prevention claims to preclude postulated pressure part failure events, as well as to provide a method for combining postulated events for consequence evaluation.

In conjunction with the structural integrity classification process (Chapter 20), it is possible to preclude the possibility of the gross failure of a pressure retaining system or component through the application of an IoF argument. The AP1000 plant structural integrity classification denotes those components with an IoF argument as highest safety significance (HSS).

Claim IH-3.1: **Pressure part failures are deterministically assumed to occur as a gross failure initiating event, except those justified by the**

Structural Integrity Classification as Highest Safety Significance

Sub-Claim IH-3.1.1: **Piping equal to or less than DN25 is considered bounded by failure of larger piping systems when they are present within the same room or compartment.**

Sub-Claim IH-3.1.2: **Failure of fluid systems of moderate-energy cannot result in pipe whip, jet impingement, compartment pressurisation, or decompression transients.**

11.4.2.4 Protection Claims

While it is not always possible to protect the SSCs present in the room/compartment of a postulated pressure part failure event, separation and segregation have primarily been used to protect redundant SSCs throughout the nuclear island (NI).

Claim IH-3.2: **Passive protective measures have been incorporated in the AP1000 design to protect SSCs that deliver Category A and post-72 hour Category B safety functions from pressure part failures.**

Sub-Claim IH-3.2.1: **Consequences of pressure part failure will be contained through the design of barriers or physical separation as to not cause the loss of a Category A or post-72 hour Category B safety function.**

Sub-Claim IH-3.2.1.1: **Class 1 civil/structural relief devices are used to control subcompartment pressure where unmitigated effects may challenge the integrity of claimed Class 1 barriers.**

Sub-Claim IH-3.2.2: **Consequences of pressure part failure will be restricted through the design of shields, restraints, barriers, or physical separation so as to not cause the loss of a Category A or post-72 hour Category B safety function.**

11.4.2.5 Mitigation Claims

Whereas protection of SSCs in rooms/compartments of origin is limited, mitigation of the resulting conditions is possible through the proper design of SSCs and selection of materials.

Claim IH-3.3: **SSCs that deliver required Category A and post-72 hour Category B safety functions will operate following a pressure part failure in the resulting environmental conditions.**

11.4.2.6 Arguments and Evidence

Prevention Arguments and Evidence

Claim: IH-3.1: **Pressure part failures are deterministically assumed to occur as a gross failure initiating event, except those justified by the Structural Integrity Classification as Highest Safety Significance**

The structural integrity assessment, and classification, of systems and components for the AP1000 plant are documented in Chapter 20. Discounting the failure of a component based on an IoF argument removes the postulated failure from the plant design basis; therefore, interfacing design criteria and assessments need not consider these events as initiating failures.

Sub-Claim IH-3.1.1: Piping equal to or less than DN25 is considered bounded by failure of larger piping systems when they are present within the same room or compartment.

Assuming similar process conditions, a larger pipe failure will result in more significant direct effects as well as the associated dynamic consequences. Environmental consequences have been deterministically developed to consider the failure of all applicable piping in a defined room to support equipment qualification as describe in Chapter 5. Further discussion and substantiation of this argument is contained in the pressure part failure topic report (Reference 11.77).

Elevations of the Non-RCA Auxiliary Building located below grade (El. 100.00m (100'-0")) which are not in the vicinity of an enveloping fluid system are limited to DN 1" (1" NPS) piping failures; however, this piping is low temperature moderate-energy piping and is evaluated for unmitigated effects as part of internal flooding in Section 11.3.

Sub-Claim IH-3.1.2: Failure of fluid systems of moderate-energy cannot result in pipe whip, jet impingement, compartment pressurisation, or decompression transients.

The AP1000 plant design applies a piping classification scheme based on the fluid energy levels. This classification system identifies those systems and components with the potential for dynamic effects, e.g., pipe whip and jet impingement, this piping is referred to as high-energy.

Two parameters used to identify high-energy piping and they are applied independently, either parameter is sufficient to consider piping as high-energy.

- Temperature – Normal operating fluid temperature of greater than 93 °C (200 °F) to identify conditions that may result in steam release upon failure.

- Pressure – Normal operating fluid pressure of 1.896 MPa(g) (275 psig) or greater to identify systems with sufficient energy to propel a pipe and create a dynamic response.

In addition to these service conditions, consideration of the frequency of use of the fluid system is also included in the AP1000 plant pressure part failure assessment. Systems or portions of systems that do not exceed the high-energy threshold for either 98% of the system total operating time or 99% of the plant operating life are considered as moderate-energy. As failure probability of these systems is not expected during plant life, additional restriction on high-energy availability adds further confidence that postulated pressure part failure will be a moderate energy event.

The fluid energy classification scheme has been reviewed and adopted internationally as relevant good practice as evidenced by applications in the United States (Reference 11.84), adoption into consensus standards applied in European applications, recognition in international safety standards (Reference 11.89), and application precedent in the UK.

Protection Arguments and Evidence

Claim IH-3.2: Passive protective measures have been incorporated in the AP1000 design to protect SSCs that deliver Category A and post-72 hour Category B safety functions from pressure part failures.

Sub-Claim IH-3.2.1: Consequences of pressure part failure will be contained through the design of barriers or physical separation as to not cause the loss of a Category A or post-72 hour Category B safety functions.

The AP1000 plant is segregated into rooms, or compartments composed of one or more rooms; these rooms/compartments are separated from one another by suitably designed civil/structural barriers constructed of reinforced concrete or composite steel construction. These barriers are identified in the AP1000 plant Hazard Barrier Matrix (Reference 11.9). The principal protection features to protect essential SSCs from the dynamic effects of a pressure part failure event are barriers. The pressure part failure assessment claims barriers consistent with the resulting mitigated consequences; i.e., flood, ventilation, pressure, radiological, missile. Environmental effects are not assumed to be constrained by barriers unless they are specifically designed for the resulting conditions.

Barriers protecting Class 1 SSCs are themselves Class 1 structures and are rated for load-bearing capacity and integrity. Specific to high-energy pipe failures in the main steam and main feedwater systems located in the Turbine Building, seismically-designed Class 2 barriers are acknowledged in the protection of SSCs inside the nuclear island. Where acceptable load conditions are not practicable, the addition of restraints or the design of essential SSCs for the resulting conditions are permissible means to address the consequences of a pressure part failure event.

If there are no barriers available, zones of influence determine the scope of consequences. These zones of influence are discussed in the pressure part failure topic report (Reference 11.77) and defined consistent with recognised consensus standards and good practice (Reference 11.89).

Sub-Claim IH-3.2.1.1: Class 1 civil/structural relief devices are used to control subcompartment pressure where unmitigated effects may challenge the integrity of claimed Class 1 barriers.

Subcompartment pressurisation is a dynamic effect of a pressure part failure in associated rooms and results in distributed loads upon the associated barriers. The magnitude of pressurisation is a function of the rate of mass and energy release, the volume of the room or compartment, and the venting capability of the room or compartment.

The Containment Vessel is claimed for retention of pressurisation effects from all postulated pressure part failures located within its pressure boundary consistent with the vessel's function as a fission product barrier. The Auxiliary Building is a reinforced concrete structure that provides structural support and protection of Class 1 SSCs outside of the Containment Vessel. Postulated failure of large diameter high-energy piping has to potential to over-pressurise rooms in the Auxiliary Building with an unmitigated consequence of damage to claimed Class 1 barriers.

Pressure relief panels are designed for those rooms that require additional venting capability to protect the integrity of a claimed Class 1 barrier. These pressure relief panels are Class 1

SSCs and designed to be self-actuating (e.g., they require no power or C&I interface to operate). These devices are controlled by passive means such as the panel mass or shear pins. Due to the inherent reliability of the control device and its passive nature of actuation, the pressure relief panels are not subject to an assumption of single active failure. Relief panels are identified in the hazard schedule.

Sub-Claim IH-3.2.2: Consequences of pressure part failure will be restricted through the design of shields, restraints, barriers, or physical separation so as to not cause the loss of a Category A or post-72 hour Category B safety function.

Where separation or the design of intervening barriers is not adequate to protect essential SSCs, the dynamic effects of the postulated pressure part failure event may be restricted through the design of restraints or shields. The application of these protective measures results in a restrained zone of influence, which decreases the extent of the dynamic effects of pipe movement.

Restraints and shields are limited to the restrictions and modifications of dynamic pipe movement and do not affect the environmental responses in affected regions of the plant.

Pipe restraints and shields protecting Class 1 SSCs are themselves Class 1 structures and are rated for load-bearing capacity and integrity. Restraints and shields are designed with structural attachment points and their corresponding faulted load conditions are analysed for acceptability.

Mitigation Arguments and Evidence

Claim IH-3.3: SSCs that deliver required Category A and post-72 hour Category B safety functions will operate in conditions following a pressure part failure event.

As described in Chapter 5, Class 1 SSCs are designed to operate in differing environmental conditions which include consideration of:

- Temperature
- Pressure
- Radiation
- Humidity
- Spray Wetting
- Submergence
- Chemical Effects

The limiting environmental conditions within the AP1000 plant are defined by room and reflect the full spectrum of pressure part failure events. Components within rooms are qualified for the resulting conditions through application of the AP1000 plant equipment qualification methodology as described in Chapter 5.

Design requirements are applied in addition to qualification testing to reduce the exposure of sensitive materials to harsh environments; these include the use of passive components with metallic parts and enclosure within an IEC IP66 or NEMA 4/4X rated enclosures for mitigation of spray effects.

For the evaluation of plant response to a postulated pressure part failure, it is assumed that all SSCs affected by the environmental consequences of a pressure part failure event that are not qualified for the conditions are not available.

11.4.3 Pressure Part Failure Safety Case Summary

11.4.3.1 Introduction and Overview

Pressurised components within the AP1000 design comprise pipes, pipe components (such as valves and sensors), vessels, tanks and HXs. Failure of such components may result in direct effects, such as the failure of a train of the system associated with the pressurised component. Such pressure part failures are considered within the AP1000 design as internal plant faults and are listed in the fault schedule (Chapter 8, Appendix 8A).

In addition, pressure part failures also have the potential to cause damage to other plant items due to indirect effects such as:

- Pipe whip
- Jet impingement
- Jet spray
- Subcompartment pressurisation
- Asymmetric pressurisation of large equipment
- Fluid Decompression (e.g., water hammer)
- Environmental effects
- Missiles
- Flooding
- Blast effects

Pipe whip, jet impingement, jet spray, subcompartment pressurisation, asymmetric pressurisation of large components, fluid decompression, and environmental conditions are discussed in this section. Missiles, flooding, and blast effects (i.e., explosions) are contained within their respective sections of this PCSR chapter.

Consideration of the pressure part failure analysis is focused on those areas containing the Class 1 SSCs, namely the AP1000 plant nuclear island. Consideration of pressure part failures in locations outside of the nuclear island is limited to a demonstration that the NI is adequately protected from postulated pressure part failures from these sources by physical barriers.

The scope of the AP1000 plant pressure part failure assessment includes pressurised systems and components, including in line components; e.g., valves, sensors, vessels, and heat exchangers. The gross failure of these inline components is evaluated as part of the pressure part failure assessment in the form of the connections to the associated piping. This approach is applied for hazard evaluation based on the following considerations:

- Components such as valves are more robust that the connecting piping as required by the ASME Code (References 11.91 and 11.3) and associated supporting standards.

- The failure of an inline component is limited to the energy and inventory of the connecting system; therefore, failure of the connecting piping envelops the consequential effects.

- Components such as valves and instruments represent constrictions in flow paths that are bounded by the assumption of flow area of the connecting pipe.

- Failure of in-line components that create missiles are discussed in Section 11.6.

- Rupture of tanks and vessels are considered inputs to the internal flooding assessment and discussed in Section 11.3.

11.4.3.2 Applicable Codes and Standards

Pressure part failure assessments have been undertaken in accordance with the following principal codes and standards, as discussed in the topic report (Reference 11.77):

- ASME Boiler and Pressure Vessel Code, Section III, 'Rules for Construction of Nuclear Power Plants' (Reference 11.90);

- ASME B31.1, 'Power Piping' (Reference 11.3);

- ANS-58.2, 'Design Basis for Protection of Light Water Nuclear Power Plants against the Effects of Postulated Pipe Rupture' (Reference 11.84);

The AP1000 Equivalence/Maturity Study of US Codes and Standards (Reference 11.25) determines, based on their importance to safety, the applicability, adequacy and sufficiency of those standards when compared with relevant UK and international good practice. It also provides a clear and auditable demonstration that all codes and standards to support the design substantiation of UK safety related or safety significant SSCs have been identified.

To evaluate the AP1000 design codes and standards against the UK expectations, the codes and standards have been organised by the relative safety significance of the SSCs to which they have been applied. The safety significance has been determined in accordance with the AP1000 UK Safety Categorisation and Classification Methodology (Reference 11.26), which describes the process for categorisation of safety functions and classification of SSCs.

11.4.3.3 Redundancy and Segregation

Measures have been applied to ensure that postulated pressure part failures cannot prevent Class 1 systems from delivering their Category A safety functions. The measures are set out in the safety design approach adopted for the control and mitigation of the pressure part failure hazard. The measures related to redundancy, separation, and segregation are described below:

- The design of the AP1000 plant ensures multiple means of delivering the Category A safety functions, such that a pressure part failure cannot prevent delivery of the Category A safety function.

- Within the Containment, segregation of Class 1 systems is provided by a combination of barriers formed by the walls/floors of compartments and the distance between systems providing redundant means of delivering Category A safety functions.

- Outside Containment, only a limited portion of the CVS and SGS have been identified as a location for high-energy breaks based on the pipe rupture design criteria. There is sufficient equipment redundancy, segregation, and protection such that all of the equipment in a single room can be lost without preventing delivery of the Category A safety functions.

- The Class 2 systems are an additional defence in depth means of delivering Category A safety functions. The Class 2 system design also features redundancy.

11.4.3.4 Pressure Part Failure Assessment Approach

Analysis of postulated pressure part failure events has been performed in accordance with the AP1000 plant pipe rupture design criteria in Reference 11.77 on a room-by-room basis. The assessment criteria provides the methodology for determining the locations of pressurised failures, the effects of such failures, and the approach to be adopted to assess the impact of such failures on Class 1 SSCs.

Each fluid system is initially analysed for gross failure, regardless of pipe size or system energy. The resulting plant-level initiating event is compared to the fault schedule in Appendix 8A to ascertain the design basis classification of the event. Design basis classification is assigned to plant faults to determine the limits for the assessment of tolerability and acceptable means and methods for evaluation. Tolerability of the resulting plant response is confirmed consistent with the plant fault study and transient analysis in Chapter 9.

Whereas the evaluation of the gross failure of pressure parts cannot be eliminated through an argument of low initiating event frequency the probability of occurrence is a consideration in the selection of the design basis classification as described in Chapter 8. In general, pressure part failure events are treated as DB1 Class (Infrequent Faults) for evaluation purposes, specific event and design basis classification assignments are contained in the hazard schedule (Tables 11.4-1 and 11.4-2)

The assessment approach has been applied in the following manner, as presented in Figure 11.4-2.

1. Identification of hazard sources, including consideration of:

    a. Pressurised system energy level
    b. Postulated rupture location

2. Evaluation of the indirect effects of the pipe break, including:

    a. Dynamic effects including hydraulic transients, pipe whip, jet effects and subcompartment pressurisation

    b. Environmental effects

    c. Flooding/Submergence (Section 11.3)

3. Evaluation of the consequence of the indirect effects on essential Class 1 equipment, namely functionality of Category A safety functions consistent with the transient and accident analysis.

4. Identification of response measures required to ensure plant response to the failure is ALARP:

    a. Prevention
    b. Protection

        i. Barriers/Arrangement of equipment
        ii. Restraints and Shields

    c. Mitigation

11.4.3.5 Implementation and Management of the Pressure Part Failure Assessment Process

The initial assessment of pressure part failure effects has been performed and includes postulated pressure part failures in high and moderate-energy systems. This assessment was supplemented by the inclusion of additional postulated events shown to not present (Reference 11.77):

1. Significant challenges to the tolerability of the AP1000 safety case,

2. Substantial design changes with high complexity affecting multiple existing designed systems, structures or components, and

3. An increased potential for lower complexity design changes.

11.4.3.6 Interface with Other Internal Hazards

With consideration of the propagation of a failure and the assessment of the plant response, the evaluation of internal pressure part hazards is an input to several other internal hazard evaluations, a summary diagram of internal hazards interfaces in included in Figure 11.4-1. Internal flooding is addressed in Section 11.3, internal explosions resulting from pressure part failures are addressed in Section 11.5, and internal missiles are addressed in Section 11.6.

11.4.3.7 Conclusions

Assessment of pressure part failures for the AP1000 plant has been completed and documented in the pressure part failure topic report (Reference 11.77) and the hazard schedule (Tables 11.4-1 and 11.4-2).

The pressure part failure assessment demonstrates that necessary Category A safety functions can be appropriately maintained following postulated pressure part failure events with AP1000 plant Class 1 SSCs. As the design criteria guiding the detailed pipe rupture assessment methodology has been clearly defined in Reference 11.77 for consideration during the development of design changes or assessment of as-installed deviations, it is concluded that future AP1000 plant pipework design activities will not invalidate the conclusions of this safety case.

11.4.4 Pressure Part Failure Analysis

11.4.4.1 Identification of Potential Sources of Pressure Part Failure

A review of the AP1000 plant design has been performed in accordance with the AP1000 plant pipe rupture design criteria in Reference 11.77. This process included consideration of:

- High-energy piping
- Moderate-energy piping
- Piping components, such as valves and sensors
- High-pressure vessels, tanks, and heat exchangers

The approach applied for high-energy piping is summarised below and can be referenced in Appendix A of the pressure part failure topic report (Reference 11.77); moderate-energy piping is not specifically discussed here as the failure of this piping is limited to environmental effects and is therefore less dependent of failure location considerations.

- DN 100 (4" NPS) and larger: Circumferential and longitudinal failures are evaluated at terminations and at intermediate locations where the pipe stress or fatigue duty is significant. Branch connections are regarded as terminations and, at terminations, only circumferential breaks are assumed.

- Larger than DN 25 (1" NPS) but less than DN 100 (4" NPS): Circumferential breaks are postulated considering the pipe stress or fatigue duty.

- DN 25 (1" NPS) and smaller: No breaks are explicitly postulated as the effects are bounded by larger piping.

Piping will be of high quality, designed as ASME Section III for Class 1 piping systems or ANSI/ASME B31.1 Power Piping Code for non-Class 1 systems.

11.4.4.2 Consequences of Postulated Pressure Part Failures

The consequences of the breaks are analysed for dynamic effects (pipe whip, hydraulic transients, jet impingement, and compartment pressurisation), environmental effects on Class 1 SSCs, and operability of essential Class 1 SSCs.

Due to reduced flow area of small diameter piping and the resulting low failure energy, effects due to breaks of pipes DN 25 (1" NPS) and smaller are assessed considering the following attributes:

- Indirect effects of pipe whip and jet impingement on small diameter pipework, tubing, and sensitive instruments.

- Indirect effects on Class 1 equipment due to the resulting environmental conditions, including flooding.

An operability review was undertaken with the objective to provide assurance that Class 1 SSCs are not adversely affected by jet impingement or pipe whip by identifying:

- SSCs that are within the unrestrained zone of influence of circumferential and longitudinal pipe breaks.

- SSCs inside of a unrestrained zone of influence that are essential to the mitigation of the effects of the postulated break

  – Consideration of protection of these Class 1 SSCs through the use of barriers or restraining the failure.

- Essential in-line components that are required to function to mitigate the postulated break and qualify them for the effects of the transients.

The evaluation of the post-rupture environmental effects made appropriately conservative assumptions about the environment that would exist following a postulated pressure part failure in order to determine the impact on exposed equipment. The assessment reviews for the potential impact of:

- Spray wetting effects

- Environmental effects such as rupture-induced pressure, steam, corrosiveness, combustibility, radiation, and chemical spills.

- Temperature and humidity effects.

Dynamic pipe effects are evaluated for high-energy piping as moderate-energy piping is not considered to have the potential to propagate the free end of a broken pipe as described in Sub-Claim 1.2.

Each of these environmental effects is addressed, with specific applications discussed below.

Spray Wetting Effects

In accordance with ANSI/ANS 58.2, "Design Basis for the Protection of Light Water Nuclear Power Plants against the Effects of Postulated Pipe Rupture" (Reference 11.84), a thin film of liquid at the jet temperature (by high-energy circumferential or longitudinal breaks) is assumed to cover the target. Class 1 systems and components are evaluated for the potential effects of spray from high-energy and moderate-energy failures. The following other key evaluation assumptions are noted:

- Spray effects are assumed to be limited to the compartment in which the pipe failure occurs.

- Spray effects are assumed to wet all systems and/or components in a compartment.

- Spray effects are not assumed to damage non-electrical passive metallic components (piping, ducts, valve bodies, mechanical components of valve operators).

- Spray effects are assumed to cause failure of electrical components and cables not designed to withstand the wetting.

- Spray effects are not assumed to affect components protected by IEC IP66 or NEMA 4/4X enclosures.

Environmental Effects

Class 1 systems and components have been evaluated for environmental effects through comparison of the calculated post-rupture environment to the environmental qualification requirements for the system or component consistent with the requirements of Chapter 5.

The escape of steam, water, combustible, or corrosive fluids, gases, and/or heat in the event of pipe rupture are ensured to not preclude:

- Habitability of the control room
- Capability of Class 1 instrumentation, electrical power supplies, electrical and mechanical components, and controls to perform their post-rupture safety function(s)

The effect of corrosive fluids is considered through the evaluation of the environmental qualification chemistry parameters. The evaluation of combustible fluids or liquid is contained within Section 11.5.

Temperature and Humidity Effects

The temperature increases resulting from a pipe rupture in compartments and sub-compartments containing Class 1 SSCs have been evaluated to verify that they bound the temperature and humidity conditions used in the environmental qualification of those SSCs and that the module frames and supporting (or overhead) structures/embedments can withstand the differential expansion between steel and concrete.

11.4.4.3 Propagation of Pressure Part Failure

Pipe rupture can result in dynamic effects, such as pipe whips and jets, which can result in damage to adjacent pipe lines and their associated functions. Testing, analysis, and a review of international design practices is summarised in the pressure part failure topic report (Reference 11.77). The evaluation of a pipe whip shall be considered to propagate:

- Gross failure to impacted pipes of smaller nominal pipe size, irrespective of pipe wall thickness.
- Gross failure is not considered for interactions between a faulted pipe and an equal or larger pipe, based on nominal size.
- Leakage cracks are considered for environmental effects where the pipe wall thickness of the impacted pipe is equal to or less than that of the pipe with a postulated gross failure.

External loads applied to pipe systems from jet spray are calculated using generally accepted methods (Reference 11.89) and applied as inputs into the pipe stress analysis.

11.4.5 Design and Construction Considerations

General

All safety-significant SSCs within the AP1000 plant have been categorised and classified in accordance with Reference 11.26. This process, which also includes fluid-retaining structures, ensures that the quality requirements placed on SSCs, in terms of their design, manufacture, testing, and operation, reflects their importance to safety and hence minimises,

so far as is reasonably practicable, the likelihood that they may fail to provide their safety function.

Section 16.5 details the relevant design standards, primarily Section III of the ASME Code, including the loading and loading combinations for the Containment and associated penetrations, which includes loads from postulated pipe breaks, jet impingement, missile impact, pressure and temperature loads.

Protection

The plant arrangement is based on maximising the physical separation of redundant Class 1 components and systems from each other and from other SSCs as appropriate. Therefore, in the event a pressure part failure occurs, there would be a minimal effect on other Class 1 systems or components required for safe shutdown of the plant or to mitigate the consequences of the failure.

The effects associated with a particular pipe failure are mechanistically consistent with the failure. Thus, pipe dimensions, piping layouts, material properties, and equipment arrangements are considered in defining the specific measures for protection against the consequences of postulated failures.

Protection against the dynamic effects of pipe failures is provided by physical separation of systems and components, barriers, equipment shields, pipe whip restraints, and qualification or analysis of failure loads. The precise method chosen depends upon considerations such as accessibility and maintenance.

The preferred method of providing protection is through separation. When separation is not practical, pipe whip restraints are used. Barriers or shields are used when neither separation nor pipe whip restraints are practical.

Separation

The plant arrangement provides separation, to the extent practicable, between redundant safety systems (including their appurtenances) to prevent loss of safety function as a result of events for which the system is required to be functional. Separation between redundant safety systems, with their related appurtenances, therefore, is the basis protective measure incorporated in the design to protect against the dynamic effects of postulated pipe failures.

In general, separation is achieved by:

- Class 1 and 2 SSCs located remotely from high-energy piping, where practicable
- Redundant safety systems located in separate compartments, where practicable

Where separation by distance is not possible, the pressure part failure assessment includes an evaluation to determine the systems and components that require a structure for separation from the effects of a break in a high-energy line. For these structures, the evaluation assumes that the break may be at the closest point in the line to the separating structure.

Design of Pipe Whip Restraints

When protection of Class 1 SSCs in the unrestrained zone of influence cannot be achieved through separation, a pipe whip restraint may be used to reduce the zone of influence down to a narrow, restrained zone of influence which may then exclude the Class 1 SSCs. Detailed

design requirements for pipe whip restraints can be referenced in the pressure part failure topic report (Reference 11.77).

Location of Pipe Whip Restraints

Pipe whip restraints are located as close to the axis of the reaction thrust force as practicable. Pipe whip restraints are generally located so that a plastic hinge does not form in the pipe. If, because of physical limitations, pipe whip restraints are located so that a plastic hinge can form, the consequences of the whipping pipe and the jet impingement effect are further investigated. Lateral guides are provided where necessary to predict and control pipe motion.

Pipe whip restraints are designed and located with sufficient clearances between the pipe and the restraint in such a way that they do not interact and cause additional piping stresses. A designed hot position gap is provided that allows maximum predicted thermal, seismic, and seismic anchor movement displacements to occur without interaction between the pipe and the pipe whip restraint.

The pipe whip restraints do not prevent the access required to conduct in-service inspection examination of piping welds. When the location of the restraint makes the piping welds inaccessible for in-service inspection, a portion of the restraint is designed to be removable to provide accessibility.

Analysis and Design of Pipe Whip Restraints

The criteria for the analysis and design of pipe whip restraints for postulated pipe break effects are provided in the pressure part failure topic report (Reference 11.77). The criteria are consistent with the guidelines in ANS-58.2-1988 (Reference 11.84).

Barriers and Shields

In addition to pipe whip restraints, other protective devices are designed to protect against the effects of postulated pipe ruptures. Barriers and shields are designed to protect against jet impingement. Guard pipes in the Containment penetration regions provide confidence that fluid discharge due to a pipe rupture will not enter the annulus between the Containment vessel and the Shield Building.

Jet Impingement Barriers and Shields

Barriers and shields, constructed of either steel or concrete, are provided to protect Class 1 equipment from the effects of jet impingement resulting from postulated pipe breaks. Barriers differ from shields in that barriers may also accept the impact of whipping pipes. Protection requirements are met through the protection afforded by walls, floors, columns, abutments, and foundations.

Barriers and shields include walls, floors, and structures specifically designed to provide protection from postulated pipe breaks. Design criteria and loading combinations are according to Chapter 16. Barriers and shield that are added to the plant design for the specific purpose of the pressure part failure assessment are designed for loads from a break in the line at the closest location to the structure.

Auxiliary Guard Pipes

Guard pipes are specialised shields applied to protect against the effects of postulated gross failures within or onto Containment penetration assemblies; guard pipes are Class 1 SSCs.

The use of guard pipes has been minimised by plant arrangement and routing of high-energy piping. Guard pipes in the Containment annulus area are designed according to the rules of Class MC, subsection NE, of the ASME Code. The guard pipe assemblies are subjected to a pressure test performed at the maximum operating pressure of the enclosed process pipe.

11.4.5.1 Discussion of Results

The following subsections briefly describe the principal conclusions of the pressure part failure assessment. Areas reviewed in this section include:

- Containment
- The Non-RCA Auxiliary Building
- The RCA Auxiliary and Shield Buildings
- Building adjacent to the NI
- Areas outside of the NI

Postulated pressure part failures are summarised in detail in the hazard schedule (Tables 11.4-1 and 11.4-2); the summary of effects provided in this section are a narrative of significant observations and conclusions from the evaluation of these events.

Although the primary issues addressed in this subsection are the potential hazards posed by pressure part failures to Class 1 equipment, consideration is also given to Class 2 equipment delivering the supporting post-72 hour Category B safety functions:

- **Long-term power supply**: Supply of long-term power to the Class 1 voltage regulating transformers (PMS divisions B and C) provided by two electrical connections in the Annex Building.

- **Post-accident monitoring**: The equipment with the Category B safety function of post-accident monitoring is located in various areas of the non-RCA Auxiliary Building, including the main control room (MCR) (room 12401), the remote shutdown room (room 12303), and control and instrumentation equipment rooms (rooms 12301, 12302, 12304, and 12305).

- **MCR lighting**: Equipment associated with this function is located in room 12401.

- **MCR and C&I room ventilation**: Equipment associated with this function is located in the MCR (room 12501) and C&I ventilation compartments (rooms 12302 and 12304).

- **Makeup to the passive containment cooling water storage tank and spent fuel storage pool**: Equipment associated this Category B safety function is located external to the NI and in room 12306, this includes the passive containment cooling system valves for alignment of post-72 hour water sources.

Additionally, the AP1000 plant design incorporates several other SSCs that are provided to minimise the severity of postulated pressure part failures or the demand rate on the passive, Class 1 safety features. The plant design also incorporates appropriate monitoring features for the detection of pressure part failures in the vicinity of the WLS sump (level detector) and RCS (inventory monitoring).

Containment

The analysis of pressure part failures indicates that all but a small number of potential break sites occur on systems entirely or principally located within the Containment vessel. These systems are:

- Reactor Coolant System (RCS)
- Steam Generator System (SGS)
- Passive Core Cooling System (PXS)
- Chemical and Volume Control System (CVS)
- Normal Residual Heat Removal System (RNS)

Postulated pressure part failures within the Containment could result in one or all of the following effects: pipe whip, jet impingement, and pressure effects. Pressure part failure evaluations have been completed and have demonstrated that the delivery of Category A safety functions is not inhibited by the indirect effects of these postulated failure events. The potential sources of such effects are further summarised below.

A number of rooms in Containment contain inboard Containment isolation valves. These Containment isolation valves are provided with redundant valves outside Containment in the RCA Auxiliary and Non-RCA Auxiliary Buildings, which will remain unaffected by the possible pipe whip, steam release and water spray events. Furthermore, Class 1 Containment isolation valves are protected and qualified for the dynamic and environmental effects of postulated gross failure events to ensure their function is not adversely affected.

Pipe Whip

Pipe whip has been evaluated in several rooms in the plant as summarised in the pressure part failure topic report (Reference 11.77) and hence safety Class 1 SSCs contained in them are protected against pipe whip. Where the potential for pipe whip cannot be precluded then protection for affected essential Class 1 SSCs is provided in the form of pipe whip restraints or barriers or shields. Chapter 16 addresses the requirements on the civil structures to protect against pipe whip.

Jet Impingement

The following systems are potential sources of jet impingement inside the Containment:

- RCS, including the:
  - Reactor vessel.
  - Pressurizer.
  - Reactor coolant pumps.
  - Steam generator channel heads.
  - ADS.
  - Associated piping and valves including automatic depressurisation features.
- The SGS, including the
  - Steam generator shell.
  - Main steam lines inside Containment.
  - Feedwater lines inside Containment.

- The PXS, including:
  - Accumulator tanks.
  - The CMTs.
  - PRHR heat exchanger.
  - RNS.
  - CVS.

The structural integrity of the reactor vessel, pressuriser, SGs, reactor coolant loop piping, RCPs, PRHR HX, CMT, and accumulator are substantiated in Chapter 20. Failure of these components within the scope of pressure part failure is not deemed credible because the pressuriser is fitted with safety valves. Rupture of the PRHR system HX is also not a credible jet impingement hazard, because the HX is normally submerged and located within the IRWST.

Safety Class 1 SSCs are protected from jet effects through separation as a result of their physical location and the function of barriers, or through the restriction of failure consequences by the application of restraints or shields.

Safety Class 1 equipment within the areas listed below is redundant and has been qualified to withstand the faulted environment without loss of operability consistent with Chapter 5. The areas are:

- Operating deck and refuelling cavity, which contain the following safety Class 1 equipment. The safety-related equipment in this location is:
  - Class 1E cable trays.
  - Class 1E electrical penetrations.
- ADS valve areas.
- SG compartments.
- Vertical access and RCDT room.
- General access and maintenance areas (includes maintenance floor, maintenance mezzanine, and portions of the operating deck away from the refuelling cavity) which contain the following safety Class 1 equipment.
- Main steam lines.
- Main feed water lines.
- SG blowdown lines.
- Start-up feed water lines.
- Passive core cooling system compartments. Under specific conditions, the following components within the PXS compartments could be exposed to indirect effects if a pressure part failure is postulated:
- Accumulators and isolation valves for the accumulators.

- CMTs and isolation valves for the CMTs.
- IRWST isolation valves.
- Containment recirculation piping and valves
- One normally closed spent fuel pit cooling system Containment isolation valve and one normally closed RNS Containment isolation valve.
- Automatically actuated Containment isolation valves.
- RCS to RNS pump suction isolation valves.

Pressurisation Effects

Where a postulated pressure part failure event may occur in the SG compartment, the structure is designed to prevent this failure from affecting the redundant SSCs in the other SG compartment or SSCs in the adjoining RCS loop compartment. The DN 80 (3" NPS) CVS purification pipe, the DN 100 (4" NPS) SG blowdown line, the DN 500 (20" NPS) main feed water line and the DN 150 (6" NPS) start-up feed water line all have postulated failures that may lead to pressurization effects within the SG compartments.

The SG compartments are provided with composite concrete-steel walls and are separated from each other by the reactor cavity and the refuelling compartment. The SSCs in the SG compartments have redundant trains, which are segregated between the two SG compartments. Segregation of these areas is such that an overpressure in the SG compartments would not affect the redundant train.

The DN 80 (3" NPS) CVS regenerative HX return line and the DN 80 (3" NPS) CVS purification supply line from the cold leg have postulated failures within the vertical access (room 11204) and RCDT room (room 11104). The boundaries of the room are designed to prevent this affecting the redundant SSCs in segregated areas.

The DN 100 (4" NPS) ADS pipe in the ADS valve area is open to the main volume of Containment, and hence, compartment differential pressures would be negligible following rupture of this pipe. Therefore, no damage to SSCs is expected to occur from the effects of postulated pressure part failures.

The DN 150 (6" NPS) start-up feedwater line within the maintenance area has such a large free volume that it is judged that the effects from a rupture of this pipe would be dissipated before it could damage the SSCs in its vicinity.

The failure of the DN 100 (4" NPS) SG blowdown or DN 80 (3" NPS) CVS purification piping in the CVS room and pipe tunnel (room 11209) will result in pressure effects. Additional mass and energy released evaluated to support the AP1000 design include the failure of the DN 100 (4" NPS) pressuriser spray line in pressuriser spray valve room (room 11403). The postulated failure of these lines all have been analysed to result in pressurisation effects (Reference 11.77).

Non-RCA Auxiliary Building

High-energy break locations within the Non-RCA Auxiliary Building are limited to the Main Steam Isolation Valve (MSIV) Compartments (rooms 12204/12505 and rooms 12406/12506) and the valve/piping penetration room (room 12306), which are separated from the balance of

the structure by suitable barriers. This piping from the high-energy systems passes through the Non-RCA Auxiliary Building between the Containment/Shield Building and the Turbine Building. Pressure part failure evaluations have been completed and have demonstrated that the delivery of Category A safety functions is not inhibited by the indirect effects of postulated failure events in the Non-RCA Auxiliary Building.

This piping is designed to ASME Section III requirements; additionally, due to the function of the piping as Containment pressure boundary and the close proximity of the Class 1 C&I equipment and facilities, this piping is designed with additional supplemental deterministic requirements to provide added confidence that the gross failure of the piping will be a very unlikely event.

The areas within the Non-RCA Auxiliary Building that contain these hazard sources are summarised in turn in the following text.

Main Steam Isolation Valve Compartments

Each compartment comprises:

- A main feedwater line.
- A startup feedwater line.
- A main steam line.
- Steam isolation valves.
- A power-operated atmospheric relief valve.
- Six safety valves.
- Heating and cooling equipment.

Failure of the feedwater and steam lines within the MSIV compartments are very low probability faults in the hazard schedule. Pipe restraints are used to prevent pipework impact with the compartment walls by limiting movement of the pipe in the event of a break for those failures that may directly impact the Class 1 C&I spaces and the integrity of the main control room. The compartment walls will also prevent the spread of steam or water from steam releases or water spray incidents from affecting the rest of the clean Auxiliary Building.

The MSIV A Compartment and MSIV B Compartment are protected from excess pressure through use of self-actuated pressure relief devices consistent with Claim IH-3.2.2.1. Devices claimed to protect the affected Class 1 barriers are identified in the hazard schedule.

Assessment of the gross failure of a main steam line in the MSIV B Compartment (rooms 12404/12504) is summarised in the pressure part failure topic report (Reference 11.77).

Valve and Piping Penetrations

The valve and piping penetration room at elevation 100 m (100' 0") contains automatically actuated Containment isolation valves for the VWS, SGS, PCS, DWS, as well as PCS recirculation equipment, piping and valves. A pipe whip from the PCS is not expected since the PCS is a moderate-energy system. Dynamic effects from the gross failure of piping in these areas are limited to the SGS blowdown piping in room 12306.

The valve and piping penetration room communicates with the MSIV A compartment through openings in the interfacing barrier. This room is protected from excess pressure

through use of self-actuated pressure relief devices consistent with Claim IH-3.2.2.1. Devices claimed to protect the affected Class 1 barriers are identified in the hazard schedule.

RCA Auxiliary and Shield Buildings

High-energy break locations have been identified in CVS pipework located in rooms 12156, 12255, 12258, and 12259. A break in these rooms does not adversely impact Class 1 SSCs. Pressure part failure evaluations have been completed and have demonstrated that the delivery of Category A safety functions is not inhibited by the indirect effects of postulated failure events in the RCA Auxiliary and Shield Buildings.

Beyond the high-energy systems for which detailed assessments have been carried out, the radiological Auxiliary Building is potentially subject to indirect, environmental effects from a variety of potential sources, including:

- Component Cooling Water System (CCS)
- Central Chilled Water System (VWS)
- Hot Water Heating System (VYS)
- Spent Fuel Pool Cooling System (SFS)
- Normal Residual Heat Removal System (RNS)
- Main Control Room Emergency Habitability System (VES)

The areas within the RCA Auxiliary and Shield Buildings that contain these hazard sources are addressed in turn in the following text.

Normal Residual Heat Removal System Pumps, Heat Exchangers and Containment Isolation Valves

The RNS pumps are located at elevation 89.79 m (66' 6") with each pump train provided in a separate room (room 12162 [RNS A] and room 12163 [RNS B]).

The RNS suction line from the RCS branches inside the Containment into two parallel trains. Each train has two RCS isolation valves inside Containment, one of which is a Containment isolation valve. The two RNS suction lines are separated and have separate Containment penetrations, separate outside Containment isolation valves, and separate piping to their corresponding RNS pump. Therefore, no potential exists for a postulated pressure part failure in one train to impact the other when the RNS is in use.

The RNS pumps, heat exchangers and their associated piping and valves are not located in the vicinity of high-energy piping, therefore there are no postulated pressure part failure that could result in dynamic effects upon this equipment. Class 1 RNS SSCs in the Auxiliary Building are qualified for their associated environmental conditions, including postulated gross failure events.

Containment Isolation Valves

A number of rooms in the RCA Auxiliary Building contain Containment isolation valves. These Containment isolation valves are provided with redundant valves inside the Containment, which will remain unaffected by the possible pipe whip, steam release and water spray events. Furthermore, Class 1 Containment isolation valves are protected and qualified for the dynamic and environmental effects of postulated gross failure events to ensure their function is not adversely affected.

Habitability System Compressed Air Tanks

Compressed air tanks for the VES are located within a structural steel frame in the VES air storage area at elevation 110.74 m (135' 3"). However, there are no other Class 1 SSCs in close proximity, piping is limited to small diameters (DN 25 (1" NPS) or less), and concrete walls segregate the compressed air tank storage area from other rooms at elevation 110.74 m (135' 3") with Class 1 SSCs.

The VES air tanks are constructed of forged, seamless pipe and conform to Section VIII and Appendix 22 of the ASME Code. Failure of the tanks is evaluated as part of the internal missile evaluation in Section 11.5. Postulated failure of the VES does not result in a plant-level fault as the system does not support normal operations; failure of the VES is controlled through the plant Operating Rules (Reference 11.92).

Buildings Adjacent to the Nuclear Island

Buildings adjacent to the NI have been reviewed to identify significant sources of pressure part failure and to define protective measures that may be deemed appropriate. The application of high-energy systems has been limited to the Turbine Building in the plant arrangement to reduce external challenges to the NI.

Turbine Building

There are no Class 1 SSCs in the Turbine Building; therefore the only hazards requiring assessment are credible pressure part failures originating in the Turbine Building that could affect the Class 1 SSCs in the NI. The First Bay of the Turbine Building contains Class 2 defence-in-depth SSCs and is a Class 2 structure with a Category A safety function (Ref. 11.59).

The high-energy fluid systems within the Turbine Building that can result in indirect effects on the NI are the main steam system (MSS), main and startup feedwater system (FWS), and steam generator blowdown system (BDS). Other high-energy power generation systems are not potential sources of interaction due to the design of the Turbine Building for defence in depth.

The barrier between the Turbine Building and the Auxiliary Building (Wall 11) is a Class 1 structure and provides a rigid anchor for the NI piping and is designed for faulted pipe loads in the First Bay of the Turbine Building; this barrier provides the principal means of protecting Class 1 SSCs from an internal hazard that would directly result in loss of a Category A safety function. The barrier between the First Bay of the Turbine Building and the balance of the Turbine Building structure (Wall 11.2) is a seismically-designed Class 2 barrier that is a significant contributor to fulfilment of the Wall 11 Category A safety function.

Hydrodynamic forces resulting from the fluid decompression transient within the faulted piping is analysed for interfacing piping and structural commodities within the NI. In summary, the NI is sufficiently designed to prevent a dynamic impact on essential SSCs in the NI.

Other Buildings and Structures Adjacent to the NI

The remaining buildings and structures adjacent to the NI are the Annex Building and the Radwaste Building; these structures contain moderate-energy systems only. None of these

buildings and structures contains, nor can they therefore be subject to, the adverse dynamic effects of high-energy pipe rupture.

There are pressure part failure locations within these buildings that can result in environmental consequences; however, there are no Class 1 SSCs in these buildings. Furthermore, water sources for consideration in submergence evaluations are quantified for all access points through exterior NI barriers as part of the internal flooding assessment in Section 11.3.

Areas Away from the Nuclear Island

None of the areas/buildings away from the NI contain Class 1 SSCs, or have the potential for a pressure part failure hazard to impinge upon the NI. Failure in these areas is treated as a hazard external to the NI and essential Class 1 SSCs are afforded protections from these events by adequate barriers (Reference 11.9). Therefore, there are no pressure part failure events of concern applicable to these areas; this conclusion includes:

- DG building
- DG fuel oil storage tanks
- Bulk gas storage area
- Diesel-driven and electric motor-driven fire pumps and fire water storage tanks
- PCCAWST
- Transformer compound
- Boric acid storage tank
- Service water cooling towers (where applicable)
- Condensate storage tank
- Demineralised water storage tank

11.4.6 Sensitivity of Results and Cliff Edge Effects

The evaluation of the AP1000 plant for postulated pressure part failure is not sensitive to cliff edge effects since:

- The design basis classification of the resulting plant-level event is consistent with the fault schedule and has been reviewed for cliff-edge effects as discussed in Chapter 8.

- Gross failure events are deterministically assumed for all components without an IoF claim documented in Chapter 20; therefore, the population of failures is not affected by cliff edge effects.

- A sensitivity analysis of the high energy classification parameters was performed in the pressure part topic report and concluded that the population of high-energy fluid systems in the AP1000 plant was not sensitive to the temperature or pressure limit.

11.4.7 Combined Hazards Discussion

The pressure part failure assessments (Reference 11.77) consider, on a deterministic basis, a single failure event and the consequential impact on SSCs in the affected plant areas. Consequential hazards are recognised between pressure part failure, flooding, explosions, and missiles as depicted in Figure 11.4-1 and described in Section 11.12.

The consideration of credible combinations of a pressure part failure with other postulated internal hazards likely to occur independently of the postulated pressure part failure is

considered in a separate document. Reference 11.75 provides a coherent approach across all internal hazard types (e.g., fire, explosion, missiles, dropped loads, pressure part failure).

Combinations of independent internal and external hazards (e.g., internal flooding and extreme low ambient air temperatures) are considered to be Beyond Design Basis events and as such have not been explicitly considered in this section. However, compliance with relevant equipment and structural design codes ensure that combinations of internal hazards with the relevant abnormal operating occurrences (including environmental hazards) are addressed.

11.4.8 ALARP Assessment and Discussion

Deterministic analysis of the effects of postulated pressure part failures demonstrate that the Class 1 SSCs would continue to provide their Category A safety function following a DBA, even in the presence of an unrelated single active failure elsewhere in the plant design. In the unlikely event that the Class 1 SSCs fail for some unrelated reason, the Category A safety function would, for the less severe events, be maintained by other, additional and redundant, Class 2 SSCs. The AP1000 plant probabilistic safety assessment (PSA, refer to Chapter 10) demonstrates that the risks associated with the secondary effects of postulated pressure part failures are not significant.

The AP1000 plant, by its very nature, makes extensive use of pressurised fluid systems to operate normally; therefore it is not possible to remove the internal hazard of pressure part failure from the design of the plant while complying with safety assessment principles for the integrity of SSCs.

The safety design of the AP1000 plant for pressure part failure has been achieved by:

- Removing pressure part failure events that challenge the tolerability of the plant safety case through the assessment of structural integrity (Chapter 20).
- Ensuring redundant essential Class 1 SSCs are protected from postulated pressure part failure events through:
- A combination of physical separation and passive barriers.
- Restraint of dynamic effects through Class 1 supports, restraints, and shields.
- Providing sufficient redundancy in the design such that the consequences of postulated pressure part failures, coincident with an unrelated single active failure, do not adversely affect the delivery of Category A and post-72 hour Category B safety functions.

11.4.8.1 Approach to Safety

Within the overall design of the AP1000 plant methods are applied to assess and apply design provisions to minimising risk. Westinghouse assessment has been performed consistent with the pressure part failure high level claims.

Prevention

Where tolerability cannot be demonstrated, pressure part failures may be prevented using a claim of incredibility of failure. This option is subject to structural integrity review and

should be minimised in the safety case to be consistent with the safety assessment principles (SAPs).

Incredibility of failure claims are currently made for the reactor vessel, steam generator, and pressuriser as documented in the Chapter 20.

Protection

Protection from postulated pressure part failure events is achieved through the use of separation, segregation, and restraint methods. Separation and segregation are primarily achieved through use of barriers and physical separation in the plant layout. Restraint is achieved through the use of pipe whip restraints or jet shields.

The application of protective SSCs is subject to location and application-specific assessment of benefits and detriments. The addition of barriers and restraints has the beneficial effect of reducing the indirect consequences of pressure part failure on the plant by means of decreasing the number of Class 1 SSCs that are affected by the dynamic and environmental effects. Other effects considered in the assessment of detriments of the addition of barriers and restraints are summarised below.

- Effects on Radiological Exposure

  Protective SSCs may require increased access for inspections and maintenance. Improvements in offsite radiological doses may be realised through improvement in overall plant safety; however, occupational radiological dose will also increase appreciably due to increased accessibility requirements.

- Effects on Piping Stresses

  Restraints may have adverse effects on piping system stress behaviour; namely, the addition of restraints introduces restrictions to piping system movement and increases the probability of restrictions on systems with large thermal expansion and dynamic response displacements.

- Other Generic Risk Considerations

  The inclusion of barriers and restraints can give rise to additional influences on the overall plant safety case, some of which are interrelated:

  – Increase in the loadings on structures and supports.
  – More complex in-service inspection requirements
  – Increased complexity of system layout and design.

Mitigation

Mitigation of the indirect effects of postulated pressure part failures is achieved through the selection of adequate design requirements for the resulting gross failure conditions. Class 1 SSCs are subject to qualification consistent with Chapter 5 of the PCSR for these conditions.

11.4.8.2 Further Mitigation Measures

In addition to the design of Class 1 SSCs, the AP1000 plant design incorporates a number of other features to minimise the demand rate on the passive Class 1 SSC. These features are designed to function following Anticipated Operational Occurrences which result in plant

trip; i.e., events that are anticipated to occur at least once in the plant lifetime. These SSCs are active and independent from the Class 1 SSCs, and are powered by the standby DGs when off-site electrical power and house power are not available.

The functions provided by these additional features include (but are not limited to):

- Make-up of borated water to the RCS using the CVS makeup pumps, boric acid tank and associated valves and pipework.
- Heat removal from the secondary side of the SGs using SG Power Operated Relief Valves.
- Feed water makeup to secondary side of the SGs using start-up feedwater pumps, condensate storage tank, and associated valves and pipework.
- Decay heat removal from the RCS (at reduced pressure).
- RNS and associated valves and pipework.
- Decay heat removal from spent fuel pool.
- SFS and associated valves and pipework.
- RNS and associated valves and pipework.
- Supporting functions include
- CCS.
- SWS.
- Standby DGs and associated ECS sets.
- VWS air cooled chillers and associated valves and pipework.
- VBS.
- I&C (PLS).

Pressure part failures within the NI are anticipated to occur at frequencies <1E-03 per year, with limited exceptions as presented in the hazard schedule; i.e., most postulated pressure part failure events are not expected to occur within the life time of the plant. Nonetheless, the design of these active, Class 2 SSC has taken into account the potential effects of pressure part failure consistent with considerations for the assessment of non-Class 1 SSCs with importance to safety (Reference 11.26) and the plant reliability assurance programme (Chapter 5).

As such, similar design measures have been taken to provide assurance that these Class 2 functions will be available, i.e.:

- Class 2 equipment is segregated from its Class 1 counterpart and typically located in a separate structure, for example

- Class 1 RCS make up with borated water is performed by the CMTs through the DVI lines. The Class 2 counterpart of CVS makeup uses a separate connection to the RCS, located in a SG compartment, and the active pumps are physically located outside of the Containment.

- Class 1 decay heat removal is performed by the PRHR Heat Exchanger within the Containment. The Class 2 counterpart at high temperature is the startup feedwater function. The active pumps, control valves, and water inventory for this function is located in the Auxiliary Building, the Turbine Building, and in the yard.

- Class 2 equipment has been separated, where practicable and demonstrated to be ALARP, through the application of design changes in the plant design reference point (Reference 11.3), for example:

- Separation of CCS, RNS, SFS, and SWS piping for protection from environmental effects and other internal hazards (e.g., fire).

Furthermore, failure of the Class 2 equipment, whether due to an inherent fault or the effects of a pressure part failure, will not prevent the Class 1 SSC from fulfilling their Category A safety function(s).

On the basis of the above discussion, and given that Category A safety functions can be maintained in the event of a pressure part failure event, it is judged that there would be minimal safety benefit from introducing additional measures to protect or mitigate the effects of pressure part failure; the risk from pressure part failure hazards is therefore considered to be broadly acceptable and ALARP.

11.4.8.3 Process Implementation

The AP1000 plant pressure part failure assessment process is developed as an on-going live process to be continuously implemented and managed throughout the life of the plant. The purpose of this process is to ensure essential Class 1 SSCs required to delivery Category A and post-72 hour Category B safety functions remain available in performing their safety function as consistent with the plant safety case, thereby ensuring the plant response to postulated failures is ALARP (see the assessment of plant transients and accidents in Chapter 8 and Chapter 9).

The assessment of pressure part failure effects includes postulated failures in high and moderate-energy systems. This population has been (or will be) supplemented by inclusion of additional deterministic gross failure events; assessment of these discrete postulated pressure part failure events will be completed to support nuclear site licensing.

In order to address the potential risk gap in the generic design assessment of the AP1000 plant, the scope of new failures added to the AP1000 plant design was reviewed to ensure that these postulated failures did not represent a risk of a major design change. Major design changes are those changes representing a potentially significant adverse radiological or safety impacts to the AP1000 plant. As consistent with safety assessment principle EHA.7, such adverse impacts are those that affect the potential performance of a Category A safety function in creating a disproportionate increase in radiological consequences.

The conclusion reached is that the remaining population of postulated failure events does not pose a risk of major design change, and therefore will not challenge the safety case bases of the GDA. This conclusion has been corroborated through the performance of supplemental

analyses in Appendix C, Appendix D, and Appendix E of the pressure part failure topic report (Reference 11.77). The identification of these supplemental analyses is documented in Appendix B of the topic report (Reference 11.77) and consists of a risk assessment of piping subject to gross failure.

11.4.8.4 Relevant Good Practice

The AP1000 plant has been designed and assessed for the incidence of gross failure of pressure retaining fluid systems consistent with relevant good practice including NUREG-0800 (Reference 11.88), ANS 58.2 (Reference 11.84), and IAEA Safety Guide NS-G-1.11 (Reference 11.82).

The location of pipe supports, restraints, and shields are determined through the application of mechanistic considerations as defined in Reference 11.77. Sensitivity to intermediate break locations is assessed using more realistic means and methods to confirm the complete population of affected Class 1 SSCs is identified; this action is consistent with current relevant good practice.

11.4.8.5 Conclusion

This layered approach to safety is seen to reduce the hazard from a postulated pressure part failure to ALARP. Additional redundancy and separation has been added to the AP1000 design reference point (Reference 11.3) to further protect plant Class 2 SSCs from the effects of pressure part failure.

Since the Category A and supporting post 72-hour Category B safety functions can be adequately maintained despite postulated pressure part failure, the safety of the plant is ensured. It is judged that the risk is broadly acceptable and ALARP.

11.5 Internal Explosions

11.5.1 Introduction

This section presents the key claims, arguments and underlying evidence made in relation to internal explosion hazards with the potential to impair safe shutdown. It aims to provide sufficient evidence to show that the delivery of Category A safety functions or supporting post 72 hour Category B safety functions will not be impaired by the effect of internal explosions. Claims, arguments and underlying evidence are presented in Section 11.5.2, whilst the internal external explosions safety case is described in Section 11.5.3.

11.5.2 Internal Explosion Claims, Arguments and Evidence

Those SSCs which deliver a Category A safety function are the principal means of ensuring nuclear safety in response to Design Basis Accident (DBA) plant faults (see Chapter 8). Whether the internal hazard initiates a plant state fault or not, by ensuring that the ability to deliver Category A safety functions is maintained following an internal hazard, the internal hazards safety case aligns with the fault studies in demonstrating that the plant risk is broadly acceptable.

This section presents the claims, arguments and underlying evidence made in relation to internal explosion hazards with the potential to impact safe shutdown.

11.5.2.1 High Level Claim

SSCs important for nuclear safety must be protected from dynamic effects within the plant, including those of internally generated explosions. An internal explosion could result in a transient from the normal operating state of the reactor and potentially lead to an uncontrolled radiological release. In response to such a transient, it may be necessary to shutdown the reactor and return it to a safe shutdown state. Depending on the exact nature of the transient, there are a number of courses of action to take to shutdown the reactor. Availability of the Class 1 SSCs required to deliver the Category A safety functions will ensure that the reactor can be safely shutdown, and is the basis of the following high level claim:

Claim IH-4.0: **Postulated internal explosions within the design basis do not prevent the delivery of the Category A safety functions and the supporting post-72 hour Category B safety functions necessary to respond to the postulated event.**

The above high level claim has been divided into claims associated with preventing explosions and, where this is not possible, protecting Class 1 SSC from the effects of an explosion. As appropriate, these divisions are further broken down into Sub-Claims. Arguments and evidence for each Sub-Claim are presented in subsection 11.5.2.5.

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.5.2.2 Prevention Claims

Preventative measures have been incorporated into the design to ensure that Class 1 SSC delivering Category A safety functions are not exposed to an explosion hazard. These claims are based on preventing the formation of an explosive atmosphere.

Claim IH-4.1: **Internal explosions which could compromise delivery of Category A safety functions are prevented by controlling flammable substances such that an explosive atmosphere does not form.**

The following Sub-Claims are defined to deliver the above higher level prevention claim:

Sub-Claim IH-4.1.1: **The risk of explosion on-site from flammable materials that have the potential to generate explosive atmospheres is minimised by inventory control.**

Sub-Claim IH-4.1.2: **Under normal conditions, flammable substances which if released could form an explosive atmosphere will be adequately contained.**

Sub-Claim IH-4.1.3: **Under fault conditions a guillotine break or leak of the CVS hydrogen injection line in the Auxiliary Building will not result in the formation of an explosive atmosphere.**

Sub-Claim IH-4.1.4: **Under normal conditions, an explosive atmosphere is prevented from forming in the Auxiliary Building battery rooms by appropriate ventilation design.**

Sub-Claim IH-4.1.5: Under fault conditions, an explosive atmosphere is prevented from forming in the Auxiliary Building battery rooms by operator action.

Sub-Claim IH-4.1.6: Under the faulted condition of a Loss of Offsite Power (LOOP), an explosive atmosphere is prevented from forming in the Auxiliary Building battery rooms by the inherent safety characteristics of the battery charging system.

Sub-Claim IH-4.1.7: Under fault conditions a guillotine break or leak of the CVS hydrogen injection line in the Containment Building will not result in the formation of an explosive atmosphere.

Sub-Claim IH-4.1.8: Explosive atmospheres will be prevented from forming in tanks/vessels by maintaining the atmosphere outside of the flammable range.

Sub-Claim IH-4.1.9: Hydrogen will not be present within the WLS in significant concentrations downstream of the degasifier.

11.5.2.3 Protection Claims

Protective measures have been incorporated into the design to ensure that Class 1 SSC delivering Category A safety functions are not affected by an explosion hazard. These claims are based on protecting Class 1 SSC form the effects of an explosion.

Claim IH-4.2: Passive protective measures have been incorporated in the AP1000 design to protect SSCs that deliver Category A safety functions from internal explosions.

The following Sub-Claim is defined to deliver the above higher level protection claim:

Sub-Claim IH-4.2.1: Safe shutdown SSCs located within the NI would not be affected by internal explosions generated in areas outside the NI.

Sub-Claim IH-4.2.2: Redundant Safe shutdown SSCs located within the NI would not be affected by a hydrogen deflagration event in the NI battery rooms.

11.5.2.4 Mitigation Claims

Explosions are deterministically assumed to result in the loss, or loss of functionality, of Class 1 SSC exposed to the effects of an explosion. Therefore, no specific claims are made on mitigation of internal explosion hazards.

11.5.2.5 Arguments and Evidence

Prevention Arguments and Evidence

Claim IH-4.1: Internal explosions which could compromise delivery of Category A safety functions are prevented by controlling flammable substances such that an explosive atmosphere does not form.

The following arguments demonstrate how the prevention claims made in subsection 11.5.2.2 are delivered:

Argument: **Only those flammable substances required to support plant operation are located in or routed through the Nuclear Island.**

Small quantities of chemicals are required to support the correct operation of a number of systems including, but not limited to, reactor and balance of plant chemistry control. These chemicals are stored in the CFS which is located outside of the NI in the yard area. Based on the results of continuous or periodic sampling, chemicals are introduced to batching tanks.

The exception to this is the hydrogen addition to the RCS via the CVS. Bottled hydrogen is piped directly into Containment from the hydrogen injection package located in the Turbine Building. A direct route for the piping, from the hydrogen injection package, into Containment is taken which minimises the number of rooms within the NI through which the pipework passes and therefore in which an explosive atmosphere could form.

Further, hydrogen is evolved during the charging of lead acid batteries. Only those batteries providing an essential power supply are housed in the NI, with all other batteries located outside the NI. The battery banks themselves have been sized to provide an uninterruptible supply for between 24 and 72 hours following a LOOP, depending on division. By this time it is postulated that emergency arrangements will be enacted and the sole reliance upon the batteries is no longer required. Minimising the size of the batteries correspondingly minimises the hydrogen generation rate and therefore the time taken to achieve an explosive atmosphere increases.

Argument: **In the short term (or the near field effects), detonation of a hydrogen plume in the Auxiliary or Containment Building during a break or leak of the CVS hydrogen injection line or WLS lines will have no influence on the broader compartment integrity.**

It is acknowledged that the local hydrogen source plume does have flammability potential near the source origin at the injection line break. Since the plume begins as a pure hydrogen plume at the source point, this plume must attain a flammable condition at some axial region in the plume rise prior to becoming sufficiently diluted and non-flammable via entrained air during the formation of the noted non-flammable stratified layer at the ceiling of auxiliary building Room 12306, for example.

As described in Section 7.8 of Reference 11.142, while plume detonation in the presence of an assumed local ignition source is possible, the ultra-small size of this region results in corresponding ultra-rapid decay of the shock wave such that it does not represent any hazard to the broader room itself. In fact, in the highly unlikely event that an ignition source is present at the precise location, the resulting detonation event is best characterized as a mere auditory nuisance, not a structural hazard. Although the analysis in Reference 11.142 is based on the CVS hydrogen injection line which contains pure hydrogen, degassing during a WLS line leak or break may develop into a hydrogen plume, though the hazard would be bounded by the pure hydrogen plume from the CVS hydrogen injection line.

Argument: **Systems within the NI containing materials that have the potential to generate explosive atmospheres are designed to prevent leakage through use of welded pipe joints and leak-tight (hermetically sealed) valves compliant with the appropriate**

codes and standards. Such systems will be pressure-tested during commissioning to ensure leak-tight integrity.

Within the NI, the only systems which contain materials with the potential to generate explosive atmospheres are specific components within the CVS, PSS, WGS and WLS.

The high pressure hydrogen gas line routed through room 12306 is seamless. All connections to the pipework, including the vent line end cap, are formed by welded joints. The section of pipework incorporates a single, air operated, Containment isolation valve and two manually operated valves all of which are hermetically sealed butt weld globe valves. During normal operation this line will therefore adequately contain the enclosed hydrogen gas without any leakage into the valve/piping penetration room. The hydrogen gas line then passes through the short section of the middle annulus to enter the Containment.

The PSS and WLS are fluid based systems. The hydrogen component in both systems is dissolved in the liquid and would not readily off-gas whilst contained within the systems. These systems use flanged bolted joints which are pressure tested and rated for the anticipated process conditions.

The WGS is operated at a slight positive pressure in order to preclude the ingress of air. All connections on the WGS are formed by welded joints.

Argument: **Under fault conditions a guillotine break of the CVS injection line in the Auxiliary building will not result in the formation of an explosive atmosphere sufficient to challenge redundant divisions of Class 1 SSC.**

Assessments of a break of the CVS hydrogen injection line in the Auxiliary building (References 11.105 and 11.142) have been performed. These assessments have determined that a worst case gross failure of the CVS hydrogen line would not lead to an explosive atmosphere in rooms 12306, 12406, and 12506, even if the break leak would continue for multiple days without mechanical ventilation active in the rooms. The results of Reference 11.142 show that even after 14 days of continuous leakage, the upper portion of room 12306 will not reach 1 v/v % hydrogen in air. Hydrogen concentrations in rooms 12406, and 12506 (specifically the upper area of room 12506 as the anticipated area of highest concentration) remain below the concentration of the upper area of room 12306 throughout the transient. This auxiliary building condition corresponds to a very benign circumstance with regard to hydrogen hazard for even this most conservative configuration of no ventilation flow. Thus in the long term, the inventory control (Claim 4.1.1) in combination with the volume of the room(s) in the Auxiliary building means that the hydrogen concentration does not exceed 1 v/v %.

In the short term (or the near field effects), during a break of the CVS injection line in the Auxiliary building, hydrogen would initially be at 100 v/v % , but would rapidly dilute due to the entrainment of air. Further, an assessment of any potential limiting localized plume was confirmed to not result in failure of the room barrier (walls, ceiling floor) (Reference 11.142); therefore, deterministically assuming loss of safety functions within the impacted room, the redundant safety function systems remain unaffected.

Argument: **The Auxiliary Building battery rooms are mechanically ventilated to maintain the concentration of evolved hydrogen below the lower flammability limit, including under the most onerous normally anticipated conditions.**

The only continuous release of hydrogen is presented by the batteries which, during charging, evolve hydrogen due to the disassociation of electrolyte at the electrodes when fully charged.

Within the NI, battery banks are located in rooms 12101, 12102, 12103, 12104, 12105, 12202 and 12205, each of which comprises 60 lead-acid cells (Reference 11.97). During normal operation the batteries revert to float charge when fully charged. Under these conditions the battery bank would generate 3.4E-06 $m^3 s^{-1}$ (7.2E-03 cfm) of hydrogen (Reference 11.97). The smallest battery room, 12101, has approximately 200 m^3 (7063 ft^3) of free space into which the hydrogen gas could accumulate. At a generation rate of 3.4E-06 $m^3 s^{-1}$ (7.2E-03 cfm) it would take approximately 163 hours before the 1 v/v % hydrogen concentration is reached, without crediting ventilation. Each of the battery rooms is ventilated at a design exhaust flow rate of 0.156 $m^3 s^{-1}$ (330 cfm). In accordance with the guidance in BS EN 60079-10 (Reference 11.98), the background concentration of hydrogen, X_b (vol/vol) can be calculated using the following equation:

$$X_b = \frac{f \times Q_g}{Q_2}$$

Where: f is a measure of the degree of mixing, 1 for good mixing; Q_g volumetric release rate of flammable gas ($m^3 s^{-1}$); Q_2 is the volumetric flow rate of air leaving the room ($m^3 s^{-1}$). Within the battery room, the background concentration would therefore be 2E-03 v/v %. This is significantly lower than the Lower Flammability Limit (LFL) for hydrogen in air and therefore a flammable atmosphere is prevented from accumulating.

Argument: **The ventilation exhaust systems servicing the Auxiliary Building battery rooms contain flow detection which provides an alarm in the MCR when the extract flow-rate drops below 75% of its design value.**

Each of the IDS battery divisions (including spare) is serviced by a VBS exhaust fan with flow detection on the outlet. At 75% of the design flow setting, an alarm is triggered which displays in the MCR.

Argument: **Battery rooms contain dual-redundant hydrogen detectors which provide an alarm in the MCR when the relevant hydrogen-in-air concentration set point is reached.**

Each of the Auxiliary Building battery rooms contains 2 hydrogen detectors which are installed as shown in Reference 11.97. Hydrogen pocketing cannot occur in the battery rooms between the I-beams, which run east-west, because the ribs of the corrugated metal deck which forms the battery room ceiling run north-south. Furthermore, hydrogen will be evolved from each of the 60 cells, rather than a single location, which are spread throughout the room. Hydrogen would therefore accumulate evenly across the battery room ceiling and within the sampling space of one (or both) of the detectors.

The hydrogen detectors provide an alarm in the main control room alerting operators to the build-up of hydrogen.

Argument: **On actuation of either the ventilation low flow alarm or the high hydrogen alarm, operators will reinstate normal conditions or isolate charging to the batteries.**

On receipt of the low exhaust flow alarm, operators will reinstate the extract flow, either by repairing the affected unit or by swapping in the redundant back-up unit.

During normal operation, the ventilation system is designed to maintain the concentration of hydrogen below 1 v/v % in air. Assuming the hydrogen concentration is being maintained at 1 v/v %, and that an equalising charge is being applied to the batteries in the affected room, it would take approximately 28.8 hours before the hydrogen concentration reached the LFL at 4 v/v % in air. This is more than sufficient time to either reinstate the ventilation extract, or isolate charging to the affected battery division.

On receipt of the high hydrogen concentration alarm, operators will undertake the following actions (Reference 11.99):

- Sampling of hydrogen levels in the room;
- Reinstate the HVAC
- In the event that the HVAC cannot be reinstated:
  - Cease charging of the batteries;
  - Heaters in the air supply lines are disabled;
  - Activities which might present an ignition source are stopped;
  - Temporary local ventilation is installed.
- Maintenance of the HVAC initiated.

From the point at which the alarm is triggered until the LFL is reached, there is sufficient time to either reinstate the ventilation extract, or isolate charging to the affected battery division.

Argument: **During a LOOP event (which would lead to loss of ventilation), batteries cease charging due to loss of AC power. As a result, hydrogen generation ceases, thereby providing an inherently safe arrangement for the battery charging system and associated compartments.**

During normal operation, the VBS is designed to maintain the concentration of hydrogen below 1 v/v % in air. The VBS is powered by the site mains supply, and as such in the event of a LOOP would cease operation. However, the IDS batteries are also charged by the site mains supply and therefore hydrogen would also cease to be generated.

On reinstatement of power, the HVAC will automatically return to normal service, as would the battery chargers. It is therefore not possible for the batteries to evolve hydrogen, in the absence of ventilation, following a LOOP. During normal operation, the ventilation system is designed to maintain the concentration of hydrogen below 1 v/v % in air. Following a LOOP the concentration of hydrogen would therefore remain at or below 1 v/v % in air, which is below the LFL.

Argument: **Under fault conditions a guillotine break of the CVS injection line in the Containment building will not result in the formation of an explosive atmosphere sufficient to challenge redundant divisions of Class 1 SSC.**

Assessments of a break of the CVS hydrogen injection line in the Containment building (Reference 11.106 and 11.142) have been performed. These assessments have determined that a worst case gross failure of the CVS hydrogen line would not lead to an explosive atmosphere in rooms 11209 and 11300, even if the break leak would continue for multiple days without mechanical ventilation active in the rooms. The results of Reference 11.142

show that even after 14 days of continuous leakage, the upper portion of room 11209 will not reach 1v/v % % hydrogen in air. Hydrogen concentrations in rooms 11300 (specifically the upper area of room 11300 as the anticipated area of highest concentration) remain below the concentration of the upper area of room 11209 throughout the transient. This containment building condition corresponds to a very benign circumstance with regard to hydrogen hazard for even this most conservative configuration of no ventilation flow.

In the short term (or the near field effects), during a break of the CVS injection line in the Containment building, hydrogen would initially be at 100 v/v % , but would rapidly dilute due to the entrainment of air. Further, an assessment of any potential limiting localized plume was confirmed to not result in failure of the room barrier (walls, ceiling floor) (Reference 11.142); therefore, deterministically assuming loss of safety functions within the impacted room, the redundant safety function systems remain unaffected.

Argument: **Air (oxygen) will be purged from the RCDT and WGS prior to processing of WLS effluent by the WGS.**

Both the WGS and RCDT are purged with nitrogen gas to expel any residual oxygen before the start of influent processing. When the WGS is purged, nitrogen gas is continually added until the effluent indicates a low oxygen concentration.

Argument: **The atmosphere of systems handling flammable materials is monitored for concentrations of oxygen (and/or) combustible material.**

The WGS sample stream oxygen concentration monitors monitor the concentration of oxygen in the gas stream discharged by the WGS vacuum pumps. Should the oxygen concentration reach a High-2 set-point of 2.4 v/v %, the WGS vacuum pumps are automatically stopped to isolate a potential source of air ingress. Furthermore, the nitrogen purge valve is opened to purge the system with nitrogen.

Hydrogen concentration monitors are installed within the gas space of the WLS effluent hold-up tanks. These monitors provide an alarm to the MCR at 1 v/v % of hydrogen in air, prompting the operator to initiate an air purge through the tank(s) using the CAS.

Argument: **The degasification process, undertaken in the degasifier, boils off dissolved hydrogen from the WLS influents and discharges into the WGS. Any dissolved hydrogen remaining in the WLS would not readily result in additional off-gas of hydrogen.**

The degasifier receives influent from the CVS letdown and RCDT at a maximum dissolved hydrogen concentration of 4.5E-05 $m^3 kg^{-1}$. Based on the maximum dissolved hydrogen concentration and the CVS letdown flowrate of 6.3E-03 $m^3 s^{-1}$ (100 gpm), the hydrogen content of the influent is approximately 2.84E-04 $m^3 s^{-1}$ (0.6 scfm). The degasifier is a vacuum type which can discharge up to 2.7E-04 $m^3 s^{-1}$ (0.58 scfm) to the WGS. The effluent discharged to the WLS hold-up tanks could therefore contain 1.4E-05 $m^3 kg^{-1}$ of hydrogen.

The hydrogen which remains dissolved in the effluent represents 3% of the initial content. The conditions within the WLS effluent hold-up tank would not promote boiling of the effluent and therefore significant quantities of dissolved hydrogen are unlikely to off-gas.

Protection Arguments and Evidence

Claim IH-4.2: Passive protective measures have been incorporated in the AP1000 design to protect SSCs that deliver Category A safety functions from internal explosions

The following arguments demonstrate how the protection claims made in subsection 11.5.2.3 are delivered:

Argument: Areas that accommodate sources of hydrogen or other materials that have the potential to generate explosive atmospheres outside the NI are located at safe distances from the NI (where the 'safe distance' is defined as that at which the maximum explosive overpressure resulting from an explosion will not damage the NI structure, and hence, the SSCs protected by the structure). Implicit to this safety argument is the ability of the external walls of the Containment Shield Building and AB to provide an external overpressure resistance capable of withstanding the explosive overpressure applicable to the defined safe distance.

The design has been developed in accordance with USNRC Regulatory Guide 1.91, which defines the safe distance from an explosion as the point at which the blast wave overpressure is limited to approximately 7 kPa (1 psi); below this no significant damage would be expected. This value is broadly similar to the hazard criteria for blast effects as used by Health & Safety Laboratory (HSL) (Reference 11.103), which are as follows:

- >60 kPa (8.7 psi) likely to cause total demolition of buildings, near certainty of fatality;
- 14-60 kPa (2-8.7 psi) likely to cause some structural damage, some fatalities of building occupants;
- 7-14 kPa (1-2 psi) structural damage unlikely, window damage, fatalities unlikely.

For those sources of flammable material, present outside the NI, which can form an explosive atmosphere, analysis has been performed (References 11.95 and 11.96) to determine the distance from the centre of the Vapour Cloud Explosion (VCE) by which point the blast overpressure would have dropped to 7 kPa.

The Civil/Structural Design Criteria (Reference 11.107) defines the overpressure resistance requirement for the external walls of the NI (including the Shield Building) as 34 kPa (5 psi). The external walls of the Auxiliary Building are composed of nominally 0.6 m (2 ft) thick reinforced concrete walls (Reference 11.104). Similarly, the Containment Shield Building (which envelopes the Containment Building) is constructed from two external 19 mm thick steel plates infilled with concrete, giving an overall thickness of 0.91 m (3 ft) (See Chapter 6). It is reasonable to assume that the construction of the NI walls is at least as strong as a similar thickness of brick panels given that concrete is homogeneous and not subject to the discontinuities inherent in brick and mortar joints. The NI overpressure resistance requirement for the external walls represents a factor of 4.8 compared to the blast overpressure experienced at a safe distance from an explosion.

Based on the standard plant layout, the assessments of explosions originating from the bulk hydrogen storage and other chemicals concludes that the blast overpressure would not exceed the 7 kPa (1 psi) threshold at the NI exterior walls. The Class 1 SSC within the NI would

therefore be unaffected by the postulated explosions and would continue to deliver their Category A safety functions.

Failure of the HVAC system servicing the Annex Building battery rooms would result in the build-up of hydrogen in the battery rooms during charging. The assessment of hydrogen explosions within the battery rooms (Reference 11.94) concludes that the blast overpressure would exceed 7 kPa at the nearest external wall of the NI.

Argument: **A deflagration event in the NI battery rooms will not prevent the delivery of redundant Category A safety functions, due to the assurance of room barrier integrity.**

Battery Room 12104 has been analysed for the scenario of unmitigated hydrogen release and accumulation using a release rate for sustained equalizing charge at maximum temperature 48.9 °C (120 °F) (Reference 11.143).

The hydrogen release in the NI battery rooms is in the form of a slow release of buoyancy-driven plumes that entrain the surrounding quiescent air, yielding a stratified layer at the ceiling that is below the LFL. This layer must grow downward and encompass the entire room. Only then can further hydrogen release increase the hydrogen concentration to the LFL at 4.5 - 4.7 v/v % of hydrogen in air. This process takes roughly 1.6 days for the smallest battery room, Room 12101 (Room volume 200 m^3 per Reference 11.97).

As the release of hydrogen from the batteries continues, the concentration of hydrogen in the room must cross the LFL to achieve flammability. If stray ignition sources in the battery rooms are postulated as an intermittent, but persistent, source that is responsible for deflagration, then the low hydrogen concentration range of 4.5 – 6.0 v/v % is the most likely candidate for deflagration. Such deflagrations can be readily handled via passive venting through HVAC ducts, remaining below the withstand of the battery room walls (5 psi).

Per Reference 11.143, elevated hydrogen concentration in the range of 8 - 12 v/v % is less likely since it requires the initial absence of an ignition source for the additional hydrogen accumulation followed by the latter-stage. If the less likely deflagration at elevated hydrogen concentrations in the range 8 - 12 v/v % must be considered for conservatism, 8 – 12 v/v % hydrogen concentration in air will exceed withstand of the battery room walls (5 psi) and remain above the limit for 45 - 60 seconds if passive venting is not credited. If passive venting through HVAC ducts is credited, then the peak pressure ratio is mitigated, and the duration above the administrative limit is reduced substantially to 5 - 6 seconds. Finally, if pressure relief via over-pressure catastrophic failure of the main access door is credited, then the peak pressure ratio remains below the administrative limit for the entirety of the deflagration duration. Note, there are no safe shut down SSCs serving Category A functions in the Corridors, Rooms 12111 and 12211, into which the battery room doors will relieve to. Further discussion of the mechanisms of the door over-pressure failure is provided in Section 3.1.4 of Reference 11.143.

While the deflagrations occurring in the concentration range 8 – 12 v/v % can be accommodated, deflagration-to-detonation (DDT) remains a concern for 10 v/v % and larger. Per Reference 11.143, detonation tolerance is not established, so a successful outcome is not assured. 8 v/v % is the highest concentration analysed that can both tolerate a deflagration and avoid a detonation. It yields a successful outcome in all respects. Furthermore, the roughly 3.3 day timeframe for development of 8 v/v % (Smallest battery room, Room 12101) provides ample time for operators to recognize an unmitigated hydrogen release scenario and take action to counteract this circumstance far in advance.

Mitigation Arguments and Evidence

There are no specific claims made on mitigating the effects of an explosion. Explosions are assumed to result in gross failure of exposed SSC.

11.5.3 Internal Explosions Safety Case Summary

11.5.3.1 Introduction and Overview

The safety design approach adopted for internal explosion hazards consists of a range of complementary design and operation measures. These are applied as appropriate to individual items of equipment or systems to prevent an internal explosion occurring or to protect Class 1 SSC from the effects of an explosion. Suitable and sufficient design basis measures are identified such that an internal hazard, which may give rise to an explosion, does not prevent the delivery of the Category A safety functions necessary to respond to a postulated event. Preservation of required safety functions ensures alignment with fault studies and structural integrity analysis. In accordance with relevant international good practice (Reference 11.23), the following approaches have been applied:

- Prevent explosions from occurring;
- Minimise the risk of an explosion, if an explosive atmosphere cannot be avoided;
- Minimise the consequences of an explosion.

Internal explosions typically occur because of occurrences that result in the build-up of concentrations of volatile or unstable materials coupled with an ignition source. Such explosive combinations could, in theory, arise from the following types of contributory events:

- Inappropriate location or storage of flammable/explosive materials;
- Accidental release of flammable/explosive material during normal operations;
- Failure to control normal accumulation of flammable/explosive materials generated during operations;
- Accidental introduction of an ignition source when a flammable/explosive concentration of material is normally present.

Explosions are assumed to occur, as a result of Postulated Initiating Events (PIEs), wherever an explosive atmosphere may be present, except where equipment is qualified to not present a source of ignition. Passive protective measures have been incorporated in the design to protect SSCs that deliver Category A safety functions from internal explosions. The consequences of an explosion will be contained through the use of passive barriers to limit the impact to and loss of a safety function. In summary, the safety case approach adopted is as follows:

- Control of flammable material inventories;
- Incorporation of component design features that prevent explosive atmospheres from forming;
- Safe routing of systems containing flammable materials;

- Location of Safety Class 1 SSCs outside the zone of influence of a postulated explosion;
- Protection where practicable using segregation and/or separation by structural barriers.

The AP1000 design employs a mixture of the approaches stated above to form levels of defence which reduce the likelihood of an internal explosion generated from equipment and also reduces the risk of internally generated explosions to ALARP. It is argued that all SSC exposed to an overpressure in excess of 7 kPa are assumed to fail. Where an explosion overpressure has not been explicitly determined (e.g., because the explosion is prevented) the failure of equipment within a segregated area because of an explosion is bounded by other hazard analyses (i.e., internal fire), which assumes that all equipment in such an area is lost as a result of the hazard.

The focus of the explosion hazard analysis is on those areas containing Class 1 SSCs; i.e., those within the NI (Shield/Containment Building and AB). Consideration of internal explosion hazards in other locations is limited to the demonstration that the NI is adequately protected from an internal explosion from these sources by appropriate separation distance and/or physical barriers.

11.5.3.2 Applicable Codes and Standards

The internal explosion assessments have been undertaken in accordance with the following codes and standards:

- BS EN 60079-10, 'Explosive Atmospheres Part 10-1: Classification of Areas – Explosive Gas Atmospheres';
- NRC Regulatory Guide 1.91, 'Evaluations of Explosions Postulated to Occur at Nearby Facilities and on Transportation Routes Near Nuclear Power Plants';
- HSL/2001/04, "Explosion Hazard Assessment: A Study of the Feasibility and Benefits of Extending Current HSE Methodology to Take Account of Blast Sheltering';
- Multi-Energy Method (MEM);
- TNT-equivalence method

Protective structures are designed to withstand and absorb peak positive incident over-pressures generated by explosions in order to prevent damage to Class 1 SSCs. Appropriate safe separation distances from explosion sources also forms an implicit part of the design process for protection against explosions.

SSC claimed in support of this assessment are designed in accordance with the relevant US codes and standards. To evaluate the codes and standards against the UK expectations, the codes and standards have been organised by the relative safety significance of the SSCs to which they have been applied. To support this organisation the AP1000 UK Safety Categorisation and Classification Methodology (Reference 11.26) describes the process for categorisation of safety functions and classification of SSCs.

The AP1000 Equivalence/Maturity Study of U.S. Codes and Standards (Reference 11.25), determines, based on their importance to safety, the applicability, adequacy and sufficiency of those standards when compared with relevant UK and international good practice. It also

provides a clear and auditable demonstration that all codes and standards to support the design substantiation of UK Class 1 or safety significant SSCs have been identified.

11.5.3.3 Redundancy and Segregation

An internal disruption within a building can lead to plant damage. In such cases, the measures for ensuring continuing delivery of safety functions up to and after 72 hours are exactly the same as for any other causes of damage to the potentially affected plant. The location and level of redundancy of Class 1 SSC within the plant is such that complete loss of operability of the SSCs within a room or compartment because of disruption resulting from an internally generated explosion would not result in loss of the Category A safety function.

Measures applied with respect to redundancy, separation, and segregation consist of the following:

- There are multiple divisions of Class 1 SSC each of which is wholly capable of delivering the Category A safety functions;
- Within the Containment Vessel there is segregation and separation of Class 1 equipment. This is provided by a combination of barriers formed by the walls and floors of compartments and the distance between systems providing redundant means of delivering the Category A functions.
- Outside the Containment Vessel there is sufficient equipment redundancy, segregation, and protection such that all of the equipment in a single room can be lost without preventing delivery of the Category A safety functions.
- The Class 2 systems are an additional means of delivering Category A safety functions. They provide a level of defence in depth. The Class 2 system designs also feature redundancy. The Category A functions provided by these systems are summarised in Chapter 6.

The plant is designed such that it can be operated with sufficient levels of protection in place to ensure that internally generated explosions will not prevent delivery of Category A safety functions. This defence in depth is provided by:

- The conservative design, manufacture, maintenance and operation of equipment in accordance with safety margins (through compliance with recognised design codes) appropriate engineering practices and monitoring of the quality of these aspects.
- The use of structural barriers to limit the impact of any explosion generated to areas where damage will not prevent the delivery of Category A safety functions.

Sufficient redundancy and defence in depth is provided to ensure that even if there is the loss of any SSC as a result of an internally generated explosion the Category A safety function can still be delivered.

11.5.3.4 Explosions Assessment Approach

The approach to assessing potential internal explosions is in accordance with the following basic steps:

1. Identify all known chemicals stored in the AP1000 plant.

2. Determine whether these chemicals present an explosion hazard.
3. Determine the location of the chemicals with potential to cause an explosion hazard.
4. Calculate the minimum safe distance for SSCs if the conditions are met for an explosion to occur[10].

In accordance with the Dangerous Substances and Explosive Atmospheres Regulations 2002 (DSEAR) (Reference 11.109), an explosive atmosphere exists where a substance(s) mixed with air, in the form of gases, vapours, mists or dust, which when ignited, combustion spreads throughout the entire unburned mixture. Explosive atmospheres will therefore form wherever flammable gases, vapours mists or dusts mix with air at concentrations which are flammable.

An explosion will result in an increase in temperature or pressure, or both simultaneously. SSC exposed to the effects of an explosion will be damaged where the temperature or pressure exceeds the capacity of the SSC to withstand the effect. In general the effect of temperature increase will be short lived and the thermal radiation dose will be low. However, the peak pressure will have a deterministic effect. On this basis, it is reasonable to assume that the effects of pressure will bound those of temperature.

The blast overpressure from a VCE has been determined using the Multi-Energy Method (MEM) developed by the Netherlands Organisation for Applied Research (TNO) (Reference 11.96).

11.5.3.5 Interface with Other Internal Hazards

The AP1000 design has been evaluated for internal hazards to confirm that SSCs delivering Category A or supporting Post-72 hours Category B safety functions will perform as required for the identified internal hazards listed in Section 11.1.

It is recognised that internal explosions may occur, due to a common initiator, coincidentally with other internal hazards or selected external hazards. In such instances, the combined effects of both hazards constitute the full extent of the internal hazard.

An assessment of the consequences of combined hazards has been completed and documented in Section 11.12 based on the combined hazards analysis (Reference 11.75). Section 11.12 demonstrates that for credible combinations of flooding with other potential internal hazards, the Category A and/or supporting Category B safety functions can continue to be delivered, as consistent with the individual internal hazard assessments.

11.5.3.6 Conclusions

Sufficient evidence has been shown throughout this section that the risk of loss of a nuclear safety-significant system as a result of internal explosions is low and controlled. Internal explosions have been shown to not prevent the delivery of the Category A safety functions and the post 72-hour Category B safety functions. This is due to the combination of inherent design features (Safe Distances), routine and non-routine early detection regimes (Hydrogen Detectors), prevention devices (mechanical HVAC), and the application of routine and non-

10. Within the NI, the approach adopted is to prevent an explosion from occurring through the provision of suitable and sufficient SSC. Explosion overpressures, and minimum safe distances, have therefore not been calculated for explosive atmospheres originating from within the NI.

routine remediation actions (Operator response to high hydrogen concentration or loss of HVAC), respectively preventing, detecting, protecting and controlling the risk to the AP1000 plant from internal explosions.

11.5.4 Internal Explosions Analysis

11.5.4.1 Flammable Substances

A detailed review of the chemical inventory has been performed (Reference 11.95) to identify those chemicals which could form an explosive atmosphere when mixed with air. An additional review has been performed to identify systems which handle or generate hydrogen. The chemicals, considered capable of developing a flammable atmosphere are listed in Table 11.5-1 of this document.

11.5.4.2 Sources of Release

For those systems which contain flammable substances, reviews have been undertaken to identify possible locations where a leak could form a flammable atmosphere. The rooms in which a flammable atmosphere could form are detailed in the Hazard Schedule, Table 11.5-2. The Containment building is, in order to maintain the free movement of gases, an open space. The majority of rooms are separated by open grate structures which would not inhibit the movement of gases. Irrespective of location, a release within Containment is therefore assumed to permeate all rooms.

11.5.4.3 Assessment of Internal Explosions

To support the claims and arguments made as part of the internal explosions hazard analyses, a number of assessments have been carried out. The following sections provide a summary of the analyses and the assessment findings.

Containment Building

Failure of the WLS pipework and/or the CVS hydrogen injection line could result in a build-up of hydrogen in Containment. The assessments of leakage from the hydrogen injection line in Containment (Reference 11.106 and 11.142) evaluate the potential for an explosion within Containment, while the WLS and WGS hydrogen leakage assessment (Reference 11.100) considers a loss of effluent from the WLS.

The hydrogen injection package is supplied from 4 high pressure hydrogen bottles located in the PGS. The high pressure hydrogen switchover station automatically switches the supply from the 2 duty bottles to the 2 standby bottles once they become depleted. Each of the high pressure hydrogen bottles has a nominal capacity of 15.6 m^3 (550 scf), giving a total available hydrogen volume of 62.3 m^3 (2200 ft^3).

The hydrogen injection package has two modes of operation, continuous and batch, depending on the plant mode, supplied via two parallel lines. The maximum flow rate during either continuous or batch mode is limited, by orifice plates, to 5 E-04 $m^3 s^{-1}$ (1.05 scfm) or 9.3 E-05 $m^3 s^{-1}$ (0.2 scfm) respectively (Reference 11.106).

The hydrogen injection package originates in the Turbine Building and passes, via rooms 12306 and 12341, into Containment. Within Containment, the hydrogen injection line is present in rooms 11209 and 11300. The pipework, valves and fittings for the CVS are butt

welded and hermetically sealed. During normal operation, there would be no leak of hydrogen within Containment.

However, should the pipework, valves or fittings fail (e.g., double guillotine failure), hydrogen would leak from the pipework into rooms 11209 or 11300.

The RCDT, located in room 11104, contains borated effluent which is potentially hydrogen bearing. As required, the RCDT is pumped out to the WLS, passing via 11300. A leak from the RCDT or associated pipework within Containment therefore has the potential to generate hydrogen off-gas from the effluent.

Rooms 11104 and 11300 have an open grate ceiling, such that any hydrogen would pass directly into the general Containment space.

The assessment of the CVS hydrogen injection line in Containment has identified that it may be possible for an explosive atmosphere to form in Room 11209 (Reference 11.106). As a result of this scenario, a detailed assessment of a break of the CVS hydrogen injection line in the Containment building was completed (Reference 11.142). This assessment has determined that a worst case gross failure of the CVS hydrogen line would not lead to an explosive atmosphere in rooms 11209 and/or 11300, even if the break leak would continue for multiple days without mechanical ventilation active in the rooms. The results of the assessment show that even after 14 days of continuous leakage, the upper portion of room 11209 will not reach 1 v/v % hydrogen in air. It would take approximately 38 days to reach 1 v/v % of hydrogen in the most limiting room, Room 11209. A continuous leak of 31 days or more is not considered credible as it would exceed the quantity of hydrogen available (4 high pressure hydrogen bottles, each containing 15.6 m^3 (550 scf) of hydrogen). Hydrogen concentrations in rooms 11300 remain below the concentration of the upper area of room 11209 throughout the transient. This containment building condition corresponds to a very benign circumstance with regard to hydrogen hazard for even this most conservative configuration of no ventilation flow.

As described in Reference 11.142 of CVS hydrogen line break assessment, while plume detonation in the presence of an assumed local ignition source is possible during a guillotine break or long term leak of the hydrogen injection line in the Containment Building, the ultra-small size of this region results in corresponding ultra-rapid decay of the shock wave such that it does not represent any hazard to the broader room itself. In the highly unlikely event that an ignition source is present at the precise location, the resulting detonation event is best characterized as a mere auditory nuisance, not a structural hazard.

In addition, the VCS system (Reference 11.144) can be credited as defence-in-depth. The VCS promotes mixing of the containment atmosphere and can reduce the likelihood of a flammable mixture of hydrogen from forming.

Auxiliary Building – Radiologically Controlled Area

Gaseous Radwaste System

The WGS receives processes and discharges the radioactive waste gases during all modes of plant operation. The primary feeds to the WGS are from the Reactor Coolant Drain Tank and the WLS system degasifier. The degasifier receives a feed from the CVS letdown and RCDT which incorporates dissolved hydrogen (Reference 11.100). The degasifier is operated under vacuum conditions to remove the dissolved hydrogen from the CVS letdown feed for onward processing by the WGS.

During normal operation of the plant, the degasifier is able to process 6.3E-03 $m^3 s^{-1}$ (100 gpm) with a dissolved H_2 concentration of 4.5E-05 $m^3 kg^{-1}$ (Reference 11.101). After processing through the degasifier, the H_2 concentration in the liquid stream drops to 1.4E-05 $m^3 kg^{-1}$, with the majority of the dissolved hydrogen off-gassing into the WGS. The WGS pipework, valves and fitting contain the gaseous stream prior to discharge via the VFS plant vent.

A leak from the WGS pipework could result in an accumulation of hydrogen in the affected room. The WGS is present in rooms 12153 and 12155. Based on the generation rate from the degasifier, hydrogen would be released into the room at a rate of 2.8E-04 $m^3 s^{-1}$ (0.6 scfm) at standard temperature and pressure. Both rooms are mechanically ventilated by the VAS. In accordance with the guidance in BS EN 60079 Part 10-1 (Reference 11.98), the background concentration of hydrogen, X_b (vol/vol) can be calculated using the following equation:

$$X_b = \frac{f \times Q_g}{Q_2}$$

Where: f is a measure of the degree of mixing, 5 for poor mixing; Q_g volumetric release rate of flammable gas ($m^3 s^{-1}$); Q_2 is the volumetric flow rate of air leaving the room ($m^3 s^{-1}$). Within room 12155, the background concentration would therefore be 0.8 v/v %. This is lower than the LFL for hydrogen in air (4 v/v %) and therefore a flammable atmosphere is prevented from accumulating by the VAS.

Liquid Radwaste System

The WLS receives borated and hydrogen bearing water from the PSS, RCDT and CVS. The liquid waste is passed through a degasifier to remove dissolved hydrogen (and other radiogases). The degasifier receives a feed from the CVS letdown and RCDT which incorporates dissolved hydrogen. The degasifier is operated under vacuum conditions to remove the dissolved hydrogen from the CVS letdown feed for onward processing by the WGS.

During normal operation of the plant, the degasifier is able to process 6.3E-03 $m^3 s^{-1}$ (100 gpm) with a dissolved H_2 concentration of 4.5E-05 $m^3 kg^{-1}$ (Reference 11.101). After processing through the degasifier, the H_2 concentration in the liquid stream drops to 1.4E-05 $m^3 kg^{-1}$, with the majority of the hydrogen passing into the WGS. The liquid is then passed to one of two effluent hold-up tanks. During hold-up in the effluent tank, some of the dissolved hydrogen may off-gas into the airspace above the effluent. The vent line from each of the effluent tanks incorporates a hydrogen monitor to detect the build-up of hydrogen. At 1 v/v % hydrogen in air, an alarm is triggered in the MCR. On receipt of the alarm an operator is required to initiate an air purge through the tank using the CAS to maintain the concentration below the flammable limit.

Auxiliary Building – Non-Radiologically Controlled Area

Auxiliary Building Battery Rooms

The hydrogen assessments of the Auxiliary Building battery rooms (References 11.97 and 11.143) evaluated the hazard presented by an explosive atmosphere and identifies those SSC necessary to prevent or protect Class 1 SSC from the effects of an explosion.

Each of the battery rooms contains 60 lead calcium cells. During charging the batteries generate hydrogen, which is released into the surrounding room. During normal operation, the VBS extracts sufficient air from the battery rooms to ensure that the hydrogen

concentration, including under the most onerous conditions, remains below 25% of the LFL. However, should the ventilation system fail, the hydrogen concentration will increase in the affected room(s).

The following table details the hydrogen generation rates under a range of conditions and the time to reach the LFL, assuming no ventilation extract, in the smallest room (Room 12101) which has a volume of 200 m^3.

Condition	Hydrogen Generation Rate (m3 s-1)	Time to LFL (4 v/v %) Days
Normal float charge at normal temperature (22.8 °C)	3.39×10^{-5}	27.3
Normal float charge at maximum temperature (48.9 °C)	2.6×10^{-5}	3.6
Equalising charge at maximum temperature (48.9 °C)	5.67×10^{-5}	1.6

The Auxiliary Building battery rooms are serviced by the VBS which when operating maintains the hydrogen concentration below 1 v/v % hydrogen in air. The exhaust of each fan (both duty and standby) incorporates a flow element to detect low, or no, exhaust flow. At 75% of normal exhaust design flow[11], the flow element will trigger an alarm in the MCR (Reference 11.99).

On low ventilation exhaust flow operators will preferentially undertake the following tasks:

1. Attempt to reinstate correct functionality of the duty fan;
2. Manually initiate the standby fan;
3. Isolate charging to the affected battery rooms.

Each of the AB battery rooms has two off hydrogen detectors. At 25% of the LFL, the hydrogen detector will trigger an alarm in the MCR alerting operators to the build-up of hydrogen (Reference 11.99).

On high hydrogen operators will:

- Isolate charging to the batteries in the affected rooms;
- Disable heaters in the ventilation supply lines;
- Halt activities which have the potential to cause a spark;
- Effect temporary ventilation of the affected rooms.

11. The VBS normally extracts 0.15 m3 s-1 (330 scfm) from each of the battery rooms. Assuming the worst case hydrogen evolution rate of 5.67 x 10-5 m3 s-1 (0.12 cfm), and poor HVAC performance, the VBS would need to extract at least 19% of its normal exhaust flow in order to maintain the hydrogen in air concentration below 1 v/v %.

During normal operation, any hydrogen evolved by the batteries during charging is removed from the room by the ventilation system. The vent system has been designed to maintain the concentration of hydrogen below 1v/v % in air. The formation of an explosive atmosphere within one of the battery rooms is postulated to arise as a result of either failure of the HVAC or a LOOP. The power to the ventilation system and the batteries is such that in the event of a LOOP, the batteries would stop charging. On reinstatement of power, the HVAC will automatically return to normal service, as would the batteries. It is therefore not possible for the batteries to evolve hydrogen, in the absence of ventilation, following a LOOP.

In the event of failure of the HVAC system and charging of the batteries continues, for the smallest battery room, it would take 28.8 hours at equalizing charge at maximum temperature before a flammable atmosphere (4 v/v % hydrogen/air) is formed. This assumes that the hydrogen concentration in the battery room was 1 v/v % prior to cessation of the HVAC although during normal operation it will be significantly lower than this.

The batteries are normally float charged to maintain their power and would only undergo equalising charge periodically. Furthermore, once charged, the batteries would revert to trickle charge. The assumed hydrogen evolution rate is based on the equalising charge being applied even after the batteries are fully charged. Given the length of time before an explosive atmosphere is formed in the battery room, it is not considered necessary to interlock the charging of the battery with the vent system.

Given the length of time, on loss of ventilation extract, to reach the LFL and the multiple warnings provided by the low ventilation extract flow alarm and the high hydrogen concentration alarm, it is considered unlikely that an explosive atmosphere would form in the battery rooms. Further, the battery rooms themselves are not claimed to be hermetically sealed and it would be expected that, either due to natural ventilation or the buoyancy of hydrogen, concentrations would not increase at the rates calculated.

In the highly unlikely event of redundant VBS fan failure and no action from operators to a high hydrogen alarm in the MCR, the hydrogen concentration in the battery rooms may increase to explosive levels. An unmitigated release of hydrogen in the battery rooms will lead to severe consequences, including structural barrier failure and ultimately the loss of redundant Class 1, Category A SSCs. The consequences of a detonation in one or more battery rooms have not been quantified, rather it is assumed that all IDS batteries and chargers are destroyed, leading to a loss of Category A safety function, including that of redundant division. In the event of unmitigated hydrogen build-up in one or more of the battery rooms, Reference 11.143 analysed the conservative scenario of unmitigated hydrogen release and accumulation using a release rate for sustained equalizing charge at maximum temperature 48.9 °C (120 °F). It would take roughly 1.6 days to reach the hydrogen LFL of 4 v/v % at equalizing charge at maximum temperature 48.9 °C (120 °F) for the smallest battery room, 12101. Using a normal float charge at normal temperature 22.8 °C (73 °F), that time period would get extended 27.3 days for Room 12101.

As the release of hydrogen from the batteries continues, the concentration of hydrogen in the room must cross the LFL to achieve flammability. If stray ignition sources in the battery rooms are postulated as an intermittent, but persistent, source that is responsible for deflagration, then the low hydrogen concentration range of 4.5 – 6.0 v/v % is the most likely candidate for deflagration. Such deflagrations can be readily handled via passive venting through HVAC ducts, remaining below the withstand of the battery room walls (5 psi). The pressure pulse will be relieved through the HVAC penetrations in the concrete room structure. It would take roughly 2.5 days to reach a hydrogen concentration of 6 v/v % at equalizing charge at maximum temperature 48.9 °C (120 °F) for the smallest battery room,

Room 12101. Using a normal float charge at normal temperature 22.8 °C (73 °F), that time period would get extended to 41 days for Room 12101.

Per the battery room hydrogen explosion analysis (Reference 11.143), elevated hydrogen concentration in the range of 8 - 12 v/v % is less likely since it requires the initial absence of an ignition source for the additional hydrogen accumulation followed by the latter-stage. If the less likely deflagration at elevated hydrogen concentrations in the range 8 - 12 v/v % must be considered for conservatism, 8 – 12 v/v % hydrogen concentration in air will exceed withstand of the battery room walls (5 psi) and remain above the limit for 45 - 60 seconds if passive venting is not credited. If passive venting through HVAC ducts is credited, then the peak pressure ratio is mitigated, and the duration above the administrative limit is reduced substantially to 5 - 6 seconds. Finally, if pressure relief via over-pressure catastrophic failure of the main access door is credited, then the peak pressure ratio remains below the administrative limit for the entirety of the deflagration duration. Note, there are no safe shut down SSCs serving Category A functions in the Corridors, Rooms 12111 and 12211, into which the battery room doors will relieve to. Further discussion of the mechanisms of the door over-pressure failure is provided in Section 3.1.4 of Reference 11.143.

While the deflagrations occurring in the concentration range 8 - 12 v/v % can be accommodated, deflagration-to-detonation (DDT) remains a concern for 10 v/v % and larger. Per the battery room hydrogen explosion analysis, Reference 11.142, detonation tolerance is not established, so a successful outcome is not assured. 8 v/v % is the highest concentration analysed that can both tolerate a deflagration and avoid a detonation. It yields a successful outcome in all respects. Furthermore, the roughly 3.3 day (Room 12101) timeframe for development of 8 v/v % provides ample time for operators to recognize an unmitigated hydrogen release scenario and take action to counteract this circumstance far in advance. Using a normal float charge at normal temperature 22.8 °C (73 °F), that time period would get extended to 54.6 days for Room 12101, giving even more time to take action.

As described in the details of this section, the Westinghouse safety case approach to the battery rooms is a multilayer approach, consisting of VBS ventilation, VBS low flow detection, hydrogen detection, operator action, and room barriers. Thus to summarize the auxiliary building battery room safety case (Timeframes based on smallest battery Room 12101):

1. Under normal conditions an explosive atmosphere is prevented by the VBS.

2. Under fault conditions of loss of VBS extract an explosive atmosphere will form. However the effects of an explosion will be confined to the room in question provided the hydrogen concentration remains below 8 v/v % (most limiting). Battery room walls can withstand a deflagration up to 12 v/v % or detonation up to 8 v/v %. As an example, at the maximum hydrogen generation rate, it would take around 3.3 days to reach 8 v/v % for Room 12101. Assuming a float charge at normal operating temperature, that time period would get extended to 54.6 days giving even more time to take action.

3. It is not considered credible that hydrogen will accumulate for 3.3 days because:

- The vent low flow alarm will sound in the MCR at 75% of the design exhaust flow (giving 3.3 days prior warning to operators);

- The hydrogen detection in the room will alarm at 1 v/v % (giving 2.9 days prior warning to operators);

- Operators perform rounds and would identify issues in the battery rooms, as an example if there is an absence of exhaust flow due to a low flow alarm, high temperatures in the room, or an alarm from the hydrogen detectors.

A host of process and equipment failures need occur before an explosive atmosphere large enough to impact multiple divisions of IDS battery rooms or other Class 1, Category A SSCs. The timeframe for the event to occur also provides ample time for operators to recognize an unmitigated hydrogen release scenario and take action to counteract this circumstance far in advance.

Valve/Piping Penetration Room (12306)

The assessment of leakages associated with the hydrogen injection package (Reference 11.105) evaluates the potential for an explosive atmosphere to form in the valve/pipe penetration room.

The hydrogen injection package is supplied from 4 high pressure hydrogen bottles located in the PGS. The high pressure hydrogen switchover station automatically switches the supply from the 2 duty bottles to the 2 standby bottles once they become depleted. Each of the high pressure hydrogen bottles has a nominal capacity of 15.6 m^3 (550 scf), giving a total available hydrogen volume of 62.3 m^3 (2200 ft^3) (Reference 11.105).

The hydrogen injection package has two modes of operation, continuous and batch, depending on the plant mode, supplied via two parallel lines. The maximum flow rate during either continuous or batch mode is limited, by orifice plates, to 5 E-04 $m^3 s^{-1}$ (1.05 scfm) or 9.3 E-05 $m^3 s^{-1}$ (0.2 scfm) respectively.

The hydrogen injection package originates in the Turbine Building and passes, via 12306, into Containment. The pipework, valves and fittings for the CVS within 12306 are butt welded and hermetically sealed. During normal operation, there would be no leak of hydrogen from the CVS into room 12306 or any room communicated to 12306.

However, should the pipework, valves or fittings fail (e.g., double guillotine failure), hydrogen would leak from the pipework into room 12306 which communicates directly with rooms 12406 and 12506 above, via pipe penetrations.

The assessment of a leak from the hydrogen injection line, Reference 11.105, has identified that it may be possible for an explosive atmosphere to form in 12306, 12406 and 12506. As a result, an assessment of a hydrogen injection line break in the Auxiliary building, Reference 11.142 was completed. This assessment has determined that a worst case gross failure of the CVS hydrogen line would not lead to an explosive atmosphere in rooms 12306, 12406, and 12506, even if the break leak would continue for multiple days without mechanical ventilation active in the rooms. The results of Reference 11.142 show that even after 14 days of continuous leakage, the upper portion of room 12306 will not reach 1% hydrogen. Hydrogen concentrations in rooms 12406, and 12506 (specifically the upper area of room 12506 as the anticipated area of highest concentration) remain below the concentration of the upper area of room 12306 throughout the transient. This auxiliary building condition corresponds to a very benign circumstance with regard to hydrogen hazard for even this most conservative configuration of no ventilation flow. It was determined that 1 v/v % of hydrogen in Room 12306 would be reached in approximately 54 days. A continuous leak of 31 days or more is not considered credible as it would exceed the quantity of hydrogen available (4 high pressure hydrogen bottles, each containing 15.6 m^3 (550 scf) of hydrogen)

Further, an assessment of any potential limiting localized plume was confirmed to not result in failure of the room barrier (walls, ceiling floor (Reference 11.142); therefore, deterministically assuming loss of safety functions within the impacted room, the redundant safety function systems remain unaffected. As described in Section 7.8 of CVS hydrogen line break assessment (Reference 11.142), while plume detonation in the presence of an assumed local ignition source is possible during a guillotine break or long term leak of the hydrogen injection line in the Auxiliary Building, the ultra-small size of this region results in corresponding ultra-rapid decay of the shock wave such that it does not represent any hazard to the broader room itself. In the highly unlikely event that an ignition source is present at the precise location, the resulting detonation event is best characterized as a mere auditory nuisance, not a structural hazard.

Areas Outside of the Nuclear Island

Areas outside of the NI include the Annex Building, Turbine Building, Radwaste Building and those buildings/structures/installation not directly abutting the NI in the wider yard area. There are no Class 1 SSCs located in areas outside of the NI and therefore the significance of any explosion is instead focussed on the overpressure experienced by the NI and Shield Building outer walls.

The following sections present the results of the analyses for the various flammable substances which have the potential to generate an explosive atmosphere.

Annex Building Battery Rooms

The explosive hazard presented by the Annex battery rooms has been evaluated (Reference 11.94), based on a series of conservative assumptions, to determine if an explosive atmosphere can be generated. For exclusion purposes, it is noted that there are no batteries used or stored within the Radwaste Building. In addition, it is also noted that, as the batteries and ventilation system will be powered from the same power source a loss of power will cease ventilation and charging, and thus, hydrogen generation.

For the battery rooms, an acceptable method for establishing safe separation distances (beyond which no adverse effect would occur following a hydrogen explosion) is based on a level of peak positive incident over-pressure (Reference 11.94). In accordance with industry guidance, the maximum peak positive incident over-pressure relevant to the SSCs of concern has been conservatively determined by the USNRC to be 1 psi (6.9 kPa) (Reference 11.102).

Each battery room contains 120 battery cells. The hydrogen generation rate for 120 battery cells operating (i.e., the amount generated in one room) is estimated to be 4.63E-02 $m^3 hr^{-1}$ (1.63 cf hr^{-1}) for an equalising charge. At an elevated temperature of 50°C the hydrogen generation rate is increased to 3.24E-01 $m^3 hr^{-1}$ (11.4 cf hr^{-1}) for an equalising charge.

The volume of battery rooms have been assessed, with battery room 40412 forming the bounding case (smallest room) with a total volume of 150 m^3 (5300 ft^3). Of the total volume, 30% is assumed to be occupied by internal structures and equipment, giving a net 'free-space' volume of 105 m^3 (3710 ft^3).

Averaging the volume of hydrogen generated during a 12-hour battery charging period (4.2E-02 m^3) over the entire free-space volume of battery room 40412 results in a concentration of less than 1 v/v % hydrogen. At the elevated temperature the LFL is reached in 12 hours if ventilation is not present.

The LFL and Lower Explosive Limit (LEL) for hydrogen in air are 4% and 18% by volume, respectively. For an equalisation charge it would take 3.8 days to reach the LFL and 17 days to reach the LEL at STP and 12 hours and 2.4 days at the elevated temperature. This would be under fault conditions as the ventilation would have had to fail.

For a float charge the hydrogen generation rate is significantly reduced (2.1E-02 $m^3 hr^{-1}$ (0.75 cf hr^{-1}) at STP, such that the time to reach the LFL and LEL is 8.2 and 37.1 days respectively. Thus, the times to LFL and LEL for the elevated temperature are 1.2 days and 5.3 days.

In the event of a loss of ventilation to the Annex battery rooms and a build-up of hydrogen, operator action is required to restore ventilation or cease battery equalisation charge. Battery rooms 40307 and 40309 contain exhaust airflow monitors that monitor VXS exhaust flow. At 75% of normal exhaust flow, the flow element will trigger an alarm in the MCR. Room 40412 contains air temperature monitors to provide temperature indication and alarm when the room air temperature is either too high or too low to support operation of the batteries. A temperature alarm in room 40412 may be used to indicate if the VXS HVAC system is working correctly.

The battery rooms also contain hydrogen detectors which trigger an alarm in the MCR at 1 v/v % hydrogen in air. Thus, the time within which operator action is required is a minimum of 9 hours assuming an equalisation charge at elevated temperature. This is the bounding case. At standard temperature and pressure conditions, the time available is 68 hours. The conditions for a float charge (the normal operation of the batteries) produces much longer times to reach the LFL. Thus, detection of a hydrogen atmosphere and sufficient response time is available for the operator to either restore ventilation or cease charging of the batteries.

Chemical Feed System – Chemical Explosion & Pool Fire Assessment

Numerous chemicals are stored and used to support normal plant operations. The main system used to manage these operations is the Chemical Feed System (CFS), which stores chemicals needed for the operation of the Condensate System (CDS), FWS, Auxiliary Steam Supply System (ASS), Steam Generator Blowdown System (BDS), SWS and Demineralised Water Treatment System (DTS). Reference 11.95 identifies the chemicals handled by the CFS that present an explosive hazard along with the relevant storage vessel identifier, each of which is vented to the outside of its associated building.

In addition to the explosively hazardous chemicals handled by the CFS, a number of other flammable and explosively hazardous chemicals are stored and used on site, including liquid hydrocarbons (e.g., bulk diesel fuel oil supplies for the DG Building) and liquefied/gaseous hydrogen supplies (Reference 11.95).

It is noted that, although a release of diesel oil at ambient temperature does not necessarily produce a potentially explosive atmosphere, however, if the tank contents were to be heated by an external source, a potentially explosive atmosphere could be formed.

As an on-site explosion involving any of the above chemicals has been assessed on the potential to affect the function of safety-related SSCs, (Reference 11.95), in accordance with the following methodologies:

- TNT-equivalence method (described in NUREG Guide 1.91 [Reference 11.102])

- Multi-Energy Method (MEM) (described in the report on 'Methods for the Calculation of Physical Effects' produced by the Committee for the Prevention of Disasters).

Although not a prescribed requirement of Reference 11.102, a 30% margin is added to the required minimum safe separation distance between the postulated explosion and Class 1 SSCs to account for the potential under-prediction of the blast radius by the TNT equivalence method (due to several factors including explosive material type, form and shape).

In addition to explosion analysis, thermal radiation effects on SSCs from a chemical pool fire have been examined where appropriate (i.e., for diesel fuel oil and waste oil spillages) using the US NRC Fire Dynamic Tool, which allows comparison of incident heat fluxes resulting from a pool fire with critical heat fluxes (associated with thermal radiation effects on structures) for the purposes of determining minimum safe separation distances between postulated pool fires and Class 1 SSCs.

The results of the chemical explosion and thermal radiation analyses (Reference 11.95) demonstrate that, in all cases (and with significant safety margins), the required safe separation distances between Class 1 SSCs and explosively hazardous chemicals, or those chemicals that have the potential to form pool fires in the event of loss of containment is satisfied.

Plant Gas System Hydrogen Assessment

Hydrogen is used in the Turbine Building for cooling the generator and in the AB for de-oxygenation of water stored in the Condensate Storage Tank (CST) and water discharged from the Demineralised Water Storage Tank (DWST).

Hydrogen is sourced from the liquid hydrogen storage tank located in the PGS storage area, which is to be located outside and away from the west-side of the Turbine Building.

The hydrogen bulk storage vessel will be charged with liquid hydrogen from bulk delivery via a transport trailer. The details of the transport trailer, consignment sizes and local management arrangements to maintain liquid hydrogen to minimum quantities are site-specific and, hence, these will be addressed during the site specific licensing process.

The hydrogen bulk storage facility is comprised of:

- One liquefied hydrogen cryogenic storage vessel and cylinder filled with liquefied hydrogen per power generating unit;
- Vapouriser;
- Interconnecting piping, fittings, valves and gauges.

The cryogenic storage vessel will be double-skinned and comprise of both an inner and outer vessel with insulation in between.

As it is postulated that a hydrogen release could occur from the PGS, an assessment of the relevant mechanisms for and consequences of hydrogen release has been undertaken (Reference 11.96) to determine the minimum safe separation distance required between the PGS (and associated storage plant) and safety-related SSCs. Credible release mechanisms include:

- Catastrophic vessel failure;
- Catastrophic pipework failure (such as a guillotine break);
- Loss of hose connection (during filling operations);
- Small leaks (at valves and glands, or from holes in the filling hose).

The hydrogen release assessment has been undertaken using the MEM. It is noted that the consequences of small leaks are bounded by catastrophic vessel and pipework failures and, as filling operations are considered site-specific (i.e., covered during the site licensing process), the scope of the hydrogen release assessment is focused on catastrophic failures of the vessel and pipework only.

The hazard to SSCs from a hydrogen flash fire is judged not to be significant compared to the potential damage caused by the blast overpressure.

The PGS is located in the yard area outside of the Nuclear Island. Class 1 SSC are only located inside of the Nuclear Island; in order for Class 1 SSC to be damaged by an explosion originating external to the NI, the resultant overpressure must exceed the withstand of the NI exterior walls.

The hydrogen gas explosion evaluation (Reference 11.96) has determined a safe separation distance, from the centre of the cloud, of 187 m (614 ft). Locating the cryogenic hydrogen storage vessel at an approach no less than this distance will ensure that the NI walls resist the overpressure.

11.5.4.4 Hazard Schedule

The internal explosion hazard schedule (see Table 11.5-2) has been prepared based on the results of the analyses of explosive atmospheres. In accordance with relevant international guidance (Reference 11.23), the explosion hazard analyses have considered an explosion wherever the possibility exists for a flammable atmosphere to form.

The hazard schedule is presented in tabular form providing a concise and comprehensive summary of the postulated explosion events, their significance and how the AP1000 plant is designed to cope with the hazard.

11.5.4.5 Discussion of Results

The analysis concluded that there are no internal explosion hazards which could result in the loss of all divisions of Class 1 SSC delivering a Category A safety function. Further, the potential hazard to operators required to undertake actions in support of Category A safety functions is low.

11.5.5 Sensitivity of Results and Cliff Edge Effects

The approach to internal explosions does not lend itself to the consideration for cliff edge effects. The inherent design features respectively prevent, detect, protect and control the risk

of an internal explosion. Design features such as conservative safe distance, or redundant detection equipment contain enough margins to keep the internal hazard in-line with analysed scenarios. It is therefore determined that cliff edge effects are not a concern for internal explosion hazards.

11.5.6 Combined Hazards Discussion

The internal explosion hazard analyses consider, on a deterministic basis, an explosion occurring in each of the rooms with a potential source for generating an explosive atmosphere.

The consideration of credible combinations of internal explosion with other postulated initiating events likely to occur independently of an explosion is considered in section 11.12. A separate document, Reference 11.75, provides a coherent approach across all internal hazard types e.g., fire, missiles, dropped loads, flooding.

Combinations of independent internal and external hazards (e.g., internal explosion and extreme low temperatures) are considered to be outside of the design basis and have not been explicitly considered in this report. However, compliance with relevant equipment and structural design codes ensure that combinations of internal hazards with the relevant abnormal operating occurrences (including environmental hazards) are addressed.

Discussion of combined and consequential hazards is presented within the Combination of Hazards section (see Section 11.12).

11.5.7 ALARP Assessment and Discussion

Deterministic analysis of postulated, design basis, internal explosions shows that the Category A safety functions will be available to provide a safe shutdown following the worst case postulated initiating event.

A number of hazardous substances are required to operate the reactor and maintain a safe state. Wherever possible, these hazardous substances are located outside the Nuclear Island and therefore are remote from the Class 1 SSC delivering Category A safety functions. Where it has not been possible to locate the bulk chemical supplies outside of the NI, the quantity has been minimised so far as is reasonably practicable.

The approach to managing hazardous substances within the Nuclear Island has been to prevent the formation of flammable atmospheres. This has been achieved through the use of containment (e.g., piping), mechanical ventilation and alarms set at a level below the LFL for the relevant substance.

With the exception of the battery rooms, which would continue to evolve hydrogen, faults leading to the release of hydrogen would result in a hydrogen concentration above the LFL but below the LEL. At a concentration of less than 8 v/v % in air, hydrogen burns in a single direction with little or no overpressure. At concentrations of 8 v/v % and above, hydrogen will burn in all directions but the flame speed is low. Only where there is congestion or a concentration of 18 v/v % or more would the ignition result in significant overpressures. Within this assessment, it has conservatively been assumed that any release above the LFL would result in significant overpressure.

Outside of the Nuclear Island, the same, preventative, approach has been adopted. However the reliance is instead placed on the structural integrity of the Nuclear Island external walls to resist the effects of an explosion.

It is further anticipated that, during site licensing, a DSEAR (Reference 11.109) assessment will be undertaken and hazardous areas classified in accordance with BS-EN-60079 (Reference 11.98). Where a hazardous area is classified, equipment will be categorised according to the hazardous area and the nature of the flammable substance (e.g., ignition temperature and energy) such that the potential for a flammable atmosphere to form and subsequently be ignited is minimised.

Since the Category A and supporting post 72-hour Category B safety functions can be adequately maintained despite the hazard posed from internal explosions, the safety of the plant is ensured. It is judged that only minimal safety benefit may result from the introduction of further design measures to reduce the risks further and on this basis the risk from internal explosions is considered to be broadly acceptable and ALARP.

11.6 Internal Missiles

11.6.1 Introduction

The Internal Missiles Hazards Analysis (Reference 11.110) has being performed in order to define the safety case in determining the effects to Systems, Structures, and Components (SSCs) as resulting from an internally generated missile arising within the AP1000 plant. Internally generated missiles are considered arising from postulated initiating events such as the failure of pressure vessels, the failure of valves, and the failure of high speed rotating equipment. AP1000 has been designed such that an internal missile within the design basis will not compromise the ability of the plant to safely shutdown the reactor. The Category A safety functions and supporting post 72-hour Category B safety functions required for safe shutdown following an internal missile scenario are shown to be maintained through a combination of claims made on equipment design, room barriers and the separation and segregation of safe shutdown SSCs.

Potential missile sources that have the potential to directly damage equipment containing SSCs required to deliver Category A or supporting Category B safety functions have been identified on a deterministic basis. The barriers that protect the Category A and supporting post 72-hour Category B safety functions are identified. These are then evaluated to confirm that they will provide protection against the identified missiles. The following credible postulated sources of internally generated missiles having sufficient energy to create a hazard to Class 1 SSCs considered are:

- Turbine disintegration
- Rotating components
- Pressurised components
- Valves
- Tanks

Additionally, rooms assessed for internal missiles are identified to demonstrate separation of sources from SSCs required as delivering diverse or redundant functions. The demonstration of the response to an internal missile hazard is performed using the following conservative assumptions:

- SSCs protection within a compartment with a potential missile source is not credited,

- SSCs within a compartment are assumed to fail (gross failure) as a result of missile strike,

- Generating an internal missile is credible in any compartment with a potential missile source,

- Hazard assessments evaluate the operating plant state applicable to each missile as appropriate defined by the missile source. Structural barriers assessed as missile barriers are claimed to prevent a missile exiting its originating compartment.

The overall scope of the internal missile analysis requires evaluation of missile sources within the Nuclear Island (NI), and in adjacent buildings for potential impact on the NI. The assessment concludes that the function of essential SSCs are protected from the effects of an internally generated missile through a combination of claims made on equipment design, structural barriers and, where necessary, separation of SSCs required to deliver safe shutdown.

11.6.2 Internal Missiles Claims, Arguments and Evidence

This section presents the key claims, arguments and evidence made in relation to internal missile hazards on the AP1000 design.

SSCs important for nuclear safety must be protected from dynamic effects within the plant, including those of internally generated missiles. An internal missile hazard has as a potential result the development of a transient from the normal operating state of the reactor which may potentially contribute to an uncontrolled radiological release. In response to such a transient, it may be necessary to shutdown the reactor and return it to a safe shutdown state. Depending on the nature of the transient, there are a number of courses of action using Category A or supporting Category B SSCs in placing the reactor into a safe state. Availability of the SSCs required to deliver the Category A or Category B post 72-hour safety functions ensures that the reactor can be safely shutdown in accordance with the design intent.

Therefore, protecting SSCs important to safety from the adverse effects of a hazard, such as an internally generated missile, prevents both failure of systems required for safe shutdown of the reactor and hence potentially significant uncontrolled release of radioactivity. This forms the basis of the high level claim as stated below.

11.6.2.1 Claims Overview

The high level claim has been divided into claims for Prevention and Protection and is broken down into Sub-Claims within these divisions. Detailed arguments and evidence for each Sub-Claim are presented in (Reference 11.110).

11.6.2.2 High Level Claim

Claim IH-5.0: **An internal missile event within the design basis does not prevent delivery of the Category A safety functions and supporting post 72-hour Category B safety functions necessary to respond to the postulated event.**

Within the AP1000 design, this has been achieved through:

- Prevention: Missiles are deterministically assumed to occur as a result of a gross failure of SSCs, except those justified as Highest Safety Significance (Reference 11.9) and those where valves are qualified to prevent missile generation.

- Protection: Passive protective measures are incorporated in the AP1000 to protect SSCs that deliver Category A and post 72-hour Category B safety functions from internal missiles.

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.6.2.3 Prevention Claims and Arguments

Missiles are deterministically assumed to occur as a result of a gross failure of SSCs, except those justified as Highest Safety Significance (Reference 11.9) and those where valves are qualified to prevent missile generation. The following claims and Sub-Claims and arguments are defined in support of the overall high level claim:

Claim IH-5.1: **Internal missiles have been eliminated from the design so far as reasonably practicable.**

Sub-Claim IH-5.1.1: **Internal missiles generated from failure of rotating equipment are eliminated by design so far as reasonably practicable.**

Argument IH-5.1.1: **To prevent abnormal operation and failures by design, the material selection, design, build and verification requirements for a selection of SSCs ensure that the total energy contained in the rotating elements of the SSC is insufficient to move the mass of rotating parts so that it breaches the equipment housing. Therefore a potential missile is retained within the SSCs equipment housing and does not result in a missile external to the SSC.**

Within containment, catastrophic failure of rotating equipment, such as pumps, fans, and compressors, but excluding the reactor coolant pumps, leading to the generation of an internal missile impacting Class 1 SSCs, is not considered credible. These components are designed to preclude having sufficient energy to move the masses of their rotating parts through the housings in which they are contained. In addition, the Design Criteria for the Protection from Internally Generated Missiles, Reference [11.145] states that the material characteristics, inspections, quality control during fabrication and erection, and prudent operation as applied to the particular component will enhance prevention.

The maintenance and inspection program for the turbine assembly and valves is based on turbine missile probability calculations, operating experience of similar equipment and inspection results. The methodology for analysis of generating missiles from fully integral rotors identifies that stress corrosion cracking is the dominant mechanism for determining missile generation from the turbine. The probability of rotor burst by

this mechanism does not exceed 1 x 10-5 per year, based on conservative analysis, Reference [11.113].

Sub-Claim IH-5.1.2: **Internal missiles will not be created from SSCs which are classified as HSS.**

Argument IH-5.1.2: **Internal missiles will not be created from SSCs which are classified as HSS. The most demanding of these, HSS, is broadly equivalent in definition to the term Incredibility of Failure (IoF), used within the UK structural integrity community to describe components where the claim is that the likelihood of gross failure is so low it can be discounted.**

The basis for the component classifications determined using the process are detailed in Appendix A of Reference [11.72]. Based on the results of this evaluation, the following AP1000 plant components are to be treated as HSS components include the Reactor Vessel, Pressuriser, Steam Generator Secondary Shell, Tube Sheet and Channel Head.

Sub-Claim IH-5.1.3: **The failure of valve stems, bonnets and thermowells in SSCs where the stored energy is high will not lead to internal missiles.**

Argument IH-5.1.3: **For the AP1000, valves will be constructed with missile retention and preventative measures in order to prevent internally generated missiles. The material selection, design, build and verification requirements for valve stems, bonnets and thermowells incorporate measures to prevent them from becoming credible missiles. Threaded connections in high-energy systems are avoided wherever possible.**

The AP1000 Valve Missile Protection report, APP-GW-M3C-013, Reference [11.146], defines how valves in high energy systems are designed to prevent missiles, as required by the AP1000 Design Criteria for the Protection from Internally Generated Missiles, Reference [11.145]. A detailed discussion of the criteria applied to valves is presented in Section 5.4.2.1 of Reference [11.110].

Sub-Claim IH-5.1.4: **Nuts, bolts and nut bolt combinations have only a small amount of stored energy and are not considered credible missiles.**

Argument IH-5.1.4: **Potential missiles are not considered a credible hazard to Class 1 SSCs when there is insufficient energy available to produce a missile, or if by design the probability of creating a missile is remote. The stored energy in ejected nuts, bolts or nut and bolt combinations is low and will not breach the internal barriers or containment.**

Sub-Claim IH-5.1.5: **Gross failure of control rod drive mechanism housing is not considered a credible missile source.**

Argument IH-5.1.5: **Gross failure of control rod drive mechanism housing is not considered a credible missile source.**

Equipment within the containment is designed to prevent generation of internal missiles as required by the Design Criteria, Reference [11.145]. Prevention of Gross failure of a control rod drive mechanism housing with sufficient energy to allow a control rod to be ejected rapidly from the core is detailed in Section 4.2.1.1 of Reference [11.110].

11.6.2.4 Protection Claims and Arguments

Passive protective measures have been incorporated in the AP1000 design to protect SSCs that protect Category A and post 72-hour Category B safety functions from internal missile.

This claim is based the provision of structural barriers that prevent a missile originating in one area of the AP1000 from impacting the SSCs outside that area, that are required for delivery of the Category A and supporting post 72-hour Category B safety functions. The following Sub-Claims and arguments are made to achieve the overall high level claim:

Claim IH-5.2: **SSCs required for delivery of Category A and supporting Category B safety functions are protected by barriers that will prevent missile penetration.**

Sub-Claim IH-5.2.1: **The consequences of missiles will be protected through the use of passive barriers to limit the impact to and/or loss of a Category A or post 72-hour Category B safety functions.**

Argument IH-5.2.1: **The consequences of missiles will be protected through the use of passive barriers to limit the impact to and/or loss of a Category A or post 72-hour Category B safety functions.**

Missile barriers and protective structures are designed to withstand and absorb missile impact loads to prevent damage to safety-related components as detailed in the AP1000 Civil/Structural Design Criteria, Reference [11.107]. Correct application of these design criteria protect the Category A and post 72-hour Category B safety functions contained within the NI.

Sub-Claim IH-5.2.1.1: **SSCs are protected from missiles through internal barriers such as walls, floors and ceiling structures. Gross failure is assumed for all SSCs within the barriers affected by the missile.**

Argument IH-5.2.1.1: **The locations of the SSCs that provide the Cat A and supporting Cat B safety functions relative to the missile sources have been identified, Reference [11.112]. The barriers that provide protection to the SSCs have been identified and the potential missiles categorised according to mass, shape, size, velocity, orientation and trajectory. The missile impact energy has therefore been assessed and the barrier withstand are therefore known and the protection claimed from the barrier can be determined using the Missile Barrier Design Procedures, Section 4.3.1 of Reference [11.107].**

The frequency of missile generation from all sources has been identified and the resulting consequences of the missiles

assessed. The barriers that will protect the SSCs providing Category A and supporting Category B safety functions are identified in the Hazard Barrier Matrix, Reference [11.9]. It is demonstrated by the missile hazard assessment, Reference [11.112] that these barriers provide adequate protection from an internal missile event.

Sub-Claim IH-5.2.2: **Orientation of equipment will protect delivery of Category A or post 72-hour Category B safety functions in the NI.**

Argument IH-5.2.2: **The turbine is oriented such that its shaft axis is perpendicular to the NI. The orientation of the turbine applies relevant good practice, minimising the possibility of a missile fragment from impacting the NI. Protection of the NI safety functions from internal missiles due to orientation of equipment is further detailed in Section 4.2.2 of Reference [11.110] and Reference [11.112].**

11.6.2.5 Mitigation Claims

Mitigation actions are not directly claimed for Internal Missiles because the passive SSCs are designed to independently mitigate Design Basis Accidents (DBAs) for the initial 72 hours following an initiating event. This capability is presented in Chapter 10.

11.6.3 Internal Missiles Safety Case Summary

11.6.3.1 Introduction and Overview

The UK AP1000 safety design approach adopted for the internal missile hazard is composed of a range of complementary approaches. These are applied as appropriate in order to minimise the frequency of an internal missile occurring and reduce the potential disruption to nearby Class 1 SSC.

Missiles are assumed to occur as a result of a gross failure initiating event for assessment, except those justified by the Structural Integrity Highest Safety Significance (HSS) classification (Reference 11.9) and those where equipment is qualified to prevent missile generation. For instance, use of valves designed and constructed with missile retention and preventative measures which prevent the generation of missiles are not considered missile sources. Such passive protective measures have been incorporated in the AP1000 design to protect SSCs that deliver Category A and post 72-hour Category B safety functions from internal missile faults. In this regard, the consequences of missile hazards are contained through the use of passive barriers, thus limiting impacts to, and loss of, a safety function.

With respect to generation of turbine missiles, the turbine generator is located north of the NI with its shaft oriented north-south according to relevant good practice (11.114). Orientation of the steam turbine provides a level of protection for the delivery of Category A or post 72-hour Category B in the NI, since postulated turbine missiles will be projected essentially perpendicular to the shaft.

The role of gross failure in the internal missiles case pertains to all missile sources, except where prevention claims are made for missile sources. In summary, the safety case accepted such prevention claims as based on the following:

- Incorporation of design features in components to prevent missiles from being generated externally to the component
- Orientation of components, such as the main turbine, to direct any missile away from Safety Class 1 SSCs
- Location of Safety Class 1 SSCs outside the zone of influence of a potential missile
- Protection where practicable using either distance or separation by a structural barrier

Further, the AP1000 design employs a mixture of the approaches stated above to form levels of defence which reduce the likelihood of an internal missile generated from equipment and also reduces the consequences of an internally generated missile to ALARP. It is argued that the gross failure of equipment within a segregated area because of a missile impact, regardless of orientation, is entirely consistent with, and bounded by, other hazard analyses (i.e., internal fire), in assuming that all equipment in such an area is lost as a result of the hazard. In this manner, consistency between other areas of the safety case is maintained.

11.6.3.2 Applicable Codes and Standards

The following guidelines and methods are used in the evaluation of the Turbine Missile Safety Case:

- R3
- Modified NDRC
- Hagg & Sankey (Reference 115)

Missile barriers and protective structures are designed to withstand and absorb missile impact loads in order to prevent damage to Class 1 SSCs.

The appropriate design codes and standards are provided in the AP1000 Civil/Structural Design Criteria (Reference 11.107). To evaluate the AP1000 codes and standards against UK expectations, the AP1000 codes and standards have been organised by the relative safety significance of the SSCs to which they have been applied. To support this organisation (Reference 11.26) describes the process for categorisation of safety functions and classification of SSCs. The classification methodology defines Safety Categories (A, B or C) which are based on how important each safety function is for maintaining nuclear safety. This leads to the Safety Classes (1, 2 or 3) which indicate the significance of an SSC to deliver the relevant safety function.

The AP1000 Equivalence/Maturity Study of US Codes and Standards (Reference 11.25), provides an assessment of the applicability of US-based codes and standards to UK, European and international codes and standards in the present Topical Report. It provides a clear and auditable demonstration that the applicable codes and standards to support the design substantiation of UK Class 1 SSCs have been identified.

Detailed discussion of applicable codes and standards is presented in Chapter 5.

11.6.3.3 Redundancy and Segregation

The location and level of redundancy of Class 1 and 2 safety systems within the plant is such that complete loss of operability of the SSCs within a room or compartment because of

disruption resulting from an internally generated missile would not result in loss of the Category A safety function. Redundant and segregated Class 1 or Class 2 SSCs are located solely within the NI. Inside buildings, the AP1000 compartmentalised design minimises the probability of internally generated missiles affecting SSCs. Should an internal missile occur as affecting Class 1 or Class 2 SSCs, redundant equipment is located elsewhere.

Measures applied with respect to redundancy, separation, and segregation ensure that missiles cannot prevent Class 1 SSCs from delivering their Category A functions. These measures consist of the following:

- The design of the AP1000 plant ensures multiple means of delivering the Category A safety functions, such that a missile cannot prevent delivery of the Category A function.

- Within the Containment there is segregation and separation of Class 1 equipment. This is provided by a combination of barriers formed by the walls and floors of compartments and the distance between systems providing redundant means of delivering the Category A functions.

- Outside the Containment there is sufficient equipment redundancy, segregation, and protection such that all of the equipment in a single room can be lost without preventing delivery of the Category A safety functions.

- The Class 2 systems are an additional means of delivering Category A safety functions. They provide a level of defence in depth. The Class 2 system designs also feature redundancy. The Category A functions provided by these systems are summarised in Section 3.5 of Reference 11.110.

- In the immediate vicinity of a missile, barriers may be employed to limit the zone of influence of the missile such that no Class 1 equipment is impacted. The civil engineering structures provide structural support to the SSCs, but also act as suitable barriers for a number of functions, including preventing accidentally generated missiles from travelling to a location where significant harm could occur.

The plant is designed such that it can be operated with sufficient levels of protection in place to ensure that internally generated missiles will not prevent delivery of Category A safety functions. This defence in depth is provided by:

- The conservative design, manufacture, maintenance and operation of equipment in accordance with safety margins (through compliance with recognised design codes) appropriate engineering practices and monitoring of the quality of these aspects.

- The use of structural barriers to limit the path of any missile generated to areas where damage will not prevent the delivery of Category A safety functions.

- Sufficient redundancy and defence in depth is provided to ensure that even if there is the loss of any SSC as a result of an internally generated missile the Category A safety function can still be delivered.

The plant is designed such that it can be operated with sufficient levels of protection in place to ensure that internally generated missiles will not prevent delivery of Category A safety functions. This defence in depth is provided by:

- The conservative design, manufacture, maintenance and operation of equipment in accordance with safety margins (through compliance with recognised design codes) appropriate engineering practices and monitoring of the quality of these aspects.

- The use of structural barriers to limit the path of any missile generated to areas where damage will not prevent the delivery of Category A safety functions.

- Sufficient redundancy and defence in depth is provided to ensure that even if there is the loss of any SSC as a result of an internally generated missile the Category A safety function can still be delivered.

11.6.4 Internal Missile Assessment Approach

For a detailed description of each missile source refer to Reference 11.110. Missile sources are identified and analysed in subsection 11.6.6.

11.6.4.1 Interface with Other Internal Hazards

The UK AP1000 Nuclear Island Missile Penetration Calculation, (Reference 11.111) consider, on a deterministic basis, a single internal missile event and the consequential impact on SSC in the affected plant areas.

The consideration of credible combinations of internal missiles with other postulated internal hazards likely to occur independently of an internal missile hazard is presented in Section 11.12 and provides a comprehensive approach across all internal hazard types (e.g., fire, explosion, flooding, dropped loads, pressure part failure).

11.6.4.2 Conclusions

No analysis is required for Type I rooms that contain either Safety Class 1 equipment with no potential missiles, or Safety Class 2/3 equipment with no potential missiles.

The Type II and III analysis performed in (Reference 11.114) identifies postulated internal missile penetration depths in all relevant rooms of the Auxiliary and Shield Buildings. The integrity of all barriers within the NI is maintained following an internal missile event. This information is presented in (Reference 11.114). The bounding case for each equipment group (valves, tanks, rotating equipment) has been presented for each room studied along with the minimum thickness of the room barriers (i.e., North, South, East, West Walls, Floor and Ceiling for typical rooms). As demonstrated the minimum barrier thickness is adequately sized to withstand the bounding penetration depths for potential missiles into neighbouring rooms with Class 1 shutdown SSCs.

11.6.5 Internal Missiles Analysis

11.6.5.1 Identification of Missile Sources

This section provides a summary of internal missile hazard analyses, as presented in the AP1000 Nuclear Island Missile Penetration calculation, (Reference 11.111) and the UK AP1000 Turbine Missile Assessment (Reference 11.113). The approach taken followed three aims: to fully understand the consequences of a potential postulated missile, to establish an extent of condition, and to document fulfilment of all relevant safety requirements, licensing claims and design features of an AP1000 Plant. From these references, the

systematic assessment of potential sources of a postulated missile determined the following likely origination sources:

- Turbine disintegration
- Rotating components
- Pressurised components

The effects of missiles originating from these sources depend on their physical characteristics, i.e., mass, shape of the impinging cross-section, and on the constraints acting on the component hit by the missile. The effect of the missile depends heavily on these variables, along with flight path and whether or not the projectile rotates or tumbles. For design purposes, it is more conservative to overestimate the velocity of the missile than to underestimate it. Simple conservative methods for calculating the velocities of postulated missiles, along with potential mass, are presented in References 11.114 and 11.115 to provide insight into the analysis.

Since structural/mechanical components for light-water reactor power plants are constructed of concrete and steel, penetration calculations were conducted to understand how a missile will be contained within its specific housing/room. All penetration formulas for concrete and steel are based on normal impact. When a missile strikes a target at an angle, the penetration depth is naturally reduced. Gross failure is assumed for all SSCs within a room containing a missile source.

11.6.5.2 Assessment of Internal Missiles

Type I Failure Analysis

Analysis is not required in rooms containing Safety Class 1 equipment or Safety Class 2/3 equipment with no potential missile sources.

Type II Failure Analysis

Valve Missiles

In the case of a valve missile, such as a valve stem that is acted upon by a constant force stream of fluid for a certain distance, a modified version of the Bernoulli's Equation can be used to establish a relationship between potential energy and kinetic energy as shown in the below equations :

$$\text{Kinetic Energy} = \text{Potential Energy}$$

$$\frac{1}{2}mv^2 = pAL$$

$$v = \sqrt{\left(\frac{2pAL}{m}\right)}$$

Where v is the initial velocity exerted onto a valve stem (ft/sec), p is the pressure of the fluid (psi), A is the cross-sectional area of the valve stem (in^2)[12], L is the length of the valve stem (ft)[13] and m is the mass of the missile, i.e., valve stem (lb-sec^2/ft, or lbm)[14].

For all valves analysed, failure is deterministically assumed. Utilising the valve stem's initial velocity, and the modified NDRC equations (Reference 11.110), the integrity of all boundaries for a particular room must retain the missile; i.e., the full missile penetration depth is less than the thickness of a given wall. Correspondingly, since the direction of a missile is unknown, gross failure of all SSCs within the originating room containing missile sources is assumed.

The summary table in (Reference 11.111) identifies the minimum boundary thicknesses and the bounding penetration for the components for a given room. From this reference, it can be seen that the integrity of each boundary wall is satisfied in protecting against the propagation of an internal missile generated by a valve failure.

Pressure Vessel Missiles

The rupture of a pressure vessel operating at high pressure can lead to large high velocity missiles as either random fragments of unknown mass and cross-sectional area or entire parts of the vessel. In the case of a cylindrical vessel, these missiles may include such large components as the top head, the bottom head, or longitudinal segments from the side wall(s). Accurate calculation of possible random fragment velocities and masses are necessarily difficult to determine. Therefore, the conservative approach is taken as based on the assumption that all stored energy within the vessel is converted into kinetic energy and applied to the largest missile mass possible, i.e., the entire tank. The change of internal energy into kinetic energy is captured by assuming an isentropic expansion of the fluid from its operating pressure to standard atmosphere, represented by total change in enthalpy. By assuming an isentropic process, no energy will be lost by heat transfer, ensuring a conservative calculation. Kinetic energy equations may then be used to evaluate a tank's initial velocity;

$$\delta H = (Volume\ of\ Tank)(\delta p)$$

$$\delta H = KE = \frac{1}{2}mv^2$$

$$v = \sqrt{\left(\frac{2KE}{m}\right)}$$

Where v is the initial velocity exerted onto a tank (ft/sec), p is the pressure of the fluid (psi), KE represented the kinetic energy (ft-lbs, ft-kips), H is the enthalpy (ft-lbs, ft-kips) and m is the mass of the missile, i.e., tank (lb-sec^2/ft, or or lbm)[15]

12. A conservative assumption of 1.5 times the connecting pipe nominal pipe diameter is used as the cross-section area of the valve stem in this calculation.
13. The internal length of all valve stems is assumed as 1.0 ft. The internal length of the valve stem is used to calculate the total work done during ejection of the valve stem missile.
14. A conservative assumption of using the entire mass of the valve is used as the mass of the missile in this calculation.

For all tanks analysed, a deterministic failure is assumed. Utilising the tank missile initial velocity and the modified NDRC equations (Reference 11.110), the integrity of all boundaries for a particular room must be maintained; i.e., the full penetration depth is less than the thickness of a given wall. Gross failure of all SSCs within rooms containing missile sources is assumed.

Reference 11.111 identifies the minimum barrier thicknesses and the bounding penetration from the pressure vessel missile components in a given room. It is demonstrated that the integrity of each barrier is satisfactory to protect against an internal missile generated by a pressure vessel failure.

Rotating Equipment Missiles

In analysing missiles from rotating machinery, varying assumptions are required in determining the missile characteristics; i.e., the impeller/flywheel/etc. Within the internal missile safety case, the size and mass of the postulated rotating equipment projectile have been conservatively assumed to overpredict both the size and mass. Characteristics of impact, such as shape factors and the percent of mass converted into a missile, have been established with probability density functions and the frequency of occurrences.

To eliminate possible ambiguity, and ensure further conservative results, the potential rotating equipment missile assumes that the full rotor/impeller will construct the postulated missile. The influence of the rotating component housing was not considered, which removes any calculations of steel perforations. The velocity of the missile from rotating equipment can be calculated using;

$$v_{missile\ source} = \left(\frac{\pi}{720}\right)(d)(overspeed\ factor)(\omega)$$

Where $v_{missile\ source}$ is the velocity of the origination point (i.e., max velocity of a rotating impeller), d is the diameter of the missile source, over speed factor defines a factor for all throttling elements (equivalent to 1.2 for the AP1000) and ω is the rotation speed of the missile source.

It is understood these assumption do not adequately depict a realistic outcome, but rather demonstrate the strength of each boundary and purpose of separating dual system paths by means of civil/structural barriers. With the rotating equipment missile velocity known, and utilising the modified NDRC equations defined in Section 6.2.4.1 of Reference 11.110, the integrity of all barriers for a particular room must be satisfactory, i.e., the full penetration depth is less than the thickness of a given wall.

Each summary table in Reference 11.111 identifies the minimum boundary thicknesses and the bounding penetration from the components in a given room. This reference demonstrates that the integrity of each barrier is satisfactory to protect against an internal missile generated by rotating equipment failures.

15. A conservative assumption of using the entire mass of the tanks (dry weight) is used as the mass of the missile in this calculation

Separation of Class 1 Equipment with Redundancy

In cases where a postulated missile eliminates the use of a Class 1 component, AP1000 plant design ensures multiple means of delivering the Category A safety function(s). Therefore, all Type II analysis results provide evidence of redundant paths that adequately separate Class 1 components in the case of single active component failure.

11.6.5.3 Hazard Schedule

The principal purpose of the hazard schedule is to identify the safety-related systems called upon for each internal missile initiating event and the overall protection claims being made for those systems.

The general structure of the hazard schedule presented within this section is as follows.

- Column 1 of the schedule designates all rooms in which the potential for missile generation is postulated to exist.
- Column 2 of the schedule lists the systems contained within each designated room that present a missile generation hazard (i.e., the sources of missiles).
- Columns 3 and 4 of the schedule list and describe the essential safe-shutdown (SSCs) contained within each designated room (i.e., the safety systems that could be impacted by a missile).
- Columns 5 and 6 of the schedule identify the 'at risk' safety functions (including UK categorisation and SSC classification) provided by the essential safe-shutdown systems contained within each designated room and the associated unmitigated consequences of failure to deliver the safety functions.
- Column 7 of the schedule identifies the main passive safety features that provide protection for essential safe-shutdown systems against internal missiles.
- Column 8 of the schedule lists the rooms or divisions that provide redundant SSCs or an explanation of how the Category A safety function is maintained (i.e., by segregation and separation or other safety features of the AP1000 design).
- Column 9 of the schedule lists additional defence-in-depth safe-shutdown SSCs provided to support maintenance of Class 1 essential safe-shutdown safety functions.
- Column 10 provides any extra information deemed relevant to the assessment.

The hazard schedule is presented Table 11.6-1.

11.6.5.4 Discussion of Results

The method of analysing internal missile hazards is detailed in Reference 11.113. Based on the calculations as presented in References 11.111 and 11.112, a detailed analysis of the protection for internal missiles within the NI has been performed. Concrete penetration depths generated by internal missiles from valves, tanks and rotating equipment are provided in these references.

The calculated penetration depths have been used to validate that the barriers within the NI are resistant to failures from a missile strike. Protection from damage to Class 1 SSCs supporting plant safe shutdown in adjacent rooms is adequately provided whilst the barrier integrity is maintained.

The analysis further demonstrates that Class 1 SSCs which are potentially affected during an internal missile scenario have sufficient redundancy elsewhere outside the missile impact range to ensure the delivery of the Category A or supporting post 72-hour Category B safety functions, required for safe shutdown.

The following sections present a summary of the analysis.

Containment/Shield Building

The AP1000 Shield Building, part of the AP1000 NI, is a steel-concrete-steel composite construction and constitutes a Class 1 3 hour fire barrier which separates it from the AB. Within the Shield Building is the steel Shield Building which is the containment for AP1000 and this fabrication is used in structural modules inside the Containment. The structure and the construction of both of these are discussed in detail in Chapter 16.

The Containment/Shield Building comprises a series of areas separated from one another using a combination of distance and physical structures. Many of the rooms (e.g., each of the SG rooms) are modular steel-concrete composite constructions which form significant physical barriers from other rooms for much of their height. However, complete segregation cannot be achieved inside Containment given the need to maintain the free exchange of gases for purposes such as passive Containment cooling.

In the internal missile hazard analysis it is assumed that a missile within a room affects all equipment within it (including the Class 1 SSCs) and the impact on AP1000 to deliver the Category A safety functions is assessed. Given the separation, and the redundancy provided outside the missile impact reach, the Category A and supporting post 72-hour Category B safety functions can be safely delivered following an internal missile event.

Auxiliary Building – Non-radiologically Controlled Areas

The non-radiological area of the Auxiliary Building comprises the portion of the NI to the north of the Shield Building. The building houses SSCs associated with the auxiliary functions that do not directly involve radioactive material but have been designed to meet their nuclear safety functions.

For segregation purposes, this building is segregated into a series of areas, each of which is enclosed by barriers. The barriers are designed to prevent a missile from penetrating from the room of origin into another area. Therefore potential safety equipment located in a neighbouring room is protected from the internal missile.

In the internal missile hazard analysis it is assumed that a missile generated within a given room potentially affects all equipment within it (including the Class 1 SSCs). Given the physical segregation, and the redundancy provided, the Category A and supporting post 72-hour Category B safety functions will be delivered following an internal missile event.

Auxiliary Building – Radiologically Controlled Areas

The radiologically controlled portions of the Auxiliary Building, located to the south side of the Shield Building, is designed to handle and store nuclear fuel outside of Containment as

well as holding the intermediate level radioactive waste, in the form of filters and spent ion exchange resin, and containing elements of the Liquid and Gaseous Radwaste Systems.

In the detailed internal missile hazard analysis it is assumed that a missile generated within a given boundary potentially affects all equipment within it (including the Class 1 SSCs) and, correspondingly, impacts the AP1000 to deliver the Category A safety functions. Based on the Internal Missile evaluations discussed previously, and the physical segregation and the redundancy provided, the Category A and supporting post 72-hour Category B safety functions will be delivered following an internal missile event. Therefore an internal missile initiating in an individual room within the radiologically controlled area of the Auxiliary Building will not prevent safe shutdown of the reactor.

Turbine Building

Within the equipment included within the AP1000 design, missiles originating from a turbine generator disintegration represent a significantly hazardous items due to the size and considerable energy or a potential missile.

The generation of an internal missile as a result of failure of a turbine rotor ('rotor burst') has the potential to impart significant kinetic energy into the turbine casing and, in the event of casing perforation, the missile has the potential to impact SSCs beyond the boundaries of the turbine. Failures of the rotor occur as a result of structural defects (stress corrosion being the dominant mechanism) or from excessive stresses created during over-speed operation.

The missiles from a turbine failure are divided into two groups:

- 'High trajectory' missiles – These are ejected in a predominantly upward direction and may cause damage if the descending missile strikes an SSC;

- 'Low trajectory' missiles (or 'direct' missiles) – These are ejected in a predominantly lateral direction directly towards SSCs.

High trajectory missiles would be directed up through the roof of the Turbine Building and then fall to earth under gravity. These missiles would not have sufficient energy to penetrate the Shield Building and are not considered credible missiles for the other on site buildings that house SSCs that deliver Category A or supporting post 72-hour Category B safety functions. The probability of an impact in the safety-related areas is the product of the probability of missile generation from the turbine, the probability that a high trajectory missile would land within a few hundred feet from the turbine (10^{-7} per square foot); and the area of the safety-related area. In the AP1000, the safety-related area is contained within the exposed roof area of the Containment Shield Building and the Auxiliary Building. Given this, the potential for a high-trajectory missile impacting safety-related areas of the AP1000 is much less than 10^{-7}. Based on this very low probability, the potential damage from a high-trajectory missile is not evaluated.

The turbine casing is designed to provide a level of missile containment capability in the unlikely event of rotor burst and subsequent missile generation. However, as a bounding case, the impact energy of a quarter-disk fragment from the last stage disk of the low pressure turbine has been evaluated using the Hagg and Sankey method (Reference 11.115) and are shown to be capable of turbine casing perforation.

Reference 11.115 evaluated the maximum velocity of a quarter-disk fragment at a 50 Hz turbine normal operating speed, design over-speed, and destructive over-speed, whilst noting that ductile burst of the rotor does not occur until 185% of normal speed

(Reference 11.113). At normal operating speed, a quarter-disk fragment is predicted to penetrate the turbine primary casing. For both the design and destructive over-speed conditions, the disk fragment will have sufficient energy to breach the turbine's protective outer casing. As stated previously, the casing would offer a significant degree of mitigation (i.e., absorption of kinetic energy) if impacted by a missile that possessed the minimum initial energy required to perforate the protective outer casing of the turbine. The AP1000 Internal Missile safety case does not credit this energy mitigation feature. In conjunction with structural calculations of wall 11.2, the turbine casing is determined to be a defence-in-depth feature.

The deterministic defence-in-depth provisions included within the design of the AP1000 to ensure essential safe-shutdown safety functions are maintained in the event of internal missile generation as a result of turbine rotor failure. These are:

- Adherence to applicable design codes, standards and criteria

  Turbine rotor integrity is ensured by appropriate material selection, design (including fracture toughness, over-speed protection and safety margin specification), manufacture, through-life testing and inspection, including quality assurance application at all stages. Via the combination of these measures, the probability of rotor burst is reduced to a level that is outside the design basis of the plant (i.e., to a frequency of occurrence that does not exceed 1E-5 per year).

  In accordance with the hierarchy of control for nuclear hazards, adherence to design codes, standards and criteria provides the first line of defence (prevention) against internal missile generation.

- Turbine orientation

  In accordance with relevant good practice as recommended in Reference 11.119, the turbine is oriented so that the axis of its shaft rotation is perpendicular to the NI. This orientation ensures that high-energy low-trajectory missiles generated on rotor disintegration are ejected within a limited range of angles essentially perpendicular to the axis of the turbine. As a result, turbine missile 'strike zones' are formed to either side of the turbine (by lines inclined at 25°, 45^0 and 90^0 to the turbine wheel planes and passing through the end wheels of the low-pressure stages), thereby defining areas from within which Class 1 essential safe-shutdown SSCs are excluded. The probability that a missile is directed away from the perpendicular decreases as the angle to the turbine axis decreases. In addition, for the AP1000 design, a significant safety margin (clearance angle) exists between the 25° turbine missile strike zone boundary and the bounding trajectory angles of the NI, as shown in Figure 11.6-1.

- Missile impact withstand capability of NI civil structures

  The Class 1 essential safe-shutdown SSCs incorporated within the AP1000 design are only located within the Containment /Shield Building and Auxiliary Building which, together, form the NI. These buildings are designed to protect the SSCs within them from seismic events and other external hazards, including tornado-induced missiles.

  In accordance with the hierarchy of control for nuclear hazards, the missile impact withstand capability of NI civil structures provide a third line of passive engineered safety protection against internal missile generation.

11.6.6 Sensitivity and Cliff Edge Effects

To combine insights from probabilistic safety analyses combined with deterministic methods, margins of safety were developed to avoid cliff edge effects. The results of sensitivity studies were analysed to assess appropriate safety margins throughout the planning phase of the both the concrete missile penetration calculation (Reference 11.114) and the turbine missile assessment (Reference 11.115).

As an example, in the concrete missile penetration calculation, missile diameters and weight were varied and used as inputs to the modified NDRC equation to determine the most conservative penetration depths. In the valve missile case, it was determined that the most realistic worst case valve missile to be examined was one with a weight of the full valve and a diameter of 1.5 times the connecting pipe size. In reality, a smaller diameter missile would penetrate concrete deeper, but it is not realistic to examine a smaller missile diameter with a weight of a full valve. The weight of the missile were maximised and the inputs into the modified NDRC formula provided results that were conservative and in line with what would be expected for worst case missiles. Similar sensitivity studies were performed for pressure vessel and rotating equipment missiles.

Margins of safety vary depending on the room analysed. For example, the passive barrier (walls) margin of safety to wall penetration for room 12306 is approximately 60 for valve missiles, approximately 50 for pressure vessel missiles, and approximately 4 for rotating equipment missiles. Refer to Reference 11.110 for more information.

In addition, for the turbine missile assessment, turbine missile weights were maximised to provide worst case results. A turbine missile mass of ~ 2800 kg consisting of a partial disc fragment was used rather than the largest turbine blade mass which has a weight of ~ 100 kg. The chosen weight creates a higher energy and thus, leads to a much deeper concrete penetration depth. Although the range of high-energy, low-trajectory turbine missile is limited due to the perpendicular orientation of the turbine axis to the Nuclear Island (Reference 11.114), various trajectory angles were studied for concrete penetration depth. Turbine missiles were considered to eject at 0, 45 and 90 degrees from the plane of rotation. Additional sensitivity analysis was conducted on the turbine with consideration of the missile generating both with and without the outer casing as to study the effects of the casing providing a passive barrier to slow down the missile.

For more information on the deterministic results using the highly conservative speed cases studied, refer to Reference 11.115.

11.6.7 Combined Hazards Discussion

The internal missile hazard analyses, summarized in Reference 11.110, deterministically evaluate a missile generated in each of the rooms having a potential internal missile source. The analysis also considers the potential penetration depth of a missile through structural barriers.

Consideration of credible combinations of internal missile with other postulated initiating events likely to occur independently of a missile is discussed in Section 11.12.

Combinations of independent internal and external hazards (e.g., internal explosion and extreme low temperatures) are considered to be outside of the design basis and have not been explicitly considered in this report. However, compliance with relevant equipment and structural design codes ensure that combinations of internal hazards with the relevant abnormal operating occurrences (including environmental hazards) are addressed.

Discussion of combined and consequential hazards is presented within the Combination of Hazards section (see Section 11.12).ALARP Assessment and Discussion

Deterministic analysis of postulated, design basis, internal missile events shows that all Class 1 SSCs will continue to provide their Category A safety functions following the worst case postulated internal missile scenario, even in the presence of an unrelated single failure elsewhere in the plant design. In the unlikely event that the Class 1 SSCs fail for some unrelated reason, the Category A and supporting post 72-hour Category B safety functions would be maintained by other, additional and redundant, Class 2 SSCs. The internal missile safety design for AP1000 has been achieved by:

- Removing potential missile sources by design where practicable with:
  - Relevant good practice using codes and standards
  - Pressurised part protection
  - Structural Integrity
- Ensuring that redundant SSCs are protected from a missile by utilising appropriate combinations of physical separation and passive barriers;
- Protect delivery of safety functions by favourable orientation of components, such as the main turbine, to direct any missile away from Safety Class 1 SSCs;
- Providing sufficient redundancy in the design such that if one train of protection fails as a result of an internal missile, coincidental with an unrelated single fault elsewhere, the safety functions continue to be provided by the equipment that remains unaffected;

This layered approach to safety is seen to reduce the threat from internal missiles to ALARP. The AP1000 design employs a mixture of the approaches stated above to form levels of defence in reducing the likelihood of an internal missile and also reduces the consequences of an internally generated missile to ALARP.

In support of the safety case presented for internal missiles, the room-by-room assessment within the Nuclear Island identifies the potential origination source and the impact on the AP1000 safety design. A summary of engineering design provisions are substantiated in Reference 11.110, including design modifications that improve the safety of the design as addressing changes to the Normal Residual Heat Removal System (RNS), Spent Fuel Pool Cooling System (SFS), and Component Cooling Water System (CCS) and Service Water System (SWS).

Since the Category A and supporting post 72-hour Category B safety functions is assured, even when considering the detrimental impact of internal missiles, the safety of the plant is ensured. It is judged that only minimal safety benefit may result from the introduction of further design measures to reduce the risks further.

11.7 Release of Toxic, Corrosive, or Flammable Material

11.7.1 Introduction

This section addresses the hazards originating from toxic, corrosive, or flammable materials that may be required to be stored onsite.

Hazardous non-nuclear materials could potentially threaten nuclear safety in the following ways should the hazard be accidentally released:

- By causing a fire (see Section 11.4 on internal fire)
- By causing an explosion (see Section 11.5 on internal explosions)
- By asphyxiating or poisoning personnel when those personnel are required to respond to a challenge to nuclear safety
- By chemical or corrosive attack on SSCs
- By causing brittle fracture of structural SSCs
- By causing a criticality excursion, should the material be a moderator and it spills onto nuclear material

Table 11.7-1 lists the principal hazardous materials present on an AP1000 plant site and where they are stored. The selection of chemicals and volumes may change based on site-specific requirements and operating experience; therefore, storage and use of chemicals not identified in this chapter or present in significantly greater concentrations or volumes will need to be justified on a site-by-site basis. Other intrinsically hazardous material is present onsite but in such small quantities that it poses a minimal threat.

11.7.2 Toxic, Corrosive, or Flammable Material Claims, Arguments and Evidence

11.7.2.1 Claims Overview

Those SSCs which deliver a Category A safety function are the principal means of ensuring nuclear safety in response to Design Basis Accident (DBA) plant faults (see Chapter 8).

Whether the internal hazard initiates a plant state fault or not, by ensuring that the ability to deliver Category A safety functions is maintained following an internal hazard, the internal hazards safety case aligns with the fault studies in demonstrating that the plant risk is broadly acceptable.

This section presents the claims, arguments and underlying evidence made in relation to toxic, corrosive or flammable material[16] hazards with the potential to impact safe shutdown.

11.7.2.2 High Level Claim

The following high level claim is made in relation to the internal hazard(s) presented by toxic, corrosive, or flammable material:

Claim IH-6.0: **Postulated internal hazards within the design basis presented by toxic, corrosive, or flammable material will not prevent the delivery of the Category A safety functions and supporting post 72 hour Category B safety functions necessary to respond to a postulated initiating event.**

16. The effects of flammable materials are bounded by the assessment of internal fires. For further details regarding the assessment of internal fires, refer to Section 11.2.

The SSCs claimed to provide post-72 hour support functions include only offsite procured SSCs and their associated Class 1 connections.

11.7.2.3 Prevention Claims

Hazardous materials are present in SSCs which, under normal conditions, provide adequate containment such that an unintended release is precluded. This is to say that the container itself will not degrade due to the presence of the hazardous material alone.

However, the deterministic assessment of hazardous materials cannot preclude their release. Given the variability in the design and integrity of hazardous material containers, no specific claim is made on the prevention of the hazard.

11.7.2.4 Protection Claims

It is recognised that, if released, hazardous materials may impair the ability of operators to correctly undertake safety related activities, such as respond to an alarm. All operations required to shut down the reactor plant can be performed from the MCR. Provided the release of hazardous materials does not infiltrate the MCR, operators will be able to undertake safety related activities. The following protection claim is made in regard to the MCR.

Claim IH-6.1: The MCR will remain habitable in the event of a release of hazardous materials

All Class 1 SSCs, delivering Category A safety functions, are located within the NI. A release of hazardous material outside of the NI will therefore not affect Class 1 SSC provided that the hazardous material does not infiltrate the NI. The following protection claim is made:

Claim IH-6.2: Class 1 SSC located within the NI will not be affected by releases of hazardous materials in locations outside of the NI

11.7.2.5 Mitigation Claims

Within the NI, the release of a corrosive chemical could result in damage or loss of a Class 1 SSC. However, provided that a single division remains unaffected, the Category A safety function can continue to be delivered.

Claim IH-6.3: A release of hazardous materials will not cause the loss of all divisions of Class 1 SSC delivering a Category A safety function

11.7.2.6 Arguments and Evidence

Claim IH-6.1: The MCR will remain habitable in the event of a release of hazardous materials

Habitability studies for the MCR (see Chapter 23) have demonstrated that for hydrogen, nitrogen, and carbon dioxide, the maximum concentrations predicted to exist at the control room inlet within 2 minutes of a plume reaching the control room inlet are significantly less than the toxicity levels for those gases. The calculations carried out assumed quantities of the above gases in excess of the maximum credible inventory held at the PGS, storage at a distance of approximately 250 m (820 ft) from the MCR, and worst-case weather conditions. The levels of toxicity reached are approximately 33 percent for liquid hydrogen release, 40 percent for liquid nitrogen release, and less than 20 percent for carbon dioxide release. Even if toxicity limits could be reached, the response time of 2 minutes provides adequate
